Given two subtrees T_{w_i} and T_{w_j}, the span linking module gives a score – score$_{\text{link}}(T_{w_i}, T_{w_j})$ to represent the probability of T_{w_j} being a subtree of T_{w_i}. This means that T_{w_i} is the parent of T_{w_j}, and that the span associated with T_{w_j}, i.e., $(T_{w_j}.s, T_{w_j}.e)$ is fully contained in the span associated with T_{w_i}, i.e., $(T_{w_i}.s, T_{w_i}.e)$.

We propose to use the machine reading comprehension framework as the backbone to compute this score. It operates on the triplet {context (X), query (q) and answer (a)}. The context X is the original sentence $\mathbf{s}$. The query q is the child span $(T_{w_j}.s, T_{w_j}.e)$. And we wish to extract the answer, which is the parent span $(T_{w_i}.s, T_{w_i}.e)$ from the context input sentence s. The basic idea here is that using the child span to query the full sentence gives direct cues for identifying the corresponding parent span, and this is more effective than simply feeding two extracted spans and then determining whether they have the parent-child relation.

Constructing Query Regarding the query, we should consider both the span and its root. The query is thus formalized as follows:

$$\begin{aligned}&\texttt{<sos>}, T_{w_j}.s, T_{w_j}.s+1, ..., T_{w_j}-1, \texttt{<sor>},\\ &T_{w_j}, \texttt{<eor>}, T_{w_j}+1, ...,\\ &T_{w_j}.e-1, T_{w_j}.e, \texttt{<eos>}\end{aligned} \tag{8}$$

where `<sos>`, `<sor>`, `<eor>`, and `<eos>` are special tokens, which respectively denote the start of span, the start of root, the end of root, and the end of span. One issue with the way above to construct query is that the position information of T_{w_j} is not included in the query. In practice, we turn to a more convenient strategy where the query is the original sentence, with special tokens `<sos>`, `<sor>`, `<eor>`, and `<eos>` used to denote the position of the child. In this way, position information for child T_{w_j} can be naturally considered.

Answer Extraction The answer is the parent, with the span $T_{w_i}.s, T_{w_i}.e$ rooted at T_{w_i}. We can directly take the framework from the MRC model by identifying the start and end of the answer span, respectively denoted by $\text{score}^s_{\text{parent}}(T_{w_i}.s|T_{w_j})$ and $\text{score}^e_{\text{parent}}(T_{w_i}.e|T_{w_j})$. We also wish to identify the root T_{w_i} from the answer, which is characterized by the score of w_i being the root of the span, denoted by $\text{score}^r_{\text{parent}}(w_i|T_{w_j})$. Furthermore, since we also want to identify the relation category between the parent and the child, the score signifying the relation label l is needed to be added, which is denoted by $\text{score}^l_{\text{parent}}(l|T_{w_j}, w_i)$.

For quadruple $(T_{w_i}.s, T_{w_i}.e, T_{w_j}, l)$, which denotes the span $T_{w_i}.s, T_{w_i}.e$ rooted at w_i, the final score for it being the answer to T_{w_j}, and the relation between the subtrees is l, is given by:

$$\begin{aligned}&\text{score}_{\text{parent}}(T_{w_i}|T_{w_j}) =\\ &\text{score}^r_{\text{parent}}(w_i|T_{w_j}) + \text{score}^s_{\text{parent}}(T_{w_i}.s|T_{w_j}) +\\ &\text{score}^e_{\text{parent}}(T_{w_i}.e|T_{w_j}) + \text{score}^l_{\text{parent}}(l|T_{w_j}, w_i)\end{aligned} \tag{9}$$

In the MRC setup, the input is the concatenation of the query and the context, denoted by {`<cls>`, query, `<sep>`, context}, where `<cls>` and `<sep>` are special tokens. The input is fed to BERT, and we obtain representations for each input token. Let $\mathbf{h}_t$ denote the representation for the token with index t output from BERT. The probability of t^{th} token being the root of the answer, which is denoted by $\text{score}^r_{\text{parent}}(w_t|T_{w_j})$ is the softmax function over all constituent tokens in the context:

$$\text{score}^r_{\text{parent}}(w_t|T_{w_j}) = \frac{\exp(\mathbf{h}^\top_{\text{root}} \times \mathbf{h}_t)}{\sum_{t' \in \text{context}} \exp(\mathbf{h}^\top_{\text{root}} \times \mathbf{h}_{t'})} \tag{10}$$

where $\mathbf{h}^\top_{\text{root}}$ is trainable parameter. $\text{score}^s_{\text{parent}}$ and $\text{score}^e_{\text{parent}}$ can be computed in the similar way:

$$\begin{aligned}\text{score}^s_{\text{parent}}(w_t|T_{w_j}) &= \frac{\exp(\mathbf{h}^\top_{\text{start}} \times \mathbf{h}_t)}{\sum_{t' \in \text{context}} \exp(\mathbf{h}^\top_{\text{start}} \times \mathbf{h}_{t'})}\\ \text{score}^e_{\text{parent}}(w_t|T_{w_j}) &= \frac{\exp(\mathbf{h}^\top_{\text{end}} \times \mathbf{h}_t)}{\sum_{t' \in \text{context}} \exp(\mathbf{h}^\top_{\text{end}} \times \mathbf{h}_{t'})}\end{aligned} \tag{11}$$

For $\text{score}^l_{\text{parent}}(l|T_{w_j}, w_i)$, which denotes the relation label between T_{w_i} and T_{w_j}, we can compute it in a simple way. Since $\mathbf{h}_{w_i}$ already encodes information for $\mathbf{h}_{w_j}$ through self-attentions, the representation $\mathbf{h}_{w_i}$ for w_i is directly fed to the softmax function over all labels in the label set $\mathcal{L}$:

$$\text{score}^l_{\text{parent}}(l|T_{w_j}, w_i) = \frac{\exp(\mathbf{h}^\top_l \times \mathbf{h}_{w_i})}{\sum_{l' \in \mathcal{L}} \exp(\mathbf{h}^\top_{l'} \times \mathbf{h}_{w_i})} \tag{12}$$

Mutual Dependency A closer look at Eq.(9) reveals that it only models the uni-directional dependency relation that T_{w_i} is the parent of T_{w_j}. This is suboptimal since if T_{w_i} is a parent answer of T_{w_j}, T_{w_j} should be a child answer of T_{w_i}. We thus propose to use T_{w_i} as the query q and T_{w_j} as the answer a.

$$\begin{aligned}&\text{score}_{\text{child}}(T_{w_j}|T_{w_i}) =\\ &\text{score}^r_{\text{child}}(w_j|T_{w_i}) + \text{score}^s_{\text{child}}(T_{w_j}.s|T_{w_i}) +\\ &\text{score}^e_{\text{child}}(T_{w_j}.e|T_{w_i}) + \text{score}^l_{\text{child}}(l|T_{w_i}, T_{w_j})\end{aligned} \tag{13}$$

The final score $\text{score}_{\text{link}}$ is thus given by:

$$\begin{aligned}\text{score}_{\text{link}}(T_{w_i}, T_{w_j}) &= \text{score}_{\text{child}}(T_{w_j}|T_{w_i})\\ &+ \text{score}_{\text{parent}}(T_{w_i}|w_j)\end{aligned} \tag{14}$$

Since one tree may have multiple children but can only have one parent, we use the multi-label cross entropy loss $\mathcal{L}_{\text{parent}}$ for $\text{score}_{\text{parent}}(T_{w_i}|T_{w_j})$ and use the binary cross entropy loss $\mathcal{L}_{\text{child}}$ for $\text{score}_{\text{child}}(T_{w_j}|T_{w_i})$. We jointly optimize these two losses $\mathcal{L}_{\text{link}} = \mathcal{L}_{\text{parent}} + \mathcal{L}_{\text{child}}$ for span linking.

3.5 Inference

Given an input sentence $\mathbf{s} = (w_0, w_1, w_2, ..., w_n)$, the number of all possible subtree spans $(w_i, T_{w_i}.s, T_{w_i}.e)$ is $\mathcal{O}(n^3)$, and therefore running MRC procedure for every candidate span is computationally prohibitive. A naive solution is to use the span proposal module to extract top-k scored spans rooted at each token. This gives rise to a set of span candidates $\mathcal{T}$ with size $1 + n \times k$ (the root token w_0 produces only one span), where each candidate span is associated with its subtree span score $\text{score}_{\text{span}}(\cdot)$. Then we construct the optimal dependency tree based only on these extracted spans by linking them. This strategy obtains a local optimum for Eq.(2), because we want to compute the optimal solution for the first part $\sum_{i=1}^{n} \text{score}_{\text{span}}(T_{w_i})$ depending on the second part of Eq.(2), i.e., $\sum_{(w_i \to w_j) \in T_{w_0}} \text{score}_{\text{link}}(T_{w_i}, T_{w_j})$. But in this naive strategy, the second part is computed after the first part.

It is worth noting that the naive solution of using only the top-k scored spans has another severe issue: spans left out at the span proposal stage can never be a part of the final prediction, since the span linking module only operates on the proposed spans. This would not be a big issue if top-k is large enough to recall almost every span in ground-truth. However, span proposal is intrinsically harder than span linking because the span proposal module lacks the triplet span information that is used by the span linking module. Therefore, we propose to use the span linking module to retrieve more correct spans. Concretely, for every span T_{w_j} proposed by the span proposal module, we use $\arg\max \text{score}_{\text{parent}}(T_{w_i} | T_{w_j})$ to retrieve its parent with the highest score as additional span candidates. Recall that span proposal proposed $1 + n \times k$ spans. Added by spans proposed by the span linking module, the maximum number of candidate spans is $1 + 2 \times n \times k$. The MRC formalization behind the span linking module improves the recall rate as missed spans at the span proposal stage can still be retrieved at this stage.

Algorithm 1: Projective Inference

```
Input  : Input sentence $\mathbf{s}$, span candidates $\mathcal{T}$, span
         scores $\text{score}_{\text{span}}(T), \forall T \in \mathcal{T}$
Output : Highest score of every span
         $\text{score}(T), \forall T \in \mathcal{T}$
/* Compute linking scores based on
   Eq.(14)                                            */
$\text{score}_{\text{link}}(T_1, T_2) \leftarrow \text{score}_{\text{parent}}(T_1 | T_2) +$
  $\text{score}_{\text{child}}(T_2 | T_1), \forall (T_1, T_2) \in \mathcal{T}$
/* Compute score(T), ∀T ∈ 𝒯                            */
for $len \leftarrow 0$ to $n$ do
    for $T \leftarrow \mathcal{T}$ do
        if $T.e - T.s = len$ then
            /* T covers a single word
            */
            if $len = 0$ then
                $\text{score}(T) \leftarrow \text{score}_{\text{span}}(T)$
            else
                /* 𝒞 is a set of direct
                   subtrees composing T
                */
                $\text{score}(T) \leftarrow \text{score}_{\text{span}}(T) +$
                  $\max_{\mathcal{C}(T)}(\sum_{T_i \in \mathcal{C}}[\text{score}(T_i) +$
                  $\lambda \text{score}_{\text{link}}(T, T_i)])$
            end
        end
    end
end
```

Projective Decoding Given retrieved spans harvested in the proposal stage, we use a CKY-style bottom-up dynamic programming algorithm to find the projective tree with the highest score based on Eq.(2). The algorithm is present in Algorithm 1. The key idea is that we can generalize the definition of $\text{score}(T_{w_0})$ in Eq.(2) to any w by the following definition:

$$\begin{aligned} \text{score}(T_w) = & \sum_{T_{w_i} \subseteq T_w} \text{score}_{\text{span}}(T_{w_i}) \\ & + \lambda \sum_{(w_i \to w_j) \in T_w} \text{score}_{\text{link}}(T_{w_i}, T_{w_j}) \end{aligned} \tag{15}$$

where $\{T_{w_i} \mid T_{w_i} \subseteq T_w, i = 0, 1, ..., n\}$ is all subtrees inside T_w, i.e. there is a path in T_w like

$$w \to w_{i_1} \to ..., \to w_i$$

Using this definition, we can rewrite $\text{score}(T_w)$ in a recursive manner:

$$\begin{aligned} & \text{score}(T_w) = \text{score}_{\text{span}}(T_w) \\ & + \sum_{T_{w_j} \in \mathcal{C}(T_w)} [\text{score}(T_{w_j}) + \lambda\, \text{score}_{\text{link}}(T_w, T_{w_j})] \end{aligned} \tag{16}$$

where $\mathcal{C}(T_w) = \{T_{w_i} \mid (w \to w_i) \in T_w, i = 0, 1, ...n\}$ is the set of all direct subtrees of T_w.

Non-Projective Decoding It is noteworthy that effectively finding a set of subtrees composing a tree T requires trees to be projective (the projective property guarantees every subtree is a continuous span in text), and experiments in Section 4 show that this algorithm performs well on datasets where most trees are projective, but performs worse when a number of trees are non-projective. To address this issue, we adapt the proposed strategy to the MST (Maximum Spanning Tree) algorithm (McDonald et al., 2005b). The key point of MST is to obtain the score for each pair of tokens w_i and w_j (rather than spans) , denoted by $\text{score}_{\text{edge}}(w_i, w_j)$. We propose that the score to link w_i and w_j is the highest score achieved by two spans respectively rooted at w_i and w_j:

$$\begin{aligned}\text{score}_{\text{edge}}(w_i, w_j) = \max_{T_{w_i}, T_{w_j}} [\text{score}_{\text{span}}(T_{w_i}) \\ + \text{score}_{\text{span}}(T_{w_j}) + \lambda\text{score}_{\text{link}}(T_{w_i}, T_{w_j})]\end{aligned} \tag{17}$$

The final score for tree T is given by:

$$\text{score}(T) = \sum_{(w_i \to w_j) \in T} \text{score}_{\text{edge}}(w_i, w_j) \tag{18}$$

Here, MST can be readily used for decoding.

4 Experiments

4.1 Datasets and Metrics

We carry out experiments on three widely used dependency parsing benchmarks: the English Penn Treebank v3.0 (PTB) dataset (Marcus et al., 1993), the Chinese Treebank v5.1 (CTB) dataset (Xue et al., 2002) and the Universal Dependency Treebanks v2.2 (UD) (Nivre et al., 2016) where we select 12 languages for evaluation. We follow Ma et al. (2018) to process all datasets. The PTB dataset contains 39832 sentences for training and 2416 sentences for test. The CTB dataset contains 16091 sentences for training and 1910 sentences for test. The statistics for 12 languages in UD dataset are the same with Ma et al. (2018). We use the unlabeled attachment score (UAS) and labeled attachment score (LAS) for evaluation. Punctuations are ignored in all datasets during evaluation.

4.2 Experiment Settings

We compare the proposed model to the following baselines: (1) **Biaffine**, (2) **StackPTR**, (3)**GNN**, (4) **MP2O**, (5) **CVT**, (6) **LRPTR**, (7) **HiePTR**, (8) **TreeCRF**, (9) **HPSG**, (10) **HPSG+LA**, (11) **MulPTR**, (12) **SynTr**. The details of these baselines are left to the supplementary materials due to page limitation. We group experiments into three categories: without pretrained models, with BERT and with RoBERTa. To implement a span-prediction parsing model without pretrained models, we use the QAnet (Yu et al., 2018) for span prediction. To enable apple-to-apple comparisons, we implement our proposed model, the Biaffine model, MP2O (Wang and Tu, 2020) based on $\text{BERT}_{\text{large}}$ (Devlin et al., 2018) and $\text{RoBERTa}_{\text{large}}$ (Liu et al., 2019) for PTB, BERT and RoBERTa-$\text{wwm}_{\text{large}}$ (Cui et al., 2019) for CTB, BERTBase-Multilingual-Cased and XLM-$\text{RoBERTa}_{\text{large}}$ for UD. We apply both projective decoding and non-projective MST decoding for all datasets. For all experiments, we concatenate 100d POS tag embedding with 1024d pretrained token embeddings, then project them to 1024d using a linear layer. Following Mrini et al. (2020), we further add 1-3 additional encoder layers on top to let POS embeddings well interact with pretrained token embeddings. POS tags are predicted using the Stanford NLP package (Manning et al., 2014). We tried two different types of additional encoders: Bi-LSTM (Hochreiter and Schmidhuber, 1997) and Transformer (Vaswani et al., 2017a). For Bi-LSTM, the number of hidden size is 1024d. For Transformer, the number of attention heads and hidden size remain the same as pretrained models (16 for attention heads and 1024d for hidden size). We use 0.1 dropout rate for pretrained models and 0.3 dropout rate for additional layers. We use Adam (Kingma and Ba, 2014) as optimizer. The weight parameter λ is tuned on the development set. The code is implemented by PyTorch 1.6.0 and MindSpore.

4.3 Main Results

Table 2 compares our model to existing state-of-the-art models on PTB/CTB test sets. As can be seen, for models without pretrained LM, the proposed span-prediction model based on QAnet outperforms all baselines, illustrating the effectiveness of the proposed span-prediction framework for dependency parsing. For BERT-based models, the proposed span-prediction models outperform Biaffine model based on BERT, along with other competitive baselines. On PTB, performances already outperform all previous baselines, except on the LAS metric in comparison to HiePTR (95.46 vs. 95.47) on PTB, but underperform RoBERTa-based models. On CTB, the proposed span-prediction model obtains a new SOTA performance of 93.14% UAS. For RoBERTa-based models, the proposed model achieves a new SOTA performance of 97.24% UAS and 95.49% LAS on PTB. As PTB and CTB contain almost only projective trees, the projective decoding strategy significantly outperforms the non-

Table 2: Results for different models on PTB and CTB. $^\flat$: These approaches utilized both dependency and constituency information in their approach, thus is not comparable to ours.

projective MST algorithm. It is worth noting that, since MulPTR, HPSG and HPSG+LA rely on additional labeled data of constituency parsing, results for HPSG are not comparable to ours. We list them here for reference purposes.

Table 3 compares our model with existing state-of-the-art methods on UD test sets. Other than es, where the proposed model slightly underperforms the SOTA model by 0.02, the proposed model enhanced with XLM-RoBERTa achieves SOTA performances on all other 11 languages, with an average performance boost of 0.3. As many languages in UD have a notable portion of non-projective trees, MST decoding significantly outperforms projective decoding, leading to new SOTA performances in almost all language sets.

5 Ablation Study and Analysis

We use PTB to understand behaviors of the proposed model. As projective decoding works best for PTB, scores reported in this section are all from projective decoding.

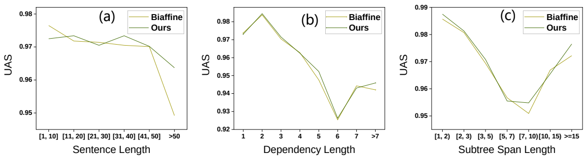

Figure 2: Performances on PTB test dev of Biaffine and our parser w.r.t. sentence length, dependency length and subtree span length.

5.1 Effect of Candidate Span Number

We would like to study the effect of the number of candidate spans proposed by the span proposal module, i.e., the value of k. We vary the value of k from 1 to 25. As shown in Table 4, increasing values of k leads to higher UAS, and the performance stops increasing once k is large enough ($k > 15$). More interestingly, even though k is set to 1, which means that only one candidate span is proposed for each word, the final UAS score is 96.94, a score that is very close to the best result 97.24 and surpasses most existing methods as shown in Table 2. These results verify that the proposed approach can accurately extract and link the dependency spans.

5.2 Effect of Span Retrieval by Span Linking

As shown in Table 5, span recall significantly improves with the presence of the span linking stage. This is in line with our expectation, since spans missing at the proposal module can be retrieved by QA model in the span linking stage. Recall boost narrows down when k becomes large, which is expected as more candidates are proposed at the proposal stage. The span linking stage can improve computational efficiency by using a smaller number of proposed spans while achieving the same performance.

5.3 Effect of Scoring Functions

We study the effect of each part of the scoring functions used in the proposed model. Table 6 shows the results. We have the following observations:
(1) **token(query)-token(answer)**: we simplify the model by only signifying root token in queries (child) and extract the root token in the context (parent). The model actually degenerates into a model similar to Biaffine by working at the token-token level. We observe significant performance decreases, 0.57 in UAS and 0.34 in LAS.
(2) **token(query)-span(answer)**: signifying only token in queries (child) and extracting span in answers (parent) leads to a decrease of 0.13 and 0.08

k	1	2	5	10	15
recall w/o link	97.09	98.88	99.57	99.77	99.86
recall w/ link	97.76	99.14	99.69	99.85	99.92

Table 5: Span recall with/without span linking module

respectively for UAS and LAS.

(3) **span(query)-token(answer)**: signifying spans in queries (child) but only extracting token in answers (parent) leads to a decrease of 0.07 and 0.05 respectively for UAS and LAS. (1), (2) and (3) demonstrate the necessity of modeling span-span rather than token-token relations in dependency parsing: replacing span-based strategy with token-based strategy for either parent or child progressively leads to performance decrease.

(4) Removing the **Mutual Dependency** module which only uses child → parent relation and ignores parent → child relation also leads to performance decrease.

5.4 Analysis

Following Ma et al. (2018); Ji et al. (2019), we analyze performances of the Biaffine parser and the proposed method with respect to sentence length, dependency length, and subtree span length. Results are shown in Figure 2.

Sentence Length. As shown in Figure 2(a), the proposed parser achieves better performances on long sentences compared with Biaffine. Specially, when sentence length is greater than 50, the performance of the Biaffine parser decreases significantly, while the proposed parser has a much smaller drop (from 0.97 to 0.964).

Model	UAS	LAS
Full	97.24	95.49
token(query)-token(answer)	96.67(-0.57)	95.15(-0.34)
span(query)-token(answer)	97.17(-0.07)	95.44(-0.05)
token(query)-span(answer)	97.11(-0.13)	95.41(-0.08)
-mutual	97.18(-0.06)	95.43(-0.06)

Table 6: The effect of removing different parts from scoring function

Dependency Length. Figure 2(b) shows the results with respect to dependency length. The proposed parser shows its advantages on long-range dependencies. We suppose span-level information is beneficial for long-range dependencies.

Subtree Span Length. We further conduct experiments on subtree span length. We divide the average lengths of the two spans in the span linking module into seven buckets. We suppose our parser should show advantages on long subtree span, and the results in Figure 2(c) verify our conjecture.

In summary, the span-span strategy works significantly better than the token-token strategy, especially for long sequences. This explanation is as follows: the token-token strategy can be viewed as a coarse simplification of the span-span strategy, where the root token in the token-token strategy can be viewed as the **average** of all spans covering it, while in the span-span strategy, it represents the exact span, rather than the average. The deviation from the average is relatively small from the extract when sequences are short, but becomes larger as sequence length grows, since the number of spans covering the token exponentially grows with length. This makes the token-token strategy work significantly worse for long sequences.

6 Conclusion

In this paper, we propose to construct dependency trees by directly modeling span-span instead of token-token relations. We use the machine reading comprehension framework to formalize the span linking module, where one span is used as a query to extract the text span/subtree it should be linked to. Extensive experiments on the PTB, CTB and UD benchmarks show the effectiveness of the proposed method.

A Baselines

We use the following baselines:

- **Biaffine**: Dozat and Manning (2016) fed pairs of words into a biaffine classifier to determine the dependency relations between them.
- **StackPTR**: Ma et al. (2018) combined pointer network with transition-based method to make it benefits from the information of whole sentence and all previously derived subtree structures.
- **GNN**: Ji et al. (2019) used graph neural networks (GNN) to learn token representations for graph-based dependency parsing.
- **MP2O**: Wang and Tu (2020) used message passing to integrate second-order information to biaffine backbone.
- **CVT**: Clark et al. (2018) proposed Cross-View Training, a semi-supervised approach to improve model performance.
- **LRPTR**: Fernández-González and Gómez-Rodríguez (2019) also took advantage of pointer networks to implement transition-based parser, which contains only n actions and is more efficient than StackPTR.
- **HiePTR**: Fernández-González and Gómez-Rodríguez (2021) introduced structural knowledge to the sequential decoding of the left-to-right dependency parser with Pointer Networks.
- **TreeCRF**: Zhang et al. (2020) presented a second-order TreeCRF extension to the biaffine parser.
- **HPSG**: Zhou and Zhao (2019) used head-driven phrase structure grammar to jointly train constituency and dependency parsing.
- **HPSG+LA**: Mrini et al. (2020) added a label attention layer to HPSG to improve model performance. HPSG+LA also relies on the additional constituency parsing dataset.
- **MulPTR**: Fernández-González and Gómez-Rodríguez (2020) jointly trained two separate decoders responsible for constituent parsing and dependency parsing.
- **SynTr**: Mohammadshahi and Henderson (2020b) proposed recursive non-autoregressive graph-to-graph Transformers for the iterative refinement of dependency graphs conditioned on the complete graph.

Adversarial Soft Prompt Tuning for Cross-Domain Sentiment Analysis

Abstract

Cross-domain sentiment analysis has achieved promising results with the help of pre-trained language models. As GPT-3 appears, prompt tuning has been widely explored to enable better semantic modeling in many natural language processing tasks. However, directly using a fixed predefined template for cross-domain research cannot model different distributions of the [MASK] token in different domains, thus making underuse of the prompt tuning technique. In this paper, we propose a novel **Ad**versarial **S**oft **P**rompt **T**uning method (AdSPT) to better model cross-domain sentiment analysis. On the one hand, AdSPT adopts separate soft prompts instead of hard templates to learn different vectors for different domains, thus alleviating the domain discrepancy of the [MASK] token in the masked language modeling task. On the other hand, AdSPT uses a novel domain adversarial training strategy to learn domain-invariant representations between each source domain and the target domain. Experiments on a publicly available sentiment analysis dataset show that our model achieves new state-of-the-art results for both single-source domain adaptation and multi-source domain adaptation.

1 Introduction

In recent years, with the emergence of a series of large-scale pre-trained language models (PLMs), such as GPT (Radford et al., 2018, 2019), BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2019), fine-tuning PLMs has achieved promising results on a wide range of natural language processing (NLP) tasks. However, as PLMs become larger and larger, fine-tuning larger PLMs becomes more challenging in most real-world applications. More recently, Brown et al. (2020) show that designing task descriptions (a.k.a. prompts) can make accurate predictions without updating any of the parameters of GPT-3 (which has 175B parameters). This inspires a new PLM-tuning method named "**prompt tuning**". Such prompt tuning method has achieved state-of-the-art results on text classification and natural language inference (Schick and Schütze, 2020; Schick et al., 2020; Gao et al., 2020), relation classification (Han et al., 2021), and natural language generation (Li and Liang, 2021).

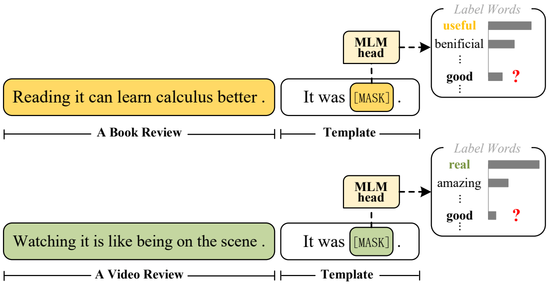

Figure 1: How domain discrepancy affects prompt tuning. Examples of a book review on the top and a video review on the bottom.

It is common to use a predefined template (e.g., "It was [MASK].") in prompt tuning for binary sentiment analysis, and the classification results of positive or negative depend on the probabilities of predefined label words (e.g., "{good, bad}") in the masked language modeling (MLM) task. However, the distributions of MLM prediction results can be different for different domains. An example is shown in Figure 1, the discrepancy between book-domain review and video-domain review leads to different possibilities of label words. The high-frequency label word in book-domain review is "*useful*", and video-domain review is "*real*", neither of which is in the predefined "{good, bad}". Therefore, it is unreasonable to predict predefined label words with fixed templates (a.k.a. hard prompts) for different domain datasets.

The intuition is that the feature distributions corresponding to the [MASK] position learned from the hard prompt are distinct among different do-

mains. And the discrepancy among different domains can have serious effects on the cross-domain setting where we train a classifier on source domain data, e.g., the book reviews, and test it on the target domain, e.g., the video review. So domain adaptation (Ben-David et al., 2007; Mansour et al., 2009) based on cluster hypothesis (Zhu and Goldberg, 2009) becomes a key point of the cross-domain research.

In order to improve the cross-domain sentiment analysis with the help of PLMs, we propose AdSPT: an **Ad**versarial **S**oft **P**rompt **T**uning method, which sheds new light on solving the domain adaptation problem. Specifically, we use soft prompts composed of multiple learnable vectors and the [MASK] token instead of hard templates for tuning. For different domains, we use independent soft prompts to represent domain-specific information, thus making them have the *domain-aware* knowledge. With different domain soft prompts, the MLM head classifier can mitigate the domain discrepancy of the [MASK] token. To enhance the effectiveness of the target domain, we design a novel adversarial training strategy to learn the *domain-invariant* knowledge of the [MASK] token, which can be seen as a two-player minimax game between the target domain and each source domain under multi-source domain adaptation setting. As a result, the collaborative effect of soft prompt tuning and domain adversarial training can more properly predict the feature distribution of the [MASK] token on the ground of domain-specific soft prompts and the domain invariance of the [MASK] token.

In experiments, we evaluate on a publicly available sentiment analysis dataset for both single-source domain adaptation and multi-source domain adaptation. Our results show the effectiveness of collaboratively leveraging domain-specific soft prompts tuning and domain adversarial training. To summarize, the main contributions of this work are as follows:

(1) In prompt tuning, we adopt separate soft prompts to learn embeddings enriched with the domain knowledge, thus alleviating the domain discrepancy of the [MASK] position.

(2) We design a novel adversarial training strategy to learn the domain-invariant representation of the [MASK] position.

(3) Experiments on the Amazon reviews dataset show our method AdSPT obtains the average accuracy 93.14% (0.46 absolute improvement) under single-source domain adaptation and the average accuracy 93.75% (0.81 absolute improvement) under multi-source domain adaptation.

2 Related Work

Prompt tuning. Fine-tuning PLMs with task-specific heads on downstream tasks has become the main paradigm and yields strong performance on many NLP tasks (Peters et al., 2018; Devlin et al., 2019; Radford et al., 2019). But there is a big gap between the fine-tuning objectives of downstream tasks and the pre-training objectives of PLMs, which could limit the exploitation of knowledge in PLMs (Liu et al., 2021b). Subsequently, GPT-3 (Brown et al., 2020) brings a new paradigm "prompt tuning" for downstream tasks, which leverages natural-language prompts and task demonstrations as context to make downstream tasks similar to language modeling.

Early works explore manually defined templates (a.k.a. hard templates) for text classification and natural language inference (Schick and Schütze, 2020, 2021). However, suitable templates require strong domain knowledge. Therefore, some automatically generated hard templates are explored (Shin et al., 2020; Gao et al., 2020; Ben-David et al., 2021). Since prompt construction is to find a method that allows PLMs to effectively perform downstream tasks, it is not necessary to limit templates to human-interpretable natural language. Some works attempt to perform prompting directly with several learnable vectors, such as soft prompt (Lester et al., 2021; Vu et al., 2021), prefix-tuning (Li and Liang, 2021) and P-tuning V2 (Liu et al., 2021a). Moreover, Schick et al. (2020) explore automatically identifying label words. Hu et al. (2021) use an external knowledge base to expand label words. This paper focuses on improving the cross-domain sentiment analysis via different soft prompts of different domains.

Domain Adaptation. Research on *domain adaptation* (DA) uses labeled or unlabeled target data to transfer labeled source information to a specific target domain (Pan and Yang, 2009; Mansour et al., 2009). Popular methods for unsupervised DA are based on domain discrepancy optimizing based on adversarial training (Ganin et al., 2016; Zhao et al., 2018; Saito et al., 2018). As for cross-domain sentiment analysis, some early works use pivot-based methods to capture the shared feature representation of different domains (Yu and Jiang, 2016; Ziser and Reichart, 2018; Li et al., 2018; Peng et al., 2018). Some other works adopt different adversarial learning methods to learn the domain-common sentiment knowledge (Li et al., 2017; Qu et al., 2019; Li et al., 2019).

Recently, with the promising performance of PLMs in NLP, many works on cross-domain sentiment analysis focus on how to improve langange model pre-training and fine-tuning, e.g., Du et al. (2020) use a target domain MLM task and a domain-distinguish task in pre-training; Zhou et al. (2020) utilize several pre-training tasks based on existing lexicons and annotations. Different from these works, our method is the first to use the combination of soft prompt tuning and adversarial training to solve the DA problem.

3 Problem Formulation

In this paper, we study cross-domain sentiment analysis in the unsupervised domain adaptation setting which contains two scenarios: a source domain and a target domain or multiple source domains and a target domain. Given $m(m \geq 1)$ source domains, the l-th ($l \in [1, \ldots, m]$) source domain contains an annotated dataset $\mathcal{S}_l = \{\boldsymbol{x}_i^s, y_i^s\}_{i=1}^{N_l^s}$, where $\boldsymbol{x}_i^s = [w_1^s, \ldots, w_n^s]$ is a input sentence with n words, y_i^s is the corresponding polarity label, and N_l^s represents the number of examples of the l-th source domain. In the target domain, there is an unannotated dataset $\mathcal{T} = \{\boldsymbol{x}_i^t\}_{i=1}^{N^t}$, where $\boldsymbol{x}_i^t = [w_1^t, \ldots, w_n^t]$ is an unlabeled sentence of the target domain and N^t is the number of the unlabeled data. The goal of cross-domain sentiment analysis is to learn a function $\mathcal{F}$ that could both retain in-domain knowledge for different domains and also learn the domain invariance between the target domain and each source domain to better predict the polarity of unlabeled sentences from the target domain.

4 Method

In this section, we first introduce a soft prompt tuning method for sentiment classification that utilizes soft prompts to capture domain-specific knowledge. Then we present a domain adversarial training method for domain adaptation. Finally, we describe the overall learning procedure.

4.1 Soft Prompt Tuning for Sentiment Classification

Prompt tuning is an approach to add extra information for PLMs by reformulating downstream tasks as cloze questions. The primary components include a template and a set of label words, where the template is a background description of current task and the label words are the high-probability vocabulary predicted by PLMs in the current context. In the binary sentiment classification, we denote the input sentence as $\boldsymbol{x} = [w_1, \ldots, w_n]$, the output label as y. Here $y \in \mathcal{Y}$, and the label space $\mathcal{Y} = \{\text{positive}, \text{negative}\}$.

Prompt tuning formalizes the classification task into a MLM task. Given a PLM $\mathcal{M}$ and its vocabulary $\mathcal{V}$, a prompt consists of a template function $T(\cdot)$ that converts the input sentence $\boldsymbol{x}$ to a prompt input $\boldsymbol{x}_{prompt} = T(\boldsymbol{x})$ with the $[\text{MASK}]$ token and a set of label words $\mathcal{V}^* \subset \mathcal{V}$, which are connected with the label space through a mapping function $v : \mathcal{Y} \mapsto \mathcal{V}^*$. As shown in Figure 2, the soft prompted input $\boldsymbol{x}_{prompt}$ contains the embeddings of the original sentence $\mathbf{e}(\boldsymbol{x})$, k learnable vectors $[\mathbf{h}_0, \ldots, \mathbf{h}_{k-1}]$, the embedding of the $[\text{MASK}]$ token $\mathbf{e}(\text{“[MASK]”})$, and the embeddings of two positional tokens $\mathbf{e}(\text{“[CLS]”})$ and $\mathbf{e}(\text{“[SEP]”})$. So the actual input of $\mathcal{M}$ is represented as:

$$\begin{aligned}\boldsymbol{x}_{prompt} = \big[&\mathbf{e}(\text{“[CLS]”}), \mathbf{e}(\boldsymbol{x}), \mathbf{h}_0, \ldots, \mathbf{h}_{k-1}, \\ &\mathbf{e}(\text{“[MASK]”}), \mathbf{e}(\text{“[SEP]”})\big]\end{aligned} \tag{1}$$

where $\mathbf{e}(\cdot)$ represents the embedding function of $\mathcal{M}$.

Here we can denote a PLM $\mathcal{M}$ as a function mapping from $\boldsymbol{x}_{prompt}$ to the feature representation and vocabulary distribution of the $[\text{MASK}]$ token, represented as:

$$\mathbf{h}_{[\text{MASK}]}, \mathbf{s}_{[\text{MASK}]} = \mathcal{M}(\boldsymbol{x}_{prompt}) \tag{2}$$

where $\mathbf{h}_{[\text{MASK}]} \in \mathbb{R}^h$ and $\mathbf{s}_{[\text{MASK}]} \in \mathbb{R}^{|\mathcal{V}|}$ are the hidden representation and vocabulary distribution of the $[\text{MASK}]$ token respectively, and $\mathbf{s}_{[\text{MASK}]} = f(\mathbf{h}_{[\text{MASK}]})$ is obtained by the MLM head function f.

The probability $p(y|\boldsymbol{x})$ is formalized according to the distribution of the label word $w \in \mathcal{V}^*$ w.r.t. the $[\text{MASK}]$ position. In binary sentiment classification, we set the label words as $\mathcal{V}^* =$

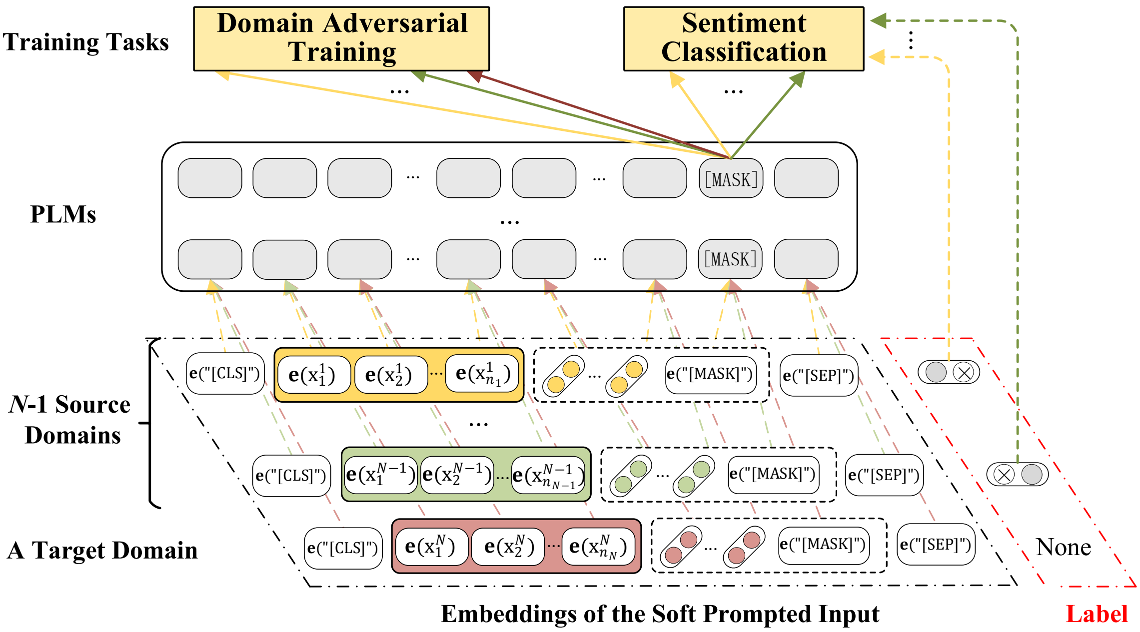

Figure 2: Overall structure of the proposed method.

$\{\text{good}, \text{bad}\}$. So,

$$p(y|\boldsymbol{x}) = p(\mathcal{V}_y^* \leftarrow [\text{MASK}]\,|\boldsymbol{x}_{prompt}) = \frac{\exp(\mathbf{s}_{[\text{MASK}]}(\mathcal{V}_y^*))}{\sum_{y' \in \mathcal{Y}} \exp(\mathbf{s}_{[\text{MASK}]}(\mathcal{V}_{y'}^*))} \tag{3}$$

Given an annotated dataset $\mathcal{S} = \{\boldsymbol{x}_i, y_i\}_{i=1}^N$, the training objective for soft prompt tuning is obtained using the binary cross-entropy loss,

$$\begin{aligned} &\mathcal{L}_{class}(\mathcal{S}; \theta_{\mathcal{M},p,f}) \\ &= -\sum_{i=1}^{N} \Big[\log p(y_i|\boldsymbol{x}_i)^{\mathbb{I}\{\hat{y}_i=1\}} \\ &\qquad + \log(1 - p(y_i|\boldsymbol{x}_i))^{\mathbb{I}\{\hat{y}_i=0\}} \Big] \end{aligned} \tag{4}$$

where $\hat{y}_i$ represents the ground truth label ranging from 1 as the positive label and 0 as the negative label). $\theta_{\mathcal{M},p,f}$ represents the overall trainable parameters of the PLM $\mathcal{M}$, several learnable vectors p and the MLM head function f.

4.2 Domain Adversarial Training

For the same task in different domains, domain adversarial training can not only transfer the generic knowledge from source domains to the target domain, but also train more domain-aware classifiers. As shown in Figure 2, domain adversarial training aims to make the feature distributions of the [MASK] position from different domains closer. More intuitively, it will encourage the MLM head classifer to obtain domain-invariant features across domains.

Based on the hidden representation $\mathbf{h}_{[\text{MASK}]}$ by the PLM, the detailed process of domain adversarial training is as follows: given m ($m \geq 1$) source domains, we assume that between each source domain $\mathcal{S}_l$ ($l \in [1, \ldots, m]$) and the target domain $\mathcal{T}$ have a domain discriminative function $g_l : \mathbb{R}^h \rightarrow \mathcal{D}$ that discriminates between the source domain and the target domain, where the domain label set is represented as $\mathcal{D} = \{0, 1\}$, 0 is the source domain label, and 1 is the target domain label. To this end, there are m domain discriminators, denoted as $\mathbf{g} = \{g_l\}_{l=1}^m$.

Given an input example $\boldsymbol{x}$ from either the l-th ($l \in [1, \ldots, m]$) source domain or the target domain, we first obtain the task-specific head representation $\mathbf{h}_{[\text{MASK}]}$ by $\mathcal{M}$ and then model the probability $p(d|\boldsymbol{x})$ for discriminating the domain label $d \in \mathcal{D}$ as:

$$p(d|\boldsymbol{x}) = \frac{\exp(g_l^d(\mathbf{h}_{[\text{MASK}]}))}{\sum_{d' \in \mathcal{D}} \exp(g_l^{d'}(\mathbf{h}_{[\text{MASK}]}))} \tag{5}$$

Given m source domain dataset $\hat{\mathcal{S}} = \{\mathcal{S}_l\}_{l=1}^m = \{\{\boldsymbol{x}_i^s\}_{i=1}^{N_l^s}\}_{l=1}^m$ and a target domain dataset $\mathcal{T} = \{\boldsymbol{x}_i^t\}_{i=1}^{N^t}$, where N_l^s is the number of samples in the l-th source domain and N^t is the number of samples in the target domain, the domain discriminative objective is to minimize the following cross-entropy loss,

$$\begin{aligned}&\mathcal{L}_{domain}(\hat{\mathcal{S}}, \mathcal{T}; \theta_{\mathcal{M},p,\mathbf{g}})\\ &= -\sum_{l=1}^{m}\sum_{i=1}^{N_l^s+N^t}\Big[\log p(d_i|\boldsymbol{x}_i)^{\mathbb{I}\{\hat{d}_i=1\}}\\ &\qquad + \log(1-p(d_i|\boldsymbol{x}_i))^{\mathbb{I}\{\hat{d}_i=0\}}\Big]\end{aligned} \tag{6}$$

where $\hat{d}_i$ represents the truth domain label and $\theta_{\mathcal{M},p,\mathbf{g}}$ represents the overall trainable parameters of the PLM $\mathcal{M}$, several learnable vectors p and m domain discriminators $\mathbf{g}$.

The domain adversarial training among m source domains and the target domain can be seen as a two-player minimax game where the domain classifiers $\mathbf{g} = \{g_l\}_{l=1}^m$ tend to minimize the domain discrimination loss so as to make the domain discriminators strong while the PLM $\mathcal{M}$ tends to maximize the domain discrimination loss so as to weaken the domain discrimination.

Formally, the domain adversarial training objective w.r.t. to $\mathbf{g}$, p and $\mathcal{M}$ can be represented as:

$$\max_{\mathcal{M},p}\min_{\mathbf{g}} \mathcal{L}_{domain}(\hat{\mathcal{S}}, \mathcal{T}; \theta_{\mathcal{M},p,\mathbf{g}}) \tag{7}$$

4.3 Learning Procedure

Joint training objective. Given m source domains $\hat{\mathcal{S}}$ and a target domain $\mathcal{T}$, the sentiment classifier and the domain discriminator are jointly trained for optimizing the PLM $\mathcal{M}$, soft prompt embeddings p, MLM head function f and domain discriminators $\mathbf{g}$, and the final training objective is formally represented as:

$$\begin{aligned}\min_{\mathcal{M},p,f}\ &\{\lambda\mathcal{L}_{class}(\mathcal{S}; \theta_{\mathcal{M},p,f})\\ &- \min_{\mathbf{g}} \mathcal{L}_{domain}(\hat{\mathcal{S}}, \mathcal{T}; \theta_{\mathcal{M},p,\mathbf{g}})\}\end{aligned} \tag{8}$$

where λ is a trade-off parameter. The sentiment classification objective $\mathcal{L}_{class}$ and the domain discrimination objective $\mathcal{L}_{domain}$ are defined in Eq. (4) and Eq. (6), respectively.

Training procedure. The iterative training procedure is summarized in Algorithm 1. In each iteration, the input samples of each source domain are first used for training the PLM $\mathcal{M}$, several learnable vectors p and the MLM head function f. The sentiment classification loss is computed in line 5. Then the samples of each source domain and the target domain are mapped to different domain discriminators to train the PLM $\mathcal{M}$, several learnable vectors p and the domain discriminator g_l. The corresponding domain discrimination loss is computed in line 6. The sentiment classification loss is used for updating the parameters of the PLM, several learnable vectors and the MLM head function (line 7, 10). The domain discrimination loss is used for updating the parameters of the PLM, several learnable vectors and the domain discriminators. Obviously, the parameters of the PLM and several learnable vectors be updated together by the above two losses.

Algorithm 1 Training Process of AdSPT.

Input: Training samples of m source domain dataset $\hat{\mathcal{S}} = \{\mathcal{S}_l\}_{l=1}^m = \{\{\boldsymbol{x}_i^s, y_i^s\}_{i=1}^{N_l^s}\}_{l=1}^m$ and a target domain dataset $\mathcal{T} = \{\boldsymbol{x}_i^t\}_{i=1}^{N^t}$; the number of training iterations n.
Output: Configurations of AdSPT $\theta_{\mathcal{M},p,f,\mathbf{g}}$
Initialize: PLM $\theta_{\mathcal{M}}$; soft prompt embeddings θ_p; MLM head function θ_f; domain discriminator $\{\theta_{g_l}\}_{l=1}^m$; learning rate η; trade-off parameter λ.

5 Experiments

In this section, we conduct experiments to evaluate the effectiveness of our methods. Our experiments are carried out on single-source domain adaptation and multi-source domain adaptation settings (§ 5.3). In addition, we also investigate how different components in the model impact the performance of cross-domain sentiment analysis with different settings.

5.1 Experimental Setup

Dataset. We evaluate on the **Amazon reviews** dataset (Blitzer et al., 2007), which has been widely used for cross-domain sentiment classification. This dataset contains reviews of binary categories from four domains: Books (B), DVDs

S → T	Fine-tuning				Prompt-tuning			
	BERT-DAAT	SENTIX$_{Fix}$	FT	FT + AT	PT(Hard)	PT(Hard) + AT	PT(Soft)	AdSPT
B → D	89.70	91.30	88.96	89.70	89.75	90.75	90.50	**92.00**
B → E	89.57	93.25	86.15	87.30	91.75	92.45	93.05	**93.75**

Avg.	90.12	92.68	88.25	88.56	91.12	92.06	92.45	**93.14**

Table 1: Results of single-source domain adaptation on Amazon reviews. There are four domains, B: Books, D: DVDs, E: Electronics, K: Kitchen appliances. In the table header, S: Source domain; T: Target domain; FT: Fine-tuning; AT: Adversarial training; PT(Hard): Prompt-tuning with the hard prompt; PT(Soft): Prompt-tuning with the soft prompt; + represents the combination, e.g., "PT(Hard) + AT" represents hard prompt tuning with the domain adversarial training. AdSPT is also called "PT(Soft) + AT". We report mean performances over 5 fold cross-validation.

(D), Electronics (E) and Kitchen appliances (K). Each domain has totally 2,000 manually labeled reviews. We use different settings for single-source domain adaptation and multi-source domain adaptation. For each domain, there are 2000 labeled reviews, including 1000 positive and 1000 negative, and 4000 unlabeled reviews. Following previous work (Ruder and Plank, 2017), we randomly select a small part (20%) of examples in each domain as the development set to save the best training model and perform a 5 fold cross-validation.

In single-source domain adaptation, we follow previous work (Ziser and Reichart, 2018) to construct 12 cross-domain sentiment analysis tasks (corresponding to 12 ordered domain pairs). In multi-source domain adaptation, we choose three-domain data as multiple source domains and the remaining one as the target domain, e.g., "BDE → K". So there are 4 combinations, corresponding to 4 tasks.

Training details. In the **Amazon reviews** experiments, we adopt a 12-layer Transformer (Vaswani et al., 2017; Devlin et al., 2019) initialized with RoBERTa$_{\text{BASE}}$ (Liu et al., 2019) as the PLM. During the training, we train with batch size of 2 for 10 epoches. The optimizer is Adam with learning rate $2e^{-5}$ for the PLM optimization and $5e^{-5}$ for optimizing domain discriminators. All experiments are conducted with an NVIDIA GeForce RTX 2080 Ti.

5.2 Baselines

We compare our method against 2 state-of-the-art methods, and also design several variants of fine-tuning and prompt tuning as baselines to demonstrate the effectivenss of adversatial training strategy in soft prompt tuning for DA.

(1) **BERT-DAAT**(Du et al., 2020): Use BERT post-training for cross-domain sentiment analysis with adversarial training.

(2) **SENTIX**$_{Fix}$(Zhou et al., 2020): Pre-train a sentiment-aware language model by several pre-training tasks.

(3) **Fine-tuning**: Standard fine-tuning vanilla PLMs in the source domain labeled data, which use the hidden representation of [CLS] for classification.

(4) **Fine-tuning + AT**: Add the adversarial training operating on standard fine-tuning vanilla PLMs.

(5) **Prompt-tuning(Hard)**: Use a manually defined template "It is [MASK]" for prompt-tuning.

(6) **Prompt-tuning(Hard) + AT**: Add the adversarial training operating on Prompt-tuning(Hard).

Following previous work (Du et al., 2020; Zhou et al., 2020), we adopt the accuracy to evaluate the performance.

5.3 Main Results

Main results contain results of single-source domain adaptation (Table 1) and multi-source domain adaptation (Table 2).

S → T	**Fine-tuning**		**Prompt-tuning**			
	FT	FT + AT	PT(HARD)	PT(HARD) + AT	PT(SOFT)	AdSPT
BDE → K	89.70	91.30	91.50	92.25	93.25	**93.75**
BDK → E	90.57	91.25	91.30	93.00	93.75	**94.25**
BEK → D	88.56	89.05	90.75	91.25	92.00	**93.50**
DEK → B	89.86	91.75	92.00	92.25	92.75	**93.50**
Avg.	89.67	90.84	91.39	92.00	92.94	**93.75**

Table 2: Results of multi-source domain adaptation on Amazon reviews.

Results of Single-source Domain Adaptation. Table 1 shows our main experimental results under single-source domain adaptation. We can observe that our method AdSPT outperforms all other methods in most of single-source domain adaptation.

Compared with previous state-of-the-art methods, AdSPT is significantly superior to BERT-DAAT and SENTIX$_{Fix}$ on average (3.02 absolute improvement and 0.46 absolute improvement, respectively). More specifically speaking, prompt-tuning methods achieve better results than BERT-DAAT on most of single-source domain adaptation. This indicates that prompt tuning can stimulate pre-encoded knowledge in PLMs to solve the DA problem. But the performance of PT(HARD) and PT(HARD) + AT is lower than that of SENTIX$_{Fix}$ on average (91.12% v.s. 92.68% and 92.06% v.s. 92.68%), showing that the feature representation of the [MASK] token in hard prompt tuning learns more domain knowledge of source domains, which leads to degraded performance on the target domain. Conversely, PT(SOFT) is comparable to SENTIX$_{Fix}$ on average (92.45% v.s. 92.68%) and AdSPT achieves better results than SENTIX$_{Fix}$ on average (0.46 absolute improvement). It shows that soft prompt tuning not only learns domain-aware continuous vectors, but also weakens the domain discrepancy of the feature distribution of the [MASK] position. In addition, prompt-tuning methods are consistently superior to FT and FT + AT, either using a hard prompt, or soft prompt.

In prompt-tuning, soft prompt tuning methods achieve better performances than corresponding hard prompt tuning methods (1.33 absolute improvement and 1.08 absolute improvement, respectively). This indicates these separate soft prompts can flexibly learn in-domain knowledge of different domains, which makes the feature representation of the [MASK] token more suitable for predicting the predefined label words. So soft prompt is more applicable to the DA problem than a hard prompt. When we add a domain adversarial training operation on soft prompt tuning, AdSPT achieves the new start-of-the-art result on average. It shows that the domain adversarial training strategy can enhance the domain-invariant feature of the [MASK] token among different domain datasets.

Results of Multi-source Domain Adaptation. Table 2 shows our main experimental results under multi-source domain adaptation.

Compared with fine-tuning methods, variants of prompt tuning achieve better performances (over at least 0.55 absolute improvement on average). This is mainly because prompt tuning uses the feature representation of [MASK] token for classification, rather than the feature representation of [CLS] token. On the one hand, fine-tuning is difficult to train the domain-specific classifier accurately from scratch on the unlabeled dataset. On the other hand, prompt tuning is used to classify by predicting the feature distribution of the [MASK] token in the set of label words, which can activate some prior knowledge in PLMs.

Compared with hard prompt tuning methods, soft prompt tuning methods achieve significant improvements on average (92.94% v.s. 91.39% and 93.75% v.s. 92.94%). Constructing the sophisticated hard template not only requires expertise knowledge and time, but the unified predefined hard template leads to the domain discrepancy of the feature representation of the [MASK] position that is unsuitable for multi-domain adaptation.

Besides, PT(HARD) + AT achieves a better result than PT(HARD) on average (0.61 absolute improvement), which shows the domain adversarial training can obtain domain-invariant features among different domains by domain discriminators for DA. So when adding the domain adversarial training into soft prompt tuning, AdSPT achieves the best results under multi-source domain adaptation setting. This shows the effectiveness of the collaboration of soft prompt tuning and the domain adversarial training strategy. In the domain ad-

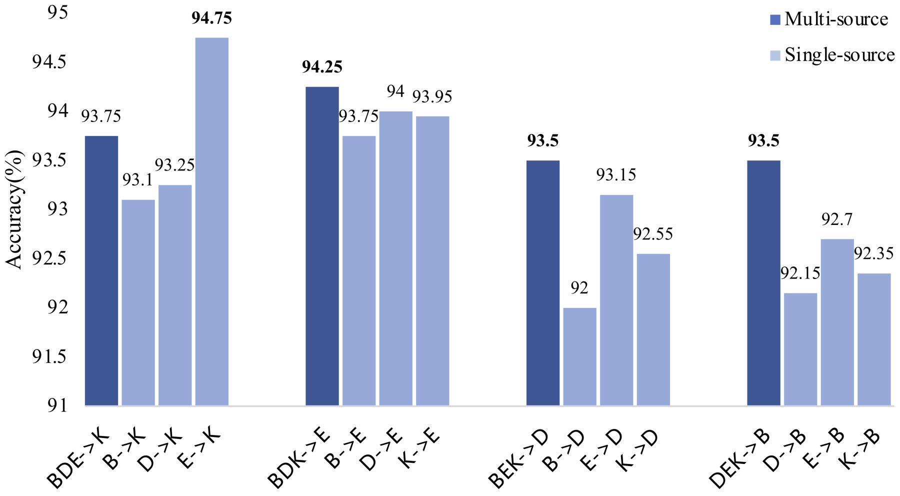

Figure 3: Analysis of multi-source and single-source

versarial training, using the feature representation of the [MASK] token to obtain domain invariance is better for predicting the predefined set of label words.

5.4 Analysis

Multi-source v.s. Single-source. We make more detailed comparisons to explore the effect of multi-source domain adaptation and single-source domain adaptation settings. Figure 3 illustrates the influence of multi-source and single-source on the predicted results of the same target domain. When the target domain is "E", "D", or "B", multi-source achieves better results in the target domain than single-source, showing that in most cases, multi-source domain adaptation is superior to single-source domain adaptation in cross-domain research. However, when the target domain is "K", the result of "E → K" is superior to that of "BDE → K" (94.75% v.s. 93.75%). It is mainly because the feature distribution of "E" and "K" is closer.

Effect of Soft Prompts. As stated in previous works (Gao et al., 2020), the choice of hard templates may have a huge impact on the performance of prompt tuning. In this subsection, we carry out experiments in "BDE → K" and "B → K" respectively to investigate the influence of different soft prompts under multi-source domain adaptation and single-source domain adaptation settings.

As shown in Figure 4, we use 6 different soft prompts (by changing the number of prompt tokens k). The results demonstrate that the choice of templates exerts a considerable influence on the performance of prompt tuning. For soft prompts, surprisingly, prompt tuning yields the best result with the fewest special tokens. Here $k = 3$.

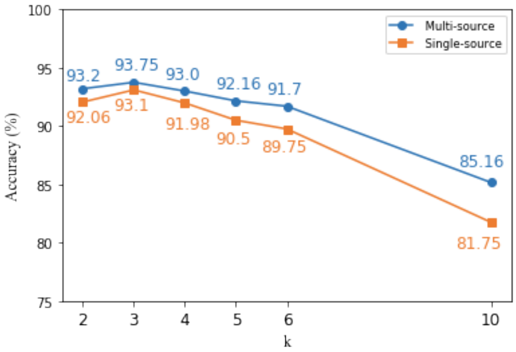

Figure 4: Results of different soft prompts k on "BDE → K" and "B → K"

6 Conclusion

In this paper, we proposed a novel **Ad**versarial **S**oft **P**rompt **T**uning method (AdSPT) for cross-domain sentiment analysis. Firstly, we use domain-specific soft prompts instead of hard templates to represent domain-specific knowledge. The domain-specific soft prompts can alleviate the domain discrepancy w.r.t. the [MASK] representations by MLM task. Meanwhile, we also design a novel adversarial training strategy to learn the domain-invariant knowledge of the [MASK] token among different domains. Experiments on the Amazon reviews dataset achieve state-of-the-art performance.

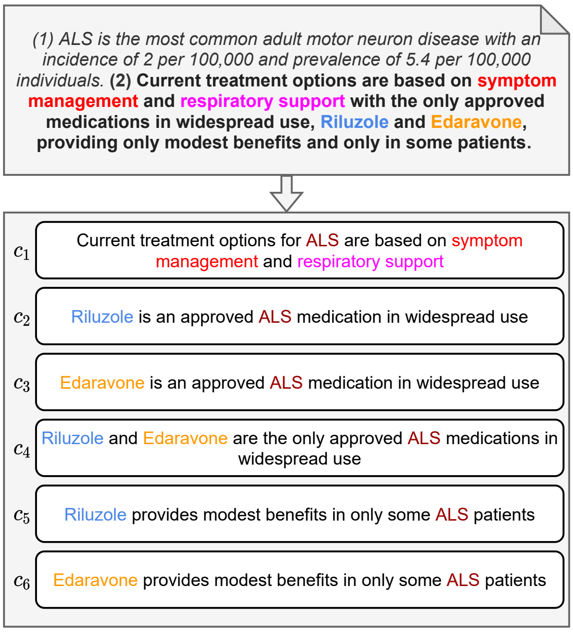
Abstract

Automated scientific fact checking is difficult due to the complexity of scientific language and a lack of significant amounts of training data, as annotation requires domain expertise. To address this challenge, we propose scientific claim generation, the task of generating one or more atomic and verifiable claims from scientific sentences, and demonstrate its usefulness in zero-shot fact checking for biomedical claims. We propose CLAIMGEN-BART, a new supervised method for generating claims supported by the literature, as well as KBIN, a novel method for generating claim negations. Additionally, we adapt an existing unsupervised entity-centric method of claim generation to biomedical claims, which we call CLAIMGEN-ENTITY. Experiments on zero-shot fact checking demonstrate that both CLAIMGEN-ENTITY and CLAIMGEN-BART, coupled with KBIN, achieve up to 90% performance of fully supervised models trained on manually annotated claims and evidence. A rigorous evaluation study demonstrates significant improvement in generated claim and negation quality over existing baselines.[1]

1 Introduction

Scientific documents contain complex assertions about scientific processes, making it difficult to automate important tasks such as claim extraction and scientific fact checking. Additionally, the collection of manually annotated labels to train models on tasks with scientific data is time consuming and expensive due to the need for domain expertise (Collins et al., 2017; Augenstein and Søgaard, 2017; Lehman et al., 2019; Wadden et al., 2020; DeYoung et al., 2021). As such, methods which require less manual annotation are especially useful in this domain. This work addresses this challenge by exploring how automatic generation of scientific claims can assist with dataset creation and zero-shot fact checking in the biomedical domain.



(1) ALS is the most common adult motor neuron disease with an incidence of 2 per 100,000 and prevalence of 5.4 per 100,000 individuals. **(2) Current treatment options are based on symptom management and respiratory support with the only approved medications in widespread use, Riluzole and Edaravone, providing only modest benefits and only in some patients.**

Figure 1: A complex excerpt from Mejzini et al. (2019) (top) and the set of valid claims that can be generated from the bolded sentence (c1-c6).

Being able to reduce scientific text to atomic assertions has numerous possible applications, and is known to be helpful for scientific communication and machine processing of scientific concepts (Kuhn et al., 2013). Claim generation can enable zero-shot fact checking, reducing the need for expert-labeled data (Pan et al., 2021), and can be used to expand existing datasets such as Wadden et al. (2020) and Saakyan et al. (2021) without additional manual annotation. In this work we focus on the use of claim generation in scientific fact checking, demonstrating that claim generation enables zero-shot biomedical fact checking.

Generating scientific claims involves distilling a complex scientific sentence into one or more valid claims (see examples in Figure 1). As in previous

work, we focus on biomedical claims as biomedical literature has long been a major focus in scientific natural language processing, as well as scientific fact checking (Saakyan et al., 2021; Wadden et al., 2020; Kotonya and Toni, 2020). While in Wadden et al. (2020), claims were rewritten by domain experts from complex citation sentences (citances), we propose methods for automatically generating claims and claim negations from this source.

Similar to other generation tasks, evaluating the quality of generated output requires multiple judgements beyond the fluency of the generated text, e.g., whether each claim is faithful to the source sentence, and is understandable on its own (Sai et al., 2020). However, there are also other quality attributes that are important to assess specifically for scientific claims, such as whether each claim is atomic or check-worthy (Wright and Augenstein, 2020). Given this, we propose a set of manual evaluation criteria and annotation guidelines for evaluating claim generation (§5.2).

Additionally, when generating claims to build datasets for tasks such as fact checking, a major challenge is creating refuted claims as negative training instances. Previous work has proposed automatic ways of generating refutations based on negating existing claims or creating claim variants via entity-replacement (Pan et al., 2021) and text-infilling using a pre-trained masked language model (Saakyan et al., 2021). We improve upon this by introducing Knowledge Base Informed Negations (KBIN), a principled method to generate refutations that performs entity-replacement using the relations and learned embeddings of entities in a domain-specific knowledge base.

Contributions In sum, our contributions are:

- The first study on scientific claim generation, comparing both unsupervised (CLAIMGEN-ENTITY) and fully supervised (CLAIMGEN-BART) generation on biomedical text.
- KBIN, a novel method for generating refuted scientific claims which produces more convincing negations than previous work.
- Application of our claim generation methods on zero-shot scientific fact checking resulting in 90% of the performance of a model trained on in-domain manually written claims. Additionally, a rigorous evaluation study showing that CLAIMGEN-BART and KBIN produce significantly higher quality claims and more convincing negations than previous work.

2 Preliminaries

Valid Claims In this work, we define a *valid claim* as one which is fluent, atomic, de-contextualized, and accurately reflects the meaning of the original sentence. Fluency is concerned with a claim being a generally well-formed English sentence, and atomicity with a claim being a "verifiable statement expressing a finding about one aspect of a scientific entity or process, which can be verified from a single source" (Wadden et al., 2020). De-contextualilzation is concerned with a sentence being interpretable on its own, requiring none of the original surrounding text to resolve aspects of the sentence such as pronouns, abbreviations, etc., and can be handled by either directly de-contextualizing a sentence (Choi et al., 2021) or by ensuring that all of the context sentences are available to a model (Wadden et al., 2021). Check-worthy claims in the wild may not be fluent, atomic, or de-contextualized, however it is useful to generate such claims as they have been shown to be useful for automated processing of science concepts (Kuhn et al., 2013) and scientific fact checking (Wadden et al., 2020).

Scientific Claim Generation At a high level, scientific claim generation is the task of distilling one or more *valid claims* from one or more sentences concerned with a scientific fact. More specifically, the task is defined as: given a scientific sentence s and optionally additional context sentences X, generate one or more claims $c_i \in C$ which are valid and entailed by s and X. In the context of fact checking, we must generate claims which are either *supported* or *refuted* by the literature, as well as those for which *not enough information* is present to make a veracity judgement, in order that they may be paired with appropriate evidence documents to serve as training data for fact checking systems. As such, we require methods which can take the claims in C which are entailed by the source sentence and generate negations to acquire *refuted* claims.

3 Generating Supported Claims

We experiment with two generation methods designed to produce claims which are *supported* by the source sentence. The first method is an entity-centric unsupervised method adapted from Pan et al. (2021) which requires no <sentence, claim> pairs (CLAIMGEN-ENTITY). We also introduce a new

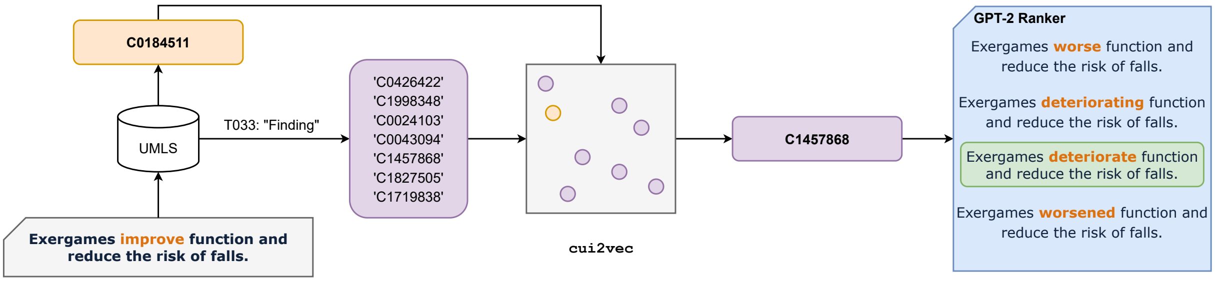

Figure 2: KBIN method. We start with NER and linking to UMLS using scispaCy. We then find the most similar concepts with the same type using `cui2vec`, replace the entity in the source sentence using the canonical name and aliases of similar entities, and rank them using GPT-2. Finally, from the highest ranked replacements, we select the claim which maximizes contradiction with the original claim using an external NLI model.

method that uses BART (Lewis et al., 2020) trained on a small set of <sentence, claim> pairs to directly generate claims (CLAIMGEN-BART). For each sample i, we refer to the input source sentence as s_i, the context sentences as $x_l^{(i)} \in X_i$ and the output claims as C_i consisting of k claims $\{c_1^{(i)} \dots c_k^{(i)}\}$ Following Wadden et al. (2020), we use citation sentences as unlabelled sentences for generation since these provide a natural link to an evidence document. Various components of our modeling pipelines take advantage of models pretrained on datasets for NER, NLI, QA, and fact-checking. We provide an overview of these datasets in §A.4.

3.1 CLAIMGEN-ENTITY

We adapt the entity-centric method presented in Pan et al. (2021) as an unsupervised claim generation approach. This method has been tested on general domain fact checking, but has not been used for science claim generation and zero-shot scientific fact checking. In particular, we re-implement the base method used for generating supported claims and adapt it to the biomedical domain, substituting in a domain specific model for named-entity recognition. The method consists of the following steps for a given sample i:

1. Run named entity recognition (NER) on the input text to obtain a set of named entities E_i.
2. For each named entity $e_j^{(i)}$, generate a question $q_j^{(i)}$ about that entity which can be answered from s_i.
3. From $q_j^{(i)}$, generate the declarative form of the question to obtain claim $c_j^{(i)}$.

Named Entity Recognition For NER, we employ scispaCy (Neumann et al., 2019), a spaCy[2] pipeline for scientific NLP. The NER model is trained on the MedMentions dataset (Mohan and Li, 2019), which consists of 4,392 PubMed abstracts exhaustively annotated for mentions of UMLS entities (Bodenreider, 2004).

Question Generation For question generation, we use BART trained on questions from SQuAD (Rajpurkar et al., 2016). As input for training, we encode a concatenation of the context and answer text from a given SQuAD question, and train the model to decode the question. During inference, we concatenate the source sentence s_i and an entity $e_j^{(i)}$ and sample a question $q_j^{(i)}$ for this pair using beam search.

Question to Claim Finally, as in Pan et al. (2021), we use a second BART model to generate declarative claims from questions. We train the model on the QA2D dataset (Demszky et al., 2018), which contains declarative full sentences paired with questions and their answer from SQuAD. The model is trained by encoding a concatenation of the question and answer, and decoding the full declarative sentence. At inference time, we concatenate and encode $q_j^{(i)}$ and $e_j^{(i)}$, and use beam search at the decoder to generate a claim $c_j^{(i)}$.

3.2 CLAIMGEN-BART

We introduce a fully-supervised model for claim generation based on BART trained on <citance, claim> pairs. For this, we use the manual citance re-writes released by the SciFact authors,[3] which consist of citances from scientific papers rewritten as one or more atomic claims which are directly entailed by the citance.

Algorithm 1 KBIN algorithm

```
function GetNegation($c$, KB, $V$, $N$)
    $E \leftarrow \text{NER}(c)$
    $\bar{C} \leftarrow []$
    for $e_j$ in $E$ do
        $u_j \leftarrow \text{LINK}(e_j)$
        $R \leftarrow \text{KB.siblings}(u_j)$
        $\text{filter}(R, \text{KB.type}(u_j))$
        $dist \leftarrow \text{cosdist}(V[u_j], V[R])$
        for $r$ in $\text{argsort}(dist)[: N]$ do
            $A \leftarrow \text{KB.aliases}(R[r])$
            $T \leftarrow \text{replace}(c, e_j, a)$ for $a$ in $A$
            $\bar{C}\text{.add}(\text{rank\_perplexity}(T)[0])$
        end for
    end for
    return $\text{rank\_contradiction}(c, \bar{C})[0]$
end function
```

For training, we encode the citance, as well as the sentences immediately before and after the citance (the context), and train the decoder to generate claims directly. We choose to encode the context as well to help *de-contextualize* generated claims. We concatenate the citance and context using a double pipe (i.e. $X_i \mid \mid s_i$), and train the encoder to generate one claim at a time. We use top-k sampling to generate multiple claims, with k set to the number of noun chunks in the original source citance.[4]

4 Knowledge Base Informed Negations

ClaimGen-entity and ClaimGen-BART only produce claims which are entailed by the source sentence. Additionally, we are interested in producing claim variants which are directly refuted by the original sentence, as these negations are needed when building fact checking datasets and for training fact checking models. Work in Wadden et al. (2020) created these negations manually, and some work has begun to explore automatically generating these negations for scientific claims (Saakyan et al., 2021). To this end, we leverage the availability of large curated biomedical knowledge bases to develop a principled approach to claim variant generation. In particular, we use the UMLS metathesaurus (Bodenreider, 2004), which unifies hundreds of different ontologies in biomedicine, as a source of term replacements for negations.

We provide an overview of the KBIN algorithm in Algorithm 1 and Figure 2. KBIN works by first performing NER on an input claim c, obtaining entities $\{e_1, \ldots, e_n\} \in E$. For each entity e_j in E, we link the entity to its unique concept u_j in UMLS using the scispaCy entity linker. If the entity is linked, we select all concepts which are siblings to u_j in the concept hierarchy, and which have the same semantic type (e.g. "Clinical Drug"). We rank all selected concepts by their cosine distance to the entity concept using pre-trained UMLS concept vectors, retaining the top 20 closest concepts. For this, we use `cui2vec` (Beam et al., 2020), which contains pre-trained concept vectors for 108,477 concepts from UMLS trained on medical documents from diverse sources.

For each of the related concepts, we generate candidate claim variants by replacing the entity text in the original claim with the canonical name and aliases of the related concept from UMLS. We rank all replacement sentences by their perplexity using a pre-trained GPT-2 model (Radford et al., 2019), keeping the sentence with least perplexity for each replacement. Finally, from among these most fluent sentences, we select the replacement which maximizes the NLI prediction of *contradiction* with the original claim. For this, we use a RoBERTa model (Liu et al., 2019) pre-trained on MNLI (Williams et al., 2018).

5 Experiments

We investigate three primary research questions:

RQ1 Do automatically generated claims enable zero-shot scientific fact checking?

RQ2 What is the percentage of high-quality claims generated using our methods?

RQ3 How does KBIN compare with previous work for claim negation in terms of generating contradictions?

For **RQ1**, we use ClaimGen-entity and ClaimGen-BART generated claims to train a fact checking model, evaluating on the SciFact dataset (Wadden et al., 2020) and comparing to relevant baselines. To answer **RQ2** and **RQ3**, we design annotation criteria and perform manual evaluations with a group of expert annotators (details in §5.2).

5.1 RQ1: Fact Checking Performance

SciFact Task The SciFact fact verification task consists of: given a claim c and a corpus of scientific abstracts D, retrieve evidence abstracts from

---

[4] We use scispaCy to identify noun chunks

D, predict if the claim is *supported* or *refuted* by those documents or if there is *not enough information (NEI)* to make a prediction, and optionally determine what the rationale sentences are that explain the prediction. Here we focus on the oracle abstract setting of the task, in which gold abstracts are provided to the model and there is no retrieval component. This setup exists in the scientific fact checking literature (Saakyan et al., 2021), and allows us to focus on one component of the fact checking pipeline for evaluating the impacts of claim generation.

Creating Training Data for the Zero-shot Setting We require a set of claim-abstract pairs for training where the abstract either supports, refutes, or does not provide evidence for the given claim. We exploit citation relationships to generate claims paired with potential evidence, using citances from the CiteWorth dataset (Wright and Augenstein, 2021) as source citances for generation. *Supports* claims are produced by directly pairing a generated claim with the abstracts of documents cited by the source citance. For *refutes* claims, we negate a generated claim using KBIN and pair it with the same abstract. For claims labelled *NEI*, we pair the generated claim or negated claim with the abstract of the source document of the citance; the source document is related to the claim but presumably does not directly support or refute the claim given the need for a citation.

Experimental Setup In our experimental setup, we use LongChecker (Wadden et al., 2021), a Longformer (Beltagy et al., 2020) model adapted for scientific fact checking. The model forms its input by concatenating a claim with its evidence abstract, inserting separator tokens between sentences, and uses a classification head to predict the veracity label from the representation of the `[CLS]` token.

We explore several different setups for our training data. As a baseline, we experiment with pre-training only on FEVER claims (Thorne et al., 2018), which are general domain fact checking data based on Wikipedia. We also include an experiment where we manually tune a threshold for the prediction of *NEI* on the SciFact training data, as we saw that the model tends to overpredict this label without any fine-tuning on in-domain data. We also provide an upper bound on performance by fine-tuning on the in-domain train split of SciFact. Finally, we experiment with both CLAIMGEN-ENTITY and CLAIMGEN-BART as sources of training data generated from CiteWorth citances, pairing both with KBIN for negations. We note that though CLAIMGEN-BART requires manually re-written claims as training data for generating *supports* claims, it does not use any claims paired with evidence manually labelled for veracity, thus making it zero-shot for the SciFact fact-checking task. In all cases we test on the SciFact dev split. Hyperparameter information, including number of training instances, is given in §A.3, and code and data will be released upon paper acceptance. In all cases, results are reported as macro-F1.

Method	P	R	F1
FEVER only	86.21	11.96	21.01
FEVER + thresh	69.15	66.51	67.80
SciFact (Upper Bound)	77.88	77.51	77.70
CLAIMGEN-ENTITY	**72.86**	69.38	**71.08**
CLAIMGEN-BART	64.09	**79.43**	70.94

Table 1: Results for veracity prediction on the SciFact dataset using different sources of training data.

Results Our results on SciFact are given in Table 1. With an upper bound of 77.70 F1, we see that a model fine-tuned on automatically generated claims is able to achieve within 90% of the performance of a model trained on in-domain manually written claims. This is also invariant to the method used to generate claims, as both CLAIMGEN-ENTITY and CLAIMGEN-BART produce similar results. Additionally, both methods provide significant gains over pre-training on FEVER only, especially when no threshold on *NEI* claims is used but also when re-calibrating the model to predict *NEI* less often.

5.2 RQ2: Claim Quality Evaluation

Next, we explore if there are differences between our methods in terms of claim quality and the percentage of valid claims. For this, we ask three expert annotators to manually assess generated claims along a number of quality criteria. One annotator has undergraduate training in the life sciences and graduate training in computer science; the other two annotators have undergraduate training in the life sciences and materials science respectively. We define a set of criteria for evaluation, given in Table 2. These criteria are inspired by the AIDA (Atomic, Independent, Declarative, and Absolute)

Metric	Labels
Fluency	3 - The claim contains no grammatical errors and its meaning can be understood
	2 - The claim contains some grammatical errors but is still understandable
	1- The claim contains many grammatical errors and cannot be understood
De-Contextualized	1 - The claim is interpretable on its own and requires no context; the addition of the original context does not alter the meaning of the claim
	0 - The claim cannot be interpreted in a meaningful way without the original context
Atomicity	1 - The claim is about a single entity/process (atomic)
	0 - The claim is non-atomic and can be broken down into multiple claims
Faithfulness	5 - The claim is correct and fully supported and complete with respect to the original sentence and context
	4 - The claim is correct with respect to the original sentence and context but leaves out information from the original sentence and context
	3 - The claim is related to the original sentence and does not contain incorrect information but is not explicitly stated in the original sentence
	2 - The claim contains explicitly incorrect information relative to the original sentence and context
	1 - The claim has nothing to do with the original sentence

Table 2: Claim quality evaluation metrics and their possible values

framework for scientific claims introduced in Kuhn et al. (2013). They are also based on similar human evaluation criteria used to assess generation quality for related tasks (Sai et al., 2020). We develop an initial set of guidelines for the annotators and conduct two rounds of pilot annotations to improve instructions and increase agreement. For the final evaluation, we generate claims on a set of 100 citances sampled from the CiteWorth dataset (Wright and Augenstein, 2021), which contains citations in context for over 1M citances spanning 10 domains.

We limit the citances to those from papers in biology and medicine to match the domain of SciFact. Annotator agreement is measured as Krippendorff's α (Krippendorff, 2011) on 236 claims for each category except fluency, where we measure the percentage of claims where all annotators agree.[5] The annotators then assess 1,049 total claims (including the 236 shared claims). Each annotator rates all criteria for an individual claim, starting with fluency, then de-contextualized, then atomicity, then faithfulness. We are mainly interested in claim quality and yield, so annotators only annotate "de-contextualized" if the claim is legible (fluency > 1), and only annotate "atomicity" and "faithfulness" if the claim is also de-contextualized (so one is able to discern meaning from the claim). This results in the following rules for acceptable claims based on the definitions for the labels in each category: Fluency > 1 AND De-Contextualized $= 1$ AND Atomicity $= 1$ AND Faithfulness > 3. An acceptable claim is thus legible, meaningful, represents a single aspect of a scientific entity or process, and accurately reflects the information presented in the original citance.

The results of claim quality annotation are given in Table 3. Note that these are on claims generated by ClaimGen-entity and ClaimGen-BART (see examples in Table 4), and thus are only *supports* claims. We first note that inter-annotator agreement is very high for fluency and moderate across all other criteria. Generated claims are quite fluent across methods, with a small minority of instances being illegible. Unsurprisingly, ClaimGen-BART improves over ClaimGen-entity across all categories except for atomicity. This intuitively makes sense as ClaimGen-entity directly produces claims which are about a single entity. ClaimGen-entity yields a higher number of claims per citance as it generates one claim for every entity in the sentence, but the precision of acceptable claims is much lower than that of ClaimGen-BART. Thus, there is a tradeoff between the two methods between the number of claims generated and their acceptability. While higher yield could lead to higher coverage of claims in the original text, this study is left to future work.

Next, we examine the similarity between generated claims and manually written claims from

---

[5] Fluency agreement is measured in terms of agreement percentage as most ratings are the same (3), thus any disagreements have an oversized influence on α.

Method	Fluency	De-Con. (%)	Atomic (%)	Faithfulness	# Gen	# Accept	P
CLAIMGEN-ENTITY	2.51	55.63	**85.28**	3.54	893	111	12.43
CLAIMGEN-BART	**2.74**	**84.35**	80.65	**4.15**	156	69	**44.23**
α (236 claims)	82.74	64.53	58.71	53.01	-	-	-

Table 3: Average annotation score, agreement, and claim yield for each category. De-contextualized is only annotated if fluency > 1; atomicity and faithfulness are only annotated if fluency > 1 and de-contextualized == 1. # Gen are the total claims generated by the method, and # Accept are the number of acceptable claims generated.

Method	R-1	R-2	R-L
Entity	47.12	27.63	42.30
BART	**56.58**	**40.12**	**53.38**

Table 5: ROUGE score between generated and manually written reference claims in the SciFact dataset

SciFact. We generate claims for each source citance s_i in the SciFact dev split, and calculate the ROUGE score (Lin, 2004) between each generated claim $c_j^{(i)}$ and each manually written claim $d_k^{(i)}$. From this, we take an average of the max ROUGE score for each generated claim. Formally, given $|C|$ claims we calculate:

$$score = \frac{1}{|C|} \sum_i \sum_j \max_k \text{ROUGE}(c_j^{(i)}, d_k^{(i)})$$

Our evaluation results are given in Table 5. Both methods produce claims which have high overlap with the reference claims, though claims generated directly using BART are significantly closer to the reference claims than those generated using CLAIMGEN-ENTITY. Finally, we note the these scores are in the range of state-of-the-art models used for paraphrase generation, establishing a solid baseline for this task (Zhou and Bhat, 2021).

5.3 RQ3: Negation Evaluation

Finally, we perform a manual evaluation to compare KBIN against other methods of negation generation. Annotators evaluate negations based on Fluency and Entailment. We adopt the definitions used to annotate the SNLI corpus (Bowman et al., 2015), in which the annotator is given an original claim (premise) and a generated negation (hypothesis) and asked to select from among the following options, including a SKIP option for Fluency:

3 The hypothesis is DEFINITELY FALSE given the premise

2 The hypothesis MIGHT BE TRUE given the premise

1 The hypothesis is DEFINITELY TRUE given the premise

SKIP The hypothesis contains a lot of grammatical errors and cannot be understood

We compare KBIN to two baselines. The first baseline replaces a single entity in the claim with

Original Claim	Method	Generated Negation
Tonic signaling from the SCFV prevents constitutive stimulation.	Entity replace	Tonic signaling from the SCFV under care of respiratory physician (finding) constitutive stimulation.
	Saakyan et al. (2021)	Tonic signaling from the inflammatory stimulation.
	KBIN	Tonic signaling from the SCFV accelerates constitutive stimulation.

KBIN	**93**	**15**	75	3

Table 7: Results for manual annotation of claim negations on 100 negations for each method. Fluent claims received annotations other than "SKIP".

a random entity of the same type, similar to the method in Pan et al. (2021). The second is the proposed negation generation method in Saakyan et al. (2021). The method is based on extracting keywords using YAKE (Campos et al., 2020) (an unsupervised method based on statistical text features), replacing those keywords using text infilling with a pre-trained language model, and selecting the replacement with the highest contradiction score using a model pre-trained for NLI. We generate negations for 100 claims using all three methods. For annotation, generated negations from all three methods are aggregated and the order of negation method randomized for each of the 100 claims.

Example negations generated by all three methods are given in Table 6 and annotation results for fluency and entailment are given in Table 7. First, KBIN produces more fluent claims than both baselines. Additionally, KBIN produces more convincing negations on average than both baselines. We observe that the most common operation performed by all three methods is to replace a noun phrase. KBIN has the benefit of being able to replace many entity types corresponding to concepts found in UMLS, which also include verb phrases that encode relations. Finally, KBIN improves over the baseline from Saakyan et al. (2021) by producing fewer claims which are directly entailed by the source claim, i.e., that maintain the original meaning and do not negate the original claim.

5.4 Further Analysis

To give further insight into the quality of claims generated using our methods, we perform an experiment where we train and test models for scientific fact checking using claims only. This "claim-only" experiment helps us assess whether the negation process introduces data artifacts that can be leveraged by the model to predict veracity. We present results from training on claims generated using CLAIMGEN-BART and KBIN, compared against training on the original SciFact training data (which has manually written negations), along with random and majority baselines, in Figure 3.

We observe that there are likely some dataset artifacts in the original SciFact claims that lead to model performance well above the majority and random baselines.[6] This phenomenon has been

---

[6] It is difficult to fully separate the contributions of data artifacts and model performance in this setting, i.e., there is no situation which guarantees *no* undesirable data artifacts. Performance ought to be better than a random baseline in this theoretical setting, due to the pretrained language model likely having had some exposure to the content of the claims during pretraining.

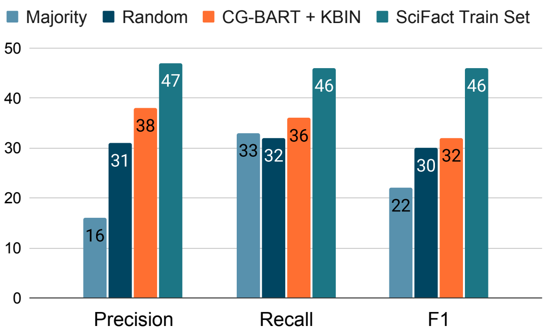

Figure 3: Fact checking performance of models trained only on claims (i.e. no evidence). Training on our generated claims result in performance closer to random (indicating fewer data artifacts) than training on the original SciFact claims.

observed in general domain natural language inference datasets as well (Poliak et al., 2018). Training on claims generated using our methods results in performance that is much more proximal to random performance on the SciFact dev set, indicating that the label-associated bias in the original training data is not present and a possible domain shift between the original SciFact claims and our generated claims. This can further explain some of the performance gap we observe between zero-shot fact-checking and the upper bound of training on manually labeled training data (Table 1).

6 Related Work

Scientific Fact Checking Our work follows a line of recent literature on scientific fact checking (Wadden et al., 2020). The goal of this task is to determine the veracity of claims related to scientific topics by retrieving appropriate documents from scientific literature, finding evidentiary sentences from those documents, and determining whether claims are supported, refuted, or there is not enough evidence to make a judgement. The task closely resembles the task of general domain fact-checking (Thorne et al., 2018; Augenstein et al., 2019). Well-performing systems on this task use large language models to perform neural document retrieval (Pradeep et al., 2020) or multi-task learning of rationale prediction and stance prediction (Li et al., 2021; Wadden et al., 2021). Recent work on general domain fact checking has also introduced methods for adversarial generation of claims which are particularly difficult to fact-check (Thorne et al., 2019; Atanasova et al., 2020), and for performing the task without any labeled data (Pan et al., 2021). Our proposed methods extend zero-shot fact checking to the scientific domain, demonstrating that one can achieve 90% of the inference performance of state-of-the-art systems without domain-specific labeled data.

Generating Training Data Our work is also related to methods for the automatic generation of training data. Generation of synthetic data has been used for multiple tasks, for example question answering (Duan et al., 2017; Riabi et al., 2021), knowledge-base completion (Safavi et al., 2021), and fact-checking (Pan et al., 2021). Most similar to our setting, the COVID-Fact dataset (Saakyan et al., 2021) contains claims related to COVID-19 crawled from Reddit, and is constructed semi-automatically. Claims which are supported by evidence are extracted from Reddit and verified by human annotators, while negations of these claims are generated automatically via masked language model infilling. KBIN improves upon the negation method proposed in this work by leveraging in-domain structured knowledge via UMLS.

7 Conclusion

In this work, we propose the task of scientific claim generation, presenting CLAIMGEN-BART, CLAIMGEN-ENTITY, and KBIN to perform the task. We demonstrate that generated claims can be used to train a model for zero-shot scientific fact checking and obtain within 90% of the performance of a model trained on human-written claims. Through a rigorous user study we demonstrate that CLAIMGEN-BART produces higher quality claims than CLAIMGEN-ENTITY, and that KBIN produces more fluent and more convincing negations than previous work. Work remains to improve claim generation quality and assess the impacts of generated claims in other domains of science, as well as how generated claims can be used in the evidence retrieval component of fact checking systems. We hope that our methods will be used to facilitate future work by enabling faster creation of training datasets and improving the performance of models on the timely and important task of scientific fact checking.

Curie grant agreement No 801199, and by the United States National Science Foundation Grant OIA-2033558. We thank Doug Downey, Hannaneh Hajishirzi, the reviewers, and members of the Semantic Scholar research team for their valuable feedback.

Ethical Considerations

Automated scientific fact checking has great potential value to the scientific community, as well as for addressing phenomenon such as the propagation of scientific misinformation. Our aim in releasing models for scientific claim generation is to improve the generalizability of science fact checking systems in domains with less training resources. When training our fact checking models with generated or synthetic data, there are questions regarding the veracity of the generated data and whether a model trained on inferred labels could produce trustworthy judgments. We hope that by introducing this task and models, we will enable the community to study such questions, while contributing to data curation in a domain in which such curation would normally require significant manual efforts and cost.

Table 8: Model sizes.

A Reproducibility

A.1 Computing Infrastructure

All experiments were run on an Amazon Web Services p3.2xlarge instance using a Tesla V100 GPU with 16GB of RAM.

A.2 Number of Parameters per Model

The sizes of each of the models used in this work are given in Table 8.

A.3 Hyperparameters

A.3.1 Fact Checking

SciFact data Learning rate: 1e-5, 5 epochs, gradient accumulation for 8 batches, 1 sample per training batch, 16-bit precision, 809 total claims.

FEVER threshold We tune the NEI threshold on the training set of SciFact, testing values in the range [1e-5, 2e-5, 3e-5, 4e-5, 5e-5, 1e-4, 2e-4, 3e-4, 4e-4, 5e-4, 1e-3, 2e-3, 3e-3, 4e-3, 5e-5, 0.01, 0.12, 0.2, 0.25, 0.4, 0.5, 0.75, 0.8, 0.8, 0.99, 0.999] and find that 5e-5 produces the best result.

CLAIMGEN-BART Learning rate: 2e-6, 5 epochs, gradient accumulation for 8 batches, 1 sample per training batch, 16-bit precision, 1,561 total training claims.

CLAIMGEN-ENTITY Learning rate: 4e-8, 5 epochs, gradient accumulation for 8 batches, 1 sample per training batch, 16-bit precision, 8,592 total training claims.

A.3.2 CLAIMGEN-BART

Learning rate: 2e-5, 3 epochs, linear warmup for 200 steps followed by linear decay, weight decay of 0.01, batch size of 8.

A.4 Description of Datasets

We use a variety of datasets in this study for different components of models, training, and testing. Here we provide a description of each and in which module the dataset is used.

SciFact The SciFact dataset and rewritten claims used to train CLAIMGEN-BART can be found at https://github.com/allenai/scifact. The dataset consists of 585 original citances with rewritten claims for each of them. Each citance consists of 1-2 rewritten claims. The SciFact rewritten claims are used to train CLAIMGEN-BART for direct claim generation. Additionally, SciFact contains biomedical claims paired with evidence abstracts and veracity labels in {*supports*, *refutes*, *not enough info*} and is split into train, dev, and test sets. We use the train set for supervised fact checking experiments, and the dev set for testing since the test set does not come with labels.

FEVER FEVER is a general domain fact checking dataset built from Wikipedia. Like SciFact, the dataset consists of claims with paired evidence documents with labels in {*supports*, *refutes*, *not enough info*}. FEVER is used as pretraining data for our fact checking models for zero-shot transfer to biomedical claims. The dataset can be found here https://fever.ai/resources.html.

MedMentions The MedMentions dataset is a dataset of 4,392 biomedical papers annotated with mentions of UMLS entities. It is used to train the named entity recognition and normalization models used by ScispaCy, which we used for named entity recognition in CLAIMGEN-ENTITY and for normalization in KBIN. The dataset can be found at https://github.com/chanzuckerberg/MedMentions

UMLS The UMLS meta-thesaurus is a large biomedical knowledge base which unifies hundreds of different ontologies in biomedicine. UMLS is used as the source knowledge base for normalization and candidate selection for KBIN. Additionally, it is the knowledge base used to train `cui2vec`, which is used for candidate concept selection in KBIN. UMLS can be found here https://www.nlm.nih.gov/research/umls/index.html.

SQuAD The SQuAD dataset can be found at: https://rajpurkar.github.io/SQuAD-explorer/. SQuAD is used as training data for the question generation module of CLAIMGEN-ENTITY. SQuAD is a question answering dataset which contains data of the form (q, c, a), where q is the question, c is a context document, and a is an answer to the question which can be found in the context.

QA2D The QA2D dataset can be found at: https://worksheets.codalab.org/worksheets/0xd4ebc52cebb84130a07cbfe81597aaf0/. QA2D is used in the second part of the zero-shot CLAIMGEN-ENTITY model to generate declarative sentences from questions. It consists of data of the form (s, q, a) where q is a question, a is the answer to the question, and s is the declarative form of the question containing the answer.

MNLI MNLI is a crowd-sourced collection of 433k sentence pairs annotated for textual entailment. In other words, the data consists of pairs (p, h), where p is the premise and h is the hypothesis, and labels in {*entailment*, *contradiction*, *neutral*} which say if the hypothesis entails, contradicts, or is neutral towards the premise. MNLI is used to train a RoBERTa model for entailment, which is used by KBIN to select the best negation among a set of generated claims for a given source citance. The dataset can be found here https://cims.nyu.edu/ sbowman/multinli/

Modeling Dual Read/Write Paths for Simultaneous Machine Translation

Shaolei Zhang [1,2], **Yang Feng** [1,2*]

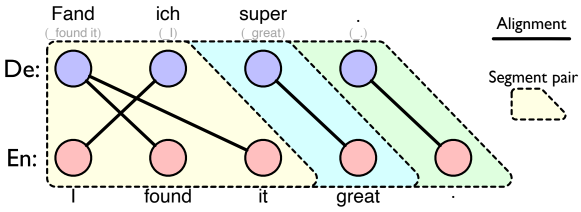
Abstract

Simultaneous machine translation (SiMT) outputs translation while reading source sentence and hence requires a policy to decide whether to wait for the next source word (READ) or generate a target word (WRITE), the actions of which form a *read/write path*. Although the read/write path is essential to SiMT performance, no direct supervision is given to the path in the existing methods. In this paper, we propose a method of dual-path SiMT which introduces duality constraints to direct the read/write path. According to duality constraints, the read/write path in source-to-target and target-to-source SiMT models can be mapped to each other. As a result, the two SiMT models can be optimized jointly by forcing their read/write paths to satisfy the mapping. Experiments on En↔Vi and De↔En tasks show that our method can outperform strong baselines under all latency.

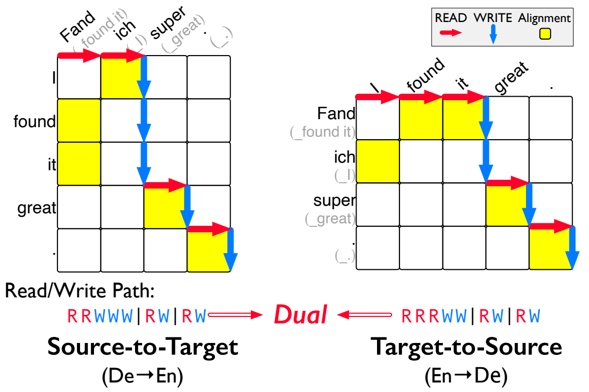
1 Introduction

Simultaneous machine translation (SiMT) (Cho and Esipova, 2016; Gu et al., 2017; Ma et al., 2019; Arivazhagan et al., 2019), which outputs translation while reading source sentence, is important to many live scenarios, such as simultaneous interpretation, live broadcast and synchronized subtitles. Different from full-sentence machine translation which waits for the whole source sentence, SiMT has to decide whether to wait for the next source word (i.e., READ action) or translate a target word (i.e., WRITE action) to complete the translation.

The sequence of READ and WRITE actions in the translation process form a *read/write path*, which is key to SiMT performance. Improper read/write path will bring damage to translation performance as compared to the following WRITE actions too many but not *necessary* READ actions will result in high translation latency while too few but not *sufficient* READ actions will exclude indispensable source information. Therefore, an ideal read/write path is that the READ actions compared to the following WRITE actions are just *sufficient* and *necessary*, which means the source words covered by consecutive READ actions and the target words generated by the following consecutive WRITE actions should be semantically equivalent.



(a) Segment pairs between the sentence pair.



(b) The duality between the read/write paths in two directions.

Figure 1: An example of duality constraints. With duality constraints, the read/write paths of source-to-target and target-to-source translation should project to the same segment pairs between two languages.

Ensuring sufficiency and necessity between READ/WRITE actions will lead to a proper read/write path and thereby good SiMT performance. But unfortunately, the existing SiMT methods, which employ a fixed or adaptive policy, do not consider the sufficiency or necessity in their policy. The fixed policy performs SiMT based on

May 22-27, 2022

a pre-defined read/write path (Dalvi et al., 2018; Ma et al., 2019), where the number of READ actions before WRITE is fixed. The adaptive policy (Gu et al., 2017; Zheng et al., 2019b; Arivazhagan et al., 2019; Zheng et al., 2019a; Ma et al., 2020; Liu et al., 2021) dynamically decides to READ or WRITE guided by translation quality and total latency, but skips the evaluation of sufficiency and necessity between READ/WRITE actions.

Under these grounds, we aim at introducing the evaluation of sufficiency and necessity between READ/WRITE actions to direct the read/write path without involving external information. As mentioned above, in an ideal read/write path, the source segment (i.e., source words read by the consecutive READ actions) and the corresponding target segment (i.e., target words generated by the following consecutive WRITE actions) are supposed to be semantically equivalent and thus translation to each other, which constitutes a separate *segment pair*. Hence, an ideal read/write path divides the whole sentence pair into a sequence of segment pairs where the source sentence and the target sentence should be translation to each other segment by segment. That means if the translation direction is reversed, an ideal read/write path for target-to-source SiMT can also be deduced from the same sequence of segment pairs. For example, according to the alignment in Figure 1(a), the ideal read/write paths should be 'RRWWW|RW|RW' in De→En SiMT and 'RRRWW|RW|RW' in En→De SiMT, as shown in Figure 1(b), both of which share the same segment pair sequence of $\langle$*Fand ich*, *I fount it*$\rangle$, $\langle$*super*, *great*$\rangle$ and $\langle .,. \rangle$. Therefore, agreement on the segment pairs derived from read/write paths in source-to-target and target-to-source SiMT, called *duality constraints*, can be a good choice to evaluate sufficiency and necessity between READ/WRITE actions.

Based on the above reasoning, we propose a method of *Dual-Path SiMT*, which uses the SiMT model in the reverse direction to guide the SiMT model in the current direction according to duality constraints between their read/write paths. With duality constraints, the read/write paths in source-to-target and target-to-source SiMT should reach an agreement on the corresponding segment pairs. Along this line, our method maintains a source-to-target SiMT model and a target-to-source SiMT model concurrently, which respectively generate their own read/write path using monotonic multi-head attention (Ma et al., 2020). By minimizing the difference between the segment pairs derived from the two read/write paths, the two SiMT models successfully converge on the segment pairs and provide supervision to each other. Experiments on IWSLT15 En↔Vi and WMT15 De↔En SiMT tasks show that our method outperforms strong baselines under all latency, including the state-of-the-art adaptive policy.

2 Background

We first briefly introduce SiMT with a focus on monotonic multi-head attention (Ma et al., 2020).

For a SiMT task, we denote the source sentence as $\mathbf{x} = \{x_1, \cdots, x_J\}$ and the corresponding source hidden states as $\mathbf{m} = \{m_1, \cdots, m_J\}$, where J is the source length. The model generates target sentence $\mathbf{y} = \{y_1, \cdots, y_I\}$ with target hidden states $\mathbf{s} = \{s_1, \cdots, s_I\}$, where I is the target length. During translating, SiMT model decides to read a source word (READ) or write a target word (WRITE) at each step, forming a read/write path.

Read/write path can be represented in multiple forms, such as an action sequence of READ and WRITE (e.g., RRWWWRW$\cdots$), or a path from $(0,0)$ to (I,J) in the attention matrix from the target to source, where moving right (i.e., $\rightarrow$) means READ action and moving down (i.e., $\downarrow$) means WRITE action, as shown in Figure 1(b).

Mathematically, a read/write path can be represented by a monotonic non-decreasing sequence $\{g_i\}_{i=1}^{I}$ of step i, where the g_i represents the number of source words read in when writing the i^{th} target word y_i. The value of $\{g_i\}_{i=1}^{I}$ depends on the specific SiMT policy, where monotonic multi-head attention (MMA) (Ma et al., 2020) is the current state-of-the-art SiMT performance via modeling READ/WRITE action as a Bernoulli variable.

Monotonic multi-head attention MMA processes the source words one by one, and concurrently predicts a selection probability p_{ij} to indicates the probability of writing y_i when reading x_j, and accordingly a Bernoulli random variable z_{ij} is calculated to determine READ or WRITE action:

$$p_{ij} = \mathrm{Sigmoid}\left(\frac{m_j V^K (s_{i-1} V^Q)^\top}{\sqrt{d_k}}\right), \tag{1}$$

$$z_{ij} \sim \mathrm{Bernoulli}\left(p_{ij}\right), \tag{2}$$

where V^K and V^Q are learnable parameters, d_k is dimension of head. If $z_{ij} = 0$, MMA performs READ action to wait for the next source word x_{j+1}.

If $z_{ij}=1$, MMA sets $g_i=j$ and performs WRITE action to generate y_i based on $x_{\leq g_i}$. Therefore, the decoding probability of $\mathbf{y}$ with parameters $\boldsymbol{\theta}$ is

$$p(\mathbf{y} \mid \mathbf{x}; \boldsymbol{\theta}) = \prod_{i=1}^{I} p\left(y_i \mid \mathbf{x}_{\leq g_i}, \mathbf{y}_{<i}; \boldsymbol{\theta}\right), \qquad (3)$$

where $\mathbf{x}_{\leq g_i}$ are first g_i source tokens, and $\mathbf{y}_{<i}$ are previous target tokens.

Note that when integrated into multi-head attention, all attention heads in decoder layers independently determine the READ/WRITE action. If and only when all heads decide to perform WRITE action, the model starts translating, otherwise the model waits for the next source word.

Expectation training Since sampling a discrete random variable z_{ij} precludes back-propagation, MMA applies expectation training Raffel et al. (2017) to replace z_{ij} with a *expected writing probability*, denoted as

$$\boldsymbol{\alpha} = \left(\alpha_{ij}\right)_{I \times J}, \qquad (4)$$

where α_{ij} calculates the expectation probability of writing y_i when reading x_j. Then, the attention distribution and context vectors are accordingly calculated in the expected form.

To trade-off between translation quality and latency, MMA introduces a latency loss $\mathcal{L}_g$ to the training loss:

$$\mathcal{L}\left(\boldsymbol{\theta}\right) = -\sum_{(\mathbf{x},\mathbf{y})} \log p\left(\mathbf{y} \mid \mathbf{x}; \boldsymbol{\theta}\right) + \lambda \mathcal{L}_g, \qquad (5)$$

where $\mathcal{L}_g$ measures the total latency, and λ is the weight of latency loss. Please refer to Arivazhagan et al. (2019) and Ma et al. (2020) for more detailed derivation and implementation.

3 The Proposed Method

Our dual-path SiMT model employs a source-to-target (*forward*) model and a target-to-source (*backward*) model, called single-path SiMT, which generate their own read/write path based on MMA. According to duality constraints that the read/write paths of the two single-path SiMT models should share the same segment pair sequence, the two read/write paths should be transposed to each other in principle as shown in Figure 1. But in practice, after transposing one of the read/write paths, there is always a gap between the transposed read/write path and the original one in the reverse translation direction. By closing the gap between the aforementioned transposed and original read/write paths, as shown in Figure 2, duality constraints are introduced into the dual-path SiMT model and thereby the two single-path SiMT models can provide guidance to each other. In what follows, we will introduce how to get the transposed read/write path (Sec.3.1) and how to reduce the gap (Sec.3.2).

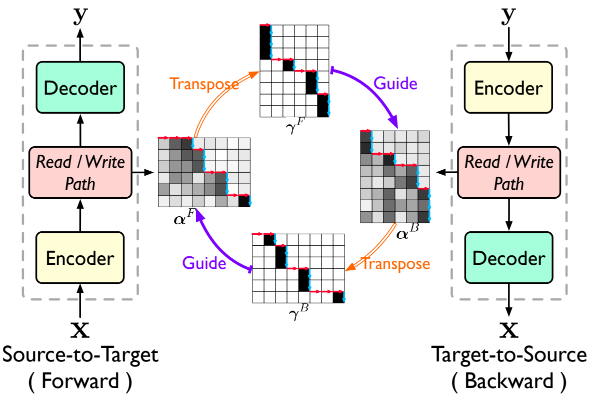

Figure 2: The architecture of dual-path SiMT, consisting of the forward and backward single-path SiMT models. To accomplish the duality constraints, we generate the transposed path of the forward (or backward) read/write path, and use this transposed path to direct the read/write path in another direction; vice versa.

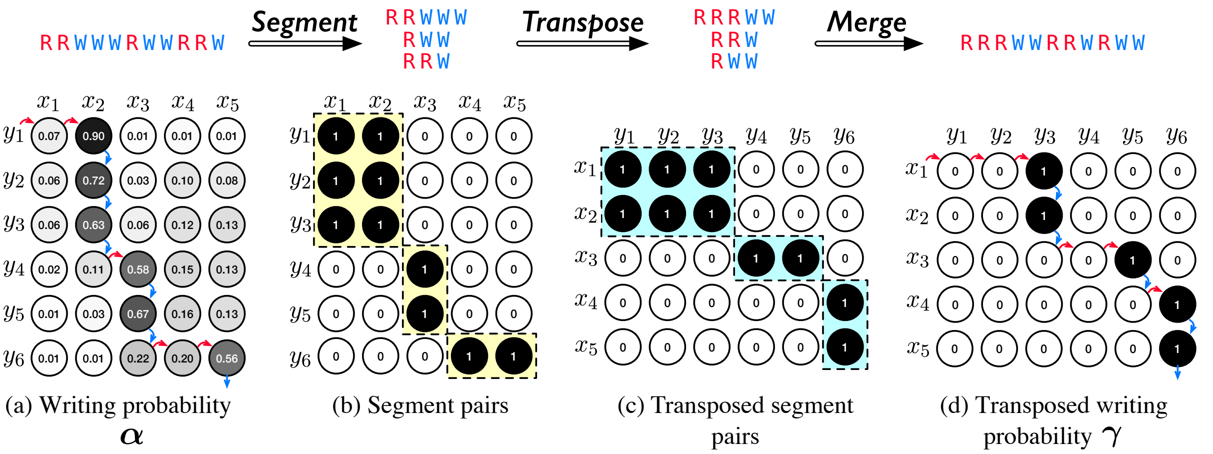
3.1 Transposing the Read/Write Path

The purpose of transposing a read/write path is to get a new read/write path in the reverse direction based on the same segment pairs as the original path. As the transposing process works in the same way for the two directions, we just introduce the process for the forward single-path SiMT. Since there is no explicit read/write path in the training of single-path SiMT model, the transposing process can only use the expected writing probability matrix $\boldsymbol{\alpha}$ as the input, shown in Eq.(4). Similarly, the output of the transposing process is the transposed writing probability matrix $\boldsymbol{\gamma} = \left(\gamma_{ji}\right)_{J \times I}$ calculated from the transposed read/write path, which will be used to guide the backward single-path SiMT.

The transposing process consists of three steps. First, derive the read/write path from the expected writing probability matrix $\boldsymbol{\alpha}$ and *segment* the sentence pair into a sequence of segment pairs. Second, *transpose* the sequence of segment pairs into the corresponding one for the backward SiMT. Last, *merge* the transposed segment pairs to get the transposed path and then project it to $\boldsymbol{\gamma}$. In the following, we will introduce the steps of segment, transpose and merge in details.



(a) Writing probability $\boldsymbol{\alpha}$ (b) Segment pairs (c) Transposed segment pairs (d) Transposed writing probability $\boldsymbol{\gamma}$

Figure 3: Simplified diagrams of generating transposed writing probability $\boldsymbol{\gamma}$ from the writing probability $\boldsymbol{\alpha}$. (a→b) Segment the sentence pair into a sequence of segment pairs. (b→c) Transpose the segment pairs to fit the backward SiMT. (c→d) Merge the transposed segment pairs to get transposed writing probability with the transposed path.

Segment Given the expected writing probability matrix $\boldsymbol{\alpha}$, to get the read/write path, we first find out the source position d_i that the WRITE action for each target position i corresponds to, which is

$$d_i = \underset{j}{\text{argmax}}\ \alpha_{ij}. \tag{6}$$

According to the property of monotonic attention, there are some consecutive WRITE actions that corresponds to the same source position, so the target words generated by the consecutive WRITE actions form a target segment. Formally, we assume there are K target segments in total, denoted as $\mathbf{y} = \{\bar{\mathbf{y}}_1, \cdots, \bar{\mathbf{y}}_k, \cdots, \bar{\mathbf{y}}_K\}$. For each target segment $\bar{\mathbf{y}}_k = (y_{b_k^y}, \cdots, y_{e_k^y})$, where b_k^y and e_k^y are its beginning and end target positions, we can get the corresponding source segment as $\bar{\mathbf{x}}_k = (x_{b_k^x}, \cdots, x_{e_k^x})$ where

$$b_k^x = \begin{cases} 1 & k=1 \\ d_{e_{k-1}^y} + 1 & \text{otherwise} \end{cases} \tag{7}$$

and

$$e_k^x = d_{b_k^y}. \tag{8}$$

Thus the sentence pairs $\langle \mathbf{x}, \mathbf{y} \rangle$ can be segmented into the sequence of segment pairs as $\langle \bar{\mathbf{x}}_1, \bar{\mathbf{y}}_1 \rangle \mid \cdots \mid \langle \bar{\mathbf{x}}_K, \bar{\mathbf{y}}_K \rangle$. By replacing the source words with READ actions and target words with WRITE actions, we can get the action segment pairs. Then, the read/write path is formed by concatenating all the action segment pairs, where the length of the read/write path is equal to the total number of source words and target words.

For the example shown in Figure 3(a), the sequence of source positions d_i corresponding to WRITE actions for the whole target sentence is $2, 2, 2, 3, 3, 5$, with the corresponding read/write path RRWWWRWWRRW. Then, we can get the sequence of segment pairs as $\langle x_1\, x_2,\ y_1\, y_2\, y_3 \rangle \mid \langle x_3,\ y_4\, y_5 \rangle \mid \langle x_4\, x_5,\ y_6 \rangle$, and thereby the sequence of action segment pairs as $\langle$RR, WWW$\rangle$ | $\langle$R, WW$\rangle$ | $\langle$RR, W$\rangle$ shown in Figure 3(b).

Transpose After getting the sequence of segment pairs, the transposed read/write path can be derived from it. As the transposed read/write path is in the form to fit the backward single-path SiMT, the sequence of segment pairs should also be transposed to fit the another direction. According to duality constraints, the sequence of segment pairs is shared by forward and backward SiMT, so we only need to exchange the source segment and target segment in each segment pair, that is from $\langle \bar{\mathbf{x}}_k, \bar{\mathbf{y}}_k \rangle$ to $\langle \bar{\mathbf{y}}_k, \bar{\mathbf{x}}_k \rangle$, where the beginning and end positions of each source/target segment remain the same. Then, we get the corresponding transposed action segment pairs by replacing target words with READ actions and source words with WRITE actions. In this way, we accomplish the transposing of segment pairs. Let's review the example in Figure 3(b), after transposing, the sequence of segment pairs as $\langle y_1\, y_2\, y_3,\ x_1\, x_2 \rangle \mid \langle y_4\, y_5,\ x_3 \rangle \mid \langle y_6,\ x_4\, x_5 \rangle$, and the corresponding sequence of transposed action segment pairs is $\langle$RRR, WW$\rangle$ | $\langle$RR, W$\rangle$ | $\langle$R, WW$\rangle$ as shown in Figure 3(c).

Merge By merging the transposed action segment pairs, we can get the transposed read/write path. The goal of the transposing process is to get the transposed writing probability matrix $\boldsymbol{\gamma}$ to constrain the excepted writing probability matrix for the backward single-path SiMT. According to the definition of the writing probability matrix, only the last column in the sub-matrix covered by each segment pair corresponds to WRITE actions. Formally, for each transposed segment pair $\langle \bar{\mathbf{y}}_k, \ \bar{\mathbf{x}}_k \rangle$, the following elements in $\boldsymbol{\gamma}$ should have the greatest probability to perform WRITE actions as $\{\gamma_{b_k^x e_k^y}, \cdots, \gamma_{e_k^x e_k^y}\}$. For the three sub-matrices shown in Figure 3(c), only the elements of the last column correspond to WRITE actions as shown in Figure 3(d), which are $\{\gamma_{13}, \gamma_{23}, \gamma_{35}, \gamma_{46}, \gamma_{56}\}$. We employ the $0-1$ distribution to set the value of elements in $\boldsymbol{\gamma}$, where the elements corresponding to WRITE actions are set to 1 and others are set to 0. This is equivalent to the situation that the selection probability for the Bernoulli distribution (in Eq.(2)) is 1.

3.2 Training

Assuming the expected writing probability matrix for the forward single-path SiMT is $\boldsymbol{\alpha}^F$ and its transposed expected writing probability matrix is $\boldsymbol{\gamma}^F$, and similarly in the backward single-path SiMT, the matrices are $\boldsymbol{\alpha}^B$ and $\boldsymbol{\gamma}^B$, respectively. We reduce the gap between the read/write path with the transposed path of read/write path in another direction by minimizing L_2 distance between their corresponding expected writing probability matrix as follows:

$$\Omega^F = \left\| \boldsymbol{\alpha}^F - \boldsymbol{\gamma}^B \right\|_2 \tag{9}$$

$$\Omega^B = \left\| \boldsymbol{\alpha}^B - \boldsymbol{\gamma}^F \right\|_2 . \tag{10}$$

Two L_2 distances are added to the training loss as a regularization term and final training loss is

$$\mathcal{L} = \mathcal{L}\big(\boldsymbol{\theta}^F\big) + \mathcal{L}\big(\boldsymbol{\theta}^B\big) + \lambda_{dual}(\Omega^F + \Omega^B), \tag{11}$$

where $\mathcal{L}\big(\boldsymbol{\theta}^F\big)$ and $\mathcal{L}\big(\boldsymbol{\theta}^B\big)$ are the loss function of the forward and backward single-path SiMT model respectively, calculated as Eq.(5). λ_{dual} is a hyper-parameter and we set $\lambda_{dual} = 1$ in our experiments.

In the inference time, the forward and backward single-path SiMT models can be used separately, depending on the required translation direction.

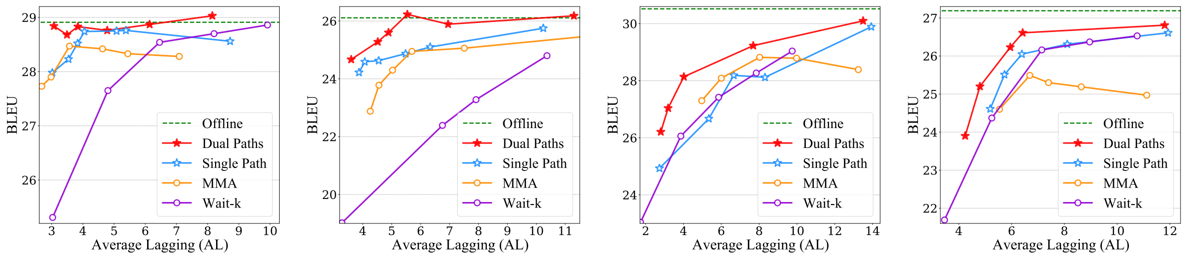
4 Related Work

Dual learning is widely used in dual tasks, especially machine translation. For both unsupervised (He et al., 2016; Artetxe et al., 2019; Sestorain et al., 2019) and supervised NMT (Xia et al., 2017; Wang et al., 2018), dual learning can provide additional constraints by exploiting the dual correlation. Unlike most previous dual learning work on NMT, which use the reconstruction between source and target sequences, we focus on SiMT-specific read/write path and explorer its intrinsic properties.

SiMT policy falls into two categories: fixed and adaptive. For fixed policy, the read/write path is defined by rules and fixed during translating. Dalvi et al. (2018) proposed STATIC-RW, which alternately read and write RW words after reading S words. Ma et al. (2019) proposed wait-k policy, which always generates target k tokens lagging behind the source input. Elbayad et al. (2020) enhanced wait-k policy by sampling different k during training. Han et al. (2020) applied meta-learning in wait-k. Zhang et al. (2021) proposed future-guided training to apply a full-sentence MT model to guide wait-k policy. Zhang and Feng (2021a) proposed a char-level wait-k policy. Zhang and Feng (2021b) proposed a universal SiMT with mixture-of-experts wait-k policy to perform SiMT under arbitrary latency levels.

For adaptive policy, the read/write path is learned and adaptive to the current context. Early adaptive policies used segmented translation (Bangalore et al., 2012; Cho and Esipova, 2016; Siahbani et al., 2018). Gu et al. (2017) trained an agent with reinforcement learning. Alinejad et al. (2018) added a predict operation based on Gu et al. (2017). Zheng et al. (2019a) trained an agent with golden READ/WRITE actions generated by rules. Zheng et al. (2019b) added a "delay" token to read source words. Arivazhagan et al. (2019) proposed MILk, which applied monotonic attention and used a Bernoulli variable to determine writing. Ma et al. (2020) proposed MMA, which is the implementation of MILk on the Transformer and achieved the current state-of-the-art SiMT performance. Zhang et al. (2020) proposed a adaptive segmentation policy. Wilken et al. (2020) used the external ground-truth alignments to train the policy. Liu et al. (2021) proposed cross-attention augmented transducer. Alinejad et al. (2021) introduced a full-sentence model to generate a ground-truth action sequence. Miao et al. (2021) proposed a generative SiMT policy.

The previous methods often lack the internal supervision on read/write path. Some works use external information such as alignment or generated



(a) En→Vi (b) Vi→En (c) De→En (d) En→De

Figure 4: Translation quality (BLEU) against latency (AL) on the En↔Vi and De↔En. We show the results of Dual Paths, Single Path, MMA (the current SOTA adaptive policy), Wait-k and Offline model.

rule-based sequences to guide the read/write path (Zheng et al., 2019a; Zhang et al., 2020; Wilken et al., 2020; Alinejad et al., 2021). However, these methods rely too much on heuristic rules, and thus their performance is not comparable to jointly optimizing read/write path and translation. Our method internally explorers the duality between the read/write paths in two directions, and accordingly uses the duality to constrain the read/write paths, thereby obtaining better SiMT performance.

5 Experiments

5.1 Datasets

We evaluated our method on four translation directions of the following two public datasets.

IWSLT15[1] English↔Vietnamese (En↔Vi) (133K pairs) (Cettolo et al., 2015) We use TED tst2012 (1553 pairs) as validation set and TED tst2013 (1268 pairs) as test set. Following Raffel et al. (2017) and Ma et al. (2020), we replace tokens that the frequency less than 5 by $\langle unk \rangle$. After replacement, the vocabulary sizes are 17K and 7.7K for English and Vietnamese, respectively.

WMT15[2] German↔English (De↔En) (4.5M pairs) Following Ma et al. (2020), we use newstest2013 (3000 pairs) as validation set and newstest2015 (2169 pairs) as test set. BPE (Sennrich et al., 2016) is applied with 32K merge operations and the vocabulary is shared across languages.

5.2 System Setting

We conducted experiments on following systems.

Offline Conventional Transformer (Vaswani et al., 2017) model for full-sentence translation.

Wait-k Wait-k policy, the widely used fixed policy Ma et al. (2019), which first reads k source tokens and then writes a target word and reads a word alternately.

MMA[3] Monotonic multi-head attention (MMA) proposed by (Ma et al., 2020), the state-of-the-art adaptive policy for SiMT, which applies monotonic attention on each head in Transformer.

Single Path SiMT model of one translation direction based on monotonic multi-head attention. To avoiding outlier heads[4] that are harmful for the read/write path, we slightly modified MMA for more stable performance. We no longer let the heads in all decoder layers independently determine the READ/WRITE action, but share the READ/WRITE action between the decoder layers.

Dual Paths Dual-path SiMT described in Sec.3.

The implementations of all systems are adapted from Fairseq Library (Ott et al., 2019), based on Transformer (Vaswani et al., 2017), where we apply Transformer-Small (4 heads) for En↔Vi, and Transformer-Base (8 heads) for De↔En. For 'Dual Paths', the forward and backward models are used to complete the SiMT on two translation directions at the same time. To perform SiMT under different latency, we set various lagging numbers[5] k for 'Wait-k', and set various latency weights[6][7] λ for 'MMA', 'Single Path' and 'Dual Paths'.

We evaluate these systems with BLEU (Papineni

[4] Since MMA requires all heads in decoder layers to independently decide READ/WRITE action and starts translating only when all heads select WRITE action, some outlier heads that perform too many READ actions will result in higher latency. Ma et al. (2020) try to control this phenomenon by adding some loss functions, but it still cannot avoid some outlier heads waiting for too many words, which seriously affects the impair the necessity between the READ/WRITE actions in read/write path (Ma et al., 2020; Zaidi et al., 2021).

et al., 2002) for translation quality and Average Lagging (AL) (Ma et al., 2019) for latency. Average lagging evaluates the number of words lagging behind the ideal policy. Given read/write path g_i, AL is calculated as

$$\mathrm{AL} = \frac{1}{\tau} \sum_{i=1}^{\tau} g_i - \frac{i-1}{|\mathbf{y}| \,/\, |\mathbf{x}|}, \qquad (12)$$

where $\tau = \underset{i}{\operatorname{argmax}} \left(g_i = |\mathbf{x}| \right)$, and $|\mathbf{x}|$ and $|\mathbf{y}|$ are the length of the source sentence and target sentence respectively. The results with more latency metrics are shown in Appendix D.

5.3 Main Results

Figure 4 shows the comparison between our method and the previous methods on 4 translation directions. 'Dual Paths' outperforms the previous methods under all latency, and more importantly, the proposed duality constraints can improve the SiMT performance on both source-to-target and target-to-source directions concurrently.

Compared to 'Wait-k', our method has significant improvement, especially under low latency, since the read/write path in 'Wait-k' is fixed and cannot be adjusted. Compared to 'MMA', the state-of-the-art adaptive policy, our 'Single Path' achieves comparable performance and is more stable under high latency. 'MMA' allows each head of each layer to independently predict a read/write path, where some outlier heads will affect the overall performance, resulting in a decline in translation quality under high latency (Ma et al., 2020). Our method applies a common read/write path instead of the heads in each layer to predict READ/WRITE, thereby reducing the possibility of outlier heads. Based on 'Single Path', 'Dual Paths' further improves the SiMT performance by modeling the duality constraints between read/write paths, especially under low latency. Besides, our method improves the SiMT performance even close to the full-sentence MT on En↔Vi, which shows that the more precise read/write path is the key to SiMT performance. Additionally, under the same latency weight λ, our method tends to have lower latency than 'MMA' on De↔En. The 'Single Path' reduces the unnecessary latency caused by outlier heads, and the duality constraints further improve the necessity of reading source content, thereby achieving lower latency.

6 Analysis

We conducted extensive analyses to understand the specific improvements of our method. Unless otherwise specified, all results are reported on De→En.

6.1 Ablation Study

We conducted ablation studies on the duality constraints, where we use direct transposition to replace transposing process of read/write path, only constrain the forward single-path model or remove the duality constraints. As shown in Table 1, the proposed method of transposing the read/write path is critical to translation quality, showing the importance of the segment operation. Besides, mutual constraining between forward and backward single-path model is more conducive to SiMT performance than only constraining one of them or removing constraints.

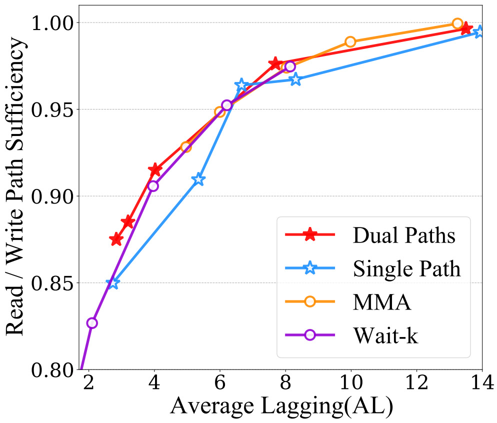
6.2 Evaluation of Read/Write Path

The read/write path needs to ensure sufficient content for translation and meanwhile avoid unnecessary latency, where the aligned source position[8] is always considered as the oracle position to perform WRITE in previous work (Wilken et al., 2020; Arthur et al., 2021). Therefore, we propose two metrics A^{Suf} and A^{Nec} to measure the *sufficiency* and *necessity* between the READ/WRITE actions in a path via alignments. We denote the ground-truth aligned source position of the i^{th} target word as a_i, and the read/write path is represented by g_i, which is the number of source words read in when writing the i^{th} target word. For sufficiency, A^{Suf} is used to evaluate whether the aligned source word is read before writing the target word, calculated as

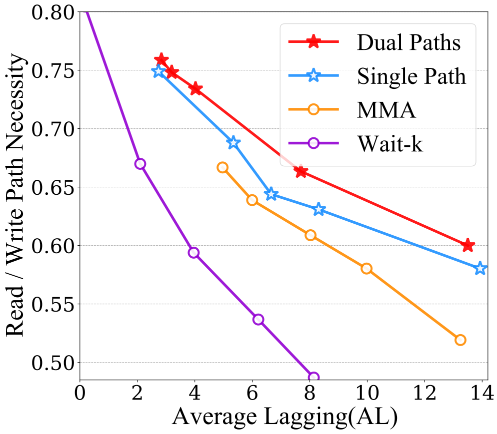
$$A^{Suf} = \frac{1}{I} \sum_{i=1}^{I} \mathbb{1}_{a_i \leq g_i}, \qquad (13)$$

---

[8] For many-to-one alignment from source to target, we choose the furthest source word. For the target words with no alignment, we ignore them.



(a) Sufficiency of read/write path A^{Suf} ↑.



(b) Necessity of read/write path A^{Nec} ↑.

Figure 5: Sufficiency evaluation and necessity evaluation of the read/write path.

where $\mathbb{1}_{a_i \leq g_i}$ counts the number of $a_i \leq g_i$, and I is the target length. For necessity, A^{Nec} is used to measure the distance between the output position g_i and the aligned source position a_i, calculated as

$$A^{Nec} = \frac{1}{|a_i \leq g_i|} \sum_{i, a_i \leq g_i} \frac{a_i}{g_i}, \tag{14}$$

where the best case is $A^{Nec} = 1$ for $g_i = a_i$, performing WRITE just at the aligned position and there is no unnecessary waiting. The more detailed description please refers to Appendix A.

As shown in Figure 5, we evaluate the A^{Suf} and A^{Nec} of read/write path on RWTH De→En alignment dataset [9], whose reference alignments are manually annotated by experts. The read/write paths of all methods perform similarly in sufficiency evaluation and our method performs slightly better at low latency. Except that the fixed policy 'Wait-k' may be forced to start translating before reading the aligned source word under the lower latency, 'MMA' and our method can almost cover more than 85% of the aligned source word when starting translating. In the necessity evaluation, our method surpasses 'Wait-k' and 'MMA', and starts translation much closer to the aligned source word, which shows that duality constraints make read/write path more precise, avoiding some unnecessary waiting. Note that while avoiding unnecessary waiting, our method also improves the translation quality (see Figure 4) under the same latency, which further shows the importance of a proper read/write path for SiMT performance.

Latency	**Duality of Read/Write Path (IoU) between De→En and En→De**		
	MMA	Single Path	Dual Path
High	0.4755	0.5328	0.6346
Middle	0.5132	0.5898	0.6962
Low	0.6046	0.7169	0.7466

Table 2: Duality of read/write path (IoU score) between De→En and En→De.

6.3 Effect of Duality Constraints

To verify that our method improves the duality of two read/write paths, we conduct duality evaluation between source-to-target and target-to-source read/write paths. Specifically, we first express both the original read/write path on target-to-source and the transposed path of source-to-target read/write path in the form of matrices, and then calculate the *Intersection over Union score* (IoU) between the area below them (see Figure 6), which is regarded as the duality between the read/write path in the two directions. The higher IoU score indicates that the two paths are more consistent on common segment pairs, i.e., stronger duality. Appendix B gives the detailed calculation of IoU score.

The results of duality evaluation are reported in Table 2, where our method effectively enhances the duality of source-to-target and target-to-source read/write paths under all latency levels. This shows that with dual-path SiMT, the read/write paths in source-to-target and target-to-source are more in agreement on the sequence of segment pairs between the sentence pair.

6.4 Dual Read/Write Paths Visualization

Figure 6 shows the read/write path visualization of a De↔En example. In 'Dual Paths', there is a

strong duality between the read/write paths in two translation directions, where the target-to-source read/write path (Figure 6(c)) and the transposed path of the source-to-target read/write path (Figure 6(b)) have a high degree of overlap. In particular, the read/write paths in our method exhibit a clear division on segment pairs.

6.5 Analysis on Forward/Backward Latency

To analyze the relationship between the forward and backward single-path SiMT model in terms of the latency setting, we set the latency weight (λ in Eq.(5)) of the forward and backward single-path SiMT model to different values, denoted as λ^F and λ^B respectively (the greater the latency weight, the lower the model latency). Table 3 reports the effect of different settings of λ^B on the performance of the forward single-path model.

After applying backward model and the duality constraints, our method has a much lower latency and similar translation quality compared with 'MMA' and 'Single Path'. As the latency of the backward model decreases (λ^B becomes larger), the latency of the forward model also gradually decreases, which shows that the latency of the forward and backward models are strongly correlated. Overall, regardless of the setting of λ^F and λ^B, 'Dual Paths' obtains a better trade-off between latency and translation quality. Furthermore, we can get a slightly larger or smaller latency by adjusting the combination of λ^F and λ^B.

7 Conclusion

In this paper, we develop the dual-path SiMT to supervise the read/write path by modeling the duality constraints between SiMT in two directions. Experiments and analyses we conducted show that our method outperforms strong baselines under all latency and achieves a high-quality read/write path.

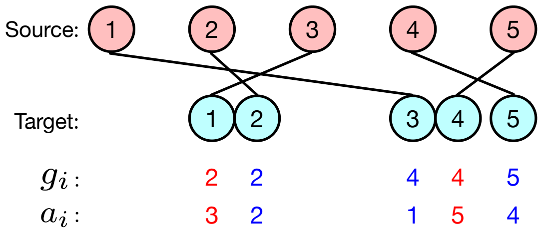

Figure 7: Schematic diagram of evaluating the read/write path in terms of sufficiency and necessity. The black line indicates the ground-truth alignments between the target and source. g_i is the number of source words read in when generating the i^{th} target word. a_i is the ground-truth aligned source position of the i^{th} target word. $a_i > g_i$ (numbers colored in red) means that the i^{th} target word is forced to be translated in advance before reading its aligned source word.

A Evaluation Metrics of Read/Write Path

In Sec.6.2, we propose two metrics A^{Suf} and A^{Nec} to measure the *sufficiency* and *necessity* of the read/write path using alignments. Here, we give a more detailed calculation of them.

Given the ground-truth alignments, we denote the aligned source position of the i^{th} target word as a_i. Specifically, for one-to-many alignment from target to source, we choose the furthest source word as it aligned source position. For a read/write path, we denote the number of source words read in when generating the i^{th} target word as g_i. Figure 7 gives an example of the calculation of a_i and g_i.

Sufficiency A^{Suf} measures how many aligned source words are read before translating the target word (i.e., $a_i \leq g_i$), which ensures the faithfulness of the translation, calculated as

$$A^{Suf} = \frac{1}{I}\sum_{i=1}^{I} \mathbb{1}_{a_i \leq g_i}, \tag{15}$$

where $\mathbb{1}_{a_i \leq g_i}$ counts the number that $a_i \leq g_i$. Taking the case in Figure 7 as an example, the sufficiency is calculated as $A^{Suf} = \frac{1}{5} \times (0+1+1+0+1) = \frac{3}{5}$, where the 1^{st} and 4^{th} target word are translated before read their aligned source word ($a_i > g_i$).

Necessity A^{Nec} measures how far the output position g_i is from the aligned position a_i, where the closer output position to the alignment position indicates that the read/write path outputs earlier, and there is less unnecessary latency. A^{Nec} is calculated as

$$A^{Nec} = \frac{1}{|a_i \leq g_i|}\sum_{i, a_i \leq g_i} \frac{a_i}{g_i}, \tag{16}$$

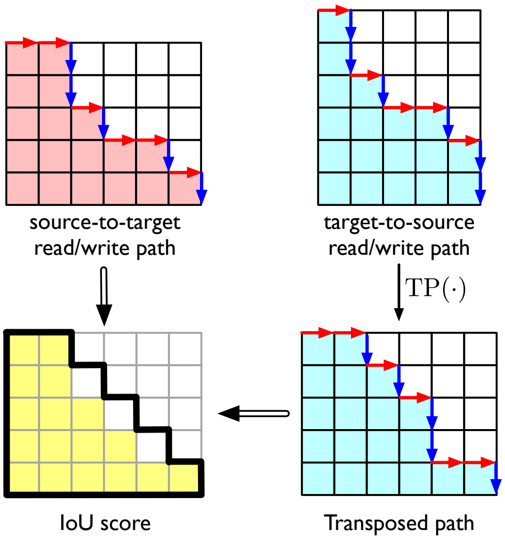

Figure 8: Schematic diagram of calculating the Intersection over Union score (IoU) to evaluate the dual degree of source-to-target and target-to-source read/write path. The yellow area represents the union of the areas below two paths, and the area enclosed by the black line represents the intersection.

Note that A^{Nec} only focuses on aligned positions that are read before output position (i.e., $a_i \leq g_i$). In the case shown in Figure 7, the necessity is calculated as $A^{Nec} = \frac{1}{3} \times \left(\frac{2}{2} + \frac{1}{4} + \frac{4}{5}\right) = \frac{41}{60}$, where we only consider the the 2^{th}, 3^{rd} and 5^{th} target word.

B IoU Score for Duality Evaluation

To verify that our proposed method does make the read/write path of source-to-target and target-to-source more dual, we calculate the *Intersection over Union score* (IoU) to evaluate the duality in Sec.6.3. Following, we describe the detailed calculation of IoU score.

Figure 8 gives an example of calculating the IoU score. Given the source-to-target and target-to-source read/write path $\mathbf{P}^{s2t}$ and $\mathbf{P}^{t2s}$ in the binary matrix form, we first generate the transposed path $\mathbf{TP}^{s2t}$ of $\mathbf{P}^{t2s}$ with proposed method of transposing the read/write path in Sec.3.1. Then, we calculate the intersection over union score between binary matrices $\mathbf{P}^{s2t}$ and $\mathbf{TP}^{s2t}$:

$$\mathrm{IoU} = \frac{\mathrm{Sum}\left(\mathbf{P}^{s2t} \cap \mathbf{TP}^{s2t}\right)}{\mathrm{Sum}\left(\mathbf{P}^{s2t} \cup \mathbf{TP}^{s2t}\right)}, \tag{17}$$

where the larger IoU score means that the source-to-target and target-to-source read/write path are much more dual. Ideally, the best case is $\mathrm{IoU} = 1$,

Table 4: Hyperparameters of our experiments.

which means the source-to-target and target-to-source read/write path are exactly in the dual form and reach the agreement on the sequence of segment pairs.

In the calculation of IoU score, for 'MMA' and 'Single Path', the source-to-target and target-to-source read/write paths come from independent models in the two directions respectively. For 'Dual Paths', the source-to-target and target-to-source read/write paths come from the forward and backward single-path SiMT model concurrently.

C Hyperparameters

All systems in our experiments use the same hyperparameters, as shown in Table 4.

D Numerical Results with More Metrics

We also compare 'Dual Paths' and 'Single Path' with previous methods on the latency metrics Average Proportion (AP) (Cho and Esipova, 2016) and Differentiable Average Lagging (DAL) (Arivazhagan et al., 2019). In this section, we first give the definition of AP and DAL, and then report the expanded results and numerical results of the main experiment (Sec.5.3), using AP, AL, DAL as latency metrics.

D.1 Latency Metrics

Average Proportion (AP) (Cho and Esipova, 2016) measures the proportion of the area above a read/write path. Given the read/write path g_i, AP is calculated as

$$\mathrm{AP} = \frac{1}{|\mathbf{x}|\,|\mathbf{y}|}\sum_{i=1}^{|\mathbf{y}|} g_i. \tag{18}$$

Differentiable Average Lagging (DAL) (Arivazhagan et al., 2019) is a differentiable version of average lagging, which can be integrated into training. Given the read/write path g_i, DAL is calculated as

$$g_i^{'} = \begin{cases} g_i & i = 1 \\ \max\left(g_i, g_{i-1}^{'} + \frac{|\mathbf{x}|}{|\mathbf{y}|}\right) & i > 1 \end{cases}, \tag{19}$$

$$\mathrm{DAL} = \frac{1}{|\mathbf{y}|}\sum_{i=1}^{|\mathbf{y}|} g_i^{'} - \frac{i-1}{|\mathbf{x}|\,/\,|\mathbf{y}|}. \tag{20}$$

D.2 Expand Results

Figure 9, 10, 11, 12 respectively show the expanded results on IWSLT15 En↔Vi and WMT15 De→En, measured by AP and DAL.

D.3 Numerical Results

Table 5, 6, 7, 8 respectively report the numerical results on IWSLT15 En↔Vi and WMT15 De→En, measured by AP, AL, DAL, and BLEU.

Abstract

Local models for Entity Disambiguation (ED) have today become extremely powerful, in most part thanks to the advent of large pre-trained language models. However, despite their significant performance achievements, most of these approaches frame ED through classification formulations that have intrinsic limitations, both computationally and from a modeling perspective. In contrast with this trend, here we propose EXTEND, a novel local formulation for ED where we frame this task as a text extraction problem, and present two Transformer-based architectures that implement it. Based on experiments in and out of domain, and training over two different data regimes, we find our approach surpasses all its competitors in terms of both data efficiency and raw performance. EXTEND outperforms its alternatives by as few as 6 F_1 points on the more constrained of the two data regimes and, when moving to the other higher-resourced regime, sets a new state of the art on 4 out of 6 benchmarks under consideration, with average improvements of 0.7 F_1 points overall and 1.1 F_1 points out of domain. In addition, to gain better insights from our results, we also perform a fine-grained evaluation of our performances on different classes of label frequency, along with an ablation study of our architectural choices and an error analysis. We release our code and models for research purposes at `https://github.com/SapienzaNLP/extend`.

1 Introduction

Being able to associate entity mentions in a given text with the correct entity they refer to is a crucial task in Natural Language Processing (NLP). Formally referred to as Entity Disambiguation (ED), this task entails, given a mention m occurring in a text c_m, identifying the correct entity e^* out of a set of candidates $e_1, \ldots, e_n$, coming from a reference knowledge base (KB). First introduced by Bunescu and Paşca (2006), ED aims to identify the actors involved in human language and, as such, has shown potential in downstream applications like Question Answering (Yin et al., 2016), Information Extraction (Ji and Grishman, 2011; Guo et al., 2013), Text Generation (Puduppully et al., 2019) and Semantic Parsing (Bevilacqua et al., 2021; Procopio et al., 2021).

Since the advent of Deep Learning within the NLP community, this task has mostly been framed as a multi-label classification problem (Shahbazi et al., 2019; Broscheit, 2019), especially leveraging the bi-encoder paradigm (Humeau et al., 2020; Wu et al., 2020). However, although simple and yet powerful enough to push scores past 90% *inKB Micro* F_1 on standard benchmarks, this formulation suffers from a number of downsides. First, the actual disambiguation is only modeled through a dot product between independent mention and entity vectors, which may not capture complex mention-entity interactions. Second, from a computational perspective, entities are represented through high-dimensional vectors that are cached in a pre-computed index. Thus, classifying against a large KB has a significant memory cost that, in fact, scales linearly with respect to the number of entities. Besides this, adding a new entity also requires modifying the index itself. To address these issues, De Cao et al. (2021b) have recently proposed an auto-regressive formulation where, given mentions in their context, models are trained to generate, token-by-token, the correct entity identifiers.[1]

While this approach has addressed the aforementioned issues effectively, it requires an auto-regressive decoding process, which has speed implications, and, what is more, does not let the model see its possible output choices, something

---

[*] Equal contribution.

[1] i.e. a textual description of the entity; in De Cao et al. (2021b), they use the titles of Wikipedia articles, since their reference KB is Wikipedia.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2478 - 2488

that has shown significant potential in other semantic tasks (Barba et al., 2021a). In this work, we focus on these shortcomings and, inspired by this latter research trend, propose Extractive Entity Disambiguation (EXTEND), the first entity disambiguator that frames ED as a text extraction task. Given as input a context c_m in which a mention m occurs, along with a text representation for each of the possible candidates $e_1, \ldots, e_n$, a model has to extract the span associated with the text representation of the entity that best suits m. We implement this formulation through 2 architectures: i) a Transformer system (Vaswani et al., 2017; Devlin et al., 2019) that features an almost identical modeling power to that of previous works, and ii) a variant that relaxes the computational requirements of our approach when using common Transformer-based architectures. Evaluating our two systems over standard benchmarks, we find our formulation to be particularly suited to ED. In particular, when restricting training resources to the AIDA-CoNLL dataset (Hoffart et al., 2011) only, EXTEND appears to be significantly more data-efficient than its alternatives, surpassing them by more than 6 *inKB Micro* F_1 points on average across *in-domain* and *out-of-domain* datasets. Furthermore, when pre-training on external ED data as in De Cao et al. (2021b), our system sets a new state of the art on 4 out of 6 benchmarks under consideration, with average improvements of 0.7 overall and 1.1 when moving out of domain. Finally, we also perform a thorough investigation of our system performances, providing insights and pinpointing the reasons behind our improvements via a fine-grained evaluation on different label-frequency classes.

Our contributions are therefore as follows:

- We propose a new framing of ED as a text extraction task;
- We put forward two architectures that implement our formulation, whose average score across different benchmarks surpasses all previous works in both data regimes we consider;
- We perform a thorough analysis of our systems' performances, evaluating their behavior over different label-frequency classes.

We release our code and models for research purposes at `https://github.com/SapienzaNLP/extend`.

2 Related Work

Entity Disambiguation (ED) is the task of identifying, given a mention in context, the most suitable entity among a set of candidates stored in a knowledge base (KB). Generally the last step in an Entity Linking system (Broscheit, 2019), coming immediately after mention detection and candidate generation, this task has been the object of a vast and diverse literature, with approaches typically clustered into two groups, depending on how they model co-occurring mentions in the same document. On the one hand, *global models* strive to enforce a global coherence across the disambiguations within the same document, leveraging different techniques and heuristics to approximate this objective[2] (Hoffart et al., 2011; Moro et al., 2014; Yamada et al., 2016; Ganea and Hofmann, 2017; Le and Titov, 2018; Yang et al., 2018).

On the other hand, *local models* disambiguate each mention independently of the others, conditioning the entity choice only on the mention and its context. Thanks to the advent of large pretrained language models, this group has recently witnessed a significant improvement in performances, which are nowadays on par with, or even above, those achieved by state-of-the-art global systems (Shahbazi et al., 2019). These approaches usually frame ED as a multi-label classification problem (Broscheit, 2019) and a diverse set of formulations have been proposed. Among these, the bi-encoder paradigm (Bromley et al., 1994; Humeau et al., 2020) has been particularly successful (Gillick et al., 2019; Tedeschi et al., 2021; Botha et al., 2020): here, two encoders are trained to learn vector representations in a shared space for mentions in context and entities, respectively. Classification of a given mention is then performed by retrieving the entity whose representation is closest according to some metric (e.g. cosine similarity).

Although remarkably powerful, these formulations present a number of disadvantages, such as their large memory footprint (each entity in the KB needs to be represented by a high-dimensional vector) and the fact that the actual disambiguation process is only expressed via a dot product of independently computed vectors, potentially neglecting mention-entity interactions. While a number of works (Logeswaran et al., 2019; Wu et al., 2020) attempt to address the latter issue via multi-stage

---

[2] Approximation is necessary as the exact computation of coherence objectives is NP-hard (Le and Titov, 2018).

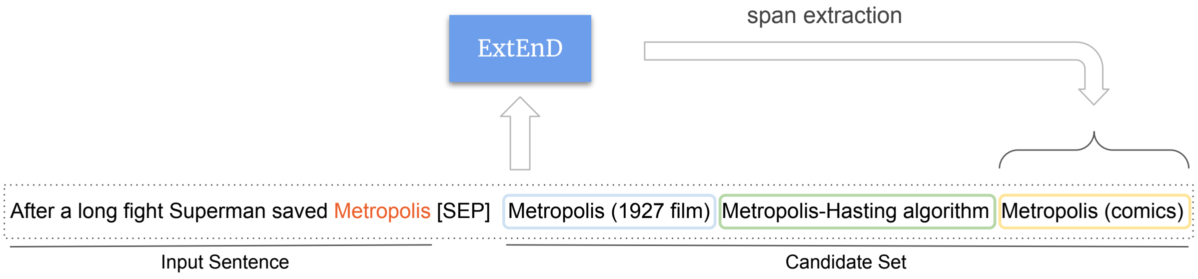

Figure 1: Illustration of EXTEND on the example sentence *After a long fight Superman saved Metropolis*. The model takes as input a sentence with the target mention to disambiguate, *Metropolis*, explicitly marked (for better visualization, we resort here to highlighting with a different color rather than surrounding it with special tokens) along with the text representation of each candidate. As in our experiments, the knowledge base here is Wikipedia and the candidate text representations are Wikipedia page titles. Then, the model performs the disambiguation by indicating the start and end token of the span containing the predicted entity representation.

approaches where a cross-encoder is stacked after an initial bi-encoder[3] or other retrieval functions, an interesting alternative direction that tackles both problems was recently presented by De Cao et al. (2021b): the authors frame ED as a generation problem and, leveraging an auto-regressive formulation, train a sequence-to-sequence model to generate the correct entity identifier for a given mention and its context.

Nevertheless, while this approach can model more complex interactions, some of these can only occur indirectly inside the backtracking of their beam search. Furthermore, the disambiguation involves an auto-regressive decoding that, although mitigated by later efforts (De Cao et al., 2021a), has intrinsic speed limitations. In contrast, here we propose an extractive formulation, where a model receives as input the mention, its context and the text representation of each candidate, and has to extract the span corresponding to the representation of the entity that best matches the (mention, context) pair under consideration. Note that this differs from the aforementioned cross-encoder formulations (Logeswaran et al., 2019; Wu et al., 2020) where, instead, each entity was encoded together with the (mention, context) pair, but independently from all the other entities. With our schema, complex mention-entity and entity-entity interactions can be explicitly modeled by the neural system, as all the information is provided in input.

Glancing over other related tasks in the area of semantics, arguably closest to our work is ESC (Barba et al., 2021a), where the authors propose a new framing of Word Sense Disambiguation (WSD) as an extractive sense comprehension task. Yet, differently from their work, we propose here a new framing for ED, i.e. focus on entity descriptions rather than word sense definitions, present a baseline system that implements it and devise an additional architecture that deals with the computational challenges that arise from such implementation.

3 Model

We now introduce EXTEND, our proposed approach for ED. We first present the formulation we adopt (Section 3.1) and, then, describe the two architectures that implement it (Section 3.2).

3.1 Formulation

Inspired by recent trends in other semantic tasks (Barba et al., 2021a), we formulate Entity Disambiguation as a text extraction problem: given a query x_q and a context x_c, a model has to learn to extract the text span of x_c that best answers x_q. Formally, let m be a mention occurring in a context c_m and denote by $Cnd(m) = \{cnd_1, \ldots, cnd_n\}$ the set of n text representations associated with each candidate of m. Then, we formulate ED as follows: we treat the tuple (m, c_m) and the concatenation of $cnd_1, \ldots, cnd_n$ as the query x_q and the context x_c, respectively, and train a model to extract the text span from x_c associated with the correct $cnd^* \in Cnd(m)$; the overall process is illustrated in Figure 1. This formulation helps to better model the input provided, with the possible

---

[3] This bi-encoder, rather than performing the actual classification, is tasked to generate a filtered set of candidates.

candidates of m included in the contextualization process, while also disposing of large output vocabularies as in De Cao et al. (2021b) and, yet, not resorting to auto-regressive decoding strategies.

3.2 Architectures

To implement our formulation, we consider two Transformer-based architectures. For both of these, the input is composed of the concatenation of the query x_q and the context x_c, subword-tokenized and separated by a *[SEP]* special symbol. Since x_q is a tuple in our formulation, whereas Transformer models only support text sequences as input, we convert x_q into a string $\hat{x}_q$ by taking only c_m and surrounding the text span where m occurs with the special tokens <*t*> and </*t*>. Additionally, to better separate entity candidate representations and ease their full span identification, we add a trailing special symbol </*ec*> to each of them; henceforth, we denote this resulting modified context by $\hat{x}_c$.

As our first architecture, we use two independent classification heads on top of BART (Lewis et al., 2020) computing, respectively, for each word w in $\hat{x}_c$, whether w is the start or end of the correct entity representation cnd^*. We train the model with a cross-entropy criterion over the start and end of cnd^*. At inference time, we select the entity candidate representation $cnd^{'} \in Cnd(m)$ whose joint probability over the 2 heads is highest.

However, framing ED as we propose here implies that the length of the input to the model scales linearly with the number of output choices m. Taking into account that the attention mechanism of Transformer architectures has quadratic complexity and that several pre-trained models actually support inputs only up to a fixed maximum length,[4] this might pose significant computational limitations depending on the dataset and knowledge base under consideration. To cope with these technical challenges, we consider a second system, similar to the previous one but for two main differences. First, we change the underlying Transformer model, replacing BART with a pre-trained Longformer model (Beltagy et al., 2020), a Transformer architecture with an attention mechanism that is linear with respect to the input length and that can handle longer sequences. This linear complexity is achieved by essentially applying a sliding attention window over each token but for a few pre-selected ones (e.g. *[CLS]*), which instead feature a symmetric global attention: they attend upon and are attended by all the other tokens in the input sequence. This global mechanism is intended to be task-specific and enables the model to learn representations potentially close to those standard fully-attentive Transformers would learn, while still maintaining the overall attention complexity linear with respect to the input size. Therefore, as our second modification, we adapt this global pattern to our setting, activating it on the *[CLS]* special token and on the first token of each $cnd_i \in Cnd(m)$; this allows to better mimic the original quadratic mechanism where different entity candidate representations can also attend upon each other. Furthermore, differently from Beltagy et al. (2020), we disable the global attention mechanism on the tokens in the query $\hat{x}_q$. In Section 5, we report and discuss the impact of these modifications. We illustrate the proposed architecture in Figure 2.

4 Entity Disambiguation Evaluation

We now assess the effectiveness of EXTEND on Entity Disambiguation. We first introduce the experimental setup we consider (Section 4.1). Then, we present the results achieved by EXTEND both in terms of raw performances (Section 4.2) and via a breakdown of its behavior on different classes of label frequency (Section 4.3). For ease of readability, we focus here only on the Longformer-based architecture, which we consider as our main model. We defer the comparison with the BART-based system to Section 5.

4.1 Experimental Setup

Data To evaluate EXTEND on Entity Disambiguation, we reproduce the same setting used by De Cao et al. (2021b). Specifically, we adopt their same candidate sets, which were originally proposed by Le and Titov (2018),[5] use Wikipedia titles (e.g. *Metropolis (comics)*) as the text representation for entities and perform training, along with *in-domain* evaluation, on the AIDA-CoNLL dataset (Hoffart et al., 2011, **AIDA**); similarly, we use their cleaned version of **MSNBC**, **AQUAINT**, **ACE2004**, WNED-CWEB (**CWEB**) and WNED-WIKI (**WIKI**) (Guo and Barbosa, 2018; Evgeniy et al., 2013) for *out-of-domain* evaluation.

---

[4] For instance, the implementation of BART available in HuggingFace Transformers (Wolf et al., 2020) supports inputs only up to 1024 subwords.

[5] These candidate sets were generated relying upon count statistics from Wikipedia, a large Web corpus and the YAGO dictionary.

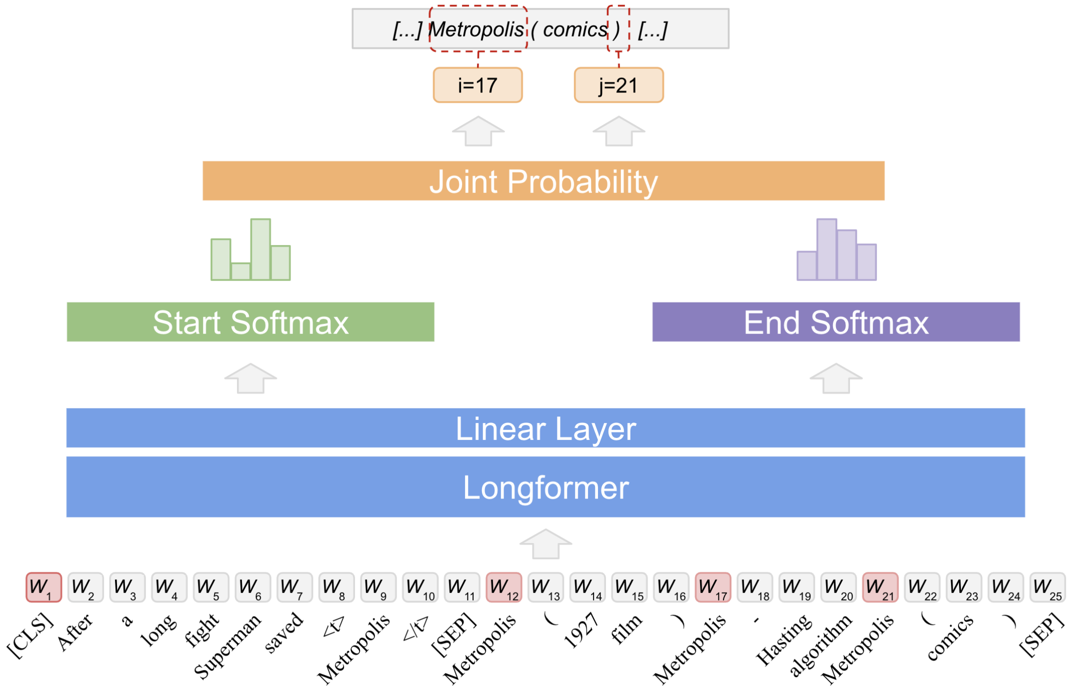

Figure 2: Longformer-based architecture for EXTEND. The input context and the candidate textual representations are fed to the model in the same sequence separated by a *[SEP]* special token. The mention is surrounded by two special tokens <t> and </t> and, for the sake of readability, we omit the trailing special tokens </ec>. We highlight in red the tokens with global attention. Best seen in colors.

While we use this AIDA-only training scenario, which we refer to as *AIDA*, to test the data efficiency of EXTEND, most ED systems actually make use of additional data and information originating from Wikipedia at training time. We denote this additional training scenario where Wikipedia is part of the training resources as *Wikipedia+AIDA*. Specifically, as our system is a supervised neural classifier, we follow De Cao et al. (2021b) and utilize BLINK data (Wu et al., 2020) for ED pretraining in this setting. A brief description of each dataset follows:

i) **AIDA**: one of the largest manually annotated corpora for Entity Linking and Disambiguation. It contains 388 articles from the Reuters Corpus with 27,724 labeled mentions. The training set contains 18,448 instances, while the validation and test sets feature 4791 and 4485 samples, respectively.

ii) **MSNBC**: a small news corpus with 20 articles from MSNBC on 10 different topics. It contains 656 annotated instances.

iii) **AQUAINT**: a news corpus composed of 50 documents with news coming from the Xhinua News Service, the New York Times and the Associated Press. It contains 727 annotated instances.

iv) **ACE2004**: a manually annotated subset of the ACE co-reference data set (Doddington et al., 2004). It contains 257 annotated instances.

v) **CWEB**: a dataset automatically extracted from the ClueWeb corpus[6] by Guo and Barbosa (2018) containing English Websites, consisting of 11,154 annotated instances.

vi) **WIKI**: an automatically extracted corpus comprised of Wikipedia pages released by Evgeniy et al. (2013), with 6821 annotated instances.

vii) **BLINK**: a dataset made up of 9 million (document, entity, mention) triples automatically extracted from Wikipedia.

For each of these resources,[7] we use the preprocessed datasets, along with the mention candidate sets, made available by De Cao et al. (2021b) in the authors' official repository.[8]

	EXTEND$_{Large}$	90.0	**94.5**	**87.9**	88.9	**76.6**	**76.7**	**85.8**	**84.9**

Table 1: Results (*inKB Micro* F_1) on the *in-domain* and *out-of-domain* settings when training on the AIDA training split only (bottom) and when using additional resources coming from Wikipedia (top). We mark in **bold** the best scores and underline the second best.

Evaluation Following common practice in ED literature, results over the evaluation datasets are expressed in terms of *inKB Micro* F_1. Furthermore, to better highlight the performance on the *out-of-domain* datasets, we report both the average score over those and AIDA (Avg) and over those alone (Avg_{OOD}), that is, when the result on AIDA is excluded from the average.

Comparison Systems In order to contextualize EXTEND performances within the current landscape of Entity Disambiguation, we evaluate our approach against recent state-of-the-art systems in the literature. Specifically, we consider:

- Global Models: Ganea and Hofmann (2017); Guo and Barbosa (2018); Yang et al. (2018, 2019); Le and Titov (2019); Fang et al. (2019);
- Local Models: Shahbazi et al. (2019) and Tedeschi et al. (2021);
- The auto-regressive approach proposed by De Cao et al. (2021b).

EXTEND Setup As previously mentioned, we use the Longformer model (Beltagy et al., 2020) as our reference architecture and retrieve the pre-trained weights, for both its *base* and *large* variants, from the HuggingFace Transformers library (Wolf et al., 2020); we refer to these variants as EXTEND$_{Base}$ (139M parameters) and EXTEND$_{Large}$ (435M parameters). Following standard practice, we use the last encoder output for the representation of each token and a simple linear layer on top of it to compute the start and end tokens probability distributions. We use a 64-token attention window and fine-tune the whole architecture using the Rectified Adam (Liu et al., 2020) optimizer with 10^{-5} learning rate for at most 100,000 steps. We use 8 steps of gradient accumulation and batches made of a maximum of 1024 tokens. We evaluate the model on the validation dataset every 2000 steps, enforcing a patience of 15 evaluation rounds. We train every model for a single run on a GeForce RTX 3090 graphic card with 24 gigabytes of VRAM. Due to computational constraints, we do not perform any hyperparameter tuning, except for the attention window where we try [32, 64, 128], and select the other hyperparameters following previous literature. We implement our work in PyTorch (Paszke et al., 2019), using *classy*[9] as the underlying framework.

4.2 Results

We report in Table 1 (top) the *inKB Micro* F_1 score EXTEND and its comparison systems attain on the evaluation datasets in the *Wikipedia+AIDA* setting.

Arguably the most interesting finding we report is the improvement EXTEND achieves over its comparison systems. EXTEND$_{Large}$ + BLINK, that is, EXTEND$_{Large}$ pre-trained on BLINK[10] and

---

`GENRE`

[9] `https://github.com/sunglasses-ai/classy`

[10] We note that, due to computational and hardware constraints, we were unable to match the training configuration

then fine-tuned on AIDA, sets a new state of the art on 4 out of 6 datasets, with the only exceptions being *in-domain* AIDA and CWEB, where we fall short compared to the global model of Yang et al. (2018). On the Avg score, EXTEND pushes performances up by 0.7 points, and this improvement becomes even more marked when considering Avg$_{OOD}$ (+1.1). These results suggest that our approach is indeed well-suited for ED and, furthermore, is particularly effective when scaling out of domain.

Additionally, we also evaluate EXTEND on the AIDA-only training setting and compare against De Cao et al. (2021b) and Tedeschi et al. (2021), the only systems available in this setting. As shown in Table 1 (bottom), EXTEND behaves better, with both EXTEND$_{Base}$ and EXTEND$_{Large}$ achieving higher Avg scores. In particular, EXTEND$_{Base}$, which features only $149M$ parameters, fares better (by almost 5 points) than De Cao et al. (2021b), whose model parameters amount to $406M$ (2.7×). Moreover, the Avg$_{OOD}$ results, which are also higher, further confirm our previous hypothesis as regards the benefits of our approach in *out-of-domain* scalability. Paired together, these results highlight the higher data efficiency that our formulation achieves, in comparison to its alternatives.

4.3 Fine-grained Results

Inspired by standard practices in the evaluation of Word Sense Disambiguation systems (Blevins and Zettlemoyer, 2020; Barba et al., 2021a), we perform a fine-grained analysis where we break down the performances of our model into different classes of label frequency. To this end, we partition both the AIDA test set and the concatenation of all the *out-of-domain* datasets in three different subsets: i) **MFC**, containing all the instances in the test set where the target mention is associated with its most frequent candidate in the training corpus (i.e. the AIDA training split).; ii) **LFC**, containing all the instances in the test set annotated with a least frequent candidate of the target mention that appeared at least once in the training corpus; iii) **Unseen**, containing all the instances in the test set whose mention was never seen in the training corpus.

We then evaluate all the systems of the *AIDA* setting, except for De Cao et al. (2021b) for which the original model is unavailable, on these six test sets. To put the results in perspective, we introduce a simple baseline (PEM-MFC) that consists in always predicting the most frequent candidate for each mention, taking mention-candidate frequencies from Le and Titov (2018).

	In-domain			**Out-of-domain**		
Model	MFC	LFC	UNS	MFC	LFC	UNS
PEM-MFC	79.2	12.6	74.0	82.2	37.1	66.1
Tedeschi et al. (2021)	**95.8**	60.9	89.0	91.1	43.0	61.7
EXTEND $_{Base}$	94.2	53.2	87.1	94.0	43.9	75.0
EXTEND $_{Large}$	94.8	**62.4**	**89.1**	**94.3**	**48.1**	**77.0**

Table 2: Results (*inKB Micro* F_1) when training on the AIDA training split only, on the MFC, LFC and UNS (Unseen) partitions for both *in-domain* and *out-of-domain* settings. We mark in **Bold** the best scores.

As we can see from Table 2, PEM-MFC is a rather strong baseline, confirming the skewness of the distribution with which each mention is annotated with one of its possible candidates towards the most frequent ones. Indeed, the gap between the performances of all the models on the MFC split and the LFC split is rather large, with a difference of almost 50 points in the *out-of-domain* setting. While future works should investigate the performances on these splits more in depth, here we can see that EXTEND$_{Base}$ and especially EXTEND$_{Large}$ outperform their competitors in the LFC and Unseen splits, in both the *in-domain* and *out-of-domain* settings. This highlights the strong generalization capabilities of our proposed approach, which is able to better handle rare or unseen instances at the cost of only 1 point in F_1 score on the MFC of the *in-domain* setting.

5 Model Ablation

While the above-mentioned experiments showed our approach to be rather effective, we only focused on the Longformer-based architecture, to which we resorted owing to the computational challenges we mentioned in Section 3.2. We now investigate this model choice, evaluating first how the BART-based system fares. Then, we ablate the attention pattern we propose for the Longformer and, finally, discuss the trade-off between our two proposed architectures.

BART Strictly speaking, the results we reported in the previous Section are not exactly conclusive as to whether or not our formulation is beneficial. Indeed, while it is true that we use a new formulation,

---

of De Cao et al. (2021b) and our pre-training performed a significantly smaller number of updates. The scores reported here are therefore likely to be higher.

we also rely upon a Transformer model that none of our comparison systems considered. Therefore, to better pinpoint the origin of the improvements, we train our BART-based architecture in the *AIDA* setting; we refer to this model as BART. Note that the underlying Transformer is identical to that of De Cao et al. (2021b), except for the final classification heads.[11] As shown in Table 3, BART with our extractive formulation attains significantly better performances. This finding suggests that the overall improvement does indeed originate from our extractive formulation. Furthermore, as the two systems are entirely identical except for the framing adopted, this finding further underlines the data efficiency of our approach.

Longformer Ablations We now compare our chosen global attention strategy with two standard alternatives. First, we consider the schema originally proposed by Beltagy et al. (2020) for question-answering tasks, where all the tokens in the input query (i.e. the text containing the mention) have a global attention (Longformer$_{query}$). Then, we compare against an EXTEND variant where the only token with global attention enabled is the start of sequence token (i.e. *[CLS]*). Table 3 shows how the three systems behave, reporting both their *in-domain* and *out-of-domain* scores, along with the average percentage of tokens in the input sequence with global attention enabled (GA%). From these results, we can see that i) our approach fares the best and that ii) Longformer$_{CLS}$ achieves performances almost in the same ballpark, making it a viable option for more computationally limited scenarios.

BART and Longformer Finally, we compare our two architectures. As we can see from Table 3, BART performs better in the *in-domain* dataset, whereas the Longformer outperforms it in the *out-of-domain* setting. Nevertheless, neither of these differences is very significant and, thus, this result confirms our initial hypothesis that using our second architecture is a valid approximation of the standard quadratic attention strategy for the extractive Entity Disambiguation task.

Model	**In-domain**	**Out-of-domain**	**GA%**
De Cao et al. (2021b)	88.6	78.2	100.0
EXTEND	90.0	**84.9**	21.1
Longformer$_{query}$	89.2	84.1	43.3
Longformer$_{CLS}$	88.8	84.3	0.8
BART	**90.4**	84.5	100.0

Table 3: Results (*inKB Micro* F_1) of the ablation study for the *in-domain* and *out-of-domain* settings along with the percentage of global tokens (GA%). We mark in **Bold** the best scores.

6 Error Analysis

To further investigate the generalization capabilities of EXTEND, we performed a black-box testing (Ribeiro et al., 2020) of our system leveraging the available test sets. Apart from the problem of label frequencies (e.g. unseen entities), we discovered two additional main classes of errors, namely i) *insufficient context*, and ii) *titles alone might not be enough*.

Insufficient Context Since the average number of candidates for each mention is roughly 50, the probability of having multiple valid candidates given the input context is far from negligible. For instance, let us consider the following example: *"In the last game Ronaldo scored two goals despite coming from a bad injury."*. In this sentence, the mention *Ronaldo* can refer both to Cristiano Ronaldo, the Portuguese player, and to Ronaldo de Lima, the Brazilian player. While this particular problem holds for several instances in the test sets, the performance drop is, in fact, mitigated by the labels skewness towards the most frequent candidates. Indeed, the model appears always to predict the most frequent candidate for this kind of instance, therefore being right in the majority of cases.

Titles might not be enough For both comparability and performance purposes, the text representation we use for a given entity in this work is simply its Wikipedia title. While article titles in Wikipedia are rather informative, in several circumstances they do not contain enough information to make them sufficiently distinguishable from other candidates. For example, several pages describing "Persons" are entitled just with their respective names and surnames. This kind of identifier is especially ineffective if the mentions taken into consideration were not present in the training dataset, or were rare or unseen during the underlying Transformer pre-

---

[11] The model of De Cao et al. (2021b) has a single head on the whole output vocabulary, whereas we have two (start and end).

training. To this end, we strongly believe that future research might benefit from focusing on enriching entities' identifiers by adding a small description of the articles (summary) or at least some keyword representing the domain the entity belongs to.

7 Conclusion

In this work we presented ExtEnd, a novel local formulation for ED that frames this task as a text extraction problem: given as input a string containing a marked mention in context and the text representation of each entity in its candidate set, a model has to extract the span corresponding to the text representation of the correct entity. Together with this formulation, we also presented two Transformer models that implement it and, by evaluating them across several experiments, we found our approach to be particularly suited to ED. First, it is extremely data efficient, surpassing its alternatives by more than 6 F_1 points when considering an AIDA-only training setting. Second, pre-training on BLINK data enables the model to set a new state of the art on 4 out of 6 benchmarks under consideration and yield average improvements of 0.7 F_1 points overall and 1.1 F_1 points when focusing only on *out-of-domain* evaluation datasets.

As future work, we plan to relax the requirements towards the candidate set and explore adapting this local formulation to a global one, so as to enforce coherence across predictions. For instance, we believe integrating the feedback loop strategy we proposed in Barba et al. (2021b) would be an interesting direction to pursue.

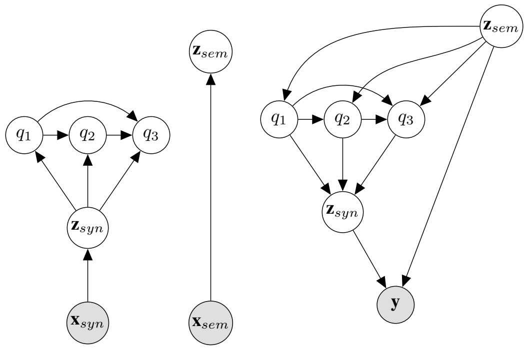
Abstract

We propose a generative model of paraphrase generation, that encourages syntactic diversity by conditioning on an explicit syntactic sketch. We introduce Hierarchical Refinement Quantized Variational Autoencoders (HRQ-VAE), a method for learning decompositions of dense encodings as a sequence of discrete latent variables that make iterative refinements of increasing granularity. This hierarchy of codes is learned through end-to-end training, and represents fine-to-coarse grained information about the input. We use HRQ-VAE to encode the syntactic form of an input sentence as a path through the hierarchy, allowing us to more easily predict syntactic sketches at test time. Extensive experiments, including a human evaluation, confirm that HRQ-VAE learns a hierarchical representation of the input space, and generates paraphrases of higher quality than previous systems.



(a) Posterior (encoder) (b) Generative model (decoder)

Figure 1: The generative models underlying our approach. Given some semantic content $\mathbf{z}_{sem}$, we predict a hierarchical set of syntactic codes q_d that describe the output syntactic form at increasing levels granularity. These are combined to give a syntactic embedding $\mathbf{z}_{syn}$, which is fed to the decoder along with the original semantic content to generate the output sentence $\mathbf{y}$. During training, the encoder is driven by a paraphrase $\mathbf{x}_{sem}$ and a syntactic exemplar $\mathbf{x}_{syn}$.

1 Introduction

Humans use natural language to convey information, mapping an abstract idea to a sentence with a specific surface form. A paraphrase is an alternative surface form of the same underlying semantic content. The ability to automatically identify and generate paraphrases is of significant interest, with applications in data augmentation (Iyyer et al., 2018), query rewriting, (Dong et al., 2017) and duplicate question detection (Shah et al., 2018).

While autoregressive models of language (including paraphrasing systems) predict one token at a time, there is evidence that in humans some degree of planning occurs at a higher level than individual words (Levelt, 1993; Martin et al., 2010). Prior work on paraphrase generation has attempted to include this inductive bias by specifying an alternative surface form as additional model input, either in the form of target parse trees (Iyyer et al., 2018; Chen et al., 2019a; Kumar et al., 2020), exemplars (Meng et al., 2021), or syntactic codes (Shu et al., 2019; Hosking and Lapata, 2021). Most of these approaches suffer from an 'all or nothing' problem: the target surface form must be fully specified during inference. However, predicting the complete syntactic structure is almost as difficult as predicting the sentence itself, negating the benefit of the additional planning step.

In this paper, we propose a generative model for paraphrase generation, that combines the diversity introduced by an explicit syntactic target with the tractability of models trained end-to-end. Shown in Figure 1, the model begins by assuming the existence of some semantic content $\mathbf{z}_{sem}$. Conditioned on this semantic information, the model predicts a syntactic 'sketch' in the form of a hierarchical set of discrete codes $q_{1:D}$, that describe the target syntactic structure with increasing granularity. The sketch is combined into an embedding $\mathbf{z}_{syn}$, and fed along with the original meaning $\mathbf{z}_{sem}$ to a de-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2489 - 2501
May 22-27, 2022

coder that generates the final output utterance $\mathbf{y}$. Choosing a discrete representation for the sketch means it can be predicted from the meaning as a simple classification task, and the hierarchical nature means that the joint probability over the codes admits an autoregressive factorisation, making prediction more tractable.

The separation between $\mathbf{z}_{sem}$ and $\mathbf{z}_{syn}$ is induced by a training scheme introduced in earlier work (Hosking and Lapata, 2021; Huang and Chang, 2021) and inspired by prior work on separated latent spaces (Chen et al., 2019b; Bao et al., 2019), whereby the model must reconstruct a target output from one input with the correct meaning, and another input with the correct syntactic form. To learn the discretized sketches, we propose a variant of Vector-Quantized Variational Autoencoders (VQ-VAE, or VQ) that learns a *hierarchy of embeddings* within a shared vector space, and represents an input encoding as a path through this hierarchy. Our approach, which we call Hierarchical Refinement Quantized Variational Autoencoders or **HRQ-VAE**, leads to a decomposition of a dense vector into embeddings of increasing granularity, representing high-level information at the top level before gradually refining the encoding over subsequent levels.

Our contributions are summarized as follows:

- We propose a generative model of natural language generation, HRQ-VAE, that induces a syntactic sketch to account for the diversity exhibited by paraphrases. We present a parameterization of our generative model that is a novel method for learning hierarchical discretized embeddings over a single latent encoding space. These embeddings are trained end-to-end and jointly with the encoder/decoder.
- We use HRQ-VAE to induce hierarchical sketches for paraphrase generation, demonstrating that the known factorization over codes makes them easier to predict at test time, and leads to higher quality paraphrases.

2 Latent Syntactic Sketches

2.1 Motivation

Let $\mathbf{y}$ be a sentence, represented as a sequence of tokens. We assume that $\mathbf{y}$ contains semantic content, that can be represented by a latent variable $\mathbf{z}_{sem}$. Types of semantic content might include the description of an image, or a question intent. However, the mapping from semantics to surface form is not unique: in general, there is more than one way to express the semantic content. Sentences with the same underlying meaning $\mathbf{z}_{sem}$ but different surface form $\mathbf{y}$ are *paraphrases*. Standard approaches to paraphrasing (e.g., Bowman et al. 2016) map directly from $\mathbf{z}_{sem}$ to $\mathbf{y}$, and do not account for this diversity of syntactic structure.

Following recent work on syntax-guided paraphrasing (Chen et al., 2019a; Hosking and Lapata, 2021), and inspired by evidence that humans plan out utterances at a higher level than individual words (Martin et al., 2010), we introduce an intermediary *sketching* step, depicted in Figure 1b. We assume that the output sentence $\mathbf{y}$ is generated as a function both of the meaning $\mathbf{z}_{sem}$ *and* of a syntactic encoding $\mathbf{z}_{syn}$ that describes the structure of the output. Moreover, since natural language displays hierarchical organization in a wide range of ways, including at a syntactic level (constituents may contain other consituents), we also assume that the syntactic encoding $\mathbf{z}_{syn}$ can be decomposed into a hierarchical set of discrete latent variables $q_{1:D}$, and that these q_d are conditioned on the meaning $\mathbf{z}_{sem}$. This contrasts with popular model architectures such as VAE (Bowman et al., 2015) which use a *flat* internal representation in a dense Euclidean vector space.

Intuitively, our generative model corresponds to a process where a person thinks of a message they wish to convey; then, they decide roughly how to say it, and incrementally refine this decision; finally, they combine the meaning with the syntactic sketch to 'spell out' the sequence of words making up the sentence.

2.2 Factorization and Objective

The graphical model in Figure 1b factorizes as

$$\begin{aligned} p(\mathbf{y}, \mathbf{z}_{sem}) = \sum_{q_{1:D}, \mathbf{z}_{syn}} & p(\mathbf{y}|\mathbf{z}_{sem}, \mathbf{z}_{syn}) \\ & \times p(\mathbf{z}_{syn}|q_{1:D}) \\ \times p(\mathbf{z}_{sem}) \times p(q_1|\mathbf{z}_{sem}) & \prod_{d=2}^{D} \times p(q_d|q_{<d}, \mathbf{z}_{sem}). \end{aligned} \quad (1)$$

Although $q_{1:D}$ are conditionally dependent on $\mathbf{z}_{sem}$, we assume that $\mathbf{z}_{sem}$ may be determined from $\mathbf{y}$ without needing to explicitly calculate $q_{1:D}$ or $\mathbf{z}_{syn}$. We also assume that the mapping from discrete codes $q_{1:D}$ to $\mathbf{z}_{syn}$ is a deterministic function $f_{q\to\mathbf{z}}(\cdot)$. The posterior therefore factorises as

$$\phi(\mathbf{z}_{sem}, \mathbf{z}_{syn}|\mathbf{y}) = \phi(\mathbf{z}_{sem}|\mathbf{y}) \times \phi(\mathbf{z}_{syn}|\mathbf{y}) \\ \times \phi(q_1|\mathbf{z}_{syn}) \times \prod_{d=2}^{D} \phi(q_d|q_{<d}, \mathbf{z}_{syn}). \quad (2)$$

The separation between $\mathbf{z}_{sem}$ and $q_{1:D}$, such that they represent the meaning and form of the input respectively, is induced by the training scheme. During training, the model is trained to reconstruct a target $\mathbf{y}$ using $\mathbf{z}_{sem}$ derived from an input with the correct meaning (a paraphrase) $\mathbf{x}_{sem}$, and $q_{1:D}$ from another input with the correct form (a syntactic exemplar) $\mathbf{x}_{syn}$. Hosking and Lapata (2021) showed that the model therefore learns to encode primarily semantic information about the input in $\mathbf{z}_{sem}$, and primarily syntactic information in $q_{1:D}$. Exemplars are retrieved from the training data following to the process described in Hosking and Lapata (2021), with examples in Appendix C. The setup is shown in Figure 1a; in summary, during training we set $\phi(\mathbf{z}_{sem}|\mathbf{y}) = \phi(\mathbf{z}_{sem}|\mathbf{x}_{sem})$ and $\phi(q_d|\mathbf{y}, q_{<d}) = \phi(q_d|\mathbf{x}_{syn}, q_{<d})$. The final objective is given by

$$\text{ELBO} = \mathbb{E}_{\phi}\big[- \log p(\mathbf{y}|\mathbf{z}_{sem}, q_{1:D})) \\ - \log p(q_1|\mathbf{z}_{sem}) - \sum_{d=2}^{D} \log p(q_d|q_{<d}, \mathbf{z}_{sem})\big] \\ + KL\big[\phi(\mathbf{z}_{sem}|\mathbf{x}_{sem})||p(\mathbf{z}_{sem})\big], \quad (3)$$

where $q_d \sim \phi(q_d|\mathbf{x}_{syn})$ and $\mathbf{z}_{sem} \sim \phi(\mathbf{z}_{sem}|\mathbf{x}_{sem})$.

3 Neural Parameterisation

We assume a Gaussian distribution for $\mathbf{z}_{sem}$, with prior $p(\mathbf{z}_{sem}) \sim \mathcal{N}(\mathbf{0}, \mathbf{1})$. The encoders $\phi(\mathbf{z}_{sem}|\mathbf{x}_{sem})$ and $\phi(\mathbf{z}_{syn}|\mathbf{x}_{syn})$ are Transformers (Vaswani et al., 2017), and we use an autoregressive Transformer decoder for $p(\mathbf{y}|\mathbf{z}_{sem}, \mathbf{z}_{syn})$. The mapping $f_{q\to\mathbf{z}}(\cdot)$ from $q_{1:D}$ to $\mathbf{z}_{syn}$ and the posterior network $\phi(q_d|q_{<d}, \mathbf{z}_{syn})$ are more complex, and form a significant part of our contribution.

Our choice of parameterization is learned end-to-end, and ensures that the sketches learned are hierarchical both in the shared embedding space and in the information they represent.

3.1 Hierarchical Refinement Quantization

Let $\mathbf{z}_{syn} \in \mathcal{R}^{\mathbb{D}}$ be the output of the encoder network $\phi(\mathbf{z}_{syn}|\mathbf{y})$, that we wish to decompose as a sequence of discrete hierarchical codes. Recall that $q_d \in [1, K]$ are discrete latent variables corresponding to the codes at different levels in the hierarchy, $d \in [1, D]$. Each level uses a distinct codebook, $\mathbf{C}_d \in \mathbb{R}^{K\times\mathbb{D}}$, which maps each discrete code to a continuous embedding $\mathbf{C}_d(q_d) \in \mathbb{R}^{\mathbb{D}}$.

The distribution over codes at each level is a softmax distribution, with the scores s_d given by the distance from each of the codebook embeddings to the residual error between the input and the cumulative embedding from all previous levels,

$$s_d(q) = -\left(\left[\mathbf{x} - \sum_{d'=1}^{d-1} \mathbf{C}_{d'}(q_{d'})\right] - \mathbf{C}_d(q)\right)^2. \quad (4)$$

Illustrated in Figure 2, these embeddings therefore represent iterative refinements on the quantization of the input. The posterior network $\phi(q_d|q_{<d}, \mathbf{z}_{syn})$ iteratively *decomposes* an encoding vector into a path through a hierarchy of clusters whose centroids are the codebook embeddings.

Given a sequence of discrete codes $q_{1:D}$, we deterministically construct its continuous representation with the composition function $f_{q\to\mathbf{z}}(\cdot)$,

$$\mathbf{z}_{syn} = f_{q\to\mathbf{z}}(q_{1:D}) = \sum_{d=1}^{D} \mathbf{C}_d(q_d). \quad (5)$$

HRQ-VAE can be viewed as an extension of VQ-VAE (van den Oord et al., 2017), with two significant differences: (1) the codes are hierarchically ordered and the joint distribution $p(q_1, \ldots, q_D)$ admits an autoregressive factorization; and (2) the HRQ-VAE composition function is a sum, compared to concatenation in VQ or a complex neural network in VQ-VAE 2 (Razavi et al., 2019). Under HRQ, latent codes describe a path through the learned hierarchy within a shared encoding space. The form of the posterior $\phi(q_d|q_{<d}, \mathbf{z}_{syn})$ and the composition function $f_{q\to\mathbf{z}}(\cdot)$ do not rely on any particular properties of the paraphrasing task; the technique could be applied to any encoding space.

Initialisation Decay Smaller perturbations in encoding space should result in more fine grained changes in the information they encode. Therefore, we encourage *ordering* between the levels of hierarchy (such that lower levels encode finer grained information) by initialising the codebook with a decaying scale, such that later embeddings have a smaller norm than those higher in the hierarchy. Specifically, the norm of the embeddings at level d is weighted by a factor $(\alpha_{init})^{d-1}$.

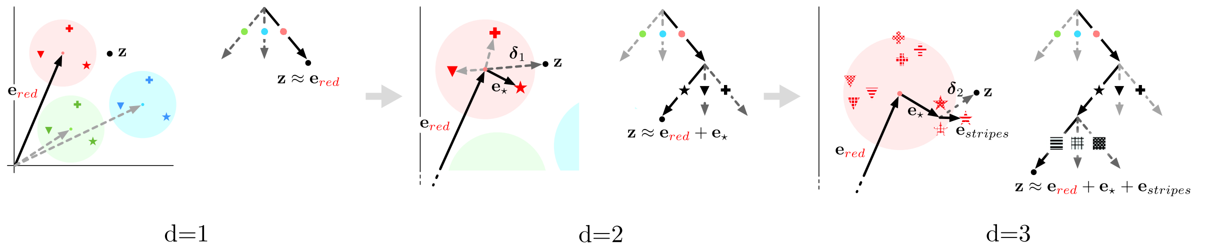


Figure 2: An illustration of how HRQ-VAE maps an input encoding vector $\mathbf{z}$ to a decomposition of hierarchical discretized encodings. HRQ-VAE compares the input to a jointly learned codebook of embeddings that become increasingly granular at lower depths of hierarchy. In this simplified example, with a depth of 3 and a codebook size of 3, the nearest top-level (colours) embedding to $\mathbf{z}$ is $\mathbf{e}_{red}$; then, the residual error $\boldsymbol{\delta}_1 = \mathbf{z} - \mathbf{e}_{red}$ is compared to the 2nd level of embeddings (shapes), with the nearest being $\mathbf{e}_\star$. Finally, the residual error $\boldsymbol{\delta}_2$ is compared to the 3rd level codebook (patterns), where the closest is $\mathbf{e}_{stripes}$. The quantized encoding of $\mathbf{z}$ is then $\mathbf{z} \approx \mathbf{e}_{red} + \mathbf{e}_\star + \mathbf{e}_{stripes}$.

Depth Dropout To encourage the hierarchy within the encoding space to correspond to hierarchical properties of the output, we introduce *depth dropout*, whereby the hierarchy is truncated at each level during training with some probability p_{depth}. The output of the quantizer is then given by

$$\mathbf{z}_{syn} = \sum_{d=1}^{D} \left(\mathbf{C}_d(q_d) \prod_{d'=1}^{d} \gamma_{d'} \right), \tag{6}$$

where $\gamma_h \sim \text{Bernoulli}(1 - p_{depth})$. This means that the model is sometimes trained to reconstruct the output based only on a *partial* encoding of the input, and should learn to cluster similar outputs together at each level in the hierarchy.

3.2 Sketch Prediction Network

During training the decoder is driven using sketches sampled from the encoder, but at test time exemplars are unavailable and we must predict a distribution over syntactic sketches $p(q_{1:D}|\mathbf{z}_{sem})$. Modelling the sketches as hierarchical ensures that this distribution admits an autoregressive factorization.

We use a simple recurrent network to infer valid codes at each level of hierarchy, using the semantics of the input sentence and the cumulative embedding of the predicted path so far as input, such that q_d is sampled from $p(q_d|\mathbf{z}_{sem}, q_{<d}) = \texttt{Softmax}(\texttt{MLP}_d(\mathbf{z}_{sem}, \mathbf{z}_{<d}))$, where $\mathbf{z}_{<d} = \sum_{d'=1}^{d-1} \mathbf{C}_{d'}(q_{d'})$. This MLP is trained jointly with the encoder/decoder model, using the outputs of the posterior network $\phi(q_d|\mathbf{x}_{syn}, q_{<d})$ as targets. To generate paraphrases as test time, we sample from the sketch prediction model $p(q_d|\mathbf{z}_{sem}, q_{<d})$ using beam search and condition generation on these predicted sketches.

3.3 Training Setup

We use the Gumbel reparameterisation trick (Jang et al., 2016; Maddison et al., 2017; Sønderby et al., 2017) for the discrete codes and the standard Gaussian reparameterisation for the semantic representation. To encourage the model to use the full codebook, we decayed the Gumbel temperature τ, according to the schedule given in Appendix A. We approximate the expectation in Equation (3) by sampling from the training set and updating via backpropagation (Kingma and Welling, 2014). The full model was trained jointly by optimizing the ELBO in Equation (3).

4 Experimental Setup

Datasets A paraphrase is 'an alternative surface form in the same language expressing the same semantic content as the original form' (Madnani and Dorr, 2010), but it is not always clear what counts as the 'same semantic content'. Our approach requires access to reference paraphrases; we evaluate on three English paraphrasing datasets which have clear grounding for the meaning of each sentence: Paralex (Fader et al., 2013), a dataset of question paraphrase clusters scraped from WikiAnswers; Quora Question Pairs (QQP)[1] sourced from the community question answering forum Quora; and MSCOCO 2017 (Lin et al., 2014), a set of images that have been captioned by multiple annotators. For the question datasets, each paraphrase is grounded to the (hypothetical) *answer* they share. We use the splits released by Hosking and Lapata (2021). For MSCOCO, each caption is grounded by the *image* that it describes. We evaluate on the public validation set, randomly selecting one cap-

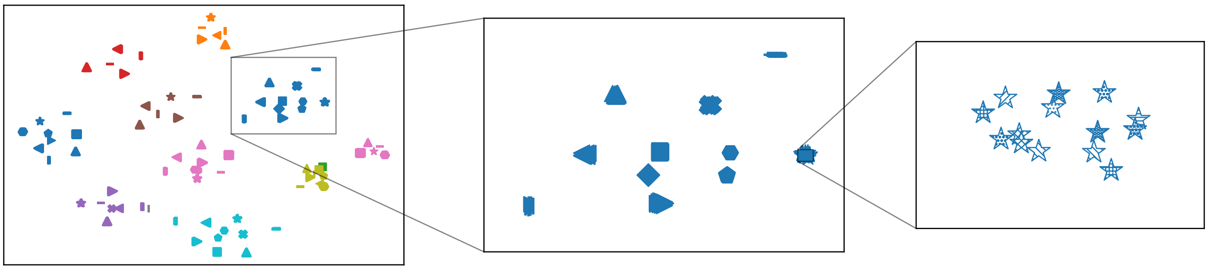

Figure 3: t-SNE visualisation of the syntactic encodings $\mathbf{z}_{syn}$ for 10k examples from Paralex: colours indicate top-level codes q_1, shapes indicate the second level, and patterns are used to label the third level. Deeper levels in the hierarchy represent finer grained information in encoding space.

tion for each image to use as input and using the remaining four as references.

Model Configuration Hyperparameters were tuned on the Paralex development set, and reused for the other evaluations. We set the depth of the hierarchy $D = 3$, and the codebook size $K = 16$. The Transformer encoder and decoder consist of 5 layers each, and we use the vocabulary and token embeddings from BERT-Base (Devlin et al., 2018). We use an initialisation decay factor of $\alpha_{init} = 0.5$, and a depth dropout probability $p_{depth} = 0.3$. A full set of hyperparameters is given in Appendix A, and our code is available at `https://github.com/tomhosking/hrq-vae`.

Comparison Systems As baselines, we consider three popular architectures: a vanilla autoencoder (AE) that learns a single dense vector representation of an input sentence; a Gaussian Variational AutoEncoder (VAE, Bowman et al., 2015), which learns a distribution over dense vectors; and a Vector-Quantized Variational AutoEncoder (VQ-VAE, van den Oord et al., 2017), that represents the full input sentence as a set of discrete codes. All three models are trained to generate a sentence from one of its paraphrases in the training data, and are not trained with an autoencoder objective. We implement a simple tf-idf baseline (Jones, 1972), retrieving the question from the training set with the highest cosine similarity to the input. Finally, we include a basic copy baseline as a lower bound, that simply uses the input sentences as the output.

We also compare to a range of recent paraphrasing systems. Latent bag-of-words (BoW, Fu et al., 2019) uses an encoder-decoder model with a discrete bag-of-words as the latent encoding. SOW/REAP (Goyal and Durrett, 2020) uses a two stage approach, deriving a set of feasible syntactic rearrangements that is used to guide a second encoder-decoder model. BTmPG (Lin and Wan, 2021) uses multi-round generation to improve diversity and a reverse paraphrasing model to preserve semantic fidelity. We use the results after 10 rounds of paraphrasing. Separator (Hosking and Lapata, 2021) uses separated, non-hierarchical encoding spaces for the meaning and form of an input, and an additional inference model to predict the target syntactic form at test time. All comparison systems were trained and evaluated on our splits of the datasets.

As an upper bound, we select a sentence from the evaluation set to use as an *oracle* syntactic exemplar, conditioning generation on a sketch that is known to represent a valid surface form.

5 Results

Our experiments were designed to test two primary hypotheses: (1) Does HRQ-VAE learn *hierarchical* decompositions of an encoding space? and (2) Does our choice of generative model enable us to generate *high quality* and *diverse* paraphrases?

5.1 Probing the Hierarchy

Figure 3 shows a t-SNE (van der Maaten and Hinton, 2008) plot of the syntactic encodings $\mathbf{z}_{syn}$ for 10,000 examples from Paralex. The encodings are labelled by their quantization, so that colours indicate top-level codes q_1, shapes denote q_2, and patterns q_3. The first plot shows clear high level structure, with increasingly fine levels of substructure visible as we zoom into each cluster. This confirms that the discrete codes are ordered, with lower levels in the hierarchy encoding more fine grained information.

To confirm that intermediate levels of hierarchy represent valid points in the encoding space, we generate paraphrases using oracle sketches, but truncate the sketches at different depths. Masking one level (i.e., using only q_1, q_2) reduces performance by 2.5 iBLEU points, and two levels by 5.5.

Table 1: Top-1 paraphrase generation results, without access to oracle sketches. HRQ-VAE achieves the highest iBLEU scores, indicating the best tradeoff between quality and diversity. Paired bootstrap resampling (Koehn, 2004) indicates that HRQ-VAE significantly improves on all other systems ($p < 0.05$).

(iBLEU is an automatic metric for assessing paraphrase quality; see Section 5.2). Although encodings using the full depth are the most informative, *partial* encodings still lead to good quality output, with a gradual degradation. This implies both that each level in the hierarchy contains useful information, and that the cluster centroids at each level are representative of the individual members of those clusters.

5.2 Paraphrase Generation

Metrics Our primary metric is iBLEU (Sun and Zhou, 2012),

$$\begin{aligned}\text{iBLEU} = {}&\alpha\text{BLEU}(outputs, references)\\ &-(1-\alpha)\text{BLEU}(outputs, inputs),\end{aligned} \tag{7}$$

that measures the fidelity of generated outputs to reference paraphrases as well as the level of diversity introduced. We use the corpus-level variant. Following the recommendations of Sun and Zhou (2012), we set $\alpha = 0.8$, with a sensitivity analysis shown in Appendix A. We also report BLEU$(outputs, references)$ as well as Self-BLEU$(outputs, inputs)$. The latter allows us to examine the extent to which models generate paraphrases that differ from the original input.

To evaluate the diversity between multiple candidates generated by the *same system*, we report pairwise-BLEU (Cao and Wan, 2020),

$$\text{P-BLEU} = \mathbb{E}_{i\neq j}[\text{BLEU}(outputs_i, outputs_j)].$$

This measures the average similarity between the different candidates, with a lower score indicating more diverse hypotheses.

Paralex	Where is the birthplace of woman pro golfer Dottie Pepper?
VAE	Where is the birthplace of Pepper pro golfer Dottie?
BTmpG	What is the birthplace of women pro golfer?
SOW/REAP	What is the birthplace for golfer?
Latent BoW	Where did the golfer golfer originate?
Separator	Where is the birthplace of Dottie?
HRQ-VAE	Where is Dottie Pepper from?

Separator	What are some of the best ways to defrost chicken?
HRQ-VAE	How do you thaw frozen lobster tails?
MSCOCO	Set of toy animals sitting in front of a red wooden wagon.
VAE	Two stuffed animals sitting in front of a toy train.
BTmpG	A herd of sheep grazing in a field of grass.
SOW/REAP	A close up of a close up of a street
Latent BoW	A toy wagon with a toy horse and a toy wagon.
Separator	A toy model of a toy horse and buggy.
HRQ-VAE	A group of stuffed animals sitting next to a wooden cart.

Table 2: Examples of generated paraphrases. HRQ-VAE is able to preserve the original meaning, while introducing significant syntactic variation.

Automatic Evaluation Shown in Table 1, the results of the automatic evaluation highlight the importance of measuring both paraphrase quality and similarity to the input: the Copy baseline is able to achieve high BLEU scores despite simply duplicating the input. The VAE baseline is competitive but tends to have a high Self-BLEU score, indicating that the semantic preservation comes at the cost of low syntactic diversity. HRQ-VAE achieves both higher BLEU scores and higher iBLEU scores than the comparison systems, indicating that it is able to generate

q_1	q_2	q_3	**Output**

Table 3: Examples of model output, for a range of different sketches. The left hand side shows the sketch (i.e., the values of the codes $q_{1:D}$), with the corresponding model output on the right. q_1 primarily specifies the wh- word (e.g., outputs with $q_1 = 13$ are all 'what' questions), while q_2, q_3 correspond to more fine grained details, e.g., the outputs with $q_3 = 6$ all use the article 'a' when referring to 'body'.

higher quality paraphrases without compromising on syntactic diversity.

The examples in Table 2 demonstrate that HRQ is able to introduce significant syntactic variation while preserving the original meaning of the input. However, there is still a gap between generation using predicted sketches and 'oracle' sketches (i.e., when the target syntactic form is known in advance), indicating ample scope for improvement.

Worked Example Since the sketches $q_{1:D}$ are latent variables, interpretation is difficult. However, a detailed inspection of example output reveals some structure.

Table 3 shows the model output for a single semantic input drawn from Paralex, across a range of different syntactic sketches. It shows that q_1 is primarily responsible for encoding the question type, with $q_1 = 13$ leading to 'what' questions and $q_1 = 2$ 'how' questions. q_2 and q_3 encode more fine grained details; for example, all outputs shown with $q_3 = 6$ use the indefinite article 'a'.

We also examine how using increasingly granular sketches refines the syntactic template of the output. Table 4 shows the model output for a single semantic input, using varying granularities of sketch extracted from the exemplar. When no sketch is specified, the model defaults to a canonical phrasing of the question. When only q_1 is specified, the output becomes a 'how many' question, and when a full sketch is included, the output closely resembles the exemplar.

Input	Two types of fat in body?
Exemplar	How many states are in the USA?
No sketch	What are the different types of fats in the body?
q_1	How many types of fats are there in the body?
q_1, q_2	How many fats does the body have?
q_1, q_2, q_3	How many fat are in the body?

Table 4: Model output for varying sketch granularities. When no sketch is used, the model defaults to the most common phrasing of the question. As more detail is included, the output converges towards the exemplar.

	Paralex		**QQP**		**MSCOCO**	
Model	iBLEU↑	P-BLEU↓	iBLEU↑	P-BLEU↓	iBLEU↑	P-BLEU↓
VAE	20.49	67.62	11.52	64.71	17.22	55.66
BTmPG	15.50	89.20	9.13	82.02	13.20	80.38
Separator	21.67	62.98	13.63	**52.87**	13.77	57.79
HRQ-VAE	**22.75**	**40.48**	**17.49**	57.29	**18.39**	**41.29**

Table 5: Top-3 generation results. P-BLEU indicates the similarity between the different candidates, while iBLEU scores reported are the mean across the 3 candidates. HRQ-VAE is able to generate multiple high quality paraphrases with more diversity between them than comparison systems.

Generating Multiple Paraphrases We evaluated the ability of our system to generate multiple diverse paraphrases for a single input, and compared to the other comparison systems capable of producing more than one output. For both HRQ-VAE and Separator, we used beam search to sample from the sketch prediction network as in the top-1 case, and condition generation on the top-3 hypotheses predicted. For BTmPG, we used the paraphrases generated after 3, 6 and 10 rounds. For the VAE, we conditioned generation on 3 different samples from the encoding space. The results in Table 5 show that HRQ-VAE is able to generate multiple high quality paraphrases for a single input, with lower similarity between the candidates than other systems.

5.3 Human Evaluation

In addition to automatic evaluation we elicited judgements from crowdworkers on Amazon Mechanical Turk. They were shown a sentence and two paraphrases, each generated by a different system, and asked to select which one was preferred along three dimensions: the *dissimilarity* of the paraphrase compared to the original sentence; how

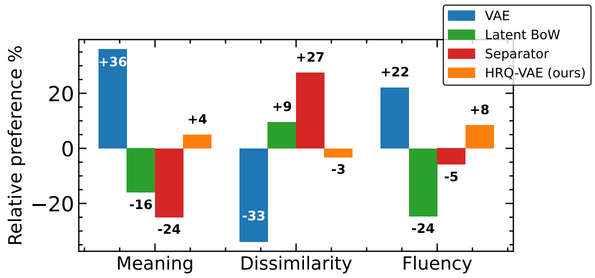

Figure 4: Results of our human evaluation. Although the VAE baseline is the best at preserving sentence meaning, it is the worst at introducing variation to the output. HRQ-VAE offers the best balance between dissimilarity and meaning preservation, and is more fluent than both Separator and Latent BoW.

well the paraphrase reflected the *meaning* of the original; and the *fluency* of the paraphrase (see Appendix B). We evaluated a total of 300 sentences sampled equally from each of the three evaluation datasets, and collected 3 ratings for each sample. We assigned each system a score of $+1$ when it was selected, -1 when the other system was selected, and took the mean over all samples. Negative scores indicate that a system was selected less often than an alternative. We chose the four best performing models for our evaluation: HRQ-VAE, Separator, Latent BoW, and VAE.

Figure 4 shows that although the VAE baseline is the best at preserving question meaning, it is also the worst at introducing variation to the output. HRQ-VAE better preserves the original question intent compared to the other systems while introducing more diversity than the VAE, as well as generating much more fluent output.

5.4 Ablations

To confirm that the hierarchical model allows for more expressive sketches, we performed two ablations. We compared to the full model using oracle sketches, so that code prediction performance was not a factor. We set the depth $D = 1$ and $K = 48$, giving equivalent total capacity to the full model ($D = 3, K = 16$) but without hierarchy. We also removed the initialisation scaling at lower depths, instead initialising all codebooks with the same scale. Table 6 shows that a non-hierarchical model with the same capacity is much less expressive.

We also performed two ablations against the model using predicted sketches; we removed depth dropout, so that the model is always trained on a full encoding. We confirm that learning the codebooks jointly with the encoder/decoder leads to a stronger model, by first training a model with a continuous Gaussian bottleneck (instead of the HRQ-VAE); then, we recursively apply k-means clustering (Lloyd, 1982), with the clustering at each level taking place over the residual error from all levels so far, analogous to HRQ-VAE. The results of these ablations shown in Table 6 indicate that our approach leads to improvements over all datasets.

Variant	Paralex	QQP	MSCOCO
HRQ-VAE (oracle)	34.85	33.01	26.07
No initialisation scaling	−3.06	−2.48	−3.02
No hierarchy	−8.84	−12.72	−3.10
HRQ-VAE	24.93	18.42	19.04
No head dropout	−0.62	−0.74	−0.81
Post-hoc k-means	−3.30	−5.35	−2.83

Table 6: Changes in iBLEU score for a range of ablations from our full model. All components lead to an improvement in paraphrase quality across datasets.

6 Related Work

Hierarchical VAEs VQ-VAEs were initially proposed in computer vision (van den Oord et al., 2017), and were later extended to be 'hierarchical' (Razavi et al., 2019). However, in vision the term refers to a 'stacked' version architecture, where the output of one variational layer is passed through a CNN and then another variational layer that can be continuous (Vahdat and Kautz, 2020) or quantized (Williams et al., 2020; Liévin et al., 2019; Willetts et al., 2021). Unlike these approaches, we induce a *single* latent space that has hierarchical properties.

Other work has looked at using the properties of hyperbolic geometry to encourage autoencoders to learn hierarchical representations. Mathieu et al. (2019) showed that a model endowed with a Poincaré ball geometry was able to recover hierarchical structure in datasets, and Surís et al. (2021) used this property to deal with uncertainty in predicting events in video clips. However, their work was limited to continuous encoding spaces, and the hierarchy discovered was known to exist a priori.

Syntax-controlled Paraphrase Generation Prior work on paraphrasing has used retrieval techniques (Barzilay and McKeown, 2001), Residual LSTMs (Prakash et al., 2016), VAEs (Bowman et al., 2016), VQ-VAEs (Roy and Grangier, 2019) and pivot languages (Mallinson et al., 2017). Syntax-controlled paraphrase generation has seen significant recent interest, as a means to explicitly generate diverse surface forms with the same meaning. However, most previous work has required knowledge of the correct or valid surface forms to be generated (Iyyer et al., 2018; Chen et al., 2019a; Kumar et al., 2020; Meng et al., 2021). It is generally assumed that the input can be rewritten without addressing the problem of predicting which template should be used, which is necessary if the method is to be useful. Hosking and Lapata (2021) proposed learning a simplified representation of the surface form using VQ, that could then be predicted at test time. However, the discrete codes learned by their approach are not independent and do not admit a known factorization, leading to a mismatch between training and inference.

7 Conclusion

We present a generative model of paraphrasing, that uses a hierarchy of discrete latent variables as a rough syntactic sketch. We introduce HRQ-VAE, a method for mapping these hierarchical sketches to a continuous encoding space, and demonstrate that it can indeed learn a hierarchy, with lower levels representing more fine-grained information. We apply HRQ-VAE to the task of paraphrase generation, representing the syntactic form of sentences as paths through a learned hierarchy, that can be predicted during testing. Extensive experiments across multiple datasets and a human evaluation show that our method leads to high quality paraphrases. The generative model we introduce has potential application for any natural language generation task; $\mathbf{z}_{sem}$ could be sourced from a sentence in a different language, from a different modality (e.g., images or tabular data) or from a task-specific model (e.g., summarization or machine translation). Furthermore, HRQ-VAE makes no assumptions about the type of space being represented, and could in principle be applied to a semantic space, learning a hierarchy over words or concepts.

A Hyperparameters

The hyperparameters given in Table 7 were selected by manual tuning, based on a combination of: (a) validation iBLEU scores with depth masking, (b) validation BLEU scores using oracle sketches, and (c) validation iBLEU scores using predicted syntactic codes.

The Gumbel temperature τ is decayed during training as a function of the step t, according to the following equation:

$$\tau(t) = \max(2 - \frac{2}{1 + e^{t/10000}}, 0.5). \qquad (8)$$

Intuitively, this smoothly decays τ from an initial value of 2, with a half-life of 10k steps, to a minimum value of 0.5.

We use $\alpha = 0.8$ when calculating iBLEU, but as shown in Figure 5 our conclusions are not sensitive

to this value, and our model outperforms all comparison systems on all datasets for $0.7 \leq \alpha \leq 0.9$.

Models were trained on a single GPU, with training taking between one and three days depending on the dataset. We use SacreBLEU (Post, 2018) to calculate BLEU scores.

B Human Evaluation

Annotators were recruited from the UK and USA via Amazon Mechanical Turk, and were compensated for their time above a living wage in those countries. A full Participant Information Sheet was provided, and the study was approved by an internal ethics committee. Annotators were asked to rate the outputs according to the following criteria:

- Which system output is the most fluent and grammatical?
- To what extent is the meaning expressed in the original sentence preserved in the rewritten version, with no additional information added?
- Does the rewritten version use different words or phrasing to the original? You should choose the system that uses the most different words or word order.

C Exemplar Retrieval Process

Input	How heavy is a moose?
Chunker output	How [heavy]$_{\text{ADVP}}$ is a [moose]$_{\text{NP}}$?
Template	How ADVP is a NP ?
Exemplar	How much is a surgeon's income?
Input	What country do parrots live in
Chunker output	What [country]$_{\text{NP}}$ do [parrots]$_{\text{NP}}$ [live]$_{\text{VP}}$ in ?
Template	What NP do NP VP in ?
Exemplar	What religion do Portuguese believe in?

Table 8: Examples of the exemplar retrieval process for training. The input is tagged by a chunker, ignoring stopwords. An exemplar with the same template is then retrieved from a different paraphrase cluster. Table reproduced with permission from Hosking and Lapata (2021).

Our approach requires exemplars during training to induce the separation between latent spaces. We follow the approach introduced by Hosking and Lapata (2021). During training, we retrieve exemplars $\mathbf{x}_{syn}$ from the training data following a process which first identifies the underlying syntax of $\mathbf{Y}$, and finds a question with the same syntactic structure but a different, arbitrary meaning. We use a shallow approximation of syntax, to ensure the availability of equivalent exemplars in the training data. An example of the exemplar retrieval process is shown in Table 8; we first apply a chunker (FlairNLP, Akbik et al., 2018) to $\mathbf{Y}$, then extract the chunk label for each tagged span, ignoring stopwords. This gives us the *template* that $\mathbf{Y}$ follows. We then select a question at random from the training data with the same template to give $\mathbf{x}_{syn}$. If no other questions in the dataset use this template, we create an exemplar by replacing each chunk with a random sample of the same type.

D Analysis of Code Properties

We define two features of sentences: (1) the presence of common auxiliary verbs that roughly indicate the tense of the sentence (present, future, etc.); and (2) the presence of different question or 'wh-' words[2]. We calculate the distributions of these features for each code q_d at different levels, with the results shown in Figure 6. Each column represents the distribution over the feature for a specific code. Figure 6a shows clear evidence that the sentences are (at least partly) clustered at the top level based on the verb used, while Figure 6b shows that level 2 encodes the question type.

---

[2] This analysis was performed for Paralex, which comprises entirely of questions.

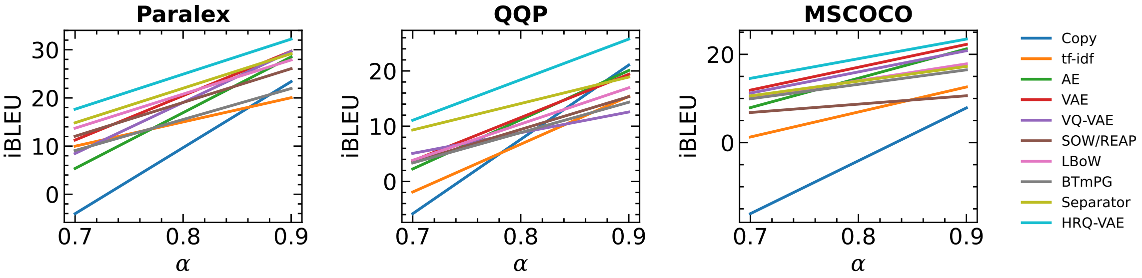

Figure 5: iBLEU scores for all comparison systems, for a range of values of α.

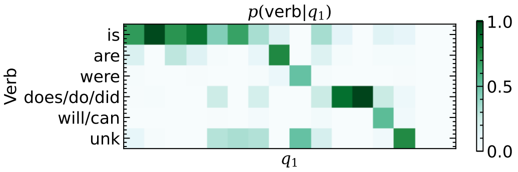
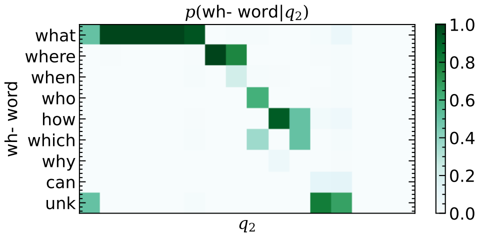


(a) Distribution of verbs for each code within level 1.



(b) Distribution of wh- words for each code within level 2.

Figure 6: Plots showing the conditional distributions of two different sentence features, auxiliary verb and question type, for different values of the latent codes q_d. Each column represents the distribution over the feature for a specific code. The plots show that level 1 is a strong predictor of verb tense, and level 2 predicts question type, giving some insight into what syntactic features each level has learned to encode. We have reordered the columns of the plot to improve readability.

Alignment-Augmented Consistent Translation for Multilingual Open Information Extraction

Abstract

Progress with supervised Open Information Extraction (OpenIE) has been primarily limited to English due to the scarcity of training data in other languages. In this paper, we explore techniques to automatically convert English text for training OpenIE systems in other languages. We introduce the Alignment-Augmented Consistent Translation (AACTRANS) model to translate English sentences and their corresponding extractions *consistently* with each other — with no changes to vocabulary or semantic meaning which may result from independent translations. Using the data generated with AACTRANS, we train a novel two-stage generative OpenIE model, which we call GEN2OIE, that outputs for each sentence: 1) relations in the first stage and 2) all extractions containing the relation in the second stage. GEN2OIE increases relation coverage using a training data transformation technique that is generalizable to multiple languages, in contrast to existing models that use an English-specific training loss. Evaluations on 5 languages — Spanish, Portuguese, Chinese, Hindi and Telugu — show that the GEN2OIE with AACTRANS data outperforms prior systems by a margin of 6-25% F1.[1]

1 Introduction

Open Information Extraction (OpenIE) is the task of converting unstructured text to semi-structured tuples of the format <*subject; relation; object*>, where these three components are textual phrases, broadly extracted from the original text (Etzioni et al., 2011). OpenIE tuples have shown utility in various downstream tasks (Mausam, 2016) like Question Answering (Fader et al., 2013; Khot et al., 2017), Machine Reading (Poon et al., 2010), Multi-Document Summarization (Christensen et al., 2014; Fan et al., 2019), Schema Induction (Balasubramanian et al., 2013), and Knowledge Base Construction (Gupta et al., 2019; Chandrahas and Talukdar, 2021).

With widespread adoption of Deep Learning in NLP, Open Information Extraction (OpenIE) systems have gone through a paradigm shift from using rule-based, statistical systems to supervised neural models. However, both types of systems have been limited to only a few languages – earlier systems required language-specific OpenIE insights, and current systems require annotated training corpus that pose a barrier, particularly for low-resource languages.

Related tasks such as Semantic Role Labeling face similar challenges in extending to multiple languages. X-SRL (Daza and Frank, 2020) addresses this by automatic translation of English sentences to the target language followed by label projection to infer the semantic role labels in the translated sentence. However, translating the sentence alone may be insufficient for OpenIE because the generated tuples (also referred to as extractions) can include additional words absent in the sentence or require some changes to the word morphology used in the sentence. Although less prevalent in English, these characteristics need to be addressed in other languages.

X-SRL approach may be extended such that each extraction can also be automatically translated and subject, relation, object labels projected from English extractions. However, *independent* translation of sentence and extraction may introduce unwanted *lexical* (e.g. synonyms) or *semantic* (e.g., change in gender) variations between the translations, as shown in Table 1. Such translation inconsistencies in the training data lead to invalid OpenIE examples.

To maintain consistency between translations of a sentence and its extractions, both the trans-

Lexical Inconsistency	
English Sentence	*The shield of Athena Parthenos, sculpted by Phideas, depicts a* ***fallen*** *Amazon*
English Extraction	*<s> The shield of Athena Parthenos </s> <r> depicts </r> <o> a* ***fallen*** *Amazon </o>*
Spanish Sentence	El escudo de Atena Parthenos, sculptado por Phideas, representa un Amazonas **fallecido**
Spanish Extraction (Indp)	<s> El escudo de Atena Parthenos </s> <r> representa </r> <o> un Amazonas **caído** </o>
Spanish Extraction (Const)	<s> El escudo de Atena Parthenos </s> <r> representa </r> <o> un Amazonas **fallecido** </o>
Semantic Inconsistency	
English Sentence	*The discovery was remarkable as the skeleton was almost identical to* ***a modern Kuvasz***
English Extraction	*<s> skeleton </s> <r> was </r> <o> almost identical to* ***a modern Kuvasz*** *</o>*
Spanish Sentence	Un descubrimiento notable porque fósil era casi idéntica a **un Kuvasz moderno**
Spanish Extraction (Indp)	<s> skeleto </s> <r> era </r> <o> casi idéntica a **una Kuvasz moderna** </o>
Spanish Extraction (Const)	<s> fósil </s> <r> era </r> <o> casi idéntica a **un Kuvasz moderno** </o>

Table 1: OpenIE examples transferred from English to Spanish, using both Independent (Indp) and Consistent (Const) translations. Independent translation results in inconsistencies which may have the same meaning (by using synonyms, fallecido vs. caído) or may change the meaning (changing gender from male to female, moderno to moderna). Consistent translation avoids these issues, resulting in better quality of training data.

lations must use same words or their morphological variants as much as possible. Hence, we propose Alignment-Augmented Consistent Translation (AACTrans), a seq2seq model that translates the given input text in a way that is consistent with a *reference translation* by biasing the translation to use words similar to the reference. To ensure that translations of sentence and extractions are consistent with each other, we use AACTrans model to translate each of them with the same reference. In Section 4.1, we describe the reference used in training and inference.

Both generation based (Kolluru et al., 2020b) and labeling based (Ro et al., 2020) architectures have shown competitive performance on English OpenIE. However, labeling based models cannot naturally introduce new words or change morphology of sentence words required in some languages. Therefore, we use a new generative model, Gen2OIE, that contains two stages: the first stage produces all the relations in the sentence and the second stage generates the extractions containing the given relation. We also use a training heuristic specific to two stage models that increases relation coverage across multiple languages.

Our major contributions are that we:

1. introduce a novel technique for transferring data from English to other languages using the AACTrans model and label projection,
2. propose two-stage generative model, Gen2OIE, for training OpenIE system in multiple languages,
3. release OpenIE evaluation datasets for two Indian languages, Hindi and Telugu, and
4. outperform prior systems by 6-25% in F1 over five languages.

2 Related Work

Our work is in line with the recent trend of extending IE and knowledge-based NLP systems to multiple languages. Recent works have explored distantly supervised relation extraction (Rathore et al., 2022; Bhartiya et al., 2022), knowledge-base completion (Singh et al., 2021), and fact linking (Kolluru et al., 2021). Our focus is OpenIE.

Many of the prior OpenIE systems, both non-neural (OpenIE-4 (Pal and Mausam, 2016; Christensen et al., 2011), OpenIE-5 (Saha et al., 2017; Saha and Mausam, 2018), ClausIE (Del Corro and Gemulla, 2013)) and neural (RnnOIE (Stanovsky et al., 2018), OpenIE-6 (Kolluru et al., 2020a)) have been deployed for English. Moreover, OpenIE systems built for other languages often work only for a single language due to their reliance on language-specific resources. For example, Bassa et al. (2018); Rahat and Talebpour (2018); Romadhony et al. (2018); Guarasci et al. (2020); Papadopoulos et al. (2021) focus on German, Persian, Indonesian, Italian, and Greek, respectively. Claro et al. (2019) present the importance of and various challenges involved with building multilingual OpenIE systems. Neural models like Logician (Sun et al., 2018) and CrossOIE (Cabral et al., 2020) use language-specific training data. Reliance on manually-annotated data or language-specific resources makes it infeasible to develop systems for the plurality of languages in the world, due to the cost and effort involved. However, our automated data conversion method can handle even low-resource languages like Telugu.

Non-neural systems such as PredPatt (White et al., 2016) and ArgOE (Gamallo and Garcia, 2015) work for multiple languages by using CoNLL-X and Universal Dependency parses respectively, to extract predicate-argument structures. Owing to their pipelined nature, their performance is below that of neural systems like Multi^{2}OIE (Ro et al., 2020). Multi^{2}OIE is a two-stage labeling model that works for English, Spanish and Portuguese. GEN2OIE extends this 2-stage design to the generative paradigm which allows for better modeling of the OpenIE task. The underlying mBERT encoder in Multi^{2}OIE allows for cross-lingual generalization across various languages even after training with only English supervised data. However, dependence on zero-shot generalization limits the performance of the model.

Two types of methods have been proposed for constraining the outputs of the machine translation systems: 1) altering the decoding algorithm (Hasler et al., 2018), or 2) modifying the training methodology (Chen et al., 2020; Dinu et al., 2019). We follow the second approach for constraining translations by AACTRANS to be consistent to that of a reference sentence. Unlike prior work which focuses on constraining translations of few words, our task requires constraining the entire translation. We make use of awesome-align (Dou and Neubig, 2021a), an unsupervised word alignment technique (Och and Ney, 2003), that outputs the alignment between words in sentences of two languages. Awesome-align is trained using only parallel set of sentences in the two languages and generates aligned target words for each source word.

Transferring linguistic annotations from source to target language has been pioneered by (David et al., 2001) and has been used in context of Semantic Role Labeling (Annesi and Basili, 2010) and PoS-tagging (Zennaki et al., 2019). After consistent translation, we make use of Crosslingual Projection (Faruqui, 2015), to transfer OpenIE tags.

3 Notation

For the transfer of OpenIE data from one language to another, we represent the source language[2] as E and the target language as F. Further, we use $sent_E$ and ext_E to represent a sentence and extraction in the source language and $aact\text{-}sent_F$ and $aact\text{-}ext_F$ to represent the transferred sentence and extraction in the target language.

To aid in the translation of extractions, we create a sub-sentence from each extraction by concatenating the phrases in all the fields of the extraction. The order of concatenation is such that the formed sub-sentence is grammatically valid. We refer to this sub-sentence as an *ext-sentence* and represent it as es_L, where the subscript L represents its language. For most English extractions, the ext-sentence corresponds to concatenating the fields in the order of subject, relation and object. However, other languages may follow a different order or allow for multiple orders. We rely on the output of system that translates the English ext-sentence to determine the ext-sentence in other languages. Moreover, each extraction can be seen as a labeling over the words of ext-sentence with either the **S**ubject, **R**elation or **O**bject tags. Tags for each word in the ext-sentence can also be regarded as the extraction.

4 Crosslingual Data Transfer

In this section we describe the technique used to convert OpenIE training data from source language E to a target language F. The source sentence, $sent_E$, and all its corresponding ext-sentences, es_E, are consistently translated to language F (Section 4.1), and then, for each extraction in language E, ext_E, the **S**, **R** or **O** labels are projected to the translated ext-sentence, es_F, to form the extraction, ext_F, in language F (Section 4.2). Figure 1 describes the pipeline with the help of an example.

4.1 Consistent Translation

We introduce a new Seq2Seq-based translation model called Alignment-Augmented Consistent Translation (AACTRANS) to ensure that sentences and ext-sentences are translated consistently from languages E to F. We define two translations as consistent if similar phrases have same grammatical structure, vocabulary and morphology while allowing for minimal changes necessary to ensure fluency.

To ensure consistency among translations of multiple pieces of text (both the sentence and respective ext-sentences present in an English OpenIE instance), we make use of a reference text in language F to guide all of their translations. By individually maintaining consistency with the reference, their respective translations end up being consistent to one another as well.

---

[2] In the current work, we always use English as source.

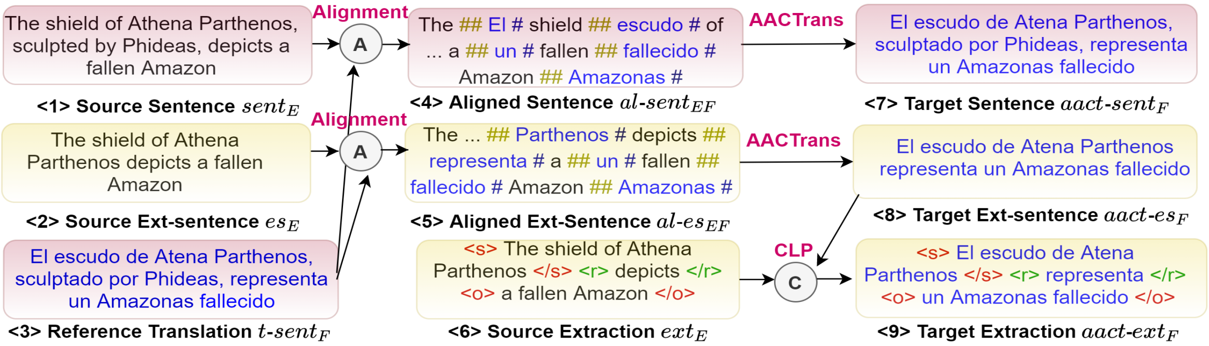

Figure 1: Crosslingual Data Transfer pipeline from English to Spanish. The sentence and ext-sentence in English are aligned with a translation of the sentence. The AACTRANS model uses the aligned text to generate the final consistent translations. Cross Lingual Projection (CLP) introduces **S**, **R**, **O** tags in the extraction.

To generate a translation **f** (language F) of text **e** (language E), consistent with a reference **r** (language F), we use the following procedure.

Firstly, given $\mathbf{e} = e_1 e_2 \ldots e_N$ and $\mathbf{r} = r_1 r_2 \ldots r_M$, we find the set of aligned words A_{e_i}=$\{r_j\}$ for each word e_i in **e**, using a word alignment model.

Secondly, the aligned text $\mathbf{e}'$ is constructed by concatenating each of the words e_i in **e**, with their aligned words A_{e_i}, using ## as a separator (shown as <1>, <3> → <4> and <2>, <3> → <5> in Figure 1). If e_i is aligned to the words r_j, r_k ($j < k$), then $\mathbf{e}'$ contains e_i ## r_j r_k #. If e_i has no aligned words, then $\mathbf{e}'$ contains e_i #.

Thirdly, the AACTRANS model takes $\mathbf{e}'$ as input and produces the sequence **f** as output, which represents a translation of **e** that is biased to use the aligned reference words (shown as <4> → <7> and <5> → <8> in Figure 1).

Next we discuss the training and inference of AACTRANS model.

Training: We use parallel sentences of languages E and F that are available in existing translation corpora for training the AACTRANS model. For each parallel sentence pair **e** and **f**, we use the sentence **f** itself as the reference **r**. Using the alignments between the words of **e** and **f**, we form the input $\mathbf{e}'$, as discussed. The AACTRANS Seq2Seq model is trained with $\mathbf{e}'$ as input and **f** as output. Since $\mathbf{e}'$ has words from **f**, the model learns to use them during training.

Inference: Here, we consistently translate English sentence $sent_E$ and each of its ext-sentences es_E. We use an off-the-shelf translation system to translate $sent_E$ to language F, represented as $t\text{-}sent_F$. $t\text{-}sent_F$ is used as the common reference **r** for constructing aligned sentence $al\text{-}sent_{EF}$ and aligned ext-sentence $al\text{-}es_{EF}$ from sentence $sent_E$ and ext-sentence es_E, respectively. We then apply the trained AACTRANS model on $al\text{-}sent_{EF}$ and $al\text{-}sent_{EF}$ to generate target sentence $aact\text{-}sent_F$ and target ext-sentence $aact\text{-}es_F$ respectively.

4.2 Crosslingual Label Projection (CLP)

Each word in the target ext-sentence, $aact\text{-}es_F$, must be labeled with either the Subject, Relation, or Object tag to form the completed extraction in language F. The tags from the corresponding ext_E are projected onto $aact\text{-}es_F$ using the Crosslingual Projection algorithm (Faruqui, 2015) (described in Appendix A), which uses word alignments between es_E and $aact\text{-}es_F$ and produces as output, the tags over $aact\text{-}es_F$, giving extraction $aact\text{-}ext_F$. The final set of <sentence, extractions> pairs constitute the data for training OpenIE system in language F.

Thus the overall flow is: 1) AACTRANS model training is done on parallel corpus, 2) AACTRANS model inference is applied on language E OpenIE examples, 3) CLP projection is used to obtain the labelled extractions, and 4) the generated data is used to train OpenIE system like GEN2OIE, which is discussed next.

5 Gen2OIE Model

To train OpenIE systems in multiple languages, we use a novel GEN2OIE model that extends the 2-stage design of Multi^{2}OIE (Ro et al., 2020) to a generative paradigm. The first stage generates all possible relations and the second stage generates all extractions that contain a given relation.

GEN2OIE can produce overlapping relations and multiple extractions containing the same rela-

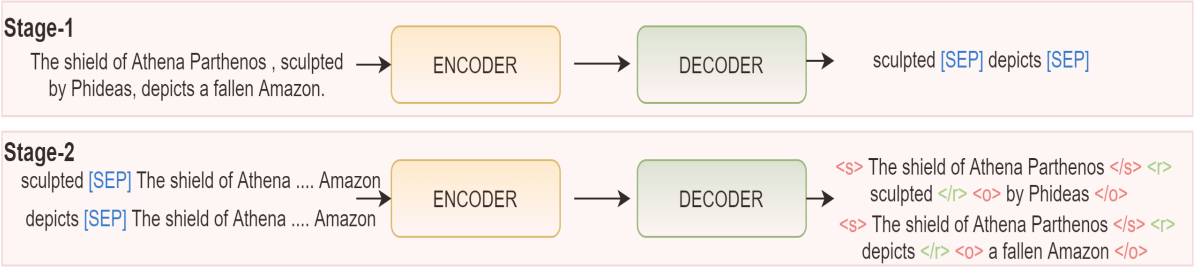

Figure 2: GEN2OIE model contains two Seq2Seq models. In Stage-1, it generates all relations in the sentence, separated by an [SEP] token. For each detected relation in Stage-2, it generates extractions containing the relation.

tion, thus overcoming the limitations of Multi^{2}OIE model. Moreover, due to its generative nature, GEN2OIE can add new words or introduce changes in morphology that may be necessary for producing correct extractions, which cannot be achieved by labeling models.

Both the stages of the GEN2OIE (shown in Figure 2) use Seq2Seq models as follows:

Stage-1 Seq2Seq: The input sentence is passed to the encoder and decoder generates a string formed by concatenating the set of relations from all the extractions, separated by an *[SEP]* token. During training, the target relations are concatenated in the order in which they occur in the sentence. We find that a deterministic order is important for adding stability to the model training.

Stage-2 Seq2Seq: To produce extractions corresponding to each relation generated in Stage-1, the relation r is concatenated with the input sentence s and passed to the encoder as "r *[SEP]* s". The decoder is trained to generate all the extractions containing the relation r. Multiple extractions are separated by an <*e*> token and each extraction contains delimiters tokens to identify the various parts of the extraction. The surrounding <*s*>...</*s*>, <*r*>...</*r*> and <*o*>...</*o*> tokens are used to identify the subject, relation and object phrases.

Labeling models like OpenIE-6 (Kolluru et al., 2020a) have used constrained training to increase the relation coverage. However, the constraints are limited to English and specific to labeling architectures. We introduce a simple parts-of-speech based heuristic during Stage-1 training of GEN2OIE that increases the relation coverage in the generative paradigm while being applicable across languages.

Relation Coverage (RC): We observe that for generating all possible extractions, all the verbs in the sentence must be contained in some relation. However, the extractions of training data may be incomplete and not satisfy this property. Therefore, during the training phase, we modify the input to the Stage-1 model by removing the verbs in the sentence which are not present in relation of any extraction. Thus the model learns that every verb must be included in some relation and applies the same during inference as well. This heuristic does not effect Stage-2 model training.

6 Confidence Scoring

The word log probabilities assigned by the Stage-2 decoder can be summed up to be used as confidence score for the extractions generated by GEN2OIE. We experiment with using a separate model for obtaining the confidence scores. A sequence-labeling model is trained on each language's extractions with ext-sentence as input and S, R, O labels over the ext-sentence as the output. The log probabilities given by the sequence-labeling model to the labels predicted by the GEN2OIE model are summed up to get the new confidence scores.

7 Experimental Setting

We train OpenIE systems in 5 languages, Spanish (ES), Portuguese (PT), Chinese (ZH), Hindi (HI) and Telugu (TE), by using the training data transferred from English to the respective language. For training the Seq2Seq models used in the data generation pipeline and the OpenIE systems based on the GEN2OIE architecture, we choose either the mBART (Liu et al., 2020) or mT5 (Xue et al., 2020) model depending on the particular language. Both of them are pre-trained multilingual Seq2Seq models that are trained with a span denoising objective on a large corpus of text containing many languages. mBART is pre-trained on CC25 and mT5 is pre-trained on mC4 corpus which contain text in 25 and 101 languages, respectively. Since mBART does not support Portuguese and Telugu, we use mT5 for these two languages and mBART for the remaining 3 languages. We use the default hyperparameters recommended for these models and they are reported in Appendix F.

Training Datasets: For training the AACTrans model, we make use of parallel English, language F sentences available in standard translation corpora using the method described in Section 4. For Spanish we use parallel sentences from EuroParl corpus (Koehn et al., 2005), and for Portuguese we use a subset of the ParaCrawl corpus (Bañón et al., 2019), as chosen by Lopes et al. (2020). For Hindi we use the IIT-B corpus (Kunchukuttan et al., 2018), and for Telugu we use the Samanantar corpus (Ramesh et al., 2021). For Chinese we use the data released for WMT19 (Barrault et al., 2019). We list the BLEU scores of the various systems in Appendix C.

We use the OIE4 training corpus from Kolluru et al. (2020b) and transfer it to other languages for training OpenIE systems.

Evaluation Datasets and Metrics: For evaluating translation systems we use the test sets available in the respective corpora and use SacreBLEU (Post, 2018) as the metric.[3] For evaluating different OpenIE systems we use the Optimal F1 and Area Under Curve (AUC) as computed by the CaRB (Bhardwaj et al., 2019) scoring function. For Spanish, Portuguese OpenIE we use test sets provided in Ro et al. (2020). For Chinese OpenIE, we randomly choose 10% of the SAOKE dataset (Sun et al., 2018).

In order to evaluate our method on medium and low resource languages, we release new OpenIE test sets in Hindi and Telugu. Human annotators who are fluent in both the language and are knowledgeable about the OpenIE task translated about 300 randomly chosen sentences and their corresponding extractions from CaRB test set. They were paid $2.5 per sentence.

Table 2 lists the number of examples in different languages used for training and evaluating translation and OpenIE systems.

8 Experiments

We perform experiments to answer the questions:

1. How effective is the Gen2OIE model?
2. What is the quality of data generated with the AACTrans+CLP pipeline, assessed both by the final performance of systems trained using it and with metrics defined for evaluating consistency?
3. What are the roles of different components in the Gen2OIE and AACTrans+CLP data?

	EN	ES	PT	ZH	HI	TE

Gen2OIE	54.4	32.3
(label-rescore)	**54.5**	**38.9**

Table 3: Performance of OpenIE systems in English, evaluated with the CaRB metric. Gen2OIE along with Label Rescoring produces the best performance.

8.1 Effectiveness of Gen2OIE

To study the baseline monolingual effectiveness of Gen2OIE, we first train and evaluate the system on English data. The results are shown in Table 3. We compare with previously proposed English OpenIE models such as Multi^{2}OIE (Ro et al., 2020), OpenIE6 (Kolluru et al., 2020a) and IMoJIE (Kolluru et al., 2020b). We also consider individual components in OpenIE6, the IGL and Constrained-IGL (CIGL) architectures. CIGL achieves the highest performance among all prior models but uses of English specific constraints in training.

We find that Gen2OIE, which uses the proposed language-agnostic relation coverage (RC) outperforms CIGL by 0.4% F1. However, its AUC remains lower. Therefore, we rescore the generated extractions with labeling-based rescoring model (Section 6). This results in a new state of the art for English in F1 and AUC with the labeling-based rescoring resulting in a 2.9% AUC gain over CIGL.

---

Table 4: F1 and AUC performance of OpenIE systems in Spanish (ES), Portuguese (PT), Chinese (ZH), Hindi (HI) and Telugu (TE). Training with AACTrans+CLP data shows strong performance with both GenOIE and Gen2OIE models. Labeling-based rescoring improves AUC in all languages. We also report the results of training Gen2OIE model with mT5 on all languages.

To further analyze the effectiveness of our 2-stage architecture, we introduce another model called GenOIE that outputs all extractions for a sentence as a single string, separated by an <*e*> token. We find that using GenOIE results in (2.3, 2.0)% drop in F1, AUC compared to Gen2OIE which leverages RC. We also report Gen2OIE performance without using RC.

8.2 Quality of AACTrans+CLP data

In order to test the quality of the OpenIE examples generated using the AACTrans+CLP pipeline, we train both the GenOIE and Gen2OIE models over the data generated for different languages. In Table 4, we compare it with examples generated from two other methods, SentTrans and SentExtTrans.

SentTrans+CLP represents an adaptation of X-SRL (Daza and Frank, 2020) for OpenIE where only the sentence is translated and each extraction, which is expressed as labeling over the words in the sentence, are projected onto the translated sentence using the CLP algorithm described in Section 4.2. The projected extraction is now a labeling over the translated sentence and hence it uses the same morphology as the sentence and cannot add new words. SentExtTrans+CLP uses independent translation of English sentence and ext-sentences followed by CLP algorithm between the English and translated ext-sentences to transfer the labels. Although this allows for adding new words and changing morphology, it can result in a lack of consistency between the translations.

We find that both GenOIE and Gen2OIE show consistent gains with AACTrans+CLP data across various languages, when compared with SentExtTrans+CLP and SentTrans+CLP data.

We further use rescoring models that are trained on the same AACTrans+CLP data. Labeling-based rescoring achieves significantly higher AUC, with as much as 8.3% gain in Telugu.

We experiment with two versions of Multi^{2}OIE: 1) trained only on English OpenIE data and applied to other languages in a zero-shot manner and 2) using language-specific training data generated from SentTrans+CLP. We specifically choose SentTrans+CLP data as all the extractions can be expressed as labels over the sentence, which is a requirement for training Multi^{2}OIE which is itself a labeling model. We find that Multi^{2}OIE model trained with SentTrans+CLP data improves over the zero-shot setting in all languages other than Chinese (discussed below). However, it performs significantly worse than Gen2OIE by (5.2, 3.3)% in (F1, AUC) on average, even on training with the same SentTrans+CLP data. This can be attributed to Multi^{2}OIE's lack of capability to handle: 1) overlapping relations, 2) multiple extractions per relation, 3) adding auxiliary words or 4) changing inflectional forms, as shown in Table 5.

We train IMoJIE and OpenIE6 (initialized with mBERT) on AACTrans+CLP and SentTrans+CLP data. We find that they underperform

Sentence Extractions	George Bluth Sr., patriarch of the Bluth family, is the founder and former CEO of the Bluth Company. <s> George Bluth Sr. </s> <r> is patriarch of </r> <o> the Bluth family </o> <s> George Bluth Sr. </s> <r> is </r> <o> the founder and former CEO of the Bluth Company </o> <s> George Bluth Sr. </s> <r> is </r> <o> patriarch of the Bluth family </o>
Telugu English Extraction	షరోన్ యొక్క దీర్ఘకాల ప్రత్యర్థి బెంజమిన్ నెతన్యాహును లికుడ్ నాయకుడిగా ఎన్నుకున్నారు *Sharon's longtime rival Benjamin Netanyahu was elected as leader of Likud* <s> షరోన్ యొక్క దీర్ఘకాల ప్రత్యర్థిని </s> <o> లికుడ్ నాయకుడిగా </o> <r> ఎన్నుకున్నారు </r>
Hindi English Extraction	जॉन लैंबर्ट ने सरकार के साधन के रूप में जाना जाने वाला एक नया संविधान सामने रखा *John Lambert put forward a new constitution known as the Instrument of Government* <s> एक नया संविधान </s> <o> सरकार के साधन के रूप में </o> <r> जाना जाता है </r>

Table 5: Sentence and OpenIE predictions of GEN2OIE in English, Telugu and Hindi. It is capable of generating overlapping relations (*is*, *is patriarch of*), multiple extractions per relation (*is*), add auxiliary words (जाने -> जाता है) or change inflection forms (ప్రత్యర్థి -> ప్రత్యర్థిని) as necessary.

Model (Data)	ES		ZH		HI	
	F1	AUC	F1	AUC	F1	AUC
GEN2OIE (AACTRANS+CLP)	**65.9**	**47.2**	**29.8**	**10.3**	**52.8**	32.0
GEN2OIE (AACTRANS w/o Sentence Consistency+CLP)	64.0	44.3	29.6	**10.3**	51.9	30.8
GEN2OIE w/o Relation Ordering (AACTRANS+CLP)	65.2	45.6	29.6	9.8	52.5	31.8
GEN2OIE w/o Relation Coverage (AACTRANS+CLP)	60.6	40.3	23.9	6.6	**52.8**	**32.3**

Table 6: Ablations of GEN2OIE model trained with AACTRANS+CLP data on ES, ZH and HI. We analyze the effect of removing 3 components and re-training the model: 1. Sentence Consistency used in AACTRANS data generation, and 2. Relation Ordering used and 3. Relation Coverage used in Stage-1 model training.

GEN2OIE and Multi^{2}OIE. Compared to the two-stage models, both IMoJIE and OpenIE6 generate all the extractions autoregressively, which makes them more susceptible to noise in the automatically generated training data.

We additionally compare with Faruqui (2015), where the test sentence is translated into English, extractions are generated using OpenIE6 and they are projected back onto the test sentence. We find that the system results in poor performance due to lack of language-specific training.

We observe that all systems have low performance on Chinese. We attribute this to the various artifacts present in the SAOKE test set, that include special relations such *DESC*, *TIME*, *ISA*, etc. Since these extractions cannot be generated in our pipeline, we observe performance of only 33.2% F1 and 15.8% AUC with our best model, when compared to training GEN2OIE with SAOKE training data, which gives 52.5% F1 and 32% AUC.

We additionally train the GEN2OIE model using mT5 on AACTRANS data for all five languages (GEN2OIE-mT5 in Table 4) and find improvements of (2.1%, 3.5%, 0.8%) F1 over the mBART models used for ES, ZH and HI.

8.3 Evaluating Consistency

In order to measure the inconsistency of the generated extractions with respect to the sentence, we compute the fraction of words that occur in the extraction but are absent in the sentence. In Table 7, we find that across languages, the fraction is lower for training examples generated through the consistent translation methodology (AACTRANS+CLP) when compared against independent translations (SentExtTrans+CLP). This indicates that AACTRANS+CLP indeed achieves better consistency.

	ES	PT	ZH	HI	TE
SenExtTrans+CLP	12.2	9.5	24.5	13.3	19.6
AACTrans+CLP	5.4	3.9	5.7	6.9	10.3

Table 7: Evaluating inconsistency between translated extractions and corresponding sentences.

In order to analyze the reasons for improvement in CaRB performance, we compute the fraction of words that are present in model predictions but absent in the gold extractions of the test set (denoted by AG - Absent in Gold). In Table 8, we see that GEN2OIE trained on AACTRANS+CLP achieves lower values than the same model trained on SentExtTrans+CLP data and this correlates with the increased CaRB performance. This shows that the model generates words closer to gold extractions (and hence closer to input sentence), which contributes to higher performance.

Data	ES		PT		ZH		HI		TE	
	AG↓	F1↑	AG↓	F1↑	AG↓	F1↑	AG↓	F1↑	AG↓	F1↑
SentExtTrans+CLP	2.74	64.7	3.51	63.7	10.55	29.3	1.78	52.5	2.36	39.8
AACTRANS+CLP	2.31	65.9	2.22	66.4	9.67	29.8	1.6	52.8	2.09	41.5

Table 8: Evaluating CaRB F1 and AG of GEN2OIE predictions trained on SentExtTrans+CLP and AACTrans+CLP data. We find a decreasing trend of AG with increasing F1.

8.4 Ablation Study

We choose three representative languages to conduct the ablation study — Spanish, Chinese, and Hindi. Portuguese and Telugu belong to the same language family as Spanish and Hindi, respectively. In Table 6, we show the results of individually removing components from the GEN2OIE trained on AACTRANS+CLP data.

In AACTRANS w/o Sentence Consistency, we use regular translation of sentence while using consistent translation of extraction. This leads to a drop of (1.9, 0.2, 0.9)% in F1 for the three languages, and shows the importance of using consistent translation on both the sentence and extraction.

In GEN2OIE w/o Relation Ordering, we train Stage-1 GEN2OIE with randomly shuffled relations. This reduces the performance as our model uses auto-regressive training which benefits from following a fixed order, which we choose as the order of occurrence of the relations in the sentence.

In GEN2OIE w/o Relation Coverage, we find that performance decreases in Spanish and Chinese by 5.3% and 5.9% in F1, respectively, but remains the same in Hindi, possibly due to the smaller number of examples in the test set.

Error Analysis: We find that the AACTRANS+CLP suffers from: 1) missing or 2) wrong word alignments and 3) inability to label discontinuous S, R, O phrases. We show examples of these cases in Appendix B.

9 Conclusion

We develop a novel AACTRANS+CLP pipeline for consistently transferring English OpenIE examples to other languages and present a novel two-stage generative model, GEN2OIE, for training OpenIE systems in various languages. We show improvements over the existing baseline of Multi^{2}OIE, with an average improvement of 7.2% in F1 and 16.1% in AUC. It is effective in five languages, which is the largest number of languages covered by a single OpenIE technique known to us. To encourage research in medium and low-resource languages, we additionally release new OpenIE evaluation examples in Hindi and Telugu.

Alignment-Augmented Consistent Translation for Multilingual Open Information Extraction (Appendix)

A Crosslingual Label Projection (CLP)

In this section, we discuss CLP algorithm for projecting labels from English extraction to other language. Consider English sentence, E: *Dutil - Dumas experiment was promoted by an organization called Encounter 2001 denotes* and Spanish sentence, S: *Experimento Dutil - Dumas fue promovido por una organización llamada Encounter 2001*. The word alignments between these sentences are listed in Figure 3 and equivalent phrases from the phrase extract algorithm are shown in Table 9. Consider the English extraction, *(Dumas experiment; was promoted; by an organization)*. For each phrase in the tuple, CLP algorithm looks for the highest BLEU match phrase from Table 9. The subject phrase *Dumas experiment* has best BLEU match to *Dutil - Dumas experiment* and so the corresponding Spanish phrase *Experimento Dutil - Dumas* will be marked as subject. Note that the phrase *Dumas experiment* is not present in Table 9 because its aligned phrase is not continuous in Spanish sentence as can be seen in Figure 3. Similarly for the relation phrase *was promoted*, we find *fue promovido* from Table 9. Continuing the same algorithm, we get *(Experimento Dutil - Dumas; fue promovido; por una organización)* as the final Spanish extraction.

B Error Analysis

We list three cases that decrease the quality of transferred data using the AACTrans+CLP pipeline.

Missing word alignments: For example, English extraction, *A couple of trojans have also been found orbiting with Mars* translates to *También se han encontrado un par de trojas en órbita con Mars* in Spanish. The verb *orbiting* changes to the form *en órbita (in orbit)* (nominalization). The word *en* in Spanish does not align with any word in the English extraction as can be seen in Figure 4. So, projection of *(A couple of trojans; have also been found; orbiting with Mars)* leads to *(un par de trojas; También se han encontrado; órbita con Mars)* which is not fluent because of missing word *en* in the object phrase.

In languages like Spanish and Portuguese, we found alignments to be of high precision but often miss some alignments, as shown above. Next, we see how wrong alignments can affect projection quality.

Wrong word alignments: Consider the following English (E) and Hindi (H) ext-sentences, E: *Many organizations like the Samskrita Bharati are conducting Speak Sanskrit workshops to popularize Sanskrit* and H: संस्कृता भारती जैसे कई संगठन संस्कृति को लोकप्रिय बनाने के लिए बोल संस्कृति कार्यशालाएं आयोजित कर रहे हैं . We find that the word *the* is wrongly aligned to the hindi word, कर . So, the subject phrase *Many organizations like the Samskrita Bharati* does not have a continuous phrase in Hindi sentence because it has many words till कर that do not map to the subject phrase in English sentence. Therefore, the CLP algorithm matches a partial phrase *Many organizations like* which is the best BLEU match to the given subject phrase and its equivalent continuous phrase जैसे कई संगठन संस्कृति को gets tagged as subject in Hindi. Whereas संस्कृता भारती जैसे कई संगठन संस्कृति को would be an ideal subject phrase.

Discontinuous phrases: Pharse extract in the CLP algorithm assumes continuous phrases in English map to continuous phrase in other language. This assumption would lead to incomplete extractions in the other languages. For example, consider English extraction E: *(Winston Churchill; twice suggested; naming a British battleship)* and its Telugu extraction sentence T: విన్స్టన్ చర్చిల్ రెండుసార్లు బ్రిటిష్ యుద్ధనౌకకు పేరు పెట్టాలని సూచించారు . The relation phrase *twice suggested* is mapped as follows in Telugu: The word *twice* is mapped to రెండుసార్లు and *suggested* is mapped to సూచించారు . The equivalent phrase *twice suggested* is no longer continuous in Telugu language. CLP algorithm looks for best BLEU match that results in matching to the phrase *twice* and its equivalent రెండుసార్లు is tagged as relation. The ideal relation in this example would be రెండుసార్లు సూచించారు

C BLEU scores

Table 10 contains the BLEU scores of both the normal as well as consistent translations. We find that the performance remains nearly the same, indicating that the improved OpenIE performance stems from the consistency in the translations.

D Effect of word alignments quality

In order to understand the effect of alignment quality, we replace the language-specific trained

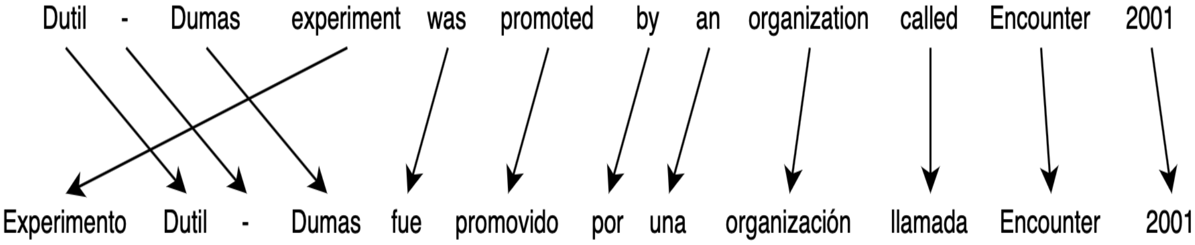

Figure 3: Equivalent English and Spanish sentence with corresponding word alignments between them

BLEU	ES	PT	ZH	HI	TE
Translation	45.2	48.4	26.8	20.5	7.0
AACTranslation	43.7	47.8	28.2	20.1	7.5

Table 10: BLEU scores of translation and AAC-translation are similar showing that the performance improvement is because of the added consistency.

Language	MA	TA
ES	0.38	0.19
HI	0.49	0.20

Table 11: Unsupervised alignment perplexity for mBERT (MA) and Trained (TA) aligners

aligners (TA), with a standard pre-trained mBERT model (MA). First note in Table 11 that MA has a much higher alignment perplexity (used as a measure of unsupervised alignment quality in (Dou and Neubig, 2021b)). We now perform an experiment to replace TA with MA in our methodology. Aligners are used at two places in our setup - 1. Alignment-Constrained Translation and 2. Crosslingual Label Projection. We replace each of them with an mBERT aligner (MA), and show the results in Table 12. We find that there is some performance drop by using MA, but it is quite less compared to the drop in alignment perplexity. This suggests that our model is relatively robust to the quality of alignment.

E Alternatives to CLP

Following (Zennaki et al., 2019), we experiment with a neural mBERT-based tagging model. We train the mBERT model for tagging the Subject, Relation and Object tags in English. Due to the language-agnostic features of mBERT, we can apply the model to other languages in a zero-shot manner. These tagged examples can then be used for training the OpenIE model. In Table 13, we find that this does not improve over our CLP-based tagging. However, combining signals from both techniques could be interesting future work. HI results in Table 12 and Table 13 use a subset of the final test set which was initially used for development purposes.

(AACTRANS,CLP)	HI		ES	
	F1	AUC	F1	AUC
(TA, TA)	62.1	38.8	65.9	47.2
(TA, MA)	58.7	34.4	64.7	46.2
(MA, TA)	59.4	37.9	65.6	46.7

Abstract

We study a new problem setting of information extraction (IE), referred to as text-to-table. In text-to-table, given a text, one creates a table or several tables expressing the main content of the text, while the model is learned from text-table pair data. The problem setting differs from those of the existing methods for IE. First, the extraction can be carried out from long texts to large tables with complex structures. Second, the extraction is entirely data-driven, and there is no need to explicitly define the schemas. As far as we know, there has been no previous work that studies the problem. In this work, we formalize text-to-table as a sequence-to-sequence (seq2seq) problem. We first employ a seq2seq model fine-tuned from a pre-trained language model to perform the task. We also develop a new method within the seq2seq approach, exploiting two additional techniques in table generation: table constraint and table relation embeddings. We consider text-to-table as an inverse problem of the well-studied table-to-text, and make use of four existing table-to-text datasets in our experiments on text-to-table. Experimental results show that the vanilla seq2seq model can outperform the baseline methods of using relation extraction and named entity extraction. The results also show that our method can further boost the performances of the vanilla seq2seq model. We further discuss the main challenges of the proposed task. The code and data are available at `https://github.com/shirley-wu/text_to_table`. [1]

The Celtics saw great team play in their Christmas Day win, and it translated to the box score. Boston had 25 assists to just 11 for New York, and the team committed just six turnovers on the night. All-Star Isaiah Thomas once again led Boston with 27 points, while star center Al Horford scored 15 points and stuffed the stat sheet with seven rebounds, five assists, three steals, and two blocks. Third-year point guard Marcus Smart impressed off the bench, dishing seven assists and scoring 15 points including the game - winning three - pointer. New York, meanwhile, saw solid play from its stars. Sophomore big man Kristaps Porzingis had 22 points and 12 rebounds as well as four blocks. All-Star Carmelo Anthony had 29 points, 22 of which came in the second half. Point guard Derrick Rose also had 25 points in one of his highest - scoring outings of the season.

Team:

	Number of team assists
Knicks	11
Celtics	25

Player:

	Assists	Points	Total rebounds	Steals
Al Horford	5	15	7	3
Isaiah Thomas		27		
Marcus Smart	7	15		
Carmelo Anthony		29		
Kristaps Porzingis		22	12	
Derrick Rose		25		

Figure 1: An example of text-to-table from the Rotowire dataset. The text is a report of a basketball game, and the tables are the scores of the teams and players.

1 Introduction

Information extraction (IE) is a task that aims to extract information of interest from text data and represent the extracted information in a structured form. Traditional IE tasks include named entity recognition which recognizes entities and their types (Huang et al., 2015; Ma and Hovy, 2016; Lample et al., 2016; Devlin et al., 2019), relation extraction which identifies the relationships between entities (Zheng et al., 2017; Zeng et al., 2018; Luan et al., 2019; Zhong and Chen, 2021), etc. Since the results of IE are structured, they can be easily used by computer systems in different applications such as text mining.

In this work, we study IE in a new setting, referred to as text-to-table. First, the system receives a training dataset containing text-table pairs. Each text-table pair contains a text and a table (or tables) representing information needed for the target application extracted from the text. The system learns a model for information extraction. Next, the system employs the learned model to conduct information extraction from a new text and outputs the result in a table (or tables). Figure 1 gives an example of text-to-table, where the input (above) is a report of a basketball game, and the output (below) is two tables summarizing the scores of the

---

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2518 - 2533
May 22-27, 2022

teams and players from the input.

Text-to-table is unique compared to the traditional IE approaches. First, text-to-data can be performed at both sentence-level and document-level. While the distinction between sentence and document level is vague, document-level extraction can produce a more complex output. As in the example in Figure 1, extraction of information is performed from the entire document. The extracted information contains multiple types of scores of teams and players in a basketball game structured in table format. Second, the schemas for extraction are implicitly included in the training data such as header names. There is no need to explicitly define the schemas, which reduces the need for manual efforts for schema design and annotations.

Our work is inspired by research on the so-called table-to-text (or data-to-text) problem, which is the task of generating a description for a given table. Table-to-text is useful in applications where the content of a table needs to be described in natural language. Thus, text-to-table can be regarded as an inverse problem of table-to-text. However, there are also differences. Most notably, their applications are different. Text-to-table systems can automatically produce tables for text summarization and text mining. For example, the score tables of sports games and infoboxes of Wikipedia articles can serve as summaries of original documents. The score tables can be utilized to evaluate the athletes' performances, and the infoboxes can be used to construct a knowledge graph.

In this work, we formalize text-to-table as a sequence-to-sequence (seq2seq) task. More specifically, we translate the text into a sequence representation of a table (or tables), where the schema of the table is implicitly contained in the representation. We build the seq2seq model on top of a pre-trained language model, which is the state-of-the-art approach for seq2seq tasks (Lewis et al., 2020; Raffel et al., 2020). Although the approach is a natural application of existing technologies, as far as we know, there has been no previous study to investigate to what extent the approach works. We also develop a new method for text-to-table within the seq2seq approach with two additional techniques, table constraint, and table relation embeddings. Table constraint controls the creation of rows in a table and table relation embeddings affect the alignments between cells and their row headers and column headers. Both are to make the generated table well-formulated.

The approach to IE based on seq2seq has already been proposed. Methods for conducting individual tasks of relation extraction (Zeng et al., 2018; Nayak and Ng, 2020; Huang et al., 2021), named entity recognition (Chen and Moschitti, 2018; Yan et al., 2021), event extraction (Li et al., 2021; Lu et al., 2021) and role-filler entity extraction (Du et al., 2021; Huang et al., 2021) have been developed. Methods for jointly performing multiple tasks of named entity recognition, relation extraction, and event extraction have also been devised (Paolini et al., 2021). Most of the methods exploit suitable pre-trained models such as BERT. However, all the existing methods rely on predefined schemas for extraction. Moreover, their models are designed to extract information from short texts, rather than long texts, and extract information with simple structures (such as an entity and its type), rather than information with complicated structures (such as a table).

We conduct extensive experiments on the four datasets. Results show that the vanilla seq2seq model fine-tuned from BART (Lewis et al., 2020) can outperform the state-of-the-art IE models fine-tuned from BERT (Devlin et al., 2019; Zhong and Chen, 2021). Furthermore, results show that our proposed approach to text-to-table with the two techniques can further improve the extraction accuracies. We also summarize the challenging issues with the seq2seq approach to text-to-table for future research.

Our contributions are summarized as follows:

1. We propose the new task of text-to-table for IE. We derive four new datasets for the task from existing datasets.
2. We formalize the task as a seq2seq problem and propose a new method within the seq2seq approach using the techniques of table constraint and table relation embeddings.
3. We conduct extensive experiments to verify the effectiveness of the proposed approach.

2 Related Work

Information Extraction (IE) is the task of extracting information (structured data) from a text (unstructured data). For example, named entity recognition (NER) recognizes entities appearing in a text. Relation extraction (RE) identifies the relationships between entities. Event extraction (EE) discovers events occurring in a text. Role-filler entity extraction (REE) fills entities into event templates and is similar to EE.

Traditionally, researchers formalize the task as a language understanding problem. The state-of-the-art methods for NER perform the task on the basis of the pre-trained language model BERT (Devlin et al., 2019). The pipeline approach to RE divides the problem into NER and relation classification, and conducts the two sub-tasks in a sequential manner (Zhong and Chen, 2021), while the end-to-end approach jointly carries out the two sub-tasks (Zheng et al., 2017; Zeng et al., 2018; Luan et al., 2019). The state-of-the-art methods for EE also employ BERT and usually jointly train the models with other tasks such as NER and RE (Wadden et al., 2019; Zhang et al., 2019; Lin et al., 2020). All the methods assume the use of pre-defined schemas (e.g., entity types for NER, entity and relation types for RE, and event templates for EE). Besides, most methods are designed for extraction from short texts. Therefore, existing methods for IE cannot be directly applied to text-to-table.

Another series of related work is open information extraction (OpenIE), which aims to extract information from texts without relying on explicitly defined schemas (Banko et al., 2007; Wu and Weld, 2010; Mausam et al., 2012; Stanovsky et al., 2018; Zhan and Zhao, 2020). However, OpenIE aims to extract information with simple structures (i.e., relation tuples) from short texts, and the methods in OpenIE cannot be directly applied to text-to-table.

IE is also conducted at document level, referred to as doc-level IE. For example, some NER methods directly perform NER on a long document (Strubell et al., 2017; Luo et al., 2018), and others encode each sentence in a document, use attention to fuse document-level information, and perform NER on each sentence (Hu et al., 2020; Xu et al., 2018). There are also RE methods that predict the relationships between entities in a document (Yao et al., 2019; Nan et al., 2020). However, existing doc-level IE approaches usually do not consider the extraction of complex relations between many items.

Sequence-to-sequence (seq2seq) is the general problem of transforming one text into another text (Sutskever et al., 2014; Bahdanau et al., 2015), which includes machine translation, text summarization, etc. The use of the pre-trained language models of BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) can significantly boost the performances of seq2seq, such as machine translation (Lewis et al., 2020; Raffel et al., 2020; Liu et al., 2020) and text summarization (Lewis et al., 2020; Raffel et al., 2020; Huang et al., 2020).

Recently, some researchers also formalize the IE problems as seq2seq, that is, transforming the input text into an internal representation. One advantage is that one can employ a single model to extract multiple types of information. Results show that this approach works better than or equally well as the traditional approach of language understanding, in RE (Zeng et al., 2018; Nayak and Ng, 2020), NER (Chen and Moschitti, 2018; Yan et al., 2021), EE (Li et al., 2021; Lu et al., 2021) and REE (Du et al., 2021; Huang et al., 2021). Methods that jointly perform multiple tasks including NER, RE, and EE have also been devised (Paolini et al., 2021).

Data-to-text aims to generate natural language descriptions from the input structured data such as sports commentaries (Wiseman et al., 2017). The structured data is usually represented as tables (Wiseman et al., 2017; Thomson et al., 2020; Chen et al., 2020), sets of table cells (Parikh et al., 2020; Bao et al., 2018), semantic representations (Novikova et al., 2017), or sets of relation triples (Gardent et al., 2017; Nan et al., 2021). The task requires the model to select the salient information from the data, organize it in a logical order, and generate an accurate and fluent natural language description (Wiseman et al., 2017). Data-to-text models usually adopt the encoder-decoder architecture. The encoders are specifically designed to model the input data, such as multi-layer perceptron (Puduppully et al., 2019a,b), recurrent neural network (Juraska et al., 2018; Liu et al., 2018; Shen et al., 2020), graph neural network (Marcheggiani and Perez-Beltrachini, 2018; Koncel-Kedziorski et al., 2019), or Transformer (Gong et al., 2019).

3 Problem Formulation

As shown in Figure 1, text-to-table takes a text as input and produces a table or several tables to summarize the content of the text.

Formally, the input is a text denoted as $\mathbf{x} = x_1, \cdots, x_{|\mathbf{x}|}$. The output is one table or multiple tables. For simplicity suppose that there is only one table denoted as T. Further, suppose that T has n_r rows and n_c columns. Thus, T contains $n_r \times n_c$ cells, where the cell of row i and column j is a sequence of words $\mathbf{t}_{i,j} = t_{i,j,1}, ..., t_{i,j,|\mathbf{t}_{i,j}|}$.

There are three types of table: one that has both column headers and row headers, one that only has column headers, and one that only has row headers. For example, the player table in Figure 1 has both column headers ("Assists", "Points", etc) and row headers ("Al Horford", "Isaiah Thomas", etc). We let $\mathbf{t}_{1,j},\ j = 2, \cdots, n_c$ denote the column headers, let $\mathbf{t}_{i,1},\ i = 2, \cdots, n_r$ denote the row headers, and let $\mathbf{t}_{i,j},\ i = 2, \cdots, n_r, j = 2, \cdots, n_c$ denote the non-header cells of the table. For example, in the player table in Figure 1, $\mathbf{t}_{1,2}$ = Assists, $\mathbf{t}_{2,1}$ = Al Horford, and $\mathbf{t}_{2,2} = 5$.

The information extracted via text-to-table can be leveraged in many different applications such as document summarization and text mining. For example, in Figure 1, one can quickly obtain the key information of the text by simply looking at the tables summarized from the text.

There are differences between text-to-table and traditional IE settings. As can be seen from the example in Figure 1, extraction of information is performed from the entire document. The extracted information (structured data) is in a complex form, specifically multiple types of scores of teams and players in a basketball game. Furthermore, the data-driven approach is taken, and the schemas of the tables do not need to be explicitly defined.

The task of text-to-table also has challenges. First, parallel data containing texts and tables is difficult to obtain. Manual construction of such data is usually expensive. Second, structured information may not be easily represented as tables. For example, a knowledge graph may not be easily converted into tables. Third, evaluation of table extraction may not be easy, which includes multiple factors, such as header, content, and structure.

4 Our Method

We develop a method for text-to-table using the seq2seq approach and the two techniques of table constraint and table relation embeddings.

4.1 Vanilla Seq2Seq

We formalize text-to-table as a sequence-to-sequence (seq2seq) problem (Sutskever et al., 2014; Bahdanau et al., 2015). Specifically, given an input text, we generate a sequence representing the output table (or tables). We introduce two special tokens, a separation token denoted as "$\langle \mathrm{s} \rangle$" and a new-line token denoted as "$\langle \mathrm{n} \rangle$". For a table $\mathbf{t}$, we represent each row $\mathbf{t}_i$ with a sequence of cells delimited by separation tokens:

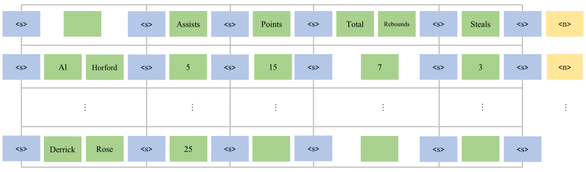

Figure 2: The sequence representation of the player table in Figure 1. The blue items are separation tokens $\langle \mathrm{s} \rangle$ and the yellow items are new-line tokens $\langle \mathrm{n} \rangle$.

$$\mathbf{t}_i = \langle \mathrm{s} \rangle, \mathbf{t}_{i,1}, \langle \mathrm{s} \rangle, \cdots, \langle \mathrm{s} \rangle, \mathbf{t}_{i,n_c}, \langle \mathrm{s} \rangle. \quad (1)$$

We represent the entire table with a sequence of rows delimited by new-line tokens:

$$\begin{aligned} \mathbf{t} = \quad & \langle \mathrm{s} \rangle, \mathbf{t}_{1,1}, \langle \mathrm{s} \rangle, \cdots, \langle \mathrm{s} \rangle, \mathbf{t}_{1,n_c}, \langle \mathrm{s} \rangle, \langle \mathrm{n} \rangle, \\ & \langle \mathrm{s} \rangle, \mathbf{t}_{2,1}, \langle \mathrm{s} \rangle, \cdots, \langle \mathrm{s} \rangle, \mathbf{t}_{2,n_c}, \langle \mathrm{s} \rangle, \langle \mathrm{n} \rangle, \\ & \qquad \cdots\cdots \\ & \langle \mathrm{s} \rangle, \mathbf{t}_{n_r,1}, \langle \mathrm{s} \rangle, \cdots, \langle \mathrm{s} \rangle, \mathbf{t}_{n_r,n_c}, \langle \mathrm{s} \rangle \end{aligned} \quad (2)$$

Figure 2 shows the sequence of the player table in Figure 1. When there are multiple tables, we create a sequence of tables using the captions of the tables as delimiters.

Let $\mathbf{x} = x_1, \cdots, x_{|\mathbf{x}|}$ and $\mathbf{y} = y_1, \cdots, y_{|\mathbf{y}|}$ denote the input and output sequences respectively. In inference, the model generates the output sequence based on the input sequence. The model conducts generation in an auto-regressive way, which generates one token at each step based on the tokens it has generated so far. In training, we learn the model based on the text-table pairs $\{(\mathbf{x}_1, \mathbf{y}_1), (\mathbf{x}_2, \mathbf{y}_2), \cdots, (\mathbf{x}_n, \mathbf{y}_n)\}$. The objective of learning is to minimize the cross-entropy loss.

We refer to the method described above as "vanilla seq2seq". There is no guarantee, however, that the output sequence of vanilla seq2seq represents a well-formulated table. We add a post-processing step to ensure that the output sequence is a table. The post-processing method takes the first row generated as well-defined, deletes extra cells at the end of the other rows, and inserts empty cells at the end of the other rows.

4.2 Techniques

We develop two techniques to improve table generation, called table constraint and table relation embeddings. We use "our method" to denote the seq2seq approach with these two techniques.[2]

---

[2] Our methods is able to generate the output containing multiple tables. This is discussed in Appendix C.

Table Constraint

Our method exploits a constraint in the decoding process to ensure that the output sequence represents a well-formulated table. Specifically, our method calculates the number of cells in the first row it generates, and then forces the following rows to contain the same number of cells.

Table Relation Embeddings

Our method also incorporates table relation embeddings including row relation embeddings and column relation embeddings into the self-attention of the Transformer decoder. Given a token in a non-header cell, the row relation embeddings τ_r^K and τ_r^V indicate which row header the token is aligned to, and the column relation embeddings τ_c^K and τ_c^V indicate which column header the token is aligned to.

Let us consider the self-attention function in one block of Transformer decoder: at each position, self-attention only attends to the previous positions. For simplicity, let us only consider one head in the self-attention. At the t-th position, the input of self-attention is the sequence of representations $z = (z_1, \cdots, z_t)$ and the output is the sequence of representations $h = (h_1, \cdots, h_t)$, where $z_i \in \mathbb{R}^d$ and $h_i \in \mathbb{R}^d$ are the representations at the i-th position $(i = 1, \cdots, t)$.

In a conventional Transformer decoder, self-attention is defined as follows,

$$h_i = \left(\sum_{j=1}^{i} \alpha_{ij} (z_j W^V) \right) W^O, \tag{3}$$

$$\alpha_{ij} = \frac{e^{e_{ij}}}{\sum_{j=1}^{i} e^{e_{ij}}}, e_{ij} = \frac{(z_i W^Q)(z_j W^K)^{\mathrm{T}}}{\sqrt{d_k}}, \tag{4}$$

$$i = 1, \cdots, t, \ j = 1, \cdots, i$$

where $W^Q, W^K, W^V \in \mathbb{R}^{d \times d_k}$ are the query, key, and value weight matrices respectively, and $W^O \in \mathbb{R}^{d_k \times d}$ is the output weight matrix.

In our method, self-attention is defined as:

$$h_i = \left(\sum_{j=1}^{i} \alpha_{ij} (z_j W^V + r_{ij}^V) \right) W^O, \tag{5}$$

$$\alpha_{ij} = \frac{e^{e_{ij}}}{\sum_{j=1}^{i} e^{e_{ij}}}, e_{ij} = \frac{(z_i W^Q)(z_j W^K + r_{ij}^K)^{\mathrm{T}}}{\sqrt{d_k}}, \tag{6}$$

$$i = 1, \cdots, t, \ j = 1, \cdots, i$$

where r_{ij}^K and r_{ij}^V are relation vectors representing the relationship between the i-th position and the j-th position.

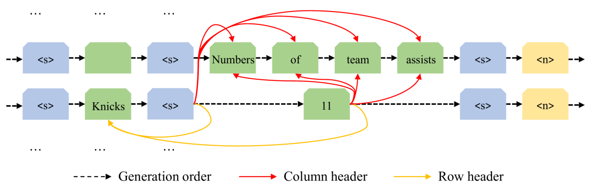

Figure 3: Construction of relation vectors. Red and yellow arrows represent alignments with column headers and row headers respectively. The relation vectors regarding tokens "11" and one $\langle \mathrm{s} \rangle$ are illustrated.

The relation vectors r_{ij}^K and r_{ij}^V are defined as follows. For the token at the i-th position, if the token at the j-th position is a part of its row header, then r_{ij}^K and r_{ij}^V are set to the row relation embeddings τ_r^K and τ_r^V. Similarly, for the token at the i-th position, if the token at the j-th position is a part of its column header, then r_{ij}^K and r_{ij}^V are set to the column relation embeddings τ_c^K and τ_c^V. Otherwise, r_{ij}^K and r_{ij}^V are set to 0. In inference, to identify the row header or the column header of a token, we parse the sequence generated so far to create a partial table using the new-line tokens and separation tokens in the sequence. Figure 3 illustrates how relation vectors are constructed.

5 Experiments

5.1 Datasets

We make use of four existing datasets which are traditionally utilized for data-to-text: Rotowire (Wiseman et al., 2017), E2E (Novikova et al., 2017), WikiTableText (Bao et al., 2018), and WikiBio (Lebret et al., 2016). In each dataset, we filter out the content in the tables that does not appear in the texts. We plan to make the processed datasets publicly available for future research. Table 2 gives the statistics of the Rotowire dataset and Table 1 gives the statistics of the other three datasets.

Rotowire is from the sports domain. Each instance is composed of a text and two tables, where the text is a report of a basketball game and the two tables represent the scores of teams and players respectively (cf., Figure 1). Each table has column headers describing the types of scores, and row headers describing the names of teams or players. The texts are long and may contain irrelevant information such as the performance of players in other games. Therefore, this is a challenging dataset.

E2E is from the restaurant domain. Each in-

Dataset	Train	Valid	Test	# of tokens	# of rows	# of columns
E2E	42.1k	4.7k	4.7k	24.90	4.58	2.00
WikiTableText	10.0k	1.3k	2.0k	19.59	4.26	2.00
WikiBio	582.7k	72.8k	72.7k	122.30	4.20	2.00

Table 1: Statistics of E2E, WikiTableText, and WikiBio datasets, including the number of instances in training, validation, and test sets, number of BPE tokens per instance, and number of rows per instance.

Train	Valid	Test	# of tokens
3.4k	727	728	351.05

	# of rows	# of columns	# of cells
Team	2.71	4.84	6.56 (85.40%)
Player	7.26	8.75	22.63 (43.93%)

Table 2: Statistics of Rotowire dataset. The first table shows sizes of training, validation, and test sets, and the number of BPE tokens per instance. The second table shows the number of rows, the number of columns, and the number and ratio of non-empty cells.

stance is a pair of short text and an automatically constructed table, where the text is a description of a restaurant, and the table has two columns with row headers summarizing the characteristics of the restaurant. The tables are automatically constructed, where the texts in the tables are from a limited set and thus lack diversity.

WikiTableText is an open-domain dataset. Each instance includes a text and a table, where the text is a description and the table has a row and two columns with row headers collected from Wikipedia. The texts are short and contain information similar to that in the tables.

WikiBio is extracted from the Wikipedia biography pages. Each instance consists of a text and a table, where the text is the introduction of Wikipedia page[3] and the table is from the infobox of a Wikipedia page and has two columns with row headers. The input texts are usually long and contain more information than the tables.

5.2 Procedure

Methods: We conduct experiments with vanilla seq2seq and our method, as well as baselines.

We know of no existing method that can be directly employed in text-to-table. For each dataset, we first define the schemas based on the training data, then use an existing method of relation extraction (RE) or named entity extraction (NER) to extract information, and finally create tables based on the schemas and extracted information. We take it as the baseline for the dataset. No baseline can be applied to all four datasets. For RE, we use PURE, a state-of-the-art method (Zhong and Chen, 2021). For NER, we use BERT (Devlin et al., 2019).

Training: For vanilla seq2seq and our method, we adopt Transformer (Vaswani et al., 2017) as the model and fine-tune the models from BART-base. We also experiment with BART-large. For RE and NER, we fine-tune the models from BERT-base-uncased. All models are trained with Adam optimizer until convergence. Hyper-parameters are shown in Appendix A. For the small datasets of Rotowire and WikiTableText, we run experiments five times with different random seeds and take the average of results to reduce variance.

Evaluation: We evaluate the performance of a method based on (1) the number of correct headers and (2) the number of correct non-header cells. We adopt the F1 score as the evaluation measure. For each table, we compare the set of predicted results $\mathbf{y}$ against the set of ground-truth $\mathbf{y}^*$. Precision is defined as the percentage of the correctly predicted results among the predicted results, i.e., $P = \frac{1}{|\mathbf{y}|}\sum_{y\in\mathbf{y}} \max_{y^*\in\mathbf{y}^*} O(y, y^*)$. Recall is defined as the percentage of the correctly predicted results among the ground-truth, i.e., $R = \frac{1}{|\mathbf{y}^*|}\sum_{y^*\in\mathbf{y}^*} \max_{y\in\mathbf{y}} O(y, y^*)$. Finally, $F1 = 2/(1/P + 1/R)$. Here, $O(\cdot)$ denotes a way of similarity calculation. We consider three ways: exact match, chrf (Popovic, 2015) and rescaled BERTScore (Zhang et al., 2020). Exact match conducts an exact match between two texts. Chrf calculates character-level n-gram similarity between two texts. BERTScore calculates the similarity of BERT embeddings between two texts. For non-header cells, we use not only the content but also the header(s) to ensure that the cell is on the right row (and column), and calculate the similarity $O(\cdot)$ as the product of header similarity and cell content similarity.[4] We evaluate the measures of a

---

[3] The original dataset only uses the first sentence of the introduction. We use the entire introduction.

[4] As shown in Figure 1, the tables in the dataset contain empty cells. The empty cells do not contain information. Therefore, we ignore the empty cells and only use the non-empty cells in the evaluation.

	Model	Row header F1			Column header F1			Non-header cell F1			Err.

Table 4: Results of our method, vanilla seq2seq, and the baseline of NER, on E2E, WikiTableText, and WikiBio. We show the F1 score based on exact match (Exact), chrf score (Chrf), and BERTScore (BERT) respectively.

generated table and then take the average on all tables. This evaluation assumes that the order of rows and columns is not important. We find that this assumption is applicable to the four datasets and many real-world scenarios. We also evaluate the percentage of output sequences that cannot represent well-formulated tables, referred to as error rate.

5.3 Results on Rotowire

Table 3 shows the results on the Rotowire dataset. One can see that our method performs the best followed by vanilla seq2seq in terms of most of the measures, especially the F1 score on non-header cells. Both outperform the baselines of doc-level RE and sent-level RE. The RE baselines perform quite well, but they heavily rely on rules and cannot beat the seq2seq approach. Among them, the doc-level RE performs better than sent-level RE, because some information in Rotowire can only be extracted when the cross-sentence context is provided.

We implement two baselines of RE, namely doc-level RE and sent-level RE. We take team names, player names, and numbers of scores as entities and take types of scores as relations. Sent-level RE predicts the relations between entities within each sentence. Doc-level RE predicts the relations between entities within a window (the window size is 12 entities) and uses the approximation model proposed by Zhong and Chen (2021) to speed up inference.

5.4 Results on E2E, WikiTableText and WikiBio

Table 4 shows the results of our method, vanilla seq2seq, and the baseline of NER on E2E, WikiTableText, and WikiBio. Again, the seq2seq approach outperforms the baseline. Our method and vanilla seq2seq are comparable, because the table structures in the three datasets are very simple (there are only two columns in the tables), and the use of the two techniques does not further improve the performances. The NER baseline has high precision but low recall, mainly because NER can only make the right decision when it is clear.

We implement the baseline of NER in the following way. We view the non-head cells in the tables as entities and their row headers as entity types. In training, we match the non-head cells into the texts

Pre	TC	TRE	Rotowire/Team	Rotowire/Player	E2E	WikiTableText	WikiBio
✗	✗	✗	28.05	7.75	94.45	46.37	67.51
✗	✓	✓	30.61	10.67	95.53	47.13	67.43
✓	✗	✗	82.97	81.96	97.87	59.26	68.98
✓	✓	✗	$83.09^{\ddagger}$	$82.24^{\ddagger}$	**97.88**	**59.29**†	68.98
✓	✗	✓	$83.30^{\dagger}$	$82.50^{\ddagger}$	97.87	59.12	**69.02**
✓	✓	✓	**83.36**†	**82.53**‡	**97.88**	59.14	**69.02**

Table 5: Results of ablation study on our method by excluding pre-trained language model (Pre), table constraint (TC) and table relation embeddings (TRE). We report F1 for non-header cells based on exact match. We conduct a significance test to check whether the performance is significantly better than vanilla seq2seq with pre-trained language models (i.e., with Pre but without TC or TRE). † and ‡ represent $p < 0.05$ and $p < 0.01$ respectively.

Method	Rotowire/Team	Rotowire/Player	E2E	WikiTableText	WikiBio
Vanilla seq2seq (BART base)	82.97	81.96	97.87	59.26	68.98
Our method (BART base)	83.36	82.53	97.88	59.14	69.02
Vanilla seq2seq (BART large)	**86.31**	86.59	**97.94**	**62.71**	69.66
Our method (BART large)	**86.31**	**86.83**	97.90	62.41	**69.71**

Table 6: Results of our method and vanilla seq2seq with base and large BART models on all four datasets.

```
...
|           |Assists|··· |Personal fouls|Points|Total rebounds|Steals|Turnovers|\n
|Rajon Rondo|  18   |··· |       7      |  8   |              |      |         \n
...
```

Figure 4: A bad case generated by vanilla seq2seq. The assists, points and total rebounds of Rajon Rondo should be 18, 7 and 8 respectively. The model generates one less column between "Assists" and "Personal fouls".

and take them as "entities" in the texts. Only a proportion of the non-header cells can be matched into the texts (85% for E2E, 74% for WikiTableText, and 69% for WikiBio).

5.5 Additional Study

We carry out an ablation study on our method. Specifically, we exclude pre-trained language model, table constraint (TC), and table relation embeddings (TRE) from our method. Note that our method without TC and TRE is equivalent to vanilla seq2seq. Table 5 gives the results on the four datasets.

It can be seen that the use of both TC and TRE can significantly improve the performance on Rotowire, which indicates that our method is particularly effective when the tables are large with many rows and columns. There are no significant improvements on E2E, WikiTableText, and WikiTableText, apparently because the formulation of tables is easy for the three datasets. Therefore, we conclude that the two techniques of TC and TRE are helpful when the task is difficult.

The use of pre-trained language model can boost the performance on all datasets, especially on Rotowire and WikiTableText. This indicates that pre-trained language model is particularly helpful when the task is difficult and the size of training data is small.

We observe that vanilla seq2seq makes more formatting errors than our method, especially on player tables in Rotowire that have a large number of columns. It indicates that for vanilla seq2seq, it is difficult to keep track of the columns in each row and make alignments with the column headers. In contrast, the two techniques of our method can help effectively cope with the problem. Figure 4 shows a bad case of vanilla seq2seq, where the model correctly infers the column of "assists" but fails to infer the columns of "personal fouls", "points", and "total rebounds" for the row of "Rajon Rondo". In contrast, our method can successfully handle the case, because TC can eliminate the incorrectly formatted output, and TRE can make correct alignments with the column headers.

We also investigate the effect of the scale of pre-trained language model BART. We use both BART-base and BART-large and conduct fine-tuning on top of them for vanilla seq2seq and our method. Table 6 gives the results on the four datasets. The results show that the use of BART-large can further boost the performances on all four datasets, indicating that it is better to use larger pre-trained models when computation cost is not an issue.

5.6 Discussions

We analyze the experimental results on the four datasets and identify five challenging issues.

(1) Text Diversity: Extraction of the same content from different expressions is one challenge. For example, the use of synonyms is very common in Rotowire. The team of "Knicks" is often referred to as "New York", its home city. Identification of the same entities from different expressions is needed in the task.

(2) Text Redundancy: There are cases such as those in WikiBio, in which the texts contain much redundant information. This poses a challenge to the text-to-table model to have a strong ability in summarization. It seems that the seq2seq approach works well to some extent but further improvement is undoubtedly necessary.

(3) Large Table: The tables in Rotowire have large numbers of columns, and the extraction from them is challenging even for our method of using TC and TRE.

(4) Background Knowledge: WikiTableText and WikiBio are from open domain. Thus, performing text-to-table on such kind of datasets require the use of much background knowledge. A possible way to address this challenge is to use more powerful pre-trained language models or external knowledge bases.

(5) Reasoning: Sometimes the information is not explicitly presented in the text, and reasoning is required to conduct correct extraction. For example, an article in Rotowire reports a game between the two teams "Nets" and "Wizards". From the sentence: "The Nets seized control of this game from the very start, opening up a 31 - 14 lead after the first quarter", humans can infer that the point of "Wizards" is 14, which is still difficult for machines.

6 Conclusion

We propose employing text-to-table as a new way of information extraction (IE), which extracts information of interest from the input text and summarizes the extracted information in tables. The advantage of the approach is that one can easily conduct information extraction from either short texts or long texts to create simple tables or complex tables without explicitly defining the schemas. Text-to-table can be viewed as an inverse problem of table-to-text. We formalize text-to-table as a sequence-to-sequence problem on top of a pre-trained model. We further propose an improved method using a seq2seq model and table constraint and table relation embeddings techniques. We conduct experiments on four datasets derived from existing table-to-text datasets. The results demonstrate that our proposed approach outperforms existing methods using conventional IE techniques. We further analyze the challenges of text-to-table for future study. The issues include diversity of text, redundancy of text, large table, background knowledge, and reasoning.

A Hyper-parameters

We list the hyper-parameters of the pre-trained models in Table 7. The training hyper-parameters for BART-base model in vanilla seq2seq and our method are listed in Table 8.

B Table Constraint Algorithm

The pseudo-codes for table constraint are in Algorithm 1.

C Our Method with Multiple Tables

Our method is able to generate the output containing multiple tables. For example, in Rotowire dataset, the output data contains two tables representing the scores of teams and players respectively. In this section, we illustrate how our method works for Rotowire dataset as a special case.

To represent the tables with a sequence, we use captions as delimiters. For Rotowire, as shown in Figure 1, the first table is the team table, and its

Pre-trained model	Methods	layers	hidden dim.	heads	parameters
BART-base	Vanilla seq2seq and ours	12	768	16	139M
BART-large	Vanilla seq2seq and ours	24	1024	16	406M
BERT-base-uncased	NER and RE	12	768	12	110M

Table 7: The hyper-parameters of the pre-trained models in our experiments. We list the number of layers, hidden dimensions (hidden dim.), heads, and parameters. BART-base and BART-large are used for vanilla seq2seq and our method, while BERT-base-uncased is used for the baselines of RE and NER.

	warmup	total upd.	lr	bsz
Rotowire	400	8000	3e-05	4096
E2E	400	8000	1e-05	4096
WikiTableText	2000	8000	1e-04	4096
WikiBio	4000	40000	1e-04	4096

Table 8: The training hyper-parameters for BART-base model on all four datasets. We list the warmup updates (warmup), total updates (total upd.), learning rate (lr), and batch size (bsz, in terms of how many tokens per batch).

caption is "Team:". The second table is the player table, and its caption is "Player:". Let $\mathbf{t}^{\text{team}}$ and $\mathbf{t}^{\text{player}}$ denote the table and player tables respectively. Therefore, the sequence representation is "Team: $\langle\text{n}\rangle$ $\mathbf{t}^{\text{team}}$ $\langle\text{n}\rangle$ Player: $\langle\text{n}\rangle$ $\mathbf{t}^{\text{player}}$". Although this example contains only two tables, the seq2seq model can generate any number of tables during the generation process until it reaches $\langle\text{eos}\rangle$ and stops decoding. Therefore, there is no need to predetermine the number of output tables.

For table constraint (TC), we only use TC when the seq2seq model is generating a table. When generating a caption, we do not pose any constraints to the decoding process. Since the captions do not start with the separation token $\langle\text{s}\rangle$, if the current line starts with the separation token $\langle\text{s}\rangle$, then the model is generating a table. Otherwise, it is generating a caption.

For table relation embeddings (TRE), we calculate the relation vectors separately for each table. However, the parameters including the row relation embeddings (i.e., τ_r^K and τ_r^V) and the column relation embeddings (i.e., τ_c^K and τ_c^V) are shared among the tables.

D Information Extraction Baselines

D.1 Relation Extraction

To use relation extraction (RE) as our baseline for Rotowire dataset, we take team names, player names, and numbers of scores as entities and take types of scores as relations. An example relation is shown in Figure 6, which can be represented as a relation tuple (Al Horford, Points, 15). "Al Horford" is the subject entity, "15" is the object en-

Algorithm 1: Decoding using table constraint. $\langle\text{eos}\rangle$, $\langle\text{s}\rangle$, and $\langle\text{n}\rangle$ denote the end of sentence, separation token, and new-line token respectively. Seq2seq denotes the seq2seq model. Decode denotes the decoding algorithm such as beam search and greedy search.

```
Input: $\mathbf{x} = [x_1, x_2, \cdots, x_{|\mathbf{x}|}]$
Output: $\mathbf{y} = [y_1, y_2, \cdots, y_{|\mathbf{y}|}]$
$\mathbf{y} \leftarrow []$

repeat
    /* generates the first row: only allows generation
       of ⟨n⟩ or ⟨eos⟩ after ⟨s⟩                          */
    $p(\cdot) \leftarrow$ seq2seq($\mathbf{x}$, $\mathbf{y}$)
    if $\mathbf{y}_{|\mathbf{y}|} \neq \langle\text{s}\rangle$ then
        $p(\langle\text{n}\rangle) \leftarrow 0,\ p(\langle\text{eos}\rangle) \leftarrow 0$
    $\mathbf{y}$.append(decode $(p)$)
until $\mathbf{y}_{|\mathbf{y}|} = \langle\text{n}\rangle$ or $\mathbf{y}_{|\mathbf{y}|} = \langle\text{eos}\rangle$
if $\mathbf{y}_{|\mathbf{y}|} = \langle\text{eos}\rangle$ then
    return $\mathbf{y}$
$n_c \leftarrow$ number of cells of the first row

repeat
    /* generates the next rows: each row contains
       exactly $n_c$ cells                                */
    repeat
        /* generates a row                                */
        $p(\cdot) \leftarrow$ seq2seq($\mathbf{x}$, $\mathbf{y}$)
        if current row has $n_c$ columns then
            $p(t) \leftarrow 0,\ \forall t \neq \langle\text{eos}\rangle$ and $t \neq \langle\text{n}\rangle$
        else
            $p(\langle\text{n}\rangle) \leftarrow 0,\ p(\langle\text{eos}\rangle) \leftarrow 0$
        $\mathbf{y}$.append(decode $(p)$)
    until $\mathbf{y}_{|\mathbf{y}|} = \langle\text{n}\rangle$ or $\mathbf{y}_{|\mathbf{y}|} = \langle\text{eos}\rangle$
    if $\mathbf{y}_{|\mathbf{y}|} = \langle\text{eos}\rangle$ then
        return $\mathbf{y}$
```

Figure 5: An example of NER data on WikiBio dataset. Each row header is an entity type, and each non-header cell is an entity.

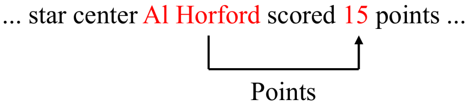

Figure 6: An example of RE data from Rotowire dataset. “Al Horford” and “15” are entities, and “Points” is the relation type.

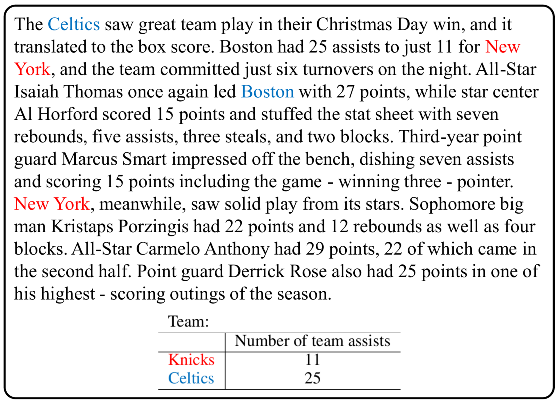

The Celtics saw great team play in their Christmas Day win, and it translated to the box score. Boston had 25 assists to just 11 for New York, and the team committed just six turnovers on the night. All-Star Isaiah Thomas once again led Boston with 27 points, while star center Al Horford scored 15 points and stuffed the stat sheet with seven rebounds, five assists, three steals, and two blocks. Third-year point guard Marcus Smart impressed off the bench, dishing seven assists and scoring 15 points including the game - winning three - pointer. New York, meanwhile, saw solid play from its stars. Sophomore big man Kristaps Porzingis had 22 points and 12 rebounds as well as four blocks. All-Star Carmelo Anthony had 29 points, 22 of which came in the second half. Point guard Derrick Rose also had 25 points in one of his highest - scoring outings of the season.

Team:

	Number of team assists
Knicks	11
Celtics	25

Figure 7: Illustration of the use of synonyms for the example in Figure 1. The red color denotes the team of “Knicks”, which is often referred to as “New York”, its home city. The blue color denotes the team of “Celtics”, which is often referred to as “Boston”, its home city.

tity, and “Points” is one of the pre-defined relation types. There are 38 relations in total.

To create synthetic training data, we match the player names, team names and score numbres to the texts. We adapt the rules provided by Wiseman et al. (2017) which is able to conduct fuzzy match.

D.2 Named Entity Recognition

We use named entity recognition (NER) as our baseline for E2E, WikiTableText, and WikiBio datasets. Specifically, since each table is a two-column table with a header column, we consider the row header as entity type and the non-header cells as entity mentions. An example is shown in Figure 5. For the row with a header “name” and a non-header cell “majda vrhnovnik”, we take “majda vrhnovnik” as an entity with the type “name”. Here, “name” is one of the pre-defined entity types. We collect all headers in the training set to collect the entity types. We have 7 entity types for E2E, 2262 entity types for WikiTableText, and 2272 entity types for WikiBio.

To create synthetic training data, we match the contents of non-header cells to the texts. However, the data is usually paraphrased or even abstracted from the text, so not all non-header cells can be matched to the text. We match 85% non-header cells for E2E, 74% for WikiTable, and 69% for WikiBio.

E Detailed Cases for Challenges

In this section, we provide cases for the challenges discussed in Section 5.6.

(1) Text Diversity: Extraction of the same content from different expressions is one challenge. For example, the use of synonyms is very common in Rotowire. Figure 7 illustrates the use of synonyms for the example in Figure 1. The team of “Knicks” is often referred to as “New York”, its home city. Similarly, “Celtics” is often referred to as “Boston”, its home city. Identification of the same entities from different expressions is needed in the task.

(2) Text Redundancy: There are cases such as those in WikiBio, in which the texts contain much redundant information. An example is shown in Figure 8, where only the highlighted information is captured in the output table. Other information such as the experience of Philippe Adnot is redundant. This poses a challenge to the text-to-table model to have a strong ability in summarization. It seems that the seq2seq approach works well to

philippe adnot (born 25 august 1945 in rhèges) is a member of the senate of france. he was first elected in 1989, and represents the aube department. a farmer by profession, he serves as an independent, and also serves as the head of the general council of aube, to which he was elected to represent the canton of méry-sur-seine in 1980. in 1998 and 2008, he was re-elected to the senate in the first round, avoiding the need for a run-off vote. having contributed to the creation of the university of technology of troyes, in 1998 he was made the first vice president of the university board, of which he is currently the president. he is a member of the senate's committee on the laws relating to the freedoms and responsibilities of universities. as of 2009, he serves as the delegate from the administrative meeting for senators not on the list of another group he is decorated as a chevalier of the ordre national de mérite agricole.

name	philippe adnot
birth place	france
occupation	farmer
residence	france
birth date	25 august 1945
constituency	aube canton de méry-sur-seine

Figure 8: An example from WikiBio dataset to illustrate the challenges of text redundancy and background knowledge. Only the highlighted information is captured in the output table. Other information such as the experience of Philippe Adnot is redundant. Moreover, the system should have background knowledge about the French political system to extract information about the constituency of Philippe Adnot.

The Denver Nuggets defeated the Milwaukee Bucks, 121 - 117, at Pepsi Center on Friday. It was n't the ideal win for Denver considering they nearly blew a monster lead, but they were able to hold on for a much needed victory. In fact, the Nuggets led by 22 in the third quarter, before allowing the Bucks to get it within two points late in the fourth. Denver were able to hold on though, despite missing their last four free - throws. Rebounding was the biggest factor in the game, with Denver winning that battle, 48 - 38. The Nuggets also dominated the assist - to - turnover ratio, recording five more assists and committing four less turnovers. The Bucks (21 - 28) put in a valiant effort to pull out a comeback win, but fell just shy to mark their 10th loss in 11 games. Jabari Parker was Milwaukee's best player, as he accrued 27 points, 11 rebounds, four assists and two steals. Giannis Antetokounmpo was n't far behind, collecting 23 points, eight rebounds, five assists, two steals and two blocks. John Henson was the only other Buck in double figures, as he amassed 16 points, five rebounds and four blocks. The Nuggets (22 - 27) have now won eight of their last 12 games, as they could n't be happier to see Nikola Jokic back and healthy. Jokic recorded his first career triple - double in the win. as he accumulated 21 points, 13 rebounds and 11 assists. Wilson Chandler started for Danilo Gallinari (groin) and tallied 23 points, eight rebounds, three assists, two steals and four blocks. Kenneth Faried recorded a double - double, totaling 19 points and 11 rebounds. Jamal Murray was the leading scorer off the bench, dropping 18 points on 5 - of - 9 from the field.

Team:

	Losses	Total points	Points in 2nd quarter	Wins
Nuggets	27	121		22
Bucks	28	117	22	21

Player:

	Assists	Blocks	Field goals attempted	Field goals made	Points	Total rebounds	Steals
Giannis Antetokounmpo	5	2			23	8	2
Jabari Parker	4				27	11	2
John Henson		4			16	5	
Wilson Chandler	3	4			23	8	2
Kenneth Faried					19	11	
Nikola Jokic	11			8		12	
Jamal Murray			9	5	18		

Figure 9: The team table has 3 rows and 4 columns, and the player table has 8 rows and 8 columns.

some extent but further improvement is undoubtedly necessary.

(3) Large Table: The tables in Rotowire have large numbers of columns, so extraction from them is challenging even for our method of using TC and TRE. As presented in Table 2, team tables have 2.71 rows and 4.84 columns on average, and player tables have 7.26 rows and 8.75 columns on average. An example is shown in Figure 9, where the team table has 3 rows and 4 columns, and the player table has 8 rows and 8 columns.

(4) Background Knowledge: WikiTableText and WikiBio are from open domain. Thus, performing text-to-table on such kind of datasets require the use of much background knowledge. Also in Figure 8, the extraction system should have background knowledge about the French political system in order to extract information about the constituency of Philippe Adnot. A possible way to address this challenge is to use more powerful pre-trained language models or external knowledge bases.

(5) Reasoning: Sometimes the information is not explicitly presented in the text, and reasoning is required to conduct correct extraction. For example, as shown in Figure 10, an article in Rotowire reports a game between the two teams “Nets” and “Wizards”. From the sentence: “The Nets seized

The Brooklyn Nets (37 - 42) defeated the Washington Wizards (45 - 34) 117 - 80 on Friday in Brooklyn. The Nets seized control of this game from the very start, opening up a 31 - 14 lead after the first quarter. …

Team:

	Points in 1st quarter
Nets	31
Wizards	14

Figure 10: An example from Rotowire which requires reasoning to perform information extraction. The article in Rotowire reports a game between the two teams "Nets" and "Wizards". From the sentence: "The Nets seized control of this game from the very start, opening up a 31 - 14 lead after the first quarter", humans can infer that the point of "Wizards" is 14, which is still difficult for machines.

control of this game from the very start, opening up a 31 - 14 lead after the first quarter", humans can infer that the point of "Wizards" is 14, which is still difficult for machines.

Accelerating Code Search with Deep Hashing and Code Classification

Abstract

Code search is to search reusable code snippets from source code corpus based on natural languages queries. Deep learning-based methods on code search have shown promising results. However, previous methods focus on retrieval accuracy, but lacked attention to the efficiency of the retrieval process. We propose a novel method CoSHC to accelerate code search with deep hashing and code classification, aiming to perform efficient code search without sacrificing too much accuracy. To evaluate the effectiveness of CoSHC, we apply our method on five code search models. Extensive experimental results indicate that compared with previous code search baselines, CoSHC can save more than 90% of retrieval time meanwhile preserving at least 99% of retrieval accuracy.

1 Introduction

Code reuse is a common practice during software development process. It improves programming productivity as developers' time and energy can be saved by reusing existing code. According to previous studies (Brandt et al., 2009; Lv et al., 2015), many developers tend to use natural language to describe the functionality of desired code snippets and search the Internet/code corpus for code reuse.

Many code search approaches (Brandt et al., 2009; McMillan et al., 2011; Lv et al., 2015; Du et al., 2021) have been proposed over the years. With the rapid growth of open source code bases and the development of deep learning technology, recently deep learning based approaches have become popular for tackling the code search problem (Gu et al., 2018; Husain et al., 2019; Gu et al., 2021). Some of these approaches adopt neural network models to encode source code and query descriptions into representation vectors in the same embedding space. The distance between the representation vectors whose original code or description are semantically similar should be small. Other approaches (Feng et al., 2020; Guo et al., 2021; Du et al., 2021) regard the code search task as a binary classification task, and calculate the probability of code matching the query.

In the past, deep learning-based methods focused on retrieval accuracy, but lacked attention to the efficiency of retrieval on large-scale code corpus. However, both types of these deep learning-based approaches directly rank all the source code snippets in the corpus during searching, which will incur a large amount of computational cost. For the approaches that separately encode code and description representation vectors, the similarity of the target query vector with all code representation vectors in the corpus needs to be calculated for every single retrieval. In order to pursue high retrieval accuracy, a high dimension is often set for the representation vectors. For example, in CodeBERT, the dimension of the final representation vector is 768. The similarity calculation between a pair of code and query vectors will take 768 multiplications and 768 additions between two variables with double data type. The total calculation of single linear scan for the whole code corpus containing around 1 million code snippets is extremely large - around 1 billion times of multiplications and additions. As for the approaches adopting binary classification, there is no representation vectors stored in advance and the inference of the target token sequence with all the description token sequences needs to be done in real time for every single retrieval. Due to the large number of parameters in the current deep learning models, the computation cost will be significant.

Hashing is a promising approach to improve the retrieval efficiency and widely adopted in other retrieval tasks such as image-text search and image-image search. Hashing techniques can convert high

dimensional vectors into low dimensional binary hash code, which greatly reduce the cost of storage and calculation (Luo et al., 2020). Hamming distance between two binary hash code can also be calculated in a very efficient way by running XOR instruction on the modern computer architectures (Wang et al., 2016). However, the performance degradation is still not avoidable during the conversion from representation vectors to binary hash codes even the state-of-the-art hashing models are adopted. The tolerance of performance degradation from most users is quite low and many of them are willing to sweep the performance with efficiency. In order to preserve the performance of the original code search models that adopt bi-encoders for the code-query encoding as much as possible, we integrate deep hashing techniques with code classification, which could mitigate the performance degradation of hashing model in the recall stage by filtering out the irrelevant data.

Specifically, in this paper, we propose a novel approach **CoSHC** (Accelerating Semantic Code Search with Deep Hashing and Code Classification) for accelerating the retrieval efficiency of deep learning-based code search approaches. CoSHC firstly clusters the representation vectors into different categories. It then generates binary hash codes for both source code and queries according to the representation vectors from the original models. Finally, CoSHC gives the normalized prediction probability of each category for the given query, and then CoSHC will decide the number of code candidates for the given query in each category according to the probability. Comprehensive experiments have been conducted to validate the performance of the proposed approach. The evaluation results show that CoSHC can preserve more than 99% performance of most baseline models. We summarize the main contributions of this paper as follows:

- We propose a novel approach, CoSHC, to improve the retrieval efficiency of previous deep learning based approaches. CoSHC is the first approach that adopts the recall and re-rank mechanism with the integration of code clustering and deep hashing to improve the retrieval efficiency of deep learning based code search models.
- We conduct comprehensive experimental evaluation on public benchmarks. The results demonstrate that CoSHC can greatly improve the retrieval efficiency meanwhile preserve almost the same performance as the baseline models.

2 Background

2.1 Code Search

In this subsection, we briefly review some deep learning based code search approaches. Sachdev et al. (2018) firstly propose the neural network based model NCS to retrieve the source code from a large source code corpus according to the given natural language descriptions. Cambronero et al. (2019) propose a neural network model UNIF based on bag-of-words, which embeds code snippets and natural language descriptions into a shared embedding space. Gu et al. (2018) propose to encode source code representation with API sequences, method name tokens and code tokens. Yao et al. (2019) treat code annotation and code search as dual tasks and utilize the generated code annotations to improve code search performance. Husain et al. (2019) explore different neural architectures for source code representation and discover that the self-attention model achieves the best performance. Gu et al. (2021) extract the program dependency graph from the source code and adopt long short term memory (LSTM) networks to model this relationship. Feng et al. (2020) propose a pre-trained model for source code representation and demonstrate its effectiveness on the code search task.

2.2 Deep Hashing

In this subsection, we briefly introduce some representative unsupervised cross-modal hashing methods. In order to learn a unified hash code, Ding et al. (2014) propose to adopt collective matrix factorization with latent factor model from different modalities to merge multiple view information sources. Zhou et al. (2014) firstly utilize sparse coding and matrix factorization to extract the latent features for images and texts, respectively. Then the learned latent semantic features are mapped to a shared space and quantized to the binary hash codes. Wang et al. (2014) suggest using stacked auto-encoders to capture the intra- and inter-modal semantic relationships of data from heterogeneous sources. He et al. (2017) and Zhang et al. (2018) adopt adversarial learning for cross-modal hash codes generation. Wu et al. (2018) propose an approach named UDCMH that integrates deep learning and matrix factorization with binary latent factor models to generate binary hash codes for multimodal data retrieval. By incorporating Laplacian constraints into the objective function, UDCMH preserve not only the nearest neighbors but also the farthest neighbors of data. Unlike using Laplacian constraints in the loss function, Su et al. (2019) construct a joint-semantic affinity matrix that integrates the original neighborhood information from different modalities to guide the learning of unified binary hash codes.

3 Method

We propose a general framework to accelerate existing Deep Code Search (DCS) models by decoupling the search procedure into a recall stage and a re-rank stage. Our main technical contribution lies in the recall stage. Figure 1 illustrates the overall framework of the proposed approach. CoSHC consists of two components, i.e., Offline and Online. In Offline, we take the code and description embeddings learned in the given DCS model as input, and learn the corresponding hash codes by preserving the relations between the code and description embeddings. In Online, we recall a candidate set of code snippets according to the Hamming distance between the query and code, and then we use the original DCS model to re-rank the candidates.

3.1 Offline Stage

Multiple Code Hashing Design with Code Classification Module Since the capacity of binary hashing space is very limited compared to Euclidean space, the Hamming distance between similar code snippets will be too small to be distinguishable if we adopt a single Hashing model. To be specific, we cluster the codebase using K-Means algorithm with the code embeddings learned from the given DCS model. The source code whose representation vectors are close to each other will be classified into the same category after the clustering.

Deep Hashing Module The deep hashing module aims at generating the corresponding binary hash codes for the embeddings of code and description from the original DCS model. Figure 2 illustrates the framework of the deep hashing module. To be specific, three fully-connected (FC) layers with $\tanh(\cdot)$ activation function are adopted to replace the output layer in the original DCS model to convert the original representation vectors into a soft binary hash code.

The objective of the deep hashing module is to force the Hamming distance between hashing representations of code pairs and description pairs approaching the Euclidean distance between the corresponding embeddings. Thus, we need to calculate the ground truth similarity matrix between code pairs and description pairs firstly. For performance consideration, we calculate the similarity matrix within a mini-batch.

To construct such a matrix, we first define the code representation vectors and the description representation vectors in the original code search model as $V_C = \{v_c^{(1)}, ..., v_c^{(n)}\}$ and $V_D = \{v_d^{(1)}, ..., v_d^{(n)}\}$, respectively. V_C and V_D represent the representation vectors matrix for the entire batch, while $v_c^{(i)}$ and $v_d^{(i)}$ represent the representation vector for the single code snippet or query. After normalizing V_C, V_D to $\hat{V}_C$, $\hat{V}_D$ with l_2-norm, we can calculate the code similarity matrices $S_C = \hat{V}_C\hat{V}_C^T$ and summary similarity matrices $S_D = \hat{V}_D\hat{V}_D^T$ to describe the similarity among code representation vectors and summary representation vectors, respectively. In order to integrate the similarity information in both S_C and S_D, we combine them with a weighted sum:

$$\tilde{S} = \beta S_C + (1-\beta)S_D, \beta \in [0,1] \tag{1}$$

where β is the weight parameter. Since the pairwise similarity among the code representation vectors and description representation vectors still cannot comprehensively present the distribution condition of them in the whole embedding space, we involve a matrix $\tilde{S}\tilde{S}^T$ to describe a high order neighborhood similarity that two vectors with high similarity should also have the close similarity to other vectors. Finally, we utilize a weighted equation to combine both of these two matrices as follows:

$$S = (1-\eta)\tilde{S} + \eta\frac{\tilde{S}\tilde{S}^T}{m}, \tag{2}$$

where η is a hyper-parameter and m is the batch size which is utilized to normalize the second term in the equation. Since we hope the binary hash codes of the source code and its corresponding description to be the same, we replace the diagonal elements in the similarity matrix with one. The final high order similarity matrix is:

$$S_{F_{ij}} = \begin{cases} 1, & i = j \\ S_{ij}, & \text{otherwise} \end{cases} \tag{3}$$

Binary Hash Code Training We propose to replace the output layer of the original code search

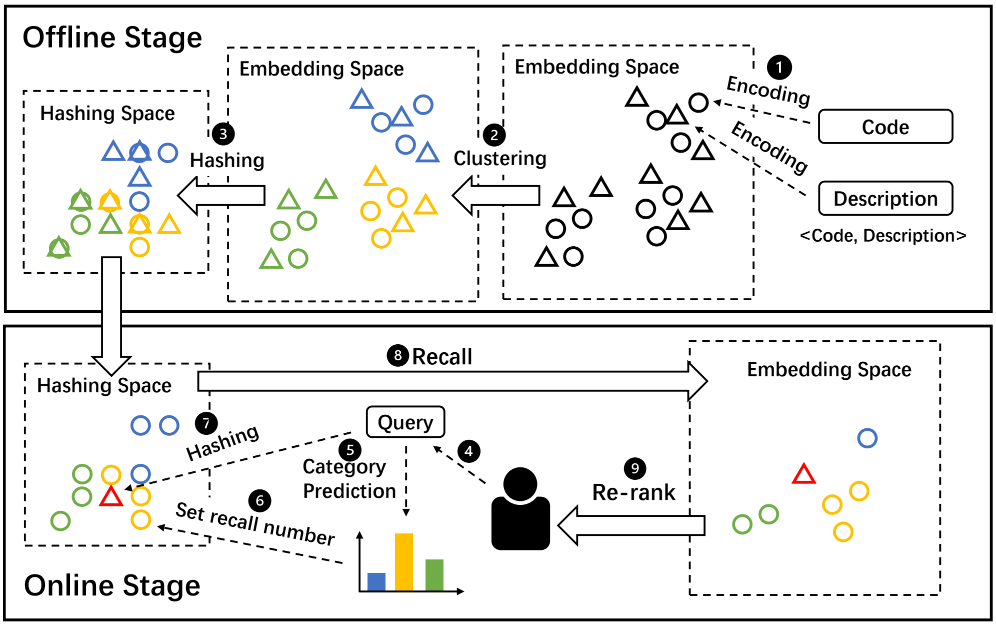

Figure 1: Overview of the proposed CoSHC. ❶ Encoding the code token sequence and description token sequence via original code retrieval models. ❷ Clustering the code representation vectors into several categories. ❸ Converting the original code representation vectors into binary hash codes.❺❻ Predicting the category of the query given by users and set the number of code candidates for different categories. ❼ Converting the input query into binary hash code. ❽ Recall the code candidates according to the hamming distance and the number of code candidates for each category. ❾ Re-ranking all the code candidates according to the cosine similarity between the input query description vectors and code candidates' representation vectors and return the results to the user.

model with three FC layers with $\tanh(\cdot)$ activate function. We define the trained binary hash code for code and description as $B_C = \{b_c^{(1)}, ..., b_c^{(n)}\}$ and $B_D = \{b_d^{(1)}, ..., b_d^{(n)}\}$, respectively. To ensure that the relative distribution of binary hash codes is similar to the distribution of representation vectors in the original embedding space, the following equation is utilized as the loss function of the deep hashing module:

$$\begin{aligned}\mathscr{L}(\theta) = \min_{B_C, B_D} & \|\min(\mu S_F, 1) - \frac{B_C B_D^T}{d}\|_F^2 \\ & + \lambda_1 \|\min(\mu S_F, 1) - \frac{B_C B_C^T}{d}\|_F^2 \\ & + \lambda_2 \|\min(\mu S_F, 1) - \frac{B_D B_D^T}{d}\|_F^2, \\ & s.t.\ B_C, B_D \in \{-1, +1\}^{m \times d},\end{aligned} \tag{4}$$

where θ are model parameters, μ is the weighted parameters to adjust the similarity score between different pairs of code and description, λ_1, λ_2 are the trade-off parameters to weight different terms in the loss function, and d is the dimension of the binary hash code generated by this deep hashing module. These three terms in the loss function are adopted to restrict the similarity among binary hash codes of the source codes, the similarity among binary hash codes of the descriptions, and the similarity between the binary hash codes of source code and description, respectively.

Note that we adopt $B_C B_D^T/d$ to replace $\cos(B_C, B_D)$ because $\cos(B_C, B_D)$ only measures the angle between two vectors but neglects the length of the vectors, which makes $\cos(B_C, B_D)$ can still be a very large value even the value of every hash bits is close to zero. Unlike $\cos(B_C, B_D)$, $B_C B_D^T/d$ can only achieve a high value when every bit of the binary hash code is 1 or -1 since the value of $B_C B_D^T/d$ will be close to zero if the value of every hash bits is close to zero.

Since it is impractical to impose on the output of neural network to be discrete values like 1 and -1, we adopt the following equation to convert the output of deep hashing module to be strict binary hash code:

$$B = \operatorname{sgn}(H) \in \{-1, +1\}^{m \times d}, \tag{5}$$

where H is the output of the last hidden layer without the activation function in the deep hashing module and $\operatorname{sgn}(\cdot)$ is the sign function and the output of this function is 1 if the input is positive and the output is -1 otherwise.

However, the gradient of the sign function will be zero in backward propagation which will induce

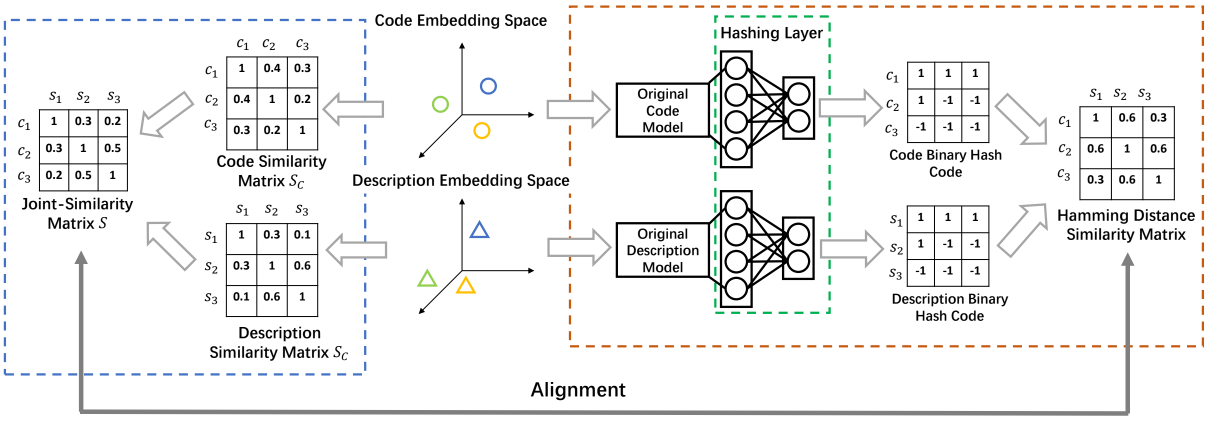

Figure 2: Architecture of the hashing module. The original representation vectors will be utilized for the joint-similarity matrix construction at first. Then the joint-similarity matrix will be utilized as the labels for training binary hash codes generation. The training objective is to make the Hamming distance similarity matrix to be identical as the joint-similarity matrix.

the vanishing gradients problem and affect model convergence. To address this problem, we follow the previous research (Cao et al., 2017; Hu et al., 2019) and adopt a scaling function:

$$B = \tanh(\alpha H) \in \{-1, +1\}^{m \times d}, \tag{6}$$

where α is the parameter which is increased during the training. The function of $\tanh(\alpha H)$ is an approximate equation of $\operatorname{sgn}(H)$ when α is large enough. Therefore, the output of Eq. 6 will finally be converged to 1 or -1 with the increasing of α during the training and the above problem is addressed.

3.2 Online Stage

Recall and Re-rank Mechanism The incoming query from users will be fed into the description category prediction module to calculate the normalized probability distribution of categories at first. Then the number of code candidates R_i for each category i will be determined according to this probability distribution. The Hamming distance between the hash code of the given query and all the code inside the database will be calculated. Then code candidates will be sorted by Hamming distance in ascending order and the top R_i code candidates in each category i will be recalled. In the re-rank step, the original representation vectors of these recalled code candidates will be retrieved and utilized for the cosine similarity calculation. Finally, code snippets will be returned to users in descending order of cosine similarity.

Description Category Prediction Module The description category prediction module aims to predict the category of source code that meets user's requirement according to the given natural language description. The model adopted for category prediction is the same as the original code search model, except that the output layer is replaced with a one-hot category prediction layer and the cross-entropy function is adopted as the loss function of the model.

Since the accuracy of the description category prediction module is not perfect, we use the probability distribution of each category instead of the category with the highest predicted probability as the recall strategy for code search. We define the total recall number of source code as N, the normalized predicted probability for each code category as $P = \{p_1, ..., p_k\}$, where k is the number of categories. The recall number of source code in each category is:

$$R_i = \min(\lfloor p_i \cdot (N - k) \rfloor, 1), \ i \in 1, ..., k, \tag{7}$$

where R_i is the recall number of source code in category i. To ensure that the proposed approach can recall at least one source code from each category, we set the minimum recall number for a single category to 1.

4 Experiments

4.1 Dataset

We use two datasets (Python and Java) provided by CodeBERT (Feng et al., 2020) to evaluate the performance of CoSHC. CodeBERT selects the data from the CodeSearchNet (Husain et al., 2019) dataset and creates both positive and negative examples of <description, code> pairs. Since all the baselines in our experiments are bi-encoder models, we do not need to predict the relevance score for the mismatched pairs so we remove all the negative examples from the dataset. Finally we get 412,178 <description, code> pairs as the training set, 23,107 <description, code> pairs as the validation set, and 22,176 <description, code> pairs as the test set in the Python dataset. We get 454,451 <description, code> pairs as the training set, 15,328 <description, code> pairs as the validation set, and 26,909 <description, code> pairs as the test set in the Java dataset.

4.2 Experimental Setup

In the code classification module, we set the number of cluster to 10. In the deep hashing module, we add three fully connected (FC) layer in all the baselines, the hidden size of each FC layer is the same as the dimension of the original representation vectors. Specifically, the hidden size of FC layer for CodeBERTa, CodeBERT, GraphCodeBERT is 768. The hidden size of FC layer for UNIF is 512 and for RNN is 2048. The size of the output binary hash code for all the baselines is 128. The hyper parameters $\beta, \eta, \mu, \lambda_1, \lambda_2$ are 0.6, 0.4, 1.5, 0.1, 0.1, respectively. The parameter α is the epoch number and will be linear increased during the training. In the query category prediction module, a cross-entropy function is adopted as the loss function and the total recall number is 100.

The learning rate for CodeBERTa, CodeBERT and GraphCodeBERT is 1e-5 and the learning rate for UNIF, RNN is 1.34e-4. All the models are trained via the AdamW algorithm (Kingma and Ba, 2015).

We train our models on a server with four 4x Tesla V100 w/NVLink and 32GB memory. Each module based on CodeBERT, GraphCodeBERT and CodeBERTa are trained with 10 epochs and Each module based on RNN and UNIF are trained with 50 epochs. The early stopping strategy is adopted to avoid overfitting for all the baselines. The time efficiency experiment is conducted on the server with Intel Xeon E5-2698v4 2.2Ghz 20-core. The programming for evaluation is written in C++ and the program is allowed to use single thread of CPU.

4.3 Baselines

We apply CoSHC on several state-of-the-art and representative baseline models. UNIF (Cambronero et al., 2019) regards the code as the sequence of tokens and embeds the sequence of code tokens and description tokens into representation vectors via full connected layer with attention mechanism, respectively. RNN baseline adopts a two-layer bi-directional LSTM (Cho et al., 2014) to encode the input sequences. CodeBERTa [1] is a 6-layer, Transformer-based model trained on the CodeSearchNet dataset. CodeBERT (Feng et al., 2020) is a pre-trained model based on Transformer with 12 layers. Similar to CodeBERT, GraphCodeBERT (Guo et al., 2021) is a pre-trained Transformer-based model pre-trained with not only tokens information but also dataflow of the code snippets. As we introduced, the inference efficiency of cross-encoder based models like CodeBERT is quite low and the purpose of our approach is to improve the calculation efficiency between the representation vectors of code and queries. Here we slightly change the model structure of CodeBERTa, CodeBERT, and GraphCodeBERT. Rather than concatenating code and query together and inputting them into a single encoder to predict the relevance score of the pair, we adopt the bi-encoder architecture for the baselines, which utilize the independent encoder to encoding the code and queries into representation vectors, respectively. Also, cosine similarity between the given representation vector pairs is adopted as the training loss function to replace the cross entropy function of the output relevance score.

4.4 Evaluation Metric

$SuccessRate@k$ is widely used by many previous studies (Haldar et al., 2020; Shuai et al., 2020; Fang et al., 2021; Heyman and Cutsem, 2020). The metric is calculated as follows:

$$SuccessRate@k = \frac{1}{|Q|}\sum_{q=1}^{Q}\delta(FRank_q \leq k), \quad (8)$$

where Q denotes the query set and $FRank_q$ is the rank of the correct answer for query q. If the correct result is within the top k returning results, $\delta(FRank_q \leq k)$ returns 1, otherwise it returns 0. A higher $R@k$ indicates better performance.

4.5 Experimental Results

In this section, we present the experimental results and evaluate the performance of CoSHC from the aspects of retrieval efficiency, overall retrieval performance, and the effectiveness of the internal classification module.

4.5.1 RQ1: How much faster is CoSHC than the original code search models?

Table 1 illustrates the results of efficiency comparison between the original code search models and CoSHC. Once the representation vectors of code and description are stored in the memory, the retrieval efficiency mainly depends on the dimension of representation vectors rather than the complexity of the original retrieval model. Therefore, we select CodeBERT as the baseline model to illustrate efficiency comparison. Since code search process in both approaches contains vector similarity calculation and array sorting, we split the retrieval process into these two steps to calculate the time cost.

In the vector similarity calculation step, CoSHC reduces 97.29% and 96.90% of time cost in the dataset of Python and Java respectively, which demonstrates that the utilization of binary hash code can effectively reduce vector similarity calculation cost in the code retrieval process.

In the array sorting step, CoSHC reduces 53.61% and 37.74% of time cost in the dataset of Python and Java, respectively. The classification module makes the main contribution on the improvement of sorting efficiency. The sorting algorithm applied in both original code search model and CoSHC is quick sort, whose time complexity is $O(n \log n)$. Classification module divides a large code dataset into several small code datasets, reducing the average time complexity of sorting to $O(n \log \frac{n}{m})$. The reason why the improvement of sorting in the Java dataset is not so significant as in the Python dataset is that the size of Java dataset is much smaller than the size of Python dataset. However, the combination of the algorithm of divide and conquer and max-heap, rather than quick sort, is widely applied in the big data sorting, which can greatly shrink the retrieval efficiency gap between these two approaches. Therefore, the improvement of efficiency in the sorting process will not be as large as what shown in Table 1.

In the overall code retrieval process, the cost time is reduced by 94.09% and 93.51% in the dataset of Python and Java, respectively. Since the vector similarity calculation takes most of cost time in the code retrieval process, CoSHC still can reduce at least 90% of cost time, which demonstrates the effectiveness on the efficiency improvement in the code search task.

4.5.2 RQ2: How does CoSHC affect the accuracy of the original models?

Table 2 illustrates the retrieval performance comparison between the original code search models and CoSHC. We have noticed that the performance of the conventional approaches like BM25 (Robertson and Zaragoza, 2009) is not good enough. For example, we set the token length for both code and queries as 50, which is the same as the setting in CodeBERT, and apply BM25 to recall top 100 code candidates for the re-rank step on the Python dataset. BM25 can only retain 99.3%, 95.6% and 92.4% retrieval accuracy of CodeBERT in terms of $R@1$, $R@5$ and $R@10$ on the Python dataset. Here we only compare the performance of our approach with the original code search models since the purpose of our approach is to preserve the performance of the original code search models. As can be observed, CoSHC can retain at least 99.5%, 99.0% and 98.4% retrieval accuracy of most original code search models in terms of $R@1$, $R@5$ and $R@10$ on the Python dataset. CoSHC can also retain 99.2%, 98.2% and 97.7% of the retrieval accuracy as all original code search baselines in terms of $R@1$, $R@5$ and $R@10$ on the Java dataset, respectively. We can find that CoSHC can retain more than 97.7% of performance in all metrics. $R@1$ is the most important and useful metric among these metrics since most users hope that the first returned answer is the correct answer during the search. CoSHC can retain at least 99.2% of performance on $R@1$ in both datasets, which demonstrates that CoSHC can retain almost the same performance as the original code search model.

Table 2: Results of code search performance comparison. The best results among the three CoSHC variants are highlighted in **bold** font.

It is interesting that CoSHC presents a relatively better performance when the performance of the original code retrieval models is worse. CoSHC$_{\text{CodeBERTa}}$ even outperforms the original baseline model in Java dataset. CoSHC$_{\text{RNN}}$ and CoSHC$_{\text{UNIF}}$ outperform the original model in both Python and Java datasets. The integration of deep learning and code classification with recall make the contribution on this result. The worse performance indicates more misalignment between the code representation vectors and description representation vectors. Since the code classification and deep hashing will filter out most of irrelevant codes in the recall stage, some irrelevant code representation vectors but has high cosine similarity with the target description representation vectors are filtered, which leads the improvement on the final retrieval performance.

4.5.3 RQ3: Can the classification module help improve performance?

Table 2 illustrates the performance comparison between the CoSHC variants which adopt different recall strategies with query category prediction results. CoSHC$_{\text{w/o classification}}$ represents CoSHC without code classification and description prediction module. CoSHC$_{\text{one classification}}$ represents the CoSHC variant that recalls $N - k + 1$ candidates in the code category with highest prediction probability and one in each of the rest categories. CoSHC$_{\text{ideal classification}}$ is an ideal classification situation we set. Assuming the correct description category is known, $N - k + 1$ candidates are recalled in the correct category and one candidate is recalled in each of the rest categories. Note that the display of CoSHC$_{\text{ideal classification}}$ is only to explore the upper threshold of performance improvement of the category prediction module and will not be counted as a variant of CoSHC we compare.

Model	Python Acc.	Java Acc.
CoSHC$_{\text{UNIF}}$	0.558	0.545
CoSHC$_{\text{RNN}}$	0.610	0.535
CoSHC$_{\text{CodeBERTa}}$	0.591	0.571
CoSHC$_{\text{CodeBERT}}$	0.694	0.657
CoSHC$_{\text{GraphCodeBERT}}$	0.713	0.653

Table 3: Classification accuracy of the code classification module in each model.

By comparing the performance between $\mathrm{CoSHC}_{\text{ideal classification}}$ and $\mathrm{CoSHC}_{\text{w/o classification}}$, we can find that correct classification can significantly improve the retrieval performance. With the ideal category labels, CoSHC can even outperform all baseline models. As mentioned in Sec. 4.5.2, code classification can mitigate the problem of vector pairs misalignment via filtering out wrong candidates whose representation vectors has high cosine similarity with the target representation vectors in the recall stage. The more serious the misalignment problem, the more effective the code classification. That is the reason why the improvement of CoSHC with ground-truth labels on UNIF, RNN, and CodeBERTa is more significant than the improvement of it on CodeBERT and GraphCodeBERT since the retrieval accuracy of former models is much lower than the latter ones. Similar conclusions can also be drawn at the aspect of binary hash code distribution via the comparison between CoSHC and $\mathrm{CoSHC}_{\text{ideal classification}}$ since CoSHC utilizes the distribution of the original representation vectors as the guidance for model training. Therefore, the distribution of binary hash codes will be similar to the distribution of original representation vectors.

Since we have explored the theoretical upper limit of the effectiveness of code classification for code retrieval, the effectiveness of code classification for code retrieval in the real application will be validated. By comparing the experimental results between $\mathrm{CoSHC}_{\text{w/o classification}}$ and $\mathrm{CoSHC}_{\text{one classification}}$, we can find that the performance of CoSHC with predicted labels is even worse than the performance of CoSHC without code classification module. The reason is that the accuracy of description category prediction is far from the satisfactory. Table 3 illustrates the accuracy of description category prediction module in all baseline models. We regard the category with the highest probability as the predicted category from the description category prediction module and check whether the module could give a correct prediction. It can be seen that the classification accuracy is not very high (less than 75%). By observing the experimental results of CoSHC in GraphCodeBERT on the Java dataset, we can also find that low accuracy greatly affect the performance of $\mathrm{CoSHC}_{\text{oneclassification}}$, which makes 7.8%, 11.6%, and 13.9% performance drop in terms of $R@1$, $R@5$, and $R@10$, respectively.

Fortunately, although the description category prediction module cannot accurately tell the exact category which this description belongs to, the module still can give a relative high predicted probability on the correct category. By comparing the experimental results among all the variants of CoSHC, we can find the performance is increased significantly once the recall strategy is replaced to that the number of code candidates for each category is determined by the normalized predication probability. CoSHC with new recall strategy almost achieve the best performance in all metrics on all baseline models. Even on RNN in the Python dataset, CoSHC still achieve the same performance as CoSHC without classification under $R@1$ and achieve similar performance in other metrics. Above experimental results have demonstrated the effectiveness of the adoption of code classification in code search.

5 Conclusion

To accelerate code search, we present CoSHC, a general method that incorporates deep hashing techniques and code classification. We leverage the two-staged recall and re-rank paradigm in information retrieval field and apply deep hashing techniques for fast recall. Furthermore, we propose to utilize a code classification module to retrieve better quality code snippets. Experiments on five code search models show that compared with the original code search models, CoSHC can greatly improve the retrieval efficiency meanwhile preserve almost the same performance.

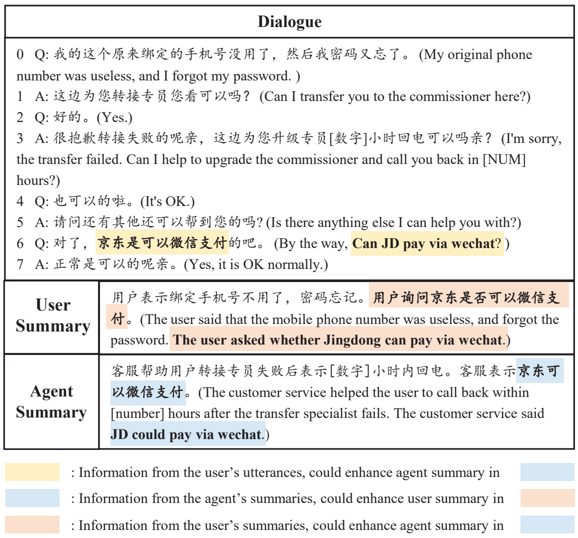
Abstract

Role-oriented dialogue summarization is to generate summaries for different roles in the dialogue, *e.g.*, merchants and consumers. Existing methods handle this task by summarizing each role's content separately and thus are prone to ignore the information from other roles. However, we believe that other roles' content could benefit the quality of summaries, such as the omitted information mentioned by other roles. Therefore, we propose a novel role interaction enhanced method for role-oriented dialogue summarization. It adopts cross attention and decoder self-attention interactions to interactively acquire other roles' critical information. The cross attention interaction aims to select other roles' critical dialogue utterances, while the decoder self-attention interaction aims to obtain key information from other roles' summaries. Experimental results have shown that our proposed method significantly outperforms strong baselines on two public role-oriented dialogue summarization datasets. Extensive analyses have demonstrated that other roles' content could help generate summaries with more complete semantics and correct topic structures.[1]

1 Introduction

Dialogue summarization aims at compressing the main content of a long conversation into a short text. With the development of online conversation tools, the amount and length of conversation are growing up rapidly. Since a dialogue often contains complicated structure and ellipsis, it is time-consuming to read the whole dialogue. Dialogue summarization thus becomes valuable since it could extract the key point of a conversation and greatly reduce the time cost. This technique is widely used in customer service (Liu et al., 2019), meeting (McCowan et al., 2005), online chatting (Gliwa et al., 2019), etc.



Dialogue

0 Q: 我的这个原来绑定的手机号没用了，然后我密码又忘了。(My original phone number was useless, and I forgot my password.)
1 A: 这边为您转接专员您看可以吗？(Can I transfer you to the commissioner here?)
2 Q: 好的。(Yes.)
3 A: 很抱歉转接失败的呢亲，这边为您升级专员[数字]小时回电可以吗亲？(I'm sorry, the transfer failed. Can I help to upgrade the commissioner and call you back in [NUM] hours?)
4 Q: 也可以的啦。(It's OK.)
5 A: 请问还有其他还可以帮到您的吗?(Is there anything else I can help you with?)
6 Q: 对了，**京东是可以微信支付**的吧。(By the way, **Can JD pay via wechat**?)
7 A: 正常是可以的呢亲。(Yes, it is OK normally.)

User Summary	用户表示绑定手机号不用了，密码忘记。**用户询问京东是否可以微信支付**。(The user said that the mobile phone number was useless, and forgot the password. **The user asked whether Jingdong can pay via wechat**.)
Agent Summary	客服帮助用户转接专员失败后表示[数字]小时内回电。客服表示**京东可以微信支付**。(The customer service helped the user to call back within [number] hours after the transfer specialist fails. The customer service said **JD could pay via wechat**.)

🟨 : Information from the user's utterances, could enhance agent summary in 🟦
🟦 : Information from the agent's summaries, could enhance user summary in 🟧
🟧 : Information from the user's summaries, could enhance agent summary in 🟦

Figure 1: An illustration of the role-oriented dialogue summarization. The task will generate *User Summary* and *Agent Summary* for the user (Q) and the agent (A), respectively. The information from other roles could help enhance the summary quality.

In a dialogue, each role has its own opinion and goal, and different roles exchange information or reach a consensus through interactions. Therefore, in addition to summarizing the whole dialogue, we could summarize the main content for each role. Lin et al. (2021) first define the role-oriented dialogue summarization task and provide a related dataset, CSDS. They define role-oriented dialogue summarization as grasping the main viewpoint of a given role from dialogue and mention the usage of role-oriented summaries in the customer service domain, *e.g.*, reflecting the user's requirements and evaluating agent service quality. Besides, role-oriented summarization is beneficial to other dialogue domains such as medical inquiry (Song et al., 2020) and court debate (Duan et al., 2019).

For role-oriented summarization, existing methods simply generate summaries for each role separately (Lin et al., 2021) or generate in a sequence

labeling process (Song et al., 2020). They ignore the strong relativeness among summaries for different roles and thus fail to utilize the information from other roles to enhance the summaries. However, information from other roles is also crucial for this task. We summarize two cases where other roles' information helps:

(1) Other roles' dialogue utterances could help enhance the informativeness of summaries. In Figure 1, utterance 7 (*Yes, it is OK normally.*) is the key utterance of the agent's content, expressing a confirmation to the user's question. While only extracting it makes the agent summary ambiguous since it lacks the confirming object (*JD can pay via wechat* in blue). In this case, the agent summary needs to integrate the content from the user's utterance (utterance 6 in yellow) to enhance its informativeness.

(2) Other roles' summaries could help judge the key content in the dialogue. In a dialogue, different roles often discuss the same topic. Therefore, considering the key content of the other role could help grasp the key content of a given role. As shown in Figure 1, the user summary contains a question about the payment (in red), and the agent summary contains the response to the payment question (in blue). If the summary of one role struggles in judging whether the discussion about payment should be contained in the summary, by referring to the summary of the other role, the summarization model could be more confident to include this information in the summary.

Although we notice the importance of other roles' information, it is difficult to extract the key information from other roles through a simple multi-task framework. The main issue is that it could not judge which information from other roles is useful without modeling the interaction between different roles. Thus, in this work, we propose two interaction methods to obtain key information from other roles for enhancing role-oriented summarization. First, we apply a cross attention interaction to let each role decoder select the most useful dialogue utterances from other roles. Specifically, we calculate the **Cross Attention** for different roles' utterances separately and add a new **Attention Divergence Loss** to interactively share the cross attention distributions between different roles. Second, we apply a decoder self-attention interaction to let each role decoder obtain other roles' summary information. We develop an interactive mechanism between decoders to consider other role summary information embedded in the decoder states. A new **Role Attention** module is added to each role decoder, where the attention object is the hidden states of other role decoders. At last, we use the role attention result and multiple context attention results to predict the word probability distribution of the summary. Through these two modules, the model could acquire more precise information from other roles and provide better role-oriented summaries.

To examine the effectiveness of our method, we conduct experiments on two dialogue summarization datasets (Lin et al., 2021; Song et al., 2020) with role-oriented summaries in different domains (customer service, medical inquiry). We apply our method on two widely-used summarization frameworks (RNN-based and Transformer-based). The results have shown that, compared with baseline systems and naive multi-task approaches, applying role interactions could significantly improve the quality of role-oriented summaries. Further analyses verify that our proposed method can help the model correctly attend to other roles' key information and generate summaries with more complete semantic and correct topic structures.

The main contributions of this paper include: (1) We are the first to enhance role-oriented dialogue summarization by focusing on other roles' key information. (2) We innovatively design two role interaction methods to obtain other roles' key information useful for generating summaries. (3) Experimental results on two datasets have shown that our method could lead to considerable improvements. Besides, our method has good generalizability since it works on multiple baseline frameworks.

2 Related Work

2.1 Dialogue Summarization

Dialogue summarization has been studied in various domains, *e.g.*, meeting (McCowan et al., 2005; Janin et al., 2003), daily chatting (Gliwa et al., 2019; Chen et al., 2021), customer service (Liu et al., 2019; Zou et al., 2021), and medical inquiry (Song et al., 2020; Krishna et al., 2021). Considering the particularity of dialogue, many studies try to improve the dialogue summarization performance by focusing on dialogue-specific features (Feng et al., 2021), such as topic information (Chen and Yang, 2020), discourse structure (Chen and Yang, 2021), coreference information (Liu et al., 2021) and speaker information (Lei et al., 2021; Zhu et al., 2020).

However, all the above studies focus on summarizing the whole dialogue. Only a few studies pay attention to role-oriented summarization, which aims to summarize the main content of a single role in the dialogue. A relative task is focused meeting summarization (Wang and Cardie, 2013; Mehdad et al., 2014; Zhong et al., 2021). It aims to summarize a specific part of the meeting dialogue, while role-oriented summarization focuses on a single role, and the relationship between different roles is much closer. Tamura et al. (2011) focus on contact center dialogue summarization, but they only extract salient sentences from the dialogue and do not summarize for different roles.

Due to the lack of labeled data, Zhang et al. (2021) propose an unsupervised method to generate summaries for the customer and the agent under a variational auto-encoder framework. As for supervised methods, there are only two datasets available for training. Lin et al. (2021) propose a customer service domain dataset named CSDS, where each dialogue has an overall summary and two role-oriented summaries for user and agent. They train two separate models for generating user summaries and agent summaries. Song et al. (2020) provide a medical inquiry dialogue summarization dataset where each dialogue has two extractive summaries for the patient and the doctor. They train a sequence labeling model to extract summaries for these two roles. Compared with these approaches, to the best of our knowledge, we are the first to enhance role-oriented summarization by explicitly considering other roles' critical information.

2.2 Interactive Decoding

Interactive decoding is a mechanism to share information between different decoders in the decoding process. Zhou et al. (2019) propose this mechanism and use it on machine translation to simultaneously decode from both left-to-right and right-to-left. Wang et al. (2019) and Liu et al. (2020) further utilize it on more complex machine translation tasks, including multilingual translation and speech translation. In this work, we first use the interactive decoding mechanism on the summarization task to decode summaries for different roles, aiming at utilizing other roles' summary information for summarization. Besides, we also propose an interaction method on cross attention to utilize other roles' critical dialogue utterance information.

3 Our Approach

3.1 Task Definition

Given a dialogue D containing m utterances $\{u_1, ..., u_m\}$ and p speakers $S = \{s_1, ..., s_p\}$, the role-oriented summarization task aims to generate a summary y^k for each speaker s_k. Each utterance u_k consists of a speaker role $r_k \in S$ and related content. By concatenating all the utterances and related speaker roles, we achieve the final input $\{x_1, ..., x_n\}$. Note that since both datasets used in this work have two speakers, one asking questions and one giving answers, we thus use y^{user} and y^{agent} to represent two role-oriented summaries in the following illustration[2].

3.2 Role Interactions

In a traditional encoder-decoder framework for dialogue summarization, the encoder hidden states represent the semantic information of input dialogue utterances, and the decoder hidden states contain the information used to generate summaries. To fully exploit the information from other roles, we apply two role interactions on the attention module of both hidden states. We present the structure of our method in Figure 2 and introduce the details of interactions in the following paragraphs.

3.2.1 Cross Attention Interaction

Our method is constructed based on a multi-task framework where an encoder is used to encode dialogue utterances and two role decoders (user decoder and agent decoder) are used to decode user summary and agent summary. First, the input $\{x_1, ..., x_n\}$ is sent to an encoder (omitted in the figure for simplicity) and the encoder outputs the context hidden representation $\{h_1, ..., h_n\}$. In the decoding phase, to calculate the cross attention results for different roles separately, we use **User Mask** and **Agent Mask** to split the context information into user context H_u^{enc} and agent context H_a^{enc}. H_u^{enc} contains the hidden representation of all user utterances, and H_a^{enc} contains the hidden representation of all agent utterances.

The cross attention module extracts the most useful information from the context according to the temporary decoder state. Here we modify the module to attend to different role contexts separately.

---

[2] Here we need to point out that our method could also apply to dialogues with more than two speakers.

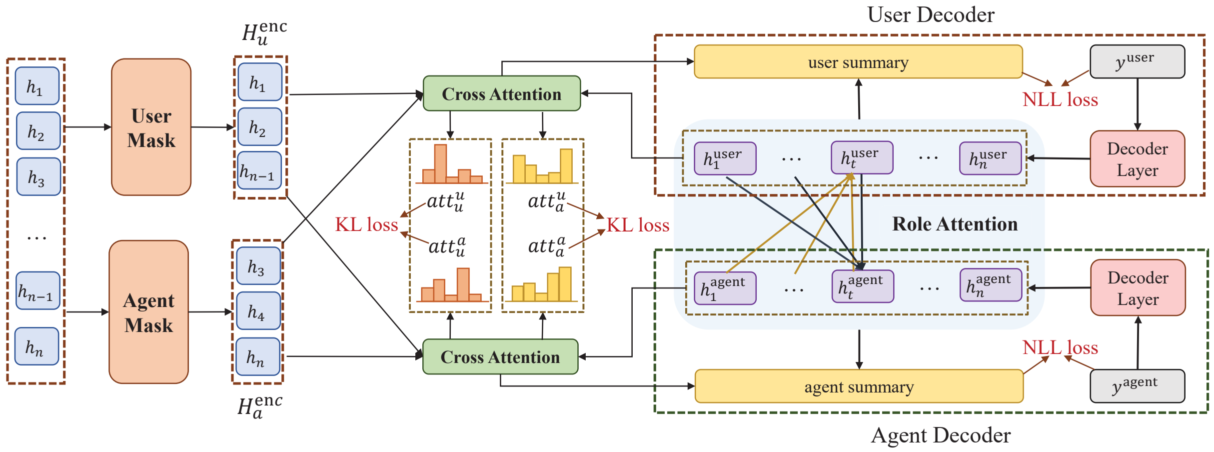

Figure 2: The model structure of our proposed method with role interactions.

Taking user decoder as example, at step k, we use the hidden state of user decoder h_k^{user} to attend to user context H_u^{enc} and agent context H_a^{enc}, obtaining two attention distributions $att_{u,k}^u$, $att_{a,k}^u$ and context attention results $c_{u,k}^u$, $c_{a,k}^u$. Both context results involve generating summaries. The process is the same with agent decoder, where two attention distributions are noted as $att_{u,k}^a$, $att_{a,k}^a$.

Since existing models are poor at extracting important information from other roles, it reflects in incorrect cross-role attentions $att_{u,k}^a$ (agent decoder to user context) and $att_{a,k}^u$ (user decoder to agent context). Meanwhile, the same-role attentions $att_{u,k}^u$ (user decoder to user context) and $att_{a,k}^a$ (agent decoder to agent context) are learned better since most information of role-oriented summaries comes from the given role's utterances. Thus we want to use the same-role attention to guide the cross-role attention. As different roles often discuss the same topic in one dialogue, the accumulated cross attention distribution for user decoder and agent decoder on the same role's utterances should be similar. A new **Attention Divergence Loss** is added to constrain this attention similarity as:

$$\mathcal{L}_{\text{att}-\text{user}} = \text{KL}(\text{Avg}(att_u^a)||\text{Avg}(att_u^u))$$

$$\mathcal{L}_{\text{att}-\text{agent}} = \text{KL}(\text{Avg}(att_a^u)||\text{Avg}(att_a^a))$$

By minimizing these two losses, the agent decoder attends to user utterances as the user decoder does, and the user decoder attends to agent utterances as the agent decoder does. Two role decoders interactively learn to focus on the key information of the other role in dialogue utterances.

3.2.2 Decoder Self-Attention Interaction

Since the decoder calculates the hidden states that could help predict summaries, the hidden states must contain much important information of summaries. We thus try to exploit the information embedded in other role decoders. Specifically, for user decoder, at time step t, we achieve the decoder hidden states h_t^{user} and use a **Role Attention** module to weigh the last t hidden states of agent decoder $\{h_1^{\text{agent}}, ..., h_t^{\text{agent}}\}$[3]. The role context information r_t^{user} is obtained by adding all the agent hidden states with their weights, and it helps generate the probability of next word $\hat{y}_t^{\text{user}}$ for user summary. The calculation formulas are given as:

$$r_t^{\text{user}} = \text{Attn}(h_t^{\text{user}}, h_{1:t}^{\text{agent}})$$

$$p(\hat{y}_t^{\text{user}}) = \mathcal{F}(h_t^{\text{user}}, r_t^{\text{user}}, c_{u,k}^u, c_{a,k}^u)$$

The function $\mathcal{F}$ includes an MLP layer to fuse different information and a softmax layer to predict the vocabulary probability distribution. The process is the same with the agent decoder, and two decoders decode interactively.

3.2.3 Training and Inference

In the training phase, we use the teacher-forcing method to jointly train two role decoders and use the Negative Log-Likelihood loss to optimize. The

---

[3] Since two decoders decode simultaneously, at step t, the other decoder could only provide the states from step 1 to t.

NLL loss for a single sample is formulized as:

$$\mathcal{L}_{\text{nll}} = -(\alpha \cdot \sum_{i=1}^{|y^{\text{user}}|} \log P(y_i^{\text{user}} | y_{<i}^{\text{user}}, y_{<i}^{\text{agent}}, D) +$$

$$(1-\alpha) \cdot \sum_{i=1}^{|y^{\text{agent}}|} \log P(y_i^{\text{agent}} | y_{<i}^{\text{agent}}, y_{<i}^{\text{user}}, D))$$

α is a hyper-parameter for balancing the weights of different summarization tasks. Besides, we add the attention divergence loss to constrain the attention distribution, and the total loss is calculated as:

$$\mathcal{L} = \mathcal{L}_{\text{nll}} + \beta(\mathcal{L}_{\text{att-user}} + \mathcal{L}_{\text{att-agent}})$$

β is a hyper-parameter for balancing the weights of different loss functions.

In the inference phase, we also make some adjustments to beam search for our proposed method. We maintain two beams, one for user summary and one for agent summary. At each step of decoding, the k^{th} sequence of the user summary beam should consider the states in the k^{th} sequence of the agent summary beam for role attention. Once one beam has finished decoding, we keep the beam fixed and search for the other one. The beam search will finish if both beams have finished searching.

4 Experiments

4.1 Datasets

There are two dialogue summarization datasets with role-oriented summarization tasks. Thus, we evaluate the effectiveness of our proposed method on both datasets. First, we experiment on a Chinese fine-grained customer service summarization dataset named CSDS[4] (Lin et al., 2021). It provides separate summaries for the user and the agent, and both may contain multiple topics. The other one is a Chinese medical inquiry summarization dataset MC[5] (Song et al., 2020). Each dialogue has a summary of the patient's description and a summary of the doctor's suggestion. We note them as user summary and agent summary as well. Most of the summaries in MC are extractive, and only a few are different from dialogue scripts. Moreover, most dialogues in MC have only one topic. Comparing two datasets, MC is easier to summarize while CSDS is more specific for role-oriented summarization and more challenging. The detailed statistics of the two datasets are given in Table 1.

	CSDS	**MC**
Train Size	9,101	29,324
Val Size	800	3,258
Test Size	800	8,146
Turns	25.92	18.48
Dial. Length	321.92	292.21
User Sum. Length	37.28	22.37
Agent Sum. Length	48.08	95.32

Table 1: Statistics of CSDS and MC. All the lengths are counted on Chinese characters.

4.2 Baselines and Experiment Settings

We apply the role interaction methods on two widely-used seq2seq models in the summarization community, including PGN (See et al., 2017) and BERTAbs (Liu and Lapata, 2019). Therefore, we will introduce these two backbone models and how we apply **Role Interactions** to them.

4.2.1 PGN-based Methods

PGN is an LSTM-based seq2seq model with a copy mechanism to copy words from the input and a coverage mechanism for constraining context attention. We set two PGN-based baselines for comparison. **PGN-single** is to separately train two PGN models for generating user summary and agent summary, while **PGN-multi** tries to jointly train two PGN models by sharing the same encoder. Both baselines adopt all the dialogue context as input.

To apply role interactions, we choose the output of the LSTM cell in the decoder as the query to calculate cross attention and role attention. The attention object in role attention is the output of the LSTM cell from the other decoder. Since we calculate the cross attention for different roles separately, we use a learnable gate p_{role} to control the weight of different cross attentions and add them together according to their weights to achieve the overall context attention distribution. It is also used for the copy and coverage mechanism. We set **PGN-cross** as adding cross attention interaction, **PGN-self** as adding decoder self-attention interaction, and **PGN-both** as adding both interactions.

4.2.2 BERTAbs-based Methods

Transformer has been widely used in language understanding and generation models due to its strong representation ability and concurrency, especially

---

[4] https://github.com/xiaolinAndy/CSDS.

[5] https://github.com/cuhksz-nlp/HET-MC. We use the official crawling script to acquire the dataset and divide some data from the training set as the validation set. Due to the website update, the data may have a slight difference compared with the version in the original paper.

in pretrained models (Devlin et al., 2019; Lewis et al., 2020). Here we choose BERTAbs (Liu and Lapata, 2019) as the backbone structure since it performs well on many summarization datasets and is available for non-English languages such as Chinese. It adopts a pretrained BERT model as encoder and a transformer decoder structure to decode summaries. Both the encoder and the decoder contain six layers, and each layer contains three sub-layers (self-attention, encoder-decoder attention, feedforward). Similar with PGN-based methods, we set **BERT-single** and **BERT-multi** as two baselines.

We apply both interactions to each layer in BERTAbs. For cross attention interaction, we change the encoder-decoder attention sub-layer into two separate cross attention modules; for decoder self-attention interaction, we add the role attention module parallel with the encoder-decoder attention module. The query, key, and value of the role attention module are all the output from the self-attention sub-layer. **BERT-cross**, **BERT-self**, and **BERT-both** are kept the same with the settings in PGN-based methods.

4.2.3 Other Experiment Settings

We add the role information to the front of the utterance in each turn and concatenate all the utterances in the dialogue sequentially as the input of the model. Both PGN[6] and BERTAbs[7] baseline methods are adopted from publicly available codes. For PGN-based methods, we use pretrained Chinese word vectors provided by Tencent[8], and the vocabulary size is 10,000. While for BERTAbs-based methods, we use the base version of Chinese BERT-wwm[9]. The best checkpoint is chosen based on validation set loss, and we use beam search to decode summaries on the best checkpoint with beam size 5. For choosing hyper-parameters, since the agent summary is more complex than the user summary in MC, we set α to be 0.2 to give the agent summary more weight. It is set to be 0.5 for CSDS. β is set to be 0.5 for PGN and 0.25 for BERTAbs. The hyper-parameter settings are chosen by experimenting on the validation set. More details are given in Appendix A.

4.3 Evaluation Metrics

We adopt six common automatic evaluation metrics to evaluate the summary quality. The metrics include traditional n-gram overlapping metrics, such as **ROUGE** (Lin and Hovy, 2002), **BLEU** (Papineni et al., 2002), and distributed representation matching metrics, including **BERTScore** (Zhang et al., 2020) and **MoverScore** (Zhao et al., 2019). We use files2rouge toolkit to calculate the F1 score of ROUGE-1, ROUGE-2, ROUGE-L. More details of evaluation scripts are given in Appendix A.

In addition to automatic metrics, we also compare the summary quality at a fine-grained level through human evaluation. Following the human evaluation process in Lin et al. (2021), we recruit several volunteers and let them evaluate the summaries in the following aspects: (1) **Informativeness**: Does the generated summary correctly cover the information in the ground truth summary? (2) **Non-redundancy**: Does the generated summary not contain repeated, meaningless or unnecessary information? (3) **Fluency**: Is the generated summary well-formed, semantically complete, and easy to understand? All three aspects are evaluated at the sub-summary level[10] on a three-point scale, 0 for the worst, 1 for the medium, and 2 for the best.

5 Results and Analysis

5.1 Automatic Evaluation Results

First, we present the results of automatic metrics with Student's t-test as significance test in Table 2 and 3. The results are similar on the two datasets. First, the multi-task mechanism could bring some improvement than separately training on most of the metrics. However, the improvement is limited, especially for the PGN model on CSDS. After adding the enhancement of other roles' information, the performance is significantly boosted.

On CSDS, PGN-single and BERT-single are two strong baselines provided in Lin et al. (2021)[11]. For PGN-based methods, the best method PGN-both utilizes two interactions and achieves 2.84 and 1.53 higher points on ROUGE-L for user summary and agent summary than PGN-single. For BERTAbs-

Table 3: The automatic metric results for MC. * represents the same with the one in Table 2.

based methods, the improvements are even greater, which are 4.73 and 2.69. We also conduct ablation studies by only applying one interaction (*-cross* or *-self*). Both settings show promising improvement over the *single* and *multi* baselines on nearly all the metrics, demonstrating the effectiveness of each interaction method. In comparison, applying two interactions together yields the best result on the majority of metrics.

The circumstance is similar on MC. User summarization is relatively simple on MC, and the baseline methods could achieve high performance (5.35 points of ROUGE-2 higher than the best performance in the original paper (Song et al., 2020)). Despite this, both cross attention interaction and decoder self-attention interaction could still increase the performance of user summary a bit. Additionally, the improvement on agent summary is more significant. PGN-both method achieves 0.90 points of ROUGE-2 and 1.29 points of MoverScore improvement, while BERT-both achieves 0.76 points of ROUGE-2 and 0.66 points of MoverScore improvement. PGN-both also beats the best result in the original paper on most of the metrics, which uses additional information such as hospital department and disease name. In conclusion, our proposed two interaction methods could bring remarkable improvement on different backbone structures and different datasets.

CSDS	Info	Non-Red	Flu	Overall
PGN-multi	**0.69**/0.65	0.54/0.55	0.70/0.79	0.64/0.66
PGN-both	0.66/**0.69**	**0.58/0.59***	**0.73/0.81**	**0.66/0.70***
BERT-multi	0.58/0.56	**0.66/0.61**	0.84/**0.87**	0.69/0.68
BERT-both	**0.62*/0.60***	0.62/0.60	**0.85/0.87**	**0.70/0.69**

Table 4: The human evaluation results for CSDS. Two values in each block represent user summary and agent summary. All the values are in range 0 to 1. * indicates that the improvement of applying two interactions over the *multi* baseline is statistically significant ($p < 0.05$).

5.2 Human Evaluation Results

To evaluate the summary quality at a more fine-grained level, we compare the summaries from different models according to the pre-defined three aspects: informativeness, non-redundancy, fluency. Since the multi-task framework works better than the single baseline, we directly compare it with applying both interactions. As CSDS is more challenging for this task, we randomly select 100 samples from the test set and obtain the outputs of two baseline methods (PGN-multi and BERT-multi) and two interaction methods (PGN-both and BERT-both). We recruit three volunteers and train them on the evaluation rules[12]. Then we let them evaluate the generated summaries according to the ground

---

[12] More details are in Appendix C with ethical concerns.

CSDS	**ROUGE-1** Type A/B	**ROUGE-2** Type A/B	**ROUGE-L** Type A/B	**BLEU** Type A/B	**BERTScore** Type A/B	**MoverScore** Type A/B
PGN-multi	55.13/59.45	37.76/41.22	52.73/56.20	30.66/28.29	76.40/77.64	23.74/25.47

BERT-multi	46.59/50.07	32.33/34.59	44.49/47.65	23.45/26.37	75.03/75.64	22.47/24.34
BERT-both	**50.96/54.62**	**35.72/37.93**	**48.82/51.93**	**27.47/30.10**	**76.27/76.94**	**24.19/26.17**

Table 5: The performance on different types of samples. Type A represents agent summaries that need to be integrated, and Type B represents for those that do not. Here all the metrics here are recall scores except for BLEU and MoverScore since they do not have a recall version. We use their available results instead.

truth and the original dialogue in the three aspects. We run the inter-annotator agreement study on three volunteers' scores, and obtain a reasonable kappa score, 0.48 on average. We also calculate an "Overall" metric by averaging the results of all three aspects to represent the summary quality in general. We normalize the result into 0 to 1 and present it in Table 4.

The result shows different trends on two backbone structures. For the PGN model, applying interactions could largely reduce the redundancy of both user and agent summary, with a comparable performance of informativeness. Besides, it also improves the fluency of the two summaries. For the BERTAbs model, the interaction method significantly improves the informativeness while the redundancy also increases a bit. The difference exists because BERTAbs prefers to generate short summaries. Thus, considering information from other roles could help generate more useful information but also induce some redundant text. In contrast, PGN tends to generate lengthy summaries. When considering information from other roles, it first tries to discard the redundant texts and only retains more important ones. The fluency improvement on both methods proves that other roles' information helps generate more semantically complete summaries. Considering the overall metric, we conclude that our proposed interaction method is also effective through human evaluation.

5.3 Further Analysis

Agent Summary Completeness Analysis The agent summary often suffers semantic incompleteness due to missing key information from other roles (Lin et al., 2021). Since our proposed role interactions aim at extracting other roles' key information, we wonder whether they work on these incomplete cases. Following the settings in Lin et al. (2021), we compare the summary quality of samples that need to integrate other roles' information and those that do not need separately[13]. The result in Table 5 shows that the interaction method could actually help improve the performance on samples that need to integrate. Besides, samples that do not need also get improved. We believe that it is because considering other roles' information could also help extract critical content from the role's own utterances as well.

Topic Structural Summary Analysis Since we assume that role interactions could help generate better summaries by sharing the same discussion topic, we wonder whether the summaries generated by our methods could include the correct topic structure. More specifically, we want to find out the performance of our methods on summarizing each topic. Following the evaluation method in (Lin et al., 2021), we treat each sentence in the summary as a sub-summary for a single topic and calculate the number of matching sub-summaries with the reference by a ROUGE-L-based matching algorithm. We calculate the precision, recall, and F1 scores of correctly matched sub-summary ratios and present them in Table 6. The result shows that two role interaction methods achieve higher recall and F1 scores on sub-summary matching. It proves that role interactions could help the model grasp the discussion topic in the dialogue and generate a more accurate summary for each topic.

We also present an example in Appendix B to prove the effectiveness of our proposed role interaction method.

6 Conclusion and Future Work

In this paper, we focus on the role-oriented dialogue summarization task. To fully exploit the information from other roles, we propose two role interaction methods on cross attention and decoder

---

[13] It is judged by considering whether the summary needs to refer to other roles' utterances, which is already labeled in CSDS.

Methods	Precison	Recall	F1
PGN-multi	28.61/18.86	28.87/19.67	28.74/19.27
PGN-both	**31.79/21.06**	**30.85/21.58**	**31.31/21.32**
BERT-multi	**40.16/23.99**	30.26/18.81	34.51/21.09
BERT-both	37.37/22.09	**32.17/20.66**	**34.57/21.35**

Table 6: Sub-summary matching ratio for baselines and our methods. Two values in each block represents user summary and agent summary.

self-attention. The cross attention interaction calculates the context information for different roles separately and uses same-role attention to guide cross-role attention. The decoder self-attention interaction adds a role attention module to attend to other role decoder states interactively. Experiments on two dialogue summarization datasets prove that both interactions perform significantly better than strong baseline methods. Adding role interactions also helps generate summaries with complete semantics and correct topic structure. In the future, we will try to apply this method to other dialogue-related tasks and conduct more experiments on stronger summarization methods.

Appendix

A Experiment Details

Here, we will introduce some detailed settings for our experiments on two datasets.

- **PGN-based methods**: We construct the vocabulary by choosing the top 10,000 most frequent words in the training data. The settings of PGN are the same as the original setting with hidden size 256. The optimizer is Adagrad and the learning rate is 0.15.

  For CSDS dataset, we use the given word split result to construct the vocabulary. The maximum input length is set as 500. The maximum output length is 100, and the minimum is 10. We train 40 epochs without coverage mechanism or KL divergence loss (if needed) and 10 epochs with coverage mechanism and KL divergence loss. Then we choose the best checkpoint by comparing the loss on the validation set and use it to decode summaries.

  For MC dataset, we use jieba[14] tool to split sentences into words for constructing the vocabulary. The length conditions of input and output are kept the same with CSDS. We train 30 epochs without coverage mechanism and do not finetune with coverage mechanism since we found that it makes the performance worse. The KL divergence loss is added to the training loss for PGN-cross and PGN-both in all the training process.

- **BERTAbs-based methods**: Since the BERT model is already finetuned, there is no need to reconstruct the vocabulary. The Chinese BERT model works on character-level. Thus we set the length limit larger. The dimension and optimizer settings of BERTAbs are also the same as the original settings.

  For CSDS dataset, the maximum input and output length are 1,000 and 200, respectively. The minimum output length is 15. We train the model for 4000 steps and save the checkpoint for every 400 steps. We use Adam optimizer with a warmup of 1000 steps. The KL divergence loss is added by finetuning 1000 more steps. During the inference time, we control the maximum non-repeat n-gram length as 5.

  For MC dataset, the maximum input and output length are kept the same as in CSDS, and the minimum output length is 10. We train the model for 8000 steps and add the KL divergence loss in all the training process.

All the PGN-based models are run on an NVIDIA TITAN Xp, and all the BERTAbs-based models are run on an NVIDIA RTX3090. The whole running time is less than a week.

We also provide the running scripts of auto evaluation metrics for better reproduction. For ROUGE metrics, we use the files2rouge[15] toolkit with the default parameters. All the Chinese characters

---

[14] https://pypi.org/project/jieba/

[15] https://github.com/pltrdy/files2rouge

are transferred into number ids for calculation, and the period is used to split each summary into several sentences for ROUGE-L calculation. For BERTScore, we use the official code[16]. For MoverScore, we use moverscore-v2[17] and the bert-base-chinese pretrained model for obtaining representations.

B Case Study

Here we use the same example illustrated in the main paper to prove the effectiveness of our proposed method. The outputs of different methods are given in Figure 3. Comparing the outputs of user summary, only PGN-both correctly summarizes the key issue "*The user asked whether wechat payment is available.*", while other baselines omit it. This could be contributed to decoder self-attention interaction by attending to the information in the decoded agent summary. As for the agent summary, PGN omits the keyword "*JD*" and PGN-multi generates a redundant clause "*The customer service replied that it can be paid by wechat*". Compared with them, PGN-both generates the agent summary with both informativeness and preciseness.

As given in Figure 4, we also present the average attention distribution for cross attention module in the PGN-both method. Although the attention distributions for user summary and agent summary are different, they also show some similarities, such as both focusing on the second line from the bottom, which is the key utterance for both summaries. This could be benefited by the cross attention interaction since we close the gap between the attention distributions of different role decoders on the same role's utterances.

C Ethical Concerns

We only use the data provided by two datasets for training. The private information in CSDS has already been anonymized, such as replacing all numbers with special token <NUM> and all order IDs with <ORDER-ID>. There is no personal information available in CSDS. The circumstance is the same for MC, where all the dialogues do not contain detailed personal information. Thus the methods provided in our experiment do not have any issues with privacy disclosure. As for human evaluation, all the participants are Chinese graduate students who volunteer to make the evaluation, and they are all proficient in Chinese. We first let them read the evaluating instructions and let them evaluate ten samples without showing the model name for each summary. After confirming that the results provided by three volunteers attain a moderate level of agreement on all the aspects, we allow them to examine the remaining samples.

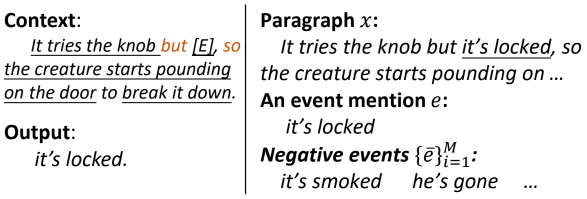
Abstract

Generating new events given context with correlated ones plays a crucial role in many event-centric reasoning tasks. Existing works either limit their scope to specific scenarios or overlook event-level correlations. In this paper, we propose to pre-train a general Correlation-aware context-to-Event Transformer (ClarET) for event-centric reasoning. To achieve this, we propose three novel event-centric objectives, i.e., whole event recovering, contrastive event-correlation encoding and prompt-based event locating, which highlight event-level correlations with effective training. The proposed ClarET is applicable to a wide range of event-centric reasoning scenarios, considering its versatility of (i) event-correlation types (e.g., causal, temporal, contrast), (ii) application formulations (i.e., generation and classification), and (iii) reasoning types (e.g., abductive, counterfactual and ending reasoning). Empirical fine-tuning results, as well as zero- and few-shot learning, on 9 benchmarks (5 generation and 4 classification tasks covering 4 reasoning types with diverse event correlations), verify its effectiveness and generalization ability.

1 Introduction



Context:
It tries the knob but [E], so the creature starts pounding on the door to break it down.

Output:
it's locked.

Paragraph x:
It tries the knob but it's locked, so the creature starts pounding on …

An event mention e:
it's locked

Negative events $\{\bar{e}\}_{i=1}^{M}$:
it's smoked he's gone …

Figure 1: *Left*: an example of abductive reasoning which aims to generate the missing event [E] given correlated events (underlined) and connectives (w/ orange) in the context. *Right*: a toy example $(x, e, \{\bar{e}\}_{i=1}^{M})$ of event-rich data for better reading. See Appendix A for real examples to pre-train our model.

An 'event', usually a text span composed of a predicate and its arguments (Zhang et al., 2020b), is a fine-grained semantic unit to describe the state of entities/things (e.g., *He looks very worried*) and how they act (e.g., *I grab his arms*). Understanding events and modeling their correlations are fundamental to many reasoning tasks (Bhagavatula et al., 2020; Qin et al., 2019), e.g., abductive reasoning, story ending classification and generation, counterfactual reasoning, script reasoning. For instance, in the left example of Figure 1, to generate the missing event *[E]* in the given context, it is essential to understand that there are four events ('*it tries the knob*', *[E]*, '*the creature starts pounding on the door*', and '*(the creature) to break it down*'), and then predict *[E]* based on the other three events and its correlations to them (i.e., the contrast relation indicated by '*but*' and the causal relation by '*so*').

Event-aware reasoning has gained much attention and achieved promising success in recent years (Lv et al., 2020; Ding et al., 2019). However, many algorithms are designed to solve only some specific tasks. For example, Qin et al. (2020) propose to improve unsupervised decoding for counterfactual and abductive reasoning; Huang et al. (2021) and Guan et al. (2019) advance story ending generation via incremental encoding and multi-level graph convolutional networks. Although these works show effectiveness in corresponding applications, they are limited to specific scenarios, and cannot generalize well to a broad scope of reasoning.

Meanwhile, some pioneering works follow a recently arising paradigm to conduct event-based pre-training for those downstream reasoning tasks (Yu et al., 2020; Han et al., 2020a; Lin et al., 2020; Zhou et al., 2021b). However, these solutions have their own limitations: COMeT (Hwang et al., 2021) learns event correlations from a human-curated knowledge graph and thus limits its scalability. Han et al. (2020a) and Lin et al. (2020) only model temporal relations and cannot be expanded to other relations (e.g., causal, contrast). EventBERT (Zhou et al., 2021b) is proposed for event-based classifi-

cations and is thus inapplicable to generation tasks.

In this work, we propose a general pre-training framework for event-centric reasoning by learning a **C**orre**la**tion-awa**r**e context-to-**E**vent **T**ransformer (ClarET) from an event-rich text corpus. We propose three novel self-supervised objectives, dubbed as whole event recovering (WER), contrastive event-correlation encoding and prompt-based event locating, respectively. The first one aims to capture event correlation by recovering a whole event from its masked context. The second one enhances the representation of the masked event in WER by contrasting it with the gold event against the negative ones. The last one is a simplified WER task by providing hints in its prompt and thus facilitates effective learning for WER.

ClarET explicitly models event correlations and contributes to various scenarios. From one aspect, it covers a variety of correlation types (e.g., causal, temporal, contrast) attributed to correlation type-agnostic objectives. From another aspect, it is applicable to both generation and classification task formulations by its unified structure. Lastly, it highlights event-level correlations and thus is more effective for diverse event-centric tasks, e.g., abductive, counterfactual and ending reasoning.

To evaluate ClarET, we compare it with strong baselines on 9 diverse benchmarks. While ClarET is continually pre-trained from BART (Lewis et al., 2020) with very limited extra resources, i.e., training on a small subset of BART-used corpus (i.e., 200M out of 2.2T tokens) within 90 GPU hours (only 0.13% of 70,000h BART pre-training), it achieves state-of-the-art (SoTA) performance on all 5 generation benchmarks. It also outperforms all unified models on 4 classification benchmarks and achieves competitive, or even better, accuracy to strong discriminative baselines. We further exhibit that the ClarET provides a good initialization for downstream tasks by zero- and few-shot learning.

2 Related Work

Unified Pre-trained Model. A recent trend is to pre-train unified (a.k.a. universal or general) models to boost downstream generation and classification tasks, rather than masked language modeling (MLM) only. GPT (Radford et al., 2019) is based on auto-regressive language modeling but incompetent in classifications due to unidirectional contextualizing. To remedy this, BART (Lewis et al., 2020) trains seq2seq models as a text denoising autoencoder with mask-infilling, etc; UniLM (Dong et al., 2019) designs advanced self-attention masks in Transformer, leading to a partially auto-regressive MLM; GLM (Du et al., 2021) proposes an auto-regressive blank-filling objective based on Transformer, achieved by bi-/uni-directional attention and 2D positional encoding. T5 (Raffel et al., 2020) pre-trains a text-to-text Transformer to recover the masked part of input by decoding. All these general-purpose pre-trained models focus on relatively short-span masking in random, whereas we focus on masking a whole semantic unit (i.e., event) and propose novel training objectives to circumvent problems in long-span event decoding. Besides, they are also vulnerable to pretrain-finetune inconsistency, leading to inferior event-centric performance.

Task-specific Models for Event Reasoning. Many recent works present task-specific neural models for various event-centric reasoning types, including (1) abductive reasoning (Ji et al., 2020; Dong et al., 2021; Zhu et al., 2020), (2) counterfactual reasoning (Qin et al., 2019, 2020), (3) ending reasoning (Guan et al., 2019; Wang and Wan, 2019; Yao et al., 2019; Huang et al., 2021; Guan et al., 2020; Wang et al., 2017; Li et al., 2018; Ding et al., 2019; Zhou et al., 2021c; Chaturvedi et al., 2017; Srinivasan et al., 2018), (4) incoherence reasoning (Mori et al., 2020). However, these methods are designed for the specific reasoning scenarios based on task-specific models so hardly generalize to other scenarios. In contrast, we aim to pre-train a general event-centric model for generalizing to various scenarios.

Event-centric Pre-training. With similar scopes, many works focus on event-centric pre-training to promote event-related tasks as 'event' is a self-contained semantic unit and also an entry of commonsense reasoning. One paradigm is to pre-train on corpora without human-labeling. Some methods focus on more specific aspects of events and their correlations. DEER (Han et al., 2020b) performs temporal and event masking predictions for temporal relations. Lin et al. (2021) propose to recover a temporally-disordered or event-missing sequence for temporal and causal relations. Wang et al. (2021) use AMR structure to design contrastive objectives for the event detection task. However, they are not general enough to various event reasoning tasks. In contrast, CoCoLM (Yu et al., 2020) learns an event-level MLM to generalize more. EventBERT (Zhou et al., 2021b) states the ineffectiveness of event-level MLM and exploits hard negatives via contrasting, contributing much to downstream multi-choice tasks. However, these methods are only competent in discriminative tasks. The other paradigm is based on supervised pre-training on similar tasks and then performs knowledge transfer, e.g., COMeT (Hwang et al., 2021), UnifiedQA (Khashabi et al., 2020) and UNICORN (Lourie et al., 2021), but they require human-curated data.

Event-rich Corpus. Although raw corpora are viewed as off-the-shelf pre-training resources, a key question is how to mine event-rich examples. Here, 'event-rich' denotes that each example contains various events and entails adequate contexts to support event reasoning via either explicit or implicit event-correlation. This is crucial to learning event-correlations and reducing unnecessary overheads. Except for human-curated resources (e.g., ATOMIC (Sap et al., 2019) and ConceptNet (Speer et al., 2017)), event-rich corpora are also mined via automatic schemes. ASER (Zhang et al., 2020b) builds an event-based graph, where each node is an event extracted from a text and the relation of an event pair is predicted by a PDTB model. In contrast, EventBERT (Zhou et al., 2021b) operates on pure text so filters out correlation-scarce contexts and extracts verb-rooted events. Besides, it offers event sampling methods for hard negatives. We adopt this data processing method as both pure-text examples and hard negatives are prerequisites of generic and robust pre-training.

3 Methodology

3.1 Prerequisite: Event-rich Corpus

In this work, we directly adopt event-rich data mining and negative sampling methods from Zhou et al. (2021b) but focus our contributions on enlarging application scope of event-centric tasks and overcoming challenges raised in the new scope.

Event-rich Data Mining. To mine event-rich data from raw corpus, we employ a story corpus, BOOKCORPUS (Zhu et al., 2015), and take a two-step procedural (i.e., '*filter*' and '*extraction*'). It *filters* out correlation-scarce paragraphs according to existence of connectives (i.e., discourse relation keywords, e.g., *however*, *while*). Then, it highlights the event spans in the filtered paragraphs by *extracting* verb-rooted sub-trees in dependency trees of the paragraphs. With a filtered paragraph x, we build each example as (x, e) where e is an event mention in x. We obtain 200M tokens (out of 1B in BOOKCORPUS) in 3.9M filtered paragraphs. ***For clear notations***, we denote a text piece as a lower case letter (e.g., e). It is tokenized into a sequence as a bold (e.g., $\boldsymbol{e} = [e_1, e_2, \dots]$), where a letter w/ subscript t is the t-th token in the sequence.

Negative Event Sampling. Following Zhou et al. (2021b), we build a pool of events from the whole corpus and then retrieve negative events by three heuristic schemes. Given an event e in (x, e), we sample its negative event, $\bar{e}$, in light of lexicon-based (20% time), PoS-based (60% time) or in-domain (20% time) retrieval. Consequently, given an event e, we sample M negative events, i.e., $\{\bar{e}\}_{i=1}^{M}$. Figure 1 (right) shows an integrated instance $(x, e, \{\bar{e}\}_{i=1}^{M})$ of the event-rich corpus[1].

3.2 Pre-training Objectives

We first present *whole event recovering* as a backbone pre-training objective in §3.2.1. After identifying incompetence of the simple backbone, we propose two other objectives in §3.2.2 and §3.2.3. An overview of the objectives is shown in Figure 2.

3.2.1 Whole Event Recovering

For the objective of whole event recovering (WER), it is straightforward to leverage an encoder-decoder structure, where a masked context is passed into the encoder to generate the missing part by decoding. Specifically, given an event e in a paragraph x, we mask out e from x at the encoder side and then generate e at the decoder side, i.e.,

$$p(e|x_{/\{e\}};\theta) = \prod\nolimits_t p(e_t|e_{<t}, x_{/\{e\}};\theta), \qquad (1)$$

where θ denotes parameters and $x_{/\{e\}}$ denotes replacing e in x with *one* special token `[M]`. We estimate Eq. (1) by the Transformer sequence-to-sequence (seq2seq) structure (Vaswani et al., 2017). First, we apply the Transformer encoder to $x_{/\{m\}}$ for contextual embeddings for all tokens in $x_{/\{m\}}$:

$$\boldsymbol{H}^{(enc)}=\text{Trans-Enc}(x_{/\{e\}};\theta^{(enc)}) \in \mathbb{R}^{d\times n}, \quad (2)$$

where n is the number of tokens in $x_{/\{e\}}$. Then, the Transformer decoder is employed to predict all tokens $\boldsymbol{e}$ of the event e in a recurrent manner, i.e.,

$$\tilde{\boldsymbol{y}}_t = \text{Trans-Dec}(e_{<t}, \boldsymbol{H}^{(enc)}; \theta^{(dec)}) \in \mathbb{R}^{|\mathcal{V}|}, \quad (3)$$

---

[1] Experimental codes are released at `https://github.com/yczhou001/ClarET`.

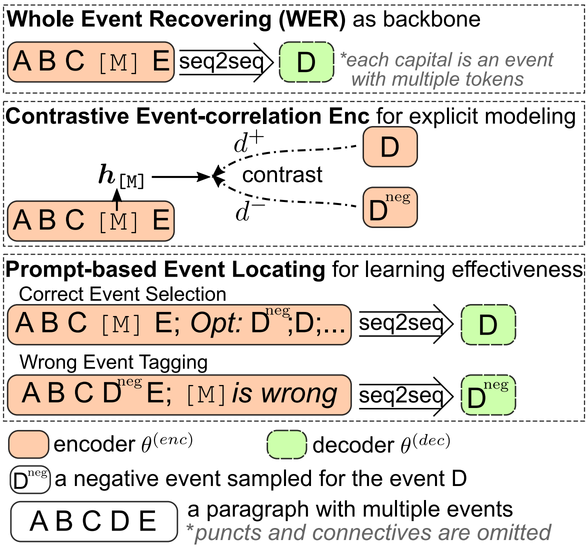

Figure 2: An overview of self-supervised objectives for our **C**or**r**e**la**tion-awa**r**e context-to-**E**vent **T**ransformer (ClarET).

where $\mathcal{V}$ denotes token vocabulary and $\tilde{\boldsymbol{y}}_t$ is the predicted categorical distribution over $\mathcal{V}$. Lastly, the training objective is defined as a maximum likelihood estimation. Its loss function is written as

$$L^{(wer)} = -\sum_{(x,e)} \frac{1}{|\boldsymbol{e}|} \sum\nolimits_{t=1}^{|\boldsymbol{e}|} \log \tilde{\boldsymbol{y}}_t[y = e_t], \quad (4)$$

where '$\boldsymbol{y}_t[y = e_t]$' denotes fetching the probability of the t-step gold token $e_t \in \boldsymbol{e}$ from $\tilde{\boldsymbol{y}}_t$.

This objective is similar to span recovering schema (Raffel et al., 2020; Joshi et al., 2020) but differs in that (i) each masked span is an event, i.e., an integrated semantic unit, so much longer (up to 22 tokens and see Figure 4 for length distribution), and (ii) only one event is masked out from the context to facilitate event-correlation modeling between the event and its contexts.

Intuitively, the success of Eq. (1) requires to capture correlations between the masked event and remaining contexts but two major problems arise due to WER with long event-level masking spans:

(1) Implicit Event-correlation: The model recovers an event based solely on token-level concurrence as in a conditional language model (e.g., T5 and BART), regardless of the rich event-level correlations between the events in context $x_{/\{e\}}$ and the masked event e. Such a correlation-implicit model would achieve inferior performance on downstream event-centric correlation reasoning tasks.

(2) Learning Difficulty: As the masked event is an integrated, self-contained, semantic unit, it is difficult for the conditional generation model to recover the whole event due to a lack of local contexts. As a result, the model cannot effectively learn from the long masked spans, which has been empirically proved in autoencoding MLM models.

To alleviate the two problems above, we propose two other novel self-supervised objectives in the following. Briefly, we present contrastive event-correlation encoding to enhance correlations between contexts and events, and prompt-based event locating to reduce generation difficulty.

3.2.2 Contrastive Event-correlation Encoding

For the *implicit event-correlation* problem, an intuitive solution is to explicitly highlight the correlation from the masked context to the missing event at the encoder side. To achieve this, we resort to contrastive learning to enhance the encoder-side representation of the masked event by contrasting it with the embedding of the gold event mention e against those of negative ones $\bar{e}$. Particularly, we first derive the embedding of e and $\bar{e}$ independently via the Transformer encoder in Eq.(2), i.e.,

$$\boldsymbol{c} = \text{Pool}(\text{Trans-Enc}(\texttt{[CLS]} + e; \theta^{(enc)})), \quad (5)$$

$$\bar{\boldsymbol{c}} = \text{Pool}(\text{Trans-Enc}(\texttt{[CLS]} + \bar{e}; \theta^{(enc)})), \quad (6)$$

where `[CLS]` is a special token prefixed to each event mention, and $\text{Pool}(\cdot)$ denotes using the contextual embedding of `[CLS]` to represent the whole event. Then, we enhance $\boldsymbol{h}_{\texttt{[m]}}$, the contextual representation of `[M]` in $x_{/\{e\}}$ from $\boldsymbol{H}^{(enc)}$ in Eq.(2), by contrasting it with $\boldsymbol{c}$ against $\bar{\boldsymbol{c}}$, i.e.,

$$L^{(cee)} = \max(0, \lambda + d(\boldsymbol{h}_{\texttt{[m]}}, \boldsymbol{c}) - d(\boldsymbol{h}_{\texttt{[m]}}, \bar{\boldsymbol{c}})), \quad (7)$$

where $d(\cdot, \cdot)$ denotes a distance metric of two vectors, which is Euclidean distance in this work. As a result, the encoder-side correlation-aware representation $\boldsymbol{h}_{\texttt{[m]}}$ also offers a straightforward pathway to transmit event-level information to decoding so mitigates the *learning difficulty* to some extent.

3.2.3 Prompt-based Event Locating

As for *learning difficulty* problem, we also propose a prompt-based event locating objective to reduce generative difficulty by providing hints in the prompt. The basic idea is to simplify WER objective as an extractive generation task to locate and copy a candidate/hint from the prompt, which aims at improving learning effectiveness. To this end, we present two prompt-based generation schemas in the following.

Correct Event Selection. Inspired by advances of prompt-based multi-choice question answering, we present correct event selection schema to select the gold event e against negative ones $\{\bar{e}\}_{i=1}^{M}$ based on the contexts $x_{/\{e\}}$. Given an event-masked paragraph $x_{/\{e\}}$ suffixed with several candidate events $\{\bar{e}\}_{i=1}^{M}$ containing the gold masked one e, it aims to generate the masked event e back, i.e.,

$$\hat{x}^{(ces)} = x_{/\{e\}} + \underline{\text{Options: (a) } e^1\text{; (b) } e^2\text{; } \cdots},$$

where $[e^1, e^2, \dots]$ is a random permutation of $[e, \{\bar{e}\}_{i=1}^{M}]$ in case of position bias. We use a random permutation as all candidates are assigned with distinct position embeddings during contextualizing, and a fixed permutation of gold events will result in a learning shortcut (position bias) to degrade the model. Thus, similar to Eq.(1), we can define its formula as $p(e|\hat{x}^{(ces)}; \theta)$.

Wrong Event Tagging. The other schema is wrong event tagging to find the wrong event in a corrupted paragraph, similar to incoherence reasoning. Thus, we re-write the encoder input as

$$\hat{x}^{(wet)} = x_{/\{e\}\&\cup\{\bar{e}\}} + \underline{\text{Event: } \texttt{[M]} \text{ is wrong}},$$

where $x_{/\{e\}\&\cup\{\bar{e}\}}$ denotes replacing the gold event e in x with a negative $\bar{e} \in \{\bar{e}\}_{i=1}^{M}$. Thus, we can define the formula of this objective as $p(\bar{e}|\hat{x}^{(wet)}; \theta)$.

Based on the two formulas above, we define the prompt-based event locating objective as

$$L^{(pel)} = \sum_{(x,e)} -\frac{1}{|\boldsymbol{e}|} \sum_{t} \log p(e_t | e_{<t}, \hat{x}^{(ces)}; \theta) - \frac{1}{|\bar{\boldsymbol{e}}|} \sum_{t} \log p(\bar{e}_t | \bar{e}_{<t}, \hat{x}^{(wet)}; \theta), \quad (8)$$

where $\theta = \{\theta^{(enc)}, \theta^{(dec)}\}$, $\bar{e}$ is sampled in $\{\bar{e}\}_{i=1}^{M}$.

3.3 Model Pre-training and Fine-tuning

Self-supervised Pre-training. The final loss to pre-train our ClarET is a linear combination of the three losses above from Eq.(4, 7, 8), i.e.,

$$L = L^{(wer)} + L^{(cee)} + L^{(pel)}. \quad (9)$$

We set the margin λ in Eq.(7) to 0.5 w/o tuning.

Supervised Downstream Fine-tuning. For generation tasks, we simply leverage the formula in Eq.(1) to establish fine-tuning objectives. For discriminative (e.g., multi-choice) tasks, we can either formulate all tasks into generation as in GPT/T5 or fine-tune with classifying heads as in BART. With pilot experiments, we found the latter one can achieve better performance and adopted it.

3.4 Comparing to Similar Works

While we adopt the same data processing in EventBERT (Zhou et al., 2021b) and share a similar motivation to learn an event-centric pre-trained model, we expand the scope from '*discriminative-only*' in EventBERT into '*unified*' by our context-to-event Transformer for a broad spectrum of scenarios. Such an expansion is non-trivial since new challenges arise in the unified formulation. Compared to the inefficient '*event-backfilling and contextualizing*' paradigm in EventBERT, our model can explicitly and effectively learn event-level correlations between contexts and events by our novel contrastive and prompt-based objectives. Moreover, COMeT (Bosselut et al., 2019; Hwang et al., 2021) is also a conditional generation model but focuses on triple-level commonsense reasoning – given (*head event*, *relation*) to generate *tail events*, whose motivation, however, is orthogonal to ours. Therefore, we focus on a different motivation or scope, not to mention evaluation formulations.

4 Experiments

This section begins with descriptions of downstream datasets and experimental setups.

Downstream Datasets. We conduct extensive evaluations on 9 datasets for 9 downstream tasks, i.e., 5 generation and 4 classification tasks. Generation tasks include abductive commonsense reasoning on $\mathfrak{ART}$ (αNLG) (Bhagavatula et al., 2020), counterfactual story generation on TIMETRAVEL (Qin et al., 2019), story ending generation (Guan et al., 2019), commonsense story generation (Guan et al., 2020), and event process completion on APSI (Zhang et al., 2020a). Classification tasks include script reasoning on MCNC (Li et al., 2018), abductive commonsense reasoning on $\mathfrak{ART}$ (αNLI) (Bhagavatula et al., 2020), narrative incoherence detection on ROCStories (Mori et al., 2020), and story cloze test (Mostafazadeh et al., 2016). Please refer to Appendix C for their details.

Pre-training Setups. Instead of learning from scratch, we perform continual pre-training from BART-large (Lewis et al., 2020) due to limited computation resources. The batch size and number of training steps are 1152 and 160k. The model is trained by Adam (Kingma and Ba, 2015) w/ learning rate of 1e-5 and warmup proportion of 0.03. The gradient clip, dropout rate and weight decay are 1.0, 0.1 and 0.01. Notably, (i) BOOKCORPUS

Table 2: Fine-tuning results on four classification benchmark datasets. We split pre-trained models into discriminative and unified groups since discriminative models usually outperforms unified ones in classification and our ClarET falls into the latter. Previous SoTA discriminative and unified results are waved and underlined, respectively. See Appendix D.2 for full results.

has already been used by BART pre-training and our data processing is based on heuristics without human-curated resources; (ii) Our continual pre-training only needs 90 GPU hours on 200M tokens, i.e., 0.13% of BART that consumes 70K hours on 2.2T tokens (see Appendix B.1). Hence, ClarET with zero newly introduced corpus and relatively negligible computing overhead makes great lifts and preserves fair comparisons with baselines.

Fine-tuning Setups. For finetuning, we train the model with an Adam w/ learning rate of 1e-5 and warmup proportion of 0.06. The dropout rate, batch size and weight decay are 0.1, 32 and 0.01. For generative downstream tasks, we take BLEU-N (B-N) (Papineni et al., 2002), ROUGE-L (R-L) (Lin, 2004) and BERTScore (BERT) (Zhang et al., 2020c) as the evaluation metrics, while the accuracy (ACC) is taken for classification tasks. Each fine-tuning runs with seeds 2, 10 and 1234, and we evaluate the best dev model on the test set.

4.1 Main Evaluation

Fine-tuning for Generation. As shown in Table 1, our proposed ClarET achieves SoTA performance across all generation tasks. For instance, ClarET increases the ROUGE-L score by 2.3 absolute value for abductive reasoning. The superior performance of ClarET on the benchmarks demonstrates that it can model event-level corre-

lation more effectively via few steps of continual pre-training and provide a general solution for a variety of event-centric correlation reasoning tasks.

Fine-tuning for Classification. Table 2 lists results on 4 classification tasks. We find ClarET performs better than all task-specific models and unified pre-trained models with 2%-4% improvement. It achieves competitive accuracy to strong discriminative models, e.g., the gap between ClarET and EventBERT is ∼0.15 for narrative incoherence detection and story cloze test. However, EventBERT is a RoBERTa-based competitor using the identical pre-training corpus. Its pre-training follows "event-backfilling and contextualizing" (similar to multi-choice QA), which has a small gap to downstream classification tasks for strong performance but brings two drawbacks. Firstly, its pre-training is slow due to repeat contextualizing over paragraphs, leading to 5.6× longer GPU hours than ours. In addition, its discriminative paradigm limits it specifically to classifications, regardless of wide generation tasks. The results show ClarET is on par with the discriminative-only EventBERT on classifications. This is non-trivial given the large formulation gap between our generative pre-training objectives and downstream multi-choice-style classification tasks, and attributed to our effective event-correlation learning. In summary, these results show ClarET serves as a unified pre-trained model for event-centric generation and classification tasks.

4.2 Quantitative Analysis

Zero-shot Learning. It is essential to verify if the targeted information was learned and retained by a pre-trained model. Compared to MLM, our generative recovering model is inherently applicable to event-centric multi-choice and generative formulations. *For generation tasks*, we apply Eq.(1) to generate answers. As shown in Table 3, ClarET achieves the best performance and outperforms DeLorean (which adapts auto-regression for counterfactual reasoning). *For classification tasks*, we apply Eq.(1) to each option for its perplexity and select the option with minimum. As shown in Table 4, ClarET surpasses previous models and beats the discriminative-only event-centric model, EventBERT. Besides, the general-purpose pre-trained models perform nearly random guesses due to their incompetence in long-span event discrimination.

Few-shot Learning. Since our model reduces pretrain-finetune inconsistency for event-centric tasks and provides a good initialization for downstream fine-tuning, it is also interesting to see few-shot performance by scaling down training data. As shown in Figure 3, ClarET achieves similar performance to strong baselines with only 10%-30% of training data for fine-tuning.

Ablation study. To measure the contribution of each objective to the final fine-tuning results, we conduct an ablation study on both generation and classification in Table 5. The first two ablations drop the two prompt schemas respectively in prompt-based event locating objective of Eq.(8), which verifies the effectiveness of reducing task difficulty. Then, the third ablation removes contrastive event-correlation encoding and shows a substantial drop, which verifies the significance of explicit event-correlation learning. Next, we keep only the prompt-based event locating objective to make our model a prompt-learning discrim-

Method	ePPL on Dev
ClarET (full model)	8.27
WER-Only Model	8.76

Table 6: Event generation of ClarET and whole event recovering (WER-only) model on a pre-training event-masked dev set (2% held-out masked paragraphs by following Zhou et al. (2021b)). The 'ePPL', i.e., event perplexity, refers to event-level token perplexity averaged over the dataset.

inative model (sharing more close methodology with EventBERT), however leading to a dramatic decrease. Lastly, when removing all the objectives, our model degenerates to BART-large.

Comparison with Larger Model. A trend of pre-training models follows the law of 'larger models for better performance' but a crucial research question is 'how to perform competitively with fewer computation resources'. To answer, we show extra fine-tuning results on the five generation datasets in Table 7 to compare our ClarET (400M parameters) with T5-large (770M) and T5-base (220M). It is observed (i) with 3× scale, T5-large notably outperforms T5-base to support the above law and (ii) with almost half model size, our ClarET performs very competitively to T5-large (even better on 3 out of 5 tasks), verifying the significance of our objectives towards event-related knowledge.

Difficulty of Event Generation. To exhibit the *learning difficulty* in pre-training (as stated in §3.2.1) and the effectiveness of our novel learning objectives, we conduct another ablation setting in Table 6. It is observed that ClarET achieves better event-level perplexity (ePPL), verifying the two novel objectives promote event generations and reduce difficulty of decoding.

Long-span Event Generation. To further check if ClarET is more competitive on longer-span event generation, we compare it with BART-large and T5-base/-large by '$-\log$' of Eq.(1). Different from recovering paradigm of others, we follow the denoising paradigm to implement BART and calculate its score by considering the masked part in decoding. Figure 4 shows that *(1) Line Chart:* the gap between ClarET and the others becomes larger with event length increasing as the general-purpose models only consider short-span masking in pre-training, leading to inferior event generation; and *(2) Bar Chart:* as for data distribution, although a majority of data falls into the 6-8 bin, there are still many examples with event length greater than nine.

		ACR	CS	SEG	CSG	EPC
	Size	R-L	B-4	B-1	B-1	B-1
T5-base	220M	38.40	81.02	52.64	41.28	56.53
T5-large	770M	40.77	**90.62**	57.04	43.82	**59.59**
ClarET	400M	**41.04**	87.18	**57.47**	**48.75**	58.88

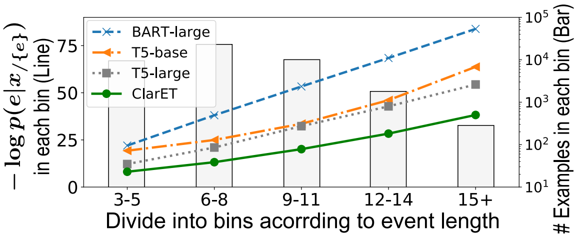

Figure 4: Event generation performance on the event-masked dev set (refer to Table 6) with event-length bins.

Natural Language Understanding (NLU). Our basic model, BART-large, is presented for general NLU tasks. To exhibit our minor event-centric continual pre-training would not interfere its NLU ability, we conduct fine-tuning experiments on GLUE benchmark (Wang et al., 2019) as in Figure 5. It is observed that, although slightly surpassed by the discriminative RoBERTa model, fine-tuning BART and ClarET achieve very comparable results, which verifies ClarET's retention of NLU capability.

4.3 Case Study and Error Analysis

Case Study. As the first case in Figure 6, we conduct a case study on generative abductive reasoning task, where the fine-tuned ClarET generates an event semantically close to the gold reference, but the BART does not. BART only generates a part of the answer but ignores the event-correlations from '*They were impressed with my phone*', while ClarET completely captures the correlations in the

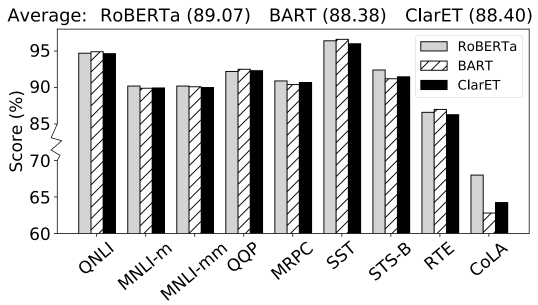

Figure 5: Fine-tuning results on GLUE dev, which verifies ClarET retains BART's natural language understanding ability.

Context: *I went to the store to buy a phone.* ***[E]*** *They were impressed with my phone.*
Reference of the Gold Event ***[E]*****:** *I bought the latest model of the phone I wanted, and showed it to my friends.*
Generation by ClarET:
I bought a new phone and showed it to my friends. (BLEU-4: 34)
Generation by BART:
I bought a new phone. (BLEU-4: 0)

Context: *Cora was starting her job as a kindergarten teacher.* ***[E]*** *At the end of the day, they all told her how much they liked her!*
Reference of the Gold Event ***[E]*****:** *Cora was nervous, but knew the students were nervous too, so she tried to be extra friendly.*
Generation by ClarET:
Cora spent the whole day with her students. (BLEU-4: 0)

Figure 6: Case study & error analysis on abductive reasoning.

contexts (e.g., '*to buy a phone*' and '*They were impressed*',) and generate a much better result.

Error Analysis and Limitation. The second case in Figure 6 shows that our ClarET is ineffective when the gold event is very complicated. In detail, the model focus only on '*at the end of the day*' to generate '... *spent the whole day* ...' but ignore very subtle contexts, e.g., '*starting her job ... teacher*' and '*they liked her*'. To expand, we found a problem in long-event decoding by pilot experiments. As shown in Figure 7, it is observed that the gap of token-level perplexity between ClarET and WER-only gradually diminishes. This is because the subsequent tokens in an event can be generated on the basis of previous generations on the decoder side, rather than context-aware representations from the encoder side. While a long span is masked, the model can see previous tokens in an event (i.e., $e_{<t}$) in decoding and incline to perform the t-th prediction based on $e_{<t}$ but not $x_{/\{e\}}$, especially with a larger t. As a result, the model would 'cheat' in the generation but learn decoder-side language modeling rather than context-aware representations. In the future, we will exploit this problem. Besides, due to computation resources, we choose the model size with 400M and continual pre-training in 90h, limiting the performance.

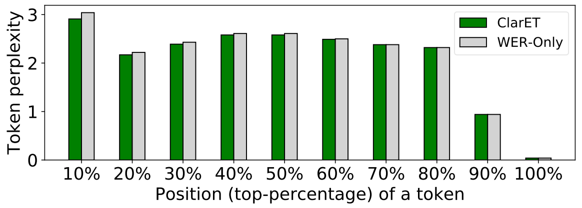

Figure 7: Token-level perplexity w.r.t tokens' percentage positions in events on held-out dev set.

5 Conclusion

We present a novel correlation-aware context-to-event Transformer to self-supervisedly learn event-correlation knowledge from text corpus and benefit various event-centric reasoning scenarios. Besides SoTA fine-tuning results on 5 generation and 4 classification tasks, we conduct zero-/few-shot learning and extensive ablation studies to exhibit our model's effectiveness. Lastly, we find our model is competitive to a twice larger general-purpose model, reduces learning difficulty for event generation, and retains NLU ability from its basic model. Although this work learns context-to-event knowledge, our self-supervised objectives are applicable to other semantically-meaningful text units besides events. For example, text units can be entities and concepts to learn relational and commonsense knowledge, which can benefit more downstream tasks.

6 Ethical Statement

This work does not involve any sensitive data, but only public unlabeled corpora, i.e., BookCorpus (Zhu et al., 2015) pre-processed by Zhou et al. (2021b), and crowd-sourced datasets released in previous works, including $\mathcal{ART}$ (Bhagavatula et al., 2020), TIMETRAVEL (Qin et al., 2019), APSI (Zhang et al., 2020a), MCNC (Li et al., 2018), ROCStories (Mori et al., 2020).

A Examples from Mined Pre-training Corpus

There are some mined pre-training examples shown in Table 8. As in (Zhou et al., 2021b), an example includes a paragraph, events, a selected positive event, connectives of the positive event, and sampled negative events of the positive event.

B More Details

B.1 BART Pre-training Resources

In this section, we analyze BART pre-training resources in terms of text corpora and computation resources.

As for tokens in BART pre-training corpora, BART paper (Lewis et al., 2020) claims using the same corpora as in RoBERTa (Liu et al., 2019) and T5 paper (Raffel et al., 2020) states RoBERTa uses a 2.2T-token text corpus. Thus, we adopt '2.2T' as the number in the main paper.

As for BART pre-training computation overheads, the contributor of BART official code repository said '*We trained for around 11-12 days on 256 gpus.*' at `https://github.com/pytorch/fairseq/issues/1525`, so the BART pre-training takes from 67584 to 73728 GPU hours. Thus, we use '70,000' as the number in the main paper.

B.2 Full Results of T5 Model

The full results of T5-base and T5-large on the five generation tasks are shown in Table 9.

Example 1	
Paragraph	It was only months later, when she saw her friend's thin gaunt face, her swollen belly and her quiet desperation, that she had come to her senses. Then she had been filled with a combination of burning rage and deep shame. This had endured over the years undiminished.
Positive Event	she had been filled with a combination of burning rage
Connectives	when; then
Negative Events	he had been loaded with a lot of vampire venom she had been trained in the art of gentler speech I had been blessed with some sort of fire ability he had been transformed into a piece of living statuary he had beened from a block of pale marble I had been circumci sculptsed in the age of infantile apathy ...

Example 2	
Paragraph	Then, when she turned twenty one at the end of last year, she had decided to act on it. A driver's license was something she needed for her business and the identity papers which went with it were needed for a range of other reasons, such as enrolling Catherine for school at the start of this year.
Positive Event	papers which went with it were needed for a range of other reasons
Connectives	then; when; and
Negative Events	bookcases that stood against it had opened like a pair of French doors it had a little bit of magic in it , just for Lizzie it only gave her a place for a couple of days which occasionally crossed a small ridge sometimes of gravel , sometimes of sand that she was going shopping in the city with a couple of other girls publish that proposal in the paper for three weeks ...

Table 8: Some mined pre-training examples.

	Abductive C.S. Reasoning			**Counterfactual Story**			**Story Ending Generation**		**C.S. Story Generation**		**Event Process Completion**	
	B-4	**R-L**	**BERT**	**B-4**	**R-L**	**BERT**	**B-1**	**B-2**	**B-1**	**B-2**	**B-1**	**B-2**
T5-base	15.65	38.40	55.98	81.02	75.95	79.12	52.64	17.55	41.28	13.76	56.53	18.84
T5-large	17.75	40.77	57.20	90.62	84.03	83.14	57.04	18.45	43.82	14.61	59.59	19.86

Table 9: Full results of T5-base and T5-large on generation tasks.

B.3 Connectives in Paragraph

As stated by Zhou et al. (2021b), connectives (i.e., discourse relations in the contexts) play important roles to express correlations among events. Therefore, we also find every possible connective r to each (x, e) where r is a connective in x, which immediately links to the verb of e on the parsing tree of x. To leverage the connectives, we also apply the correct event selection in prompt-based event locating objective to r its negatives $\{\bar{r}\}_1^M$, as correct connective selection. Here, $\bar{r}$ is randomly sampled from discourse relations in the PDTB annotation manual (Webber et al., 2019). At 20% times, we use correct connective selection to replace correct event selection in the prompt-based event locating objective.

C Details of Evaluation Datasets

We detail the nine evaluation datasets in the following. The training example in each dataset is shown in Table 10.

- $\mathcal{ART}$ (**αNLG).** Given two observations in natural language, it aims to generate an explicative hypothesis between them. We follow the official data split (Bhagavatula et al., 2020) with 169,654/1,532/3,059 in training/dev/test.
- **TIMETRAVEL.** Given an original story and a counterfactual event, it aims to rewrite the subsequent events to complete a story, which is compatible with the counterfactual event. We follow the official data split (Qin et al., 2019) with 98,159/5,613/7,484 in training/dev/test.

- **Story Ending Generation.** We evaluate the story ending generation based on ROCStories, which aims to generate a story ending for a given story context. We follow the data split (Guan et al., 2019) with 90,000/4,081/4,081 in training/dev/test.

- **Commonsense Story Generation.** It is based on ROCStories. Given a leading context, it aims to generate a reasonable story. We follow the data split (Guan et al., 2020) with 88,344/4,908/4,909 in training/dev/test.

- **APSI.** We evaluate event process completion on the APSI dataset, where the goal is to generate a subevent for a given event context. We follow the data split (Zhang et al., 2020a) with 13,501/1,316 in training/test.

- **Multi-choice narrative cloze (MCNC).** Given an event chain, it aims to predict the subsequent event from 5 candidates. We follow the data split (Li et al., 2018) with 140,331/10,000/10,000 in training/dev/test.

- $\mathcal{ART}$ (**αNLI).** Given two observations in natural language, it aims to choose the most explicative hypothesis from 2 candidates. We follow the data split (Bhagavatula et al., 2020) with 169,654/1532 samples in training/dev.

- **ROCStories.** We follow (Mori et al., 2020) to use ROCStories for narrative incoherence detection. A random sentence is removed for each five-sentence story, and the goal is to predict the missing position. We follow the data split (Mori et al., 2020) with 78,528/9,816/9,817 in training/dev/test.

- **Story Cloze Test.** Given a 4-sentence context, it aims to select the right ending from two alternative endings. We follow the data split (Mostafazadeh et al., 2016) with 98,161/1,871/1,871 in training/dev/test.

D Detailed Evaluation Results

We detail the full results on nine evaluation datasets as follows.

D.1 Generation Tasks

Generation tasks include abductive commonsense reasoning (αNLG), counterfactual story generation, story ending generation, commonsense story generation, and event process completion. The detailed results of these generation tasks are shown in Table 11, Table 12, Table 13, Table 14, and Table 15, respectively. ClarET achieves state-of-the-art performance on all five generation tasks. In addition, pre-trained language models show their strong generation ability on story generation tasks, i.e., story ending generation and commonsense story generation.

D.2 Classification Tasks

Classification tasks include script reasoning, abductive commonsense reasoning (αNLI), narrative incoherence detection, and story cloze test. The detailed results of these classification tasks are shown in Table 16, Table 17, Table 18, and Table 19, respectively. Compared with unified language models, ClarET achieves state-of-the-art performance. Although strong discriminative models show their great ability on classification tasks, ClarET still achieves competitive performance.

Dataset 1: $\mathcal{ART}$ (αNLG)	
Input	Observation1: The hayride was in October. Observation2: It was the perfect start to the fall season.
Label	Keeping tradition we drank hot cocoa on the ride.
Dataset 2: TIMETRAVEL	
Input	Premise: On my way to work I stopped to get some coffee. Initial: I went through the drive through and placed my order. Original_ending: I paid the cashier and patiently waited for my drink. When she handed me the drink, the lid came off and spilled on me. The coffee hurt and I had to go home and change clothes. Counterfactual: I went inside to place my order.
Label	I paid the cashier and patiently waited at the counter for my drink. When she handed me the drink, the lid came off and spilled on me. The coffee hurt and I had to go home and change clothes.
Dataset 3: Story Ending Generation	
Input	Dan's parents were overweight. Dan was overweight as well. The doctors told his parents it was unhealthy. His parents understood and decided to make a change.
Label	They got themselves and Dan on a diet.
Dataset 4: Commonsense Story Generation	
Input	Carrie had just learned how to ride a bike.
Label	She didn't have a bike of her own. Carrie would sneak rides on her sister's bike. She got nervous on a hill and crashed into a wall. The bike frame bent and Carrie got a deep gash on her leg.
Dataset 5: APSI	
Input	Process name: Treat Pain. Process: Identify cause. learn injury.
Label	Recognize symptom.
Dataset 6: Multi-choice narrative cloze (MCNC)	
Input	Context: compare basketball. buck get basketball. whirl basketball bench. shout out basketball center. Options: A. look basketball. B. weaken basketball. C. throw basketball lot youngster. D. client deny basketball. E. client deny basketball.
Label	C
Dataset 7: $\mathcal{ART}$ (αNLI)	
Input	Observation1: Chad went to get the wheel alignment measured on his car. Observation2: The mechanic provided a working alignment with new body work. Hypothesis1: Chad was waiting for his car to be washed. Hypothesis2: Chad was waiting for his car to be finished.
Label	2
Dataset 8: ROCStories	
Input	Laverne needs to prepare something for her friend's party. She decides to bake a batch of brownies. Laverne tests one of the brownies to make sure it is delicious. The brownies are so delicious Laverne eats two of them.
Label	3
Dataset 9: Story Cloze Test	
Input	Context: Rick grew up in a troubled household. He never found good support in family, and turned to gangs. It wasn't long before Rick got shot in a robbery. The incident caused him to turn a new leaf. Options: A. He is happy now. B. He joined a gang.
Label	A

Measuring and Mitigating Name Biases in Neural Machine Translation

Jun Wang and **Benjamin I. P. Rubinstein** and **Trevor Cohn**

Abstract

Neural Machine Translation (NMT) systems exhibit problematic biases, such as stereotypical gender bias in the translation of occupation terms into languages with grammatical gender. In this paper we describe a new source of bias prevalent in NMT systems, relating to translations of sentences containing person names. To correctly translate such sentences, a NMT system needs to estimate the gender of names. We show that leading systems are particularly poor at this task, especially for female given names. This bias is deeper than given name gender: we show that the translation of terms with ambiguous sentiment can also be affected by person names, and the same holds true for proper nouns denoting race. To mitigate these biases we propose a simple but effective data augmentation method based on randomly switching entities during translation, which effectively eliminates the problem without any effect on translation quality.

1 Introduction

Natural language processing systems are seeing widespread adoption, prompting careful study into cultural biases they exhibit, and methods for bias mitigation. Gender bias is common in automated systems (Park et al., 2018; Borkan et al., 2019; Stanovsky et al., 2019; Saunders and Byrne, 2020), with a leading cause being training corpora that include far more sentences referring to men than to women. A neural machine translation (NMT) system naïvely trained on such data is more likely to translate text that should be feminine into masculine when translating into a language with grammatical gender. Previously, researchers (Stanovsky et al., 2019; Escudé Font and Costa-jussà, 2019; Saunders and Byrne, 2020; Stafanovics et al., 2020) have demonstrated that NMT systems can still be biased even when there are explicit gender pronouns in the input sentences.

NMT systems are not only biased for gender, and gender bias is not limited to gender pronouns. Other biases include racial biases, professional biases, and individual biases, among others. In this paper, we focus on two kinds of biases of *person name translations* by NMT systems: gender biases and sentiment biases. As an important category of named entity, person names are particularly sensitive to translation errors since they refer to real-world individuals, and systematic biases may cause serious distress to users, and reputational damage, libel or other legal consequences for vendors.

Gender bias in the translation of person names is a natural extension of gender biases in previous work. For instance, (Stanovsky et al., 2019; Escudé Font and Costa-jussà, 2019; Saunders and Byrne, 2020; Stafanovics et al., 2020) considered whether translation systems can translate keywords such as occupation terms into the correct form when there is explicit gender information in the text. This paper can be seen as replacing this explicit gender information (pronouns) with implicit gender information (person names), to test whether an NMT system can correctly determine the gender of a name. Our results indicate that NMT systems often mistakes female names for males, but the reverse is rarely seen; a situation that may cause widespread offence.

Biases pertaining to sentiment of sentences containing person names have been studied in sentiment analysis (Kiritchenko and Mohammad, 2018), where model predictions of sentiment are sensitive to changing the person name. We present a method for detecting sentiment bias in translation based on the translation of sentiment ambiguous words, where the system must choose between a commendatory and derogatory translation (*e.g.*, *proud* can mean either satisfied or arrogant about one's achievements). When the correct translation is not clear from the context, NMT systems use the person name to decide. When this occurs consistently

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2576 - 2590
May 22-27, 2022

towards a specific sentiment, this can result in insidious bias against (or towards) individuals (or as we also show, racial groups.)

To mitigate the above biases against person names in translation, we propose a data-augmentation method 'switch-entity' (SE), which works by altering training sentences containing named entities by randomly switching the entities for other entities of the same type (*e.g.*, with matching gender). This simple strategy normalises the distribution of named entities, such that all names are observed sufficiently many times and in a diverse range of contexts. This ensures gender signals are learned correctly, and also stops the translation system from associating the name with idiosyncracies of the contexts in which is appears, thus mitigating sentiment bias. Modifying the training data carries the risk of degrading sentence quality, and thus degrading accuracy. Although replacing a named entity with another does change sentence meaning, it is unlikely to compromise grammaticality or render the sentence semantically incoherent. Our results show that SE beneficially mitigates gender bias when translating names into gendered languages, which we show leads to more accurate morphological inflection in sentences with female entities. At the same time, it does not sacrifice accuracy: the BLEU score of the SE-trained model is the same as for standard training.

Our contributions:

- We show two new biases for person names in NMT, relating to gender and sentiment.
- Using constructed templates we show this is a widespread problem affecting state-of-the-art NMT systems.
- We propose a data augmentation method, switch-entity, to mitigate these biases in training, without the need for extra data.

2 Gender bias on names

In languages with rich grammatical gender, the gender of people referenced in a sentence will often affect the morphology of the other words in the sentence. For example, "[PER] is a Royal Designer" translates into German as either

Masc. [PER] ist *ein königlicher Designer*; or

Fem. [PER] ist *eine königliche Designerin.*

where gender agreement holds between the person (PER) and the determiner, adjective and occupation noun. Accordingly, knowing the gender of the person is critical when translating from a language like English, where gender is rarely marked, into a gendered language. Ignoring this issue will affect the quality of outputs, and consistent mistakes can constitute a form of gender bias. Previous works (Stanovsky et al., 2019; Escudé Font and Costa-jussà, 2019; Saunders and Byrne, 2020; Stafanovics et al., 2020) showed that NMT systems exhibit gender biases, due to a large skew towards male persons in the training data, resulting in NMT systems producing gender agreement mistakes when translating sentences containing a feminine pronoun. A more complex situation arises when presented with person names: gender is not explicitly marked, but is only implied, and the translation system must deduce the gender in order to correctly inflect the translation.[1] Being able to correctly translate sentences with gender pronouns does not guarantee the correct translation of name sentences, as illustrated in the examples in Table 1.

Input (English)	Translation (German)
She is the developer of the company.	*Sie* ist *die Entwicklerin* der Unternehmens.
Gloria is the developer of the company.	*Gloria* ist **der Entwickler** der Unternehmens.
He wants to be an excellent dancer.	Er möchte **ein** *hervorragende* **Tänzer** sein.
Reggie wants to be an excellent dancer.	**Reggie** möchte *eine hervorragende Tänzerin* sein.

Table 1: Translation examples from the Fairseq `wmt19.en-de` model. *Italic* means female terms and **bold** means male terms, errors underlined.

2.1 Template for person name bias

Here, we propose an evaluation method for assessing whether gender is translated accurately for English→German and English→French. We created a range of templates encoding various syntactic relations which require gender agreement, and assess whether the translation includes the correct morphological inflection (*e.g.*, for the above, the choice between *Designer* vs. *Designerin*). Table 2 shows a selection of the 30 templates we use for measuring the accuracy of gender agreement. Each template includes a person name slot, which we replace with a name from a list of male and female names.

---

[1] Without additional resources, gender deduction will never be perfect. A natural extension would include named entity linking to a knowledge base which stores gender inflection and pronouns for each individual.

Template input English sentence	German		French	
	Masculine	Feminine	Masculine	Feminine
[**PERSON**] is the developer of the Sexual Compulsivity Scale.	Entwickler	Entwicklerin	développeur	développeuse
[**PERSON**] trained as a school teacher for Estonian and Sport.	Lehrer	Lehrerin	d'enseignant	d'enseignante
[**PERSON**] is a citizen of St. Gallen and Neunkirch.	Staatsbürger	Staatsbürgerin	citoyen	citoyenne
Among the families was the physicist [**PERSON**] who survived the war.	Physiker	Physikerin	physicien	physicienne
[**PERSON**] is the author of numerous essays as well as creative works	Autor	Autorin	auteur	auteure

Table 2: Selection of templates used for the gender test. A person name is substituted for [**PERSON**] in each of the above, and the sentence is given as input to a translation system. The translation for the underlined noun is compared to the masculine or feminine noun, to check for gender agreement with the person name. See Appendix Table 10 for the complete list. Sentences are adapted from Wikipedia (CC BY-SA).

The main body of the grammatical gender system is the name, and it forms an agreement system with other verbs, articles and adjectives. Words will change to some extent (usually inflectional affixes) according to gender. For example, in German, feminine occupation nouns end with 'in'. In our test, we check whether the translation includes the correct form of the underlined noun, which should agree with the gender of the person. Strictly speaking, for the translation to be perfect, other words in the translation will also require gender agreement, however for the sake of simplicity we limit our attention to the noun. From visual inspection, when the form of the noun is correctly predicted most often means all tokens have correct gender agreement.

2.2 Evaluation

To evaluate gender bias with respect to names, we must first account for the confound of bias on key nouns. For example, some en-de models always translate "teacher" into feminine form "Lehrerin", and never the masculine form. Thus for these models a test template for "teacher" will not help to measure gender bias for names. Thus, we first filter the templates using the pronouns "he" and "she" and remove from consideration all templates for the which key noun only has one translation. Then we tested each machine translation system with these filtered templates using a set of 200 full names and 200 first names.

Metrics: We measure accuracy, Acc, the proportion of the number of key nouns are translated into the correct form to the total number of templates tested, to evaluate name gender bias. We report the mean accuracy for male and female names separately, denoted Acc_m and Acc_f, respectively, as well as the absolute difference between these scores, denoted $\triangle Acc$.

Names: Generally speaking, a name may be first name, last name or full name. The last name usually does not carry gender information, so we only tested the first name and full name (full lists of names are in the Appendix, Table 12). For first names, we used a data set of first names and their frequencies from U.S. births.[2] We find the set of names with obvious gender, where the frequency of one gender is more than three times that of the other, and the absolute value of the difference is more than 100. We reduce this list to 100 female and 100 male names by selecting for each gender the top 1000 names by frequency then randomly sampling 100 names uniformly. Full names were extracted from the ParaCrawl corpus, and the U.S. births data set was used to label their gender based on the first name, the names were filtered as above, and finally we randomly selected 100 names each male and female. Note that this process is limited to binary gender, but could feasibly be extended to non-binary gender with the right resources, which we leave to future work.

Language and Models: We tested English→German and English→French, chosen based on English not having grammatical gender while German and French both do. In both settings we compare three online translation systems,[3]

Table 3: Gender agreement test results for various NMT models. BLEU score reported on wmt18 test set for en-de and wmt14 test set for en-fr.

Sentence (English)	Translation (Chinese)
Alice's speech is very sensational. James's speech is very sensational.	爱丽丝的演讲非常耸人听闻[appalling]。 詹姆斯的演讲非常轰动[startling]。
Alice is slack. James is slack.	爱丽丝很懒散[lazy]。 詹姆斯很闲[leisurely]。
Alice concocted this plan. James concocted this plan.	爱丽丝编造[fabricate]了这个计划。 詹姆斯制定[formulate]了这个计划。

Table 4: Translation examples from **Online A**, negative words mark with under-wave and positive words mark with underline. The system is biased towards James over Alice.

off-the-shelf pretrained research systems, and several custom trained models. Overall the systems cover both transformer and convolutional network architectures, and are trained over different corpora. Please see Appendix A for further details.

2.3 Results

The test results are shown in Table 3, it can be clearly seen that the NMT system favours male names, with all results far better than for female names, even for the commercial translation systems. The smallest $\triangle Acc$ is as high as 13.7%. However, better performance does not guarantee fewer biases, the BLEU value of *custom.wmt18* is higher than *transformer.wmt16*, but both first name and full name Acc_f are lower. All models perform better on full names than first names, it may be because there are more uncommon names in the first names, and full names will contain more information. *conv.wmt17* has a large bias, it barely detects the female names at all. Compared with *custom.iwslt17*, which also has a high bias, *conv.wmt17* uses much larger corpus and its predictive performance is much higher than *custom.iwslt17*. Such a high bias may be caused by the convolutional architecture, which cannot capture word level phenomena as well as the transformer. Comparing two en-fr *wmt14* models, the evaluation results of *conv* model is also worse than transformer model. In general, the larger corpus, the less the name bias is present. This is because the larger the amount of data, the model is exposed to more names, and can better distinguish their gender. However, obtaining more data is usually not easy, especial for low-resource language.

3 Sentiment biases

In NMT training corpora, names appear in different contexts, which can result in sentiment biases for specific names. For instance, a popular celebrity is likely to appear in many more positive sentiment contexts than a reviled mafioso, which may mean a NMT system mistakenly associate person names with translation sentiment. We set about measuring whether this manifests in NMT output using templated ambiguous contexts in English in which the ambiguity must be resolved when translating into the target language. To do so we use *sentiment ambiguous words*: a kind of homograph which has both commendatory and derogatory meanings. This is illustrated in Table 4, which shows a translation system is biased towards James over Alice. We chose a cross-language family translation of English→Chinese for this experiment, inspired by the work of Si et al. (2019).

3.1 Templates for sentiment biases

Si et al. (2019) constructed ambiguous test sentences based on 110 sentiment ambiguous words. Starting with their list, we filtered out words that did not fit with PERSON entities, leaving 30 words. We then constructed a template for each word to test for sentiment bias on names. Table 5 show a selection of the templates (see also Table 11 in the Appendix for the full set). We kept the sentences

---

denote them as A-C.

Template en sentence	**Positive/Negative**
[PERSON] is so proud.	自豪[satisfaction] 骄傲[arrogant]
[PERSON] is very slick.	圆滑[flexible] 狡猾[cunning]
[PERSON]'s speech is very sensational.	轰动[startling] 耸人听闻[appalling]
[PERSON] used tricks to win the game.	技巧[skill] 诡计[deception]

Table 5: A selection of templates for the sentiment biases test. Some sentences adapted from Si et al. (2019).

simple since we want to eliminate the influence of context, and thereby assess how person names affect the translations of sentiment ambiguous words.

3.2 Evaluation

We conducted similar evaluation progress as gender agreement test (Section 2.2). The labelled translation words shown in the Table 5 present some examples. Because en-zh translation has high entropy, words can have many different translations and the use of dictionaries often fails to cover all possibilities. Therefore, when using these templates, we manually check the translation results and add any new translations to our inventory of positive and negative words.

Metrics We have two evaluation metrics for names' sentiment tendencies: word-level positiveness t and sentence-level positiveness s. The word-level positiveness is evaluated by checking the translations of sentiment ambiguous words, calculating the ratio of the number of sentences that sentiment ambiguous words translated to positive words, to the total number of template sentences. The sentence-level positiveness is scored by a sentiment analysis classifier (Tian et al., 2020), applied to the translation to get the probability the sentence is a positive sentence,[4] after which we report the mean score over the 30 templates for each name.

In order to measure the overall degree of sentiment bias of models, we report the highest and lowest mean scores among all person names, as well as the gap between these values, denoted $\triangle t$ and $\triangle s$ for word and sentence level, respectively.

System	t_{min}	t_{max}	$\triangle t$	s_{min}	s_{max}	$\triangle s$
Online A	0.47	0.67	0.20	0.40	0.49	0.09
Online B	0.40	0.70	0.30	0.38	0.57	0.20
Online C	0.43	0.60	0.17	0.46	0.65	0.09
opus.en-zh	0.23	0.50	0.27	0.23	0.38	0.15
wmt17	0.26	0.67	0.40	0.40	0.67	0.27

Table 6: The sentiment biases test results on five NMT systems. Sentiment is measured as the word (t) and sentence (s) level, and we report the average score for the minimum and maximum scoring person names, as well as their difference Δ.

Names For sentiment biases, we used the full names of celebrities, for which we expect sufficient data for NMT systems to learn biases. We selected the top 10 popular male celebrities and 10 female celebrities across 7 different occupations (see list in Table 13 in the Appendix). We expect different professions to have a substantial impact on training contexts, which may result in different degrees of bias.

Gender, race and nationality Our templates can be used not only to test names but also to test other sentiment biases, such as gender, race and nationality. We used 8 different races and nationalities to fill the templates, which we minimally adapted to ensure they are grammatically correct. Additionally, we add "man" or "woman" (*e.g.*, "Asian men") to measure intersectional racial and gender bias.

Models We tested three commercial systems, as before; and two research models: a pretrained model `opus.en-zh` and a custom transformer model `custom.wmt17` trained with wmt17 en-zh corpus.

3.3 Results

Overall bias Table 6 shows the results of the sentiment bias test for several en-zh NMT systems. [5] It can be seen that *wmt17* has the largest bias, and **Online C** the smallest, although even this system has a substantial range of sentiment with $\triangle t = 0.17$. The *opus.en-zh* trained system is uniformly more negative than the other systems.

Biases per profession and gender We further split the results by occupation and gender, as shown in Figure 1 for **Online A**. From this it is clear that some occupations are more positively translated than others (*e.g.*, atheletes vs. actors/actresses) and

---

[4] To remove potentially confound bias from the sentiment classier, we masked PERSON names, replacing all names with masculine pronouns "他"[en: he]. For example, when we use sentiment analysis to score translation "爱丽丝很自豪。", we first convert sentence into "他很自豪。"

[5] The BLEU score of opus.en-zh and wmt17 on newstest2017 is 26.19 and 34.87, respectively.

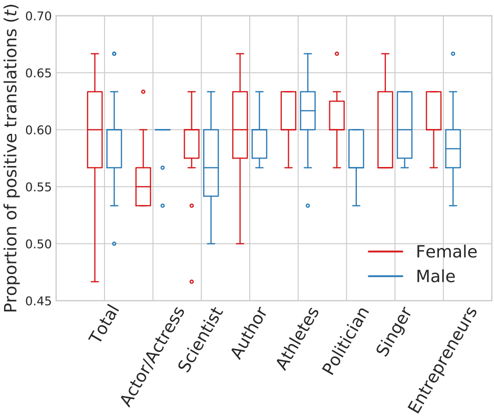

Figure 1: Sentiment bias for celebrities, split by professional group and gender, based on **Online A**.

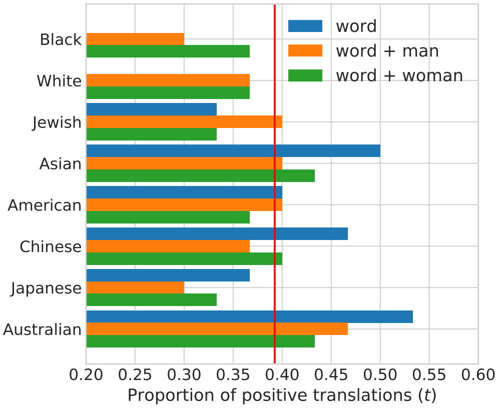

Figure 2: The results of sentiment bias test on race and nationality from **Online A**, 'Black' and 'White' does not have self form cause the translation system treats them as colours. The red line shows the mean value.

in some professions there appears to be evidence of gender bias, such as preferential treatment of actors over actresses, and female politicians and entrepreneurs over their male counterparts. Overall there is limited evidence for general gender bias, as the average scores for male and female entities are similar, but note that the results for men is more concentrated than for women, which is more polarized.

Biases on race and nationality The results for testing race and nationality terms are shown in Figure 2, which overall shows that race and nationality have substantial influence on translation sentiment. "Black man" and "Japanese man" have the most negative results, and "Asian" and "Australian" the most positive. There is no consistent evidence of gender bias, however it is surprising that there is often a sizeable (mostly positive) difference between using a race or nationality term on its own versus its use alongside a gender term (man/woman).

4 Mitigating biases

Bias in NMT models are mainly caused by the training data, which is typically unbalanced, *e.g.*, females are much rarer than males in the training corpus, leading to gender bias. One simple way to balance out gender biases is to add a number of female data to balance the ratio of male to female sentences. However, obtaining new data can be difficult, especially for low-resource languages. Here, we propose a data augmentation method that does not require additional data, SWITCHENTITY. By switching names in the training corpus, the model can train with more correct translation patterns about female names, so that the model can correctly identify the gender of the name, and achieve the effect of reducing biases. This method can be applied not only to PERSON entities, but also to other classes of named entities.

4.1 The SWITCHENTITY method

Let $\langle x_t, y_t \rangle$ be the language pair containing the named entity t and $\langle t_x, t_y \rangle$ be the named entity pair. L_l^e be the candidate list of named entities, where e is the entity type and l the language. The replacement candidate list L can be obtained from different resources. Here we present a method to extract L from the original corpus, NER models (at least one side) and alignment tool are required:

1. Use NER to identify named entities on both the source and target sentences;[6]
2. Perform automatic word-alignment over the parallel corpus; and
3. Use the alignment to find the corresponding $\langle t_x, t_y \rangle$, which form a named entity pair.

To ensure precision in step 3 we adopt a conservative approach: If some aligned tokens of a named entity are parts of a named entity in the other language with the same type, they will be regarded detected as a pair. One further step is performed only on person entities, where this category is further split into male and female classes based on the person's given name, if available.

Once the candidate list of entities has been computed, the last step in applying SE involves switching each of the named entities identified above with another named entity during each epoch training,

---

[6] The method also works with NER on one side only, but it may sacrifice precision.

which is drawn uniformly from the set of entities of the same type (and gender, when considering persons). To illustrate, in the following we switch out “Al Gore” for “JAY-Z”:

(1) Candidate Al Gore concedes the US election.
Kandidat Al Gore räumt die US-Wahlen ein.

(2) Candidate JAY-Z concedes the US election.
Kandidat JAY-Z räumt die US-Wahlen ein.

In corpora, the distribution of names is usually skewed such that the majority of names have very low frequency, and these names are not well learned by the model. SE has the effect of flattening the distribution over entity strings, while preserving the natural distribution over entity types, ensuring the model focuses more on learning to translate names in the tail.

Switching any parts of a training sentence carries the risk of corrupting the data, both grammatically and semantically, and this will depend on the granularity of named entity labels. Switching named entities with others of the same type is key to maintain the sentences’ quality. For instance, if we mistakenly switch male and female names, it will corrupt training and may result in gender agreement mistakes in translation. In the example shown above, we cannot switch “Al Gore” with a female name without changing “Kandidat” from masculine to feminine gender. For this reason we refine the PERSON entity category to include gender, and only switch like-gender entities.

4.2 Experiments

We experimented with SE on the three custom models we mentioned in Section 2, use the same training configuration (see Appendix A for details).

Quality of translation First, we test whether SE has an effect on translation accuracy. In terms of BLEU score, Table 7 shows SE has a negligible effect versus a vanilla baseline over both languages. Inspection of the translation outputs (see Table 9 in the Appendix) shows that the translations for the SE and vanilla models are overall very similar, exhibiting changes in case, entity translation and transliteration, as well as morphological inflection.

Gender detection Table 7 show that SE has a substantial effect on gender inflection when both translating en→de and en→fr. SE shows marked improvements for females for both IWSLT (+14.4% accuracy) and WMT (+27.3% accuracy), at the expense of a small drop for males (-2.9% and -3.3%, respectively). Our method goes some way to addressing the significant bias towards males in these NMT systems (especially true of WMT), which reflect the large gender skew in their training corpora. For the two IWSLT tasks, the training corpora are small and the models show substantial gender bias in general, not only pertaining to name gender detection. Therefore, the SE method has a significant effect of mitigating biases for those models (increasing the accuracy of female name gender by between 7 and 25 times for en→fr and en→de, respectively), but despite these improvements the bias remains large.

	Model	BLEU	Acc_f	Acc_m
IWSLT17 en→de	Vanilla	19.8	0.01	0.99
	SE	19.5	0.15	0.96
WMT18 en→de	Vanilla	38.1	0.51	0.96
	SE	38.3	0.79	0.93
IWSLT16 en→fr	Vanilla	25.4	0.02	1.00
	SE	25.5	0.16	0.97

Table 7: Performance comparison of models between vanilla training and SE training, showing BLEU score (on wmt18 and wmt14 test sets, for de and fr, resp.), and gender agreement accuracy for female and male entities, using full names and the templates from §2.1

.

Although SE does not introduce the new female training samples, it does balance the frequency of female names, such that contexts of high-frequency female names are shared with low-frequency female names, thereby better training the NMT model to learn general gender cues.

Sentiment bias We also tested SE on sentiment biases, the results show SE can help to mitigate sentiment biases on names, with $\triangle t$ reducing from 0.40 to 0.21. This is because training with SE means PERSON names will have chance to appear in different contexts during training, instead of may only appearing in a specific context like vanilla training, which can help to reduce the model’s stereotype of names. We did not attempt to use SE to mitigate race or nationality biases, although in principle this could be possible using the method.

5 Related work

Gender bias is a central concern in machine translation research. Stanovsky et al. (2019) introduced the WinoMT challenge data set from the study of coreference gender bias (Zhao et al., 2018;

Rudinger et al., 2018) to test the gender bias of machine translation systems. Researchers tried many different methods to mitigate gender bias. Saunders and Byrne (2020) and Costa-jussà and de Jorge (2020) both used transfer learning to reduce gender bias by fine-tuning models with a small gender-balanced data set. Stafanovics et al. (2020) annotated source language sentence with grammatical gender information from target language to reduce the stereotype of gender for translation systems. Escudé Font and Costa-jussà (2019) used word embedding techniques, debiased the word embedding and then used these embeddings in training translationn models from scratch. All of this work was focused on sentences with gender pronouns, studying whether translation systems can correctly determine the grammatical gender of the words associated with gender pronouns. The gender bias we proposed in this paper is focused on names with implicit gender information.

Other social biases and stereotypes have also been investigated. Kiritchenko and Mohammad (2018) evaluated gender and race biases on two hundred sentiment analysis systems, similar to our work, they also tested the influence of names on biases. Davidson et al. (2019) examined racial biases on a hate speech task, finding that tweets written in African-American English are more likely to be marked as offensive than tweets written in Standard American English. Rudinger et al. (2017) used pointwise mutual information to evaluate over the SNLI natural language inference data set, and uncover a wider range of biases, including gender, age, race, and nationality. Shwartz et al. (2020) is the closest to our work, they evaluated the sentiment bias in a language generation model on given names, finding evidence of bias whereby generated sentences related to specific given names being more negative than others.

Our mitigation method SwitchEntity is based on data augmentation. Similar methods of entity switching have been proposed for named entity recognition (NER), either for data augmentation in training to increase model coverage over named entities (Agarwal et al., 2020); or during testing as a diagnostic tool to model generalization (Dai and Adel, 2020). Wang et al. (2018) proposed more general methods of random lexical substitutions for NMT, which designed to improve translation performance. Song et al. (2019) use data augmentation for name entity translation by replacing source words with their corresponding target translation.

6 Conclusion

In this paper, we revealed two biases in the NMT systems, gender biases and sentiment biases against names. Our results show that the existing research models and commercial translation systems have serious biases, which not only affects translation quality, but also have ethical implications on fairness and bias. In order to mitigate biases, we proposed SwitchEntity, a simple training strategy which can reduce name biases without the need for any additional data.

7 Ethical considerations

We discuss ethical considerations and limitations of our work. First, we focus solely on binary gender, as this can be directly observed in many languages with grammatical gender. Our use of binary gender is not intended to promulgate an inappropriate binary gender focus, but rather allows the study of gender bias in translation, based on the text contained in translation corpora. Admittedly our method has limitations, for instance, it will not be able to adequately handle trans-gendered and non-binary individuals; to do so would require substantial additional translation corpora, as well as extensions to the technique, which we leave for future research. Second, we evaluate only a small number of language pairs, but we expect similar behaviour for translation into many other gendered languages, the exploration of which we leave for future work.

A Models and Training configuration

For English→German, we evaluated a range of models, the pre-trained models being: `transformer.wmt19`, `transformer.wmt16` and `conv.wmt17` from FairSeq;[7] and custom models: `custom.wmt18` and `custom.iwslt17`, those two models were trained on the WMT18 en-de corpus and the IWSLT17 en-de corpus respectively. For English→French, we compare two pretrained models `conv.wmt14` and `transformer.wmt14` and a custom model, `custom.iwslt16`. For all custom models we use the FAIRSEQ(Ott et al., 2019) transformer models with byte-pair encoding (Sennrich et al., 2016) for tokenization.

For the IWSLT tasks, we used 16,384 joint vocabulary and the training configuration we follow FairSeq's translation example;[8] For the WMT tasks, 30k joint vocabulary was used and the training configuration we follow (Edunov et al., 2018). The statistics summary of training datasets are shown in Table 8.

Dataset	#train	#valid	#test
IWSLT2017 (de-en)	209.5k	8,967	1,138
WMT18 (de-en)	5.9m	59,326	2,000
IWSLT2016 (en-fr)	218.3k	5,519	2,213
WMT17 (en-zh)	8.5m	8,856	2,679

Table 8: Statistics of the datasets for training.

B Auxiliary tools

To perform SE, we need NER models for both parallel setting and monolingual setting, and need an alignment tool for parallel setting. Here, we used **SpaCy** to recognized named entities, `en_core_web_trf` for English and `de_core_news_lg` for German `fr_core_news_lg` for French. We used **fast align** (Dyer et al., 2013) for alignment parallel data, run in both directions and symmetrized using `grow-diag-final-and` to get the final alignment.

Abstract

In this paper, we present a substantial step in better understanding the SOTA sequence-to-sequence (Seq2Seq) pretraining for neural machine translation (NMT). We focus on studying the impact of the jointly pretrained decoder, which is the main difference between Seq2Seq pretraining and previous encoder-based pretraining approaches for NMT. By carefully designing experiments on three language pairs, we find that Seq2Seq pretraining is a double-edged sword: On one hand, it helps NMT models to produce more diverse translations and reduce adequacy-related translation errors. On the other hand, the discrepancies between Seq2Seq pretraining and NMT finetuning limit the translation quality (i.e., domain discrepancy) and induce the over-estimation issue (i.e., objective discrepancy). Based on these observations, we further propose simple and effective strategies, named in-domain pretraining and input adaptation to remedy the domain and objective discrepancies, respectively. Experimental results on several language pairs show that our approach can consistently improve both translation performance and model robustness upon Seq2Seq pretraining.

1 Introduction

There has been a wealth of research over the past several years on self-supervised pre-training for natural language processing tasks (Devlin et al., 2019; Liu et al., 2019; Conneau et al., 2020; Jiao et al., 2020a), which aims at transferring the knowledge of large-scale unlabeled data to downstream tasks with labeled data. Despite its success in other understanding and generation tasks, self-supervised pretraining is not a common practice in machine translation (MT). One possible reason is the architecture discrepancy between pretraining model (e.g., Transformer **encoder**) and NMT models (e.g., Transformer **encoder-decoder**).

To remedy the architecture gap, several researchers propose sequence-to-sequence (Seq2Seq) pretraining models for machine translation, e.g., MASS (Song et al., 2019) and BART (Zhu et al., 2019; Lewis et al., 2020). Recently, Liu et al. (2020) extend BART by training on large-scale multilingual language data (i.e., mBART), leading to significant improvement on translation performance across various language pairs. While previous pretraining approaches for NMT generally focus only on Transformer encoder (Lample and Conneau, 2019), mBART pretrains a complete autoregressive Seq2Seq model by recovering the input sentences that are noised by masking phrases. One research question naturally arises: *how much does the jointly pretrained decoder matter?*

In this work, we present a substantial step in better understanding the SOTA Seq2Seq pretraining model. We take a fine-grained look at the impact of the jointly pretrained decoder by carefully designing experiments, which are conducted on several WMT and IWSLT benchmarks across language pairs and data scales using the released mBART-25 model (Liu et al., 2020). By carefully examining the translation outputs, we find that (§ 2.2):

- Jointly pretraining decoder produces more diverse translations with different word orders, which calls for multiple references to accurately evaluate its effectiveness on large-scale data.
- Jointly pretraining decoder consistently reduces adequacy-related translation errors over pretraining encoder only.

Although jointly pretraining decoder consistently improves translation performance, we also identify several side effects due to the discrepancies between pretraining and finetuning (§2.3):

- **domain discrepancy**: Seq2Seq pretraining model is generally trained on general domain

data while the downstream translation models are trained on specific domains (e.g., news). The domain discrepancy requires more efforts for the finetuned model to adapt the knowledge in pretrained models to the target in-domain.

- **objective discrepancy**: NMT training learns to translate a sentence from one language to another, while Seq2Seq pretraining learns to reconstruct the input sentence. The objective discrepancy induces the over-estimation issue and tends to generate more hallucinations with noisy input. The over-estimation problem along with more copying translations induced by Seq2Seq pretraining (Liu et al., 2021) make it suffer from more serious beam search degradation problem.

To remedy the above discrepancies, we propose simple and effective strategies, named in-domain pretraining and input adaptation in finetuning (§3). In in-domain pretraining, we propose to reduce the domain shift by continuing the pretraining of mBART on in-domain monolingual data, which is more similar in data distribution with the downstream translation tasks. For input adaptation, we add noises to the source sentence of bilingual data, and combine the noisy data with the clean bilingual data for finetuning. We expect the perturbed inputs to better transfer the knowledge from pretrained model to the finetuned model. Experimental results on the benchmark datasets show that in-domain pretraining improves the translation performance significantly and input adaptation enhances the robustness of NMT models. Combining the two approaches gives us the final solution to a well-performing NMT system. Extensive analyses show that our approach can narrow the domain discrepancy, particularly improving the translation of low-frequency words. Besides, our approach can alleviate the over-estimation issue and mitigate the beam search degradation problem of NMT models.

2 Understanding Seq2Seq Pretraining

In this section, we conduct experiments and analyses to gain a better understanding of current Seq2Seq pretraining for NMT. We first present the translation performance of the pretrained components (§2.2), and then show the discrepancy between pretraining and finetuning (§2.3).

2.1 Experimental Setup

Data. We conduct experiments on several benchmarks across language pairs, including high-resource WMT19 English-German (W19 En-De, 36.8M instances), and low-resource WMT16 English-Romanian (W16 En-Ro, 610K instances) and IWSLT17 English-French (I17 En-Fr, 250K instances). To eliminate the effect of different languages, we also sample a subset from WMT19 En-De (i.e., W19 En-De (S), 610K instances) to construct a low-resource setting for ablation studies.

For the proposed *in-domain pretraining*, we collect the NewsCrawl monolingual data as the in-domain data for WMT tasks (i.e., 200M English, 200M German, and 60M Romanian), and the TED monolingual data for IWSLT tasks (i.e., 1M English and 0.9M French). Since the monolingual data from TED is rare, we expand it with pseudo in-domain data, OpenSubtitle (Tiedemann, 2016), which also provides spoken languages as TED. Specifically, we use the latest 200M English subtitles and all the available French subtitles (i.e., 100M). We follow Liu et al. (2020) to use their released sentence-piece model (Kudo and Richardson, 2018) with 250K subwords to tokenize both bilingual and monolingual data. We evaluate the translation performance using the SacreBLEU (Post, 2018).

Models. As for the pretrained models, we adopt the officially released mBART25 model (Liu et al., 2020)[1], which is trained on the large-scale CommonCrawl (CC) monolingual data in 25 languages. As a result, the vocabulary is very large in mBART25, including 250K words. mBART uses a larger Transformer model which extends both the encoder and decoder of Transformer-Big to 12 layers. We use the parameters of either encoder or encoder-decoder from the pretrained mBART25 for finetuning. Then, in the following section, we use pretrained encoder, and pretrained encoder-decoder for short. We follow the officially recommended finetuning setting with dropout of 0.3, label smoothing of 0.2, and warm-up of 2500 steps. We finetune on the high-resource task for 100K steps and the low-resource tasks for 40K steps, respectively.

We also list the results of vanilla Transformer without pretraining as baseline. The vocabulary is built on the bilingual data, hence is much smaller (e.g., En-De 44K) than mBART25. Specifically, for high-resource tasks we train 6L-6L Transformer-Big with 460K tokens per batch for 30K steps, and

Table 1: BLEU scores on MT benchmarks. "Enc:×, Dec:×" represents that we use only the pre-trained embeddings for fair comparisons, and we highlight performance improvement over this setting in red color.

for low-resource tasks we train 6L-6L Transformer-Base with 16K tokens per batch for 50K steps.

2.2 Impact of Jointly Pretrained Decoder

The main difference of Seq2Seq pretraining models (e.g., mBART) from previous pretraining models (e.g., BERT and XLM-R) lies in whether to train the decoder together. In this section, we investigate the impact of the jointly pretrained decoder in terms of BLEU scores, and provide some insights on where the jointly pretrained decoder improves performance.

Translation Performance. Table 1 lists the BLEU scores of pretraining different components of NMT models, where we also include the results of NMT models trained on the datasets from scratch ("no pretrain"). For fair comparisons, we use the same vocabulary size for all variants of pretraining NMT components. We use the pretrained word embedding for the model variant with randomly initialized encoder-decoder ("Enc:×, Dec:×"), which makes it possible to train 12L-12L NMT models on the small-scale datasets. Accordingly, the results of ("Enc:×, Dec:×") is worse than the "no pretrain" model due to the larger vocabulary (e.g., 250K vs. 44K) that makes the model training more difficult.

Pretraining encoder only ("Enc:✓, Dec:×") significantly improves translation performance, which is consistent with the findings in previous studies (Zhu et al., 2019; Weng et al., 2020). We also conduct experiments with the pretrained encoder XLM-R (Conneau et al., 2020), which achieves comparable performance as the mBART encoder (see Appendix A.1). For fair comparisons, we only use the mBART encoder in the following sections. Encouragingly, jointly pretraining decoder can further improve translation performance, although the improvement is not significant on the large-scale WMT19 En-De data. These results seem to provide empirical support for the common cognition – pretraining is less effective on large-scale data. However, we have some interesting findings of the generated outputs, which may draw different conclusions. To eliminate the effect of language and data bias, we use the full set and sampled subset of WMT19 De⇒En data as representative large-scale and small-scale data scenarios.

(×, ×)	It accuses (the) adults of children trafficking.
(✓, ×)	She accuses the adults of children trafficking.
(✓, ✓)	She accuses the adults of trafficking in children.
	Small-Scale Data
no pre.	It accuses the adults to trade children.
(×, ×)	It requires adult trafficking on children.
(✓, ×)	It accuses (the) adults of children trafficking.
(✓, ✓)	She accuses the adults of trafficking in children.

Table 2: Translation examples on WMT19 De⇒En test set. The translation errors are highlighted in red and changes of word order are highlighted in blue.

Table 2 shows some translation examples. Firstly, jointly pretraining decoder can produce good translations that are different in the word order from the ground-truth reference (e.g., "trafficking in children" vs. "child trafficking"), thus are assigned low BLEU scores. This may explain why jointly pretraining decoder only marginally improves performance on large-scale data. Secondly, jointly pretraining decoder can reduce translation errors, especially on small-scale data (e.g., correct the mistaken translation of "*It*" to "*She*"). We empirically validate the above two findings in the following experiments.

Pretrain	**Single**		**Multiple**	
	BLEU	△	BLEU	△

Table 4: Human evaluation of mBART pretrained NMT models in terms of under-translation (Ut), mis-translation (Mt), and over-translation (Ot) errors.

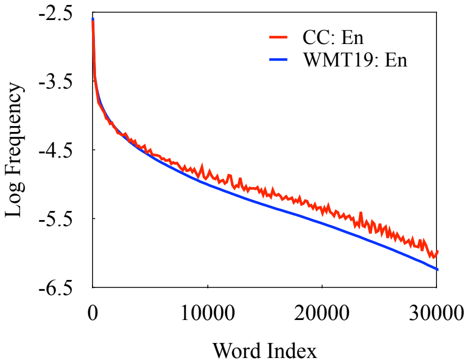

Figure 1: Word distributions of English corpora from general domain (i.e., CC data) and in-domain (i.e., WMT19 En-De news domain), respectively. The word frequency is normalized and reported in log-scale.

Impact on Translation Diversity. We follow Du et al. (2021) to better evaluate the translation quality for different word orders using multiple references. We use the test set released by Ott et al. (2018), which consists of 10 human translations for 500 sentences taken from the WMT14 En⇒De test set. As shown in Table 3, the pretrained decoder achieves more significant improvement in all cases when measured by multiple references. These results provide empirical support for our claim that jointly pretraining decoder produces more diverse translations with different word orders, which can be better measured by multiple references. These results may renew our cognition of pretraining, that is, *they are also effective on large-scale data when evaluated more accurately*.

Impact on Adequacy. We conduct a human evaluation to provide a more intuitive understanding of how jointly pre-training decoder improves translation quality. Specifically, we ask two annotators to annotate under-translation, mis-translation and over-translation on 100 sentences randomly sampled from WMT19 De⇒En test set. As listed in Table 4, inheriting the pretrained decoder reduces more translation errors on small data than on large data, which is consistent with the results of BLEU score in Table 1. Interestingly, inheriting only the pretrained encoder introduces more over-translation errors on small data, which can be solved by combining the pretrained decoder. One possible reason is that inheriting only the pretrained encoder excessively enlarges the impact of source context.[2] This problem does not happen on large data, since the large amount of in-domain data can balance the relation between encoder and decoder to accomplish the translation task well.

2.3 Pretraining-and-Finetuning Discrepancy

Although Seq2Seq pretraining consistently improves translation performance across data scales, we find several side effects of Seq2Seq pretraining due to the discrepancy between pretraining and finetuning. In this section, we present two important discrepancies: *domain discrepancy* and *objective discrepancy*. Unless otherwise stated, we report results on WMT19 En-De test set using small data.

2.3.1 Domain Discrepancy

Seq2Seq pretraining model is generally trained on **general domain** data while the downstream translation models are trained on **specific domains** (e.g., news). Such a domain discrepancy requires more efforts for the finetuned models to adapt the knowledge in pretrained models to the target in-domain. We empirically show the domain discrepancy in terms of lexical distribution and domain classifier.

Lexical Distribution in Training Data. Inspired by lexicon distribution analysis (Ding et al.,

---

[2] Tu et al. (2017a) showed that more impact of source context leads to over-translation errors.

Set	En⇒De	De⇒En
Source	77.5	73.7
Target	71.0	75.4

Table 5: Ratio of sentences in WMT19 En-De test sets that are classified as WMT news domain.

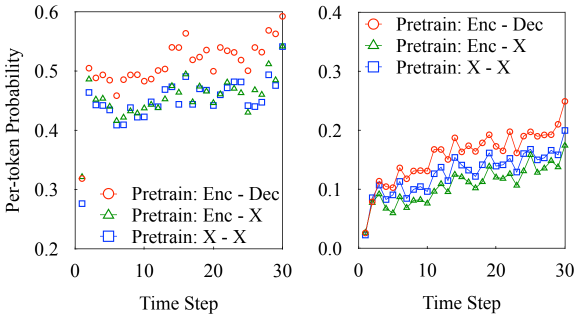
2021), we first plot the word distributions of English corpora from general domain (i.e., CC data) and in-domain (i.e., WMT19 En-De news domain) to study their difference at the lexicon level. The words are ranked according to their frequencies in the WMT19 En-De training data. As shown in Figure 1, we observe a clear difference between WMT news data and CC data in the long tail region, which is supposed to carry more domain-specific information. Accordingly, there will be a domain shift from pretraining to finetuning.

Domain Classifier for Test Data. We further demonstrate that the test data also follows a consistent domain as the training data. To distinguish general domain and in-domain, we build a domain classifier based on the WMT19 En-De training data and the CC data. We select a subset from the WMT training data with some trusted data (Wang et al., 2018; Jiao et al., 2020b, 2022), which includes 22404 sample from WMT newstest2010-2017 (see Appendix A.2 for details). Specifically, we select 1.0M samples from the WMT training data and the CC data, respectively, to train the domain classifier. The newstest2018 is combined with an equally sized subset of CC data for validation. We adopt the domain classifier to classify each sample in the test sets of WMT19 En-De. As shown in Table 5, most of the sentences (e.g., 70% - 80%) are recognized as WMT news domain, which demonstrates the domain consistency between the training data and test data in the downstream tasks.

2.3.2 Objective Discrepancy

The learning objective discrepancy between Seq2Seq pretraining and NMT training is that NMT learns to translate a sentence from one language to another, while Seq2Seq pretraining learns to reconstruct the input sentence (Liu et al., 2021). In this section, we study the side effects of the objective discrepancy by evaluating the predicting behaviors that are highly affected by the learning objective.

Model Uncertainty. We follow Ott et al. (2018) to analyze the model's uncertainty by computing the average probability at each time step across a set of sentence pairs. To evaluate the capability of LM modeling on the target language, we also follow Wang and Sennrich (2020) to consider a set of "distractor" translations, which are random sentences from the CC data that match the corresponding reference translation in length. Figure 2 plots model uncertainties for both references (Y) and distractors ($\hat{Y}$). We find that jointly pretraining decoder significantly improves model certainty after the first few time steps (Figure 2a). As for the distractors, pretraining encoder only results in certainties even lower than training from scratch (Figure 2b), which suggests that the corresponding NMT model is more dominated by the source context. It reconfirms the finding in our human evaluation (Table 4). In contrast, jointly pretraining decoder leads to a significant improvement of certainties, suggesting that the pretrained decoder tends to induce the **over-estimation issue** of NMT models. A possible reason is that Seq2Seq pretraining does not establish the connection between languages, such that its strong capability of LM modeling still recognizes the distractor as a valid target sentence even though it is mismatched with the source sentence in semantics.



(a) Reference (b) Distractor

Figure 2: Per-token generation probability on the test set of WMT19 En⇒De (S). Higher probabilities are expected for the groundtruth references (a), and lower probabilities are expected for the distractors (b).

Hallucination under Perturbation. One translation problem associated with over-estimation is hallucination (Wang and Sennrich, 2020), where NMT models generate fluent translation but is unrelated to the input. In this section, we follow Lee et al. (2018) to evaluate the model's tendency of generating hallucination under noisy input, to which NMT models are highly sensitive (Belinkov and Bisk, 2018). Specifically, we employ

Pretrain		**FPI (%)**		**RSM (%)**	
Enc	*Dec*	$\triangle_{\text{BLEU}}$	HUP	$\triangle_{\text{BLEU}}$	HUP
×	×	-1.3	0.5	-8.8	2.4

✓	✓	**-3.2**	**7.8**	**-17.8**	**15.5**

Table 6: BLEU change of model performance under perturbed inputs over the standard inputs, and hallucinations under perturbation (HUP) score.

Pretrain		**BLEU**		**Copy (%)**	
Enc	*Dec*	5	100	5	100
×	×	26.7	26.6	12.9	13.9
✓	×	31.7	31.6	12.7	12.9
✓	✓	35.3	33.5	**13.2**	**19.4**

Table 7: Beam search degradation and ratio of copying tokens in translation outputs.

two different perturbation strategies: (1) First position insertion (FPI) that inserts a single additional input token into the source sequence, which can completely divorce the translation from the input sentence (Lee et al., 2018). (2) Random span masking (RSM) that simulates the noisy input in the Seq2Seq pretraining of mBART (Liu et al., 2020). We follow Lee et al. (2018) to count a translation as hallucination under perturbation (HUP) when: (1) BLEU between reference sentence and translation of unperturbed sentence is bigger than 5 and (2) BLEU between the translation of perturbed sentence and the translation of unperturbed sentence is lower than 3. We calculate the percentage of hallucination as the HUP score. Table 6 lists the BLEU change and HUP score for the perturbed inputs. As expected, jointly pretraining decoder is less robust to perturbed inputs (more decline of BLEU scores), and produces more hallucinations than the other two model variants.

Beam Search Problem. One commonly-cited weakness of NMT model is the beam search problem, where the model performance declines as beam size increases (Tu et al., 2017b). Previous studies demonstrate that over-estimation is an important reason for the beam search problem (Ott et al., 2018; Cohen and Beck, 2019). We revisit this problem for NMT models with Seq2Seq pretraining, as shown in Table 7. We also list the ratio of copying tokens in translation outputs (i.e., directly copy source words to target side without translation) for different beam sizes, which has been shown as a side effect of Seq2Seq pretraining models (Liu et al., 2021). As seen, jointly pretraining decoder suffers from more serious beam search degradation problem, which reconfirms the connection between beam search problem and over-estimation. In addition, larger beam size introduces more copying tokens than the other model variants (i.e., 19.4 vs. 13.9, 12.9), which also links copying behaviors associated with Seq2Seq pretraining to the beam search problem.

3 Improving Seq2Seq Pretraining

3.1 Approach

To bridge the above gaps between Seq2Seq pretraining and finetuning, we introduce *in-domain pretraining* and *input adaptation* to improve the translation quality and model robustness.

In-Domain Pretraining. To bridge the domain gap, we propose to continue the training of mBART (Liu et al., 2020) on the in-domain monolingual data. Specifically, we first remove spans of text and replace them with a mask token. We mask 35% of the words in each sentence by random sampling a span length according to a Poisson distribution ($\lambda = 3.5$). We also permute the order of sentences within each instance. The training objective is to reconstruct the original sentence at the target side. We expect the in-domain pretraining to reduce the domain shift by re-pretraining on the in-domain data, which is more similar in data distribution with the downstream translation tasks.

Input Adaptation in Finetuning. To bridge the objective gap and improve the robustness of models, we propose to add noises (e.g., mask, delete, permute) to the source sentences during finetuning, and keep target sentences as original ones. Empirically, we add noises to 10% of the words in each source sentence, and combine the noisy data with the clean data by the ratio of 1:9, which are used to finetune the pretraining model. We expect the introduction of perturbed inputs in finetuning can help to better transfer the knowledge from pretrained model to the finetuned model, thus alleviate over-estimation and improve the model robustness.

3.2 Experimental Results

Main Results on Translation Performance and Robustness. The main results are listed in Table 8. We report the results of input adaptation, in-

Table 10: BLEU scores of in-domain pretraining only.

domain pretraining, and the combination of these two approaches, respectively. For input adaptation, it achieves comparable translation quality as the general domain pretrained model and significantly reduces the ratio of HuP, indicating the enhancement of model robustness. In-domain pretraining generally improves the translation quality but does not make the model more robust. On the contrary, it may increase the ratio of HuP in some cases (e.g., En⇒Ro 5.6 vs. 8.2). Conducting input adaptation right after in-domain pretraining will combine the advantages of these two approaches, and improve both the translation quality and model robustness. The effectiveness of our approaches, especially input adaptation, is more significant when evaluated with multiple references, as shown in Table 9.

In-Domain Only. Given the promising performance of in-domain pretraining, we investigate whether pretraining on in-domain data only can also obtain significant improvement. We report the results in Table 10. We can observe that pretraining solely on the in-domain data can improve the translation performance noticeably over the models without pretraining. However, the improvement is less competitive than the pretrained mBART25 (e.g., En⇒Ro: 36.1 v.s. 37.1 in Table 8), which may result from the much larger scale of multilingual data used in general pretraining.

3.3 Analysis

We provide some insights into how our approach improves model performance over general pretraining. We report results on WMT19 En⇒De test set using small-scale data.

Narrowing Domain Gap. Since the difference of lexical distribution between general domain and in-domain data mainly lies in the long tail region (see Figure 1), we study how our approach performs on low-frequency words. Specifically, we calculate the word accuracy of the translation outputs for WMT19 En-De (S) by the `compare-mt`[3] tool. We follow previous studies (Wang et al., 2021; Jiao et al., 2021) to divide words into three

---

Approach	**Frequency**		
	Low	*Med*	*High*
Baseline	36.8	45.3	57.5
General	44.5	54.3	64.2
+ In-Domain	46.2	54.3	64.9

Table 11: F-measures of word prediction for different frequencies that are calculated in the bilingual data.

categories based on their frequency in the bilingual data, including High: the most 3,000 frequent words; Medium: the most 3,001-12,000 frequent words; Low: the other words. Table 11 lists the results. The improvements on low-frequency words are the major reason for the performance gains of in-domain pretraining, where it outperforms general pretraining on the translation accuracy of low/medium/high- frequency words by 1.7, 0.0, and 0.7 BLEU scores, respectively. These findings confirm our hypothesis that in-domain pretraining can narrow the domain gap with in-domain data, which is more similar in the lexical distribution as the test sets.

Alleviating Over-Estimation. Figure 3 shows the impact of our approach on model uncertainty. Clearly, our approach successfully alleviates the over-estimation issue of general pretraining in both the groundtruth and distractor scenarios.

Mitigating Beam Search Degradation. We recap the beam search degradation problem with the application of our approaches in Table 12. The input adaptation approach can noticeably reduce the performance decline when using a larger beam size (e.g., from -1.8 to -0.9), partially due to a reduction of copying tokens in generated translations (e.g., from 19.4% to 15.3%). Although in-domain pretraining does not alleviate the beam search degradation problem, it can be combined with input adaptation to build a well-performing NMT system.

4 Related Work

Pretraining for NMT. Previous pretraining approaches for NMT generally focus on how to effectively integrate pretrained BERT (Devlin et al., 2019) or GPT (Radford et al., 2019) to NMT models. For example, Yang et al. (2020) propose a concerted training framework, and Weng et al. (2020) propose a dynamic fusion mechanism and a distillation paradigm to acquire knowledge from BERT and GPT. In this work, we aim to provide a better understanding of how Seq2Seq pretraining model works for NMT, and propose a simple and effective approach to improve model performance based on these observations.

+ Input Adapt	36.1	35.0	12.6$^{\downarrow}$	15.6$^{\downarrow}$

Table 12: Beam search degradation and "copy" translations when adopting our approaches.

Intermediate Pretraining. Our in-domain pretraining approach is related to recent successes on intermediate pretraining and intermediate task selection in NLU tasks. For example, Ye et al. (2021) investigate the influence of masking policies in intermediate pretraining. Poth et al. (2021) explore to select tasks for intermediate pretraining. Closely related to our work, Gururangan et al. (2020) propose to continue the pretraining of RoBERTa (Liu et al., 2019) on task-specific data. Inspired by these findings, we employ in-domain pretraining to narrow the domain gap between general Seq2Seq pretraining and NMT training. We also show the necessity of target-side monolingual data on in-domain pretraining (see Appendix A.3), which has not been studied in previous works of in-domain pretraining.

5 Conclusion

In this paper we provide a better understanding of Seq2Seq pretraining for NMT by showing both the benefits and side effects. We propose simple and effective approaches to remedy the side effects by bridging the gaps between Seq2Seq pretraining and NMT finetuning, which further improves translation performance and model robustness. Future directions include validating our findings on more Seq2Seq pretraining models and language pairs.

Abstract

Multimodal machine translation and textual chat translation have received considerable attention in recent years. Although the conversation in its natural form is usually multimodal, there still lacks work on multimodal machine translation in conversations. In this work, we introduce a new task named **M**ultimodal **C**hat **T**ranslation (MCT), aiming to generate more accurate translations with the help of the associated dialogue history and visual context. To this end, we firstly construct a **M**ultimodal **S**entiment **C**hat **T**ranslation **D**ataset (MSCTD) containing 142,871 English-Chinese utterance pairs in 14,762 bilingual dialogues and 30,370 English-German utterance pairs in 3,079 bilingual dialogues. Each utterance pair, corresponding to the visual context that reflects the current conversational scene, is annotated with a sentiment label. Then, we benchmark the task by establishing multiple baseline systems that incorporate multimodal and sentiment features for MCT. Preliminary experiments on four language directions (English↔Chinese and English↔German) verify the potential of contextual and multimodal information fusion and the positive impact of sentiment on the MCT task. Additionally, as a by-product of the MSCTD, it also provides two new benchmarks on multimodal dialogue sentiment analysis. Our work can facilitate research on both multimodal chat translation and multimodal dialogue sentiment analysis.[1]

1 Introduction

Multimodal machine translation (Huang et al., 2016; Calixto and Liu, 2017) and textual chat translation (Wang et al., 2016; Farajian et al., 2020; Liang et al., 2021a) mainly focus on investigating the potential visual features and dialogue context, respectively. Both of them have received much attention. Although plenty of studies on them have been carried out based on either image captions (Calixto et al., 2017, 2019; Ive et al., 2019; Yin et al., 2020; Yao and Wan, 2020) or textual dialogues (Wang et al., 2017; Maruf et al., 2018; Liang et al., 2021c), to our knowledge, little research work has been devoted to multimodal machine translation in conversations. One important reason is the lack of multimodal bilingual conversational datasets.

Generally, conversation in its natural form is multimodal (Poria et al., 2019; Liang et al., 2021b). When humans converse, what a speaker would say next depends largely on what he/she sees. That is, the visual information plays a key role in (*i*) supplementing some crucial scene information (*e.g.*, the specific locations or objects, or facial expressions), (*ii*) resolving ambiguous multi-sense words (*e.g.*, bank), and (*iii*) addressing pronominal anaphora issues (*e.g.*, it/this). For instance, as shown in Fig. 1 (a), the image obviously points out the current location "on the sea", which may help disambiguate the meaning of "course" in the utterance X_5. Specifically, the dialogue history (*i.e.*, talking about maritime affairs) and the corresponding visual context (*i.e.*, on the sea/boat) assist us to determine that the word "course" means "route/direction" instead of "curriculum". In Fig. 1 (b), the visual context indicates object information, *i.e.*, the "defibrillator" in X_1, which may help with translation. In Fig. 1 (c), the image of the utterance X_1 also demonstrates that it can provide appropriate candidates (*i.e.,* the jeans) when translating the pronoun "these". Besides, the image offers some clues to judge the sentiment when it is hard to judge the polarity based only on the utterance (*e.g.*, Y_2 in Fig. 1 (b) and X_3 in Fig. 1 (c)). All of the above call for a real-life multimodal bilingual conversational data resource that can encourage further research in chat transla-

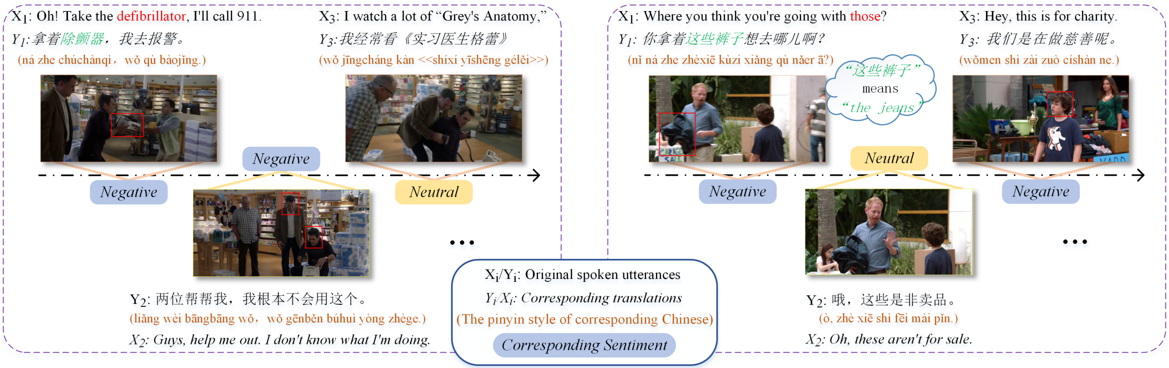
(a) The current location "on the sea" helps disambiguate polysemy ("course" in X_5).



(b) The red framed object in the image of X_1 may help the translation of "defibrillator" in X_1.

(c) The red framed object (means "jeans") in the image of X_1 may help the translation of the pronoun "those" in X_1.

Figure 1: Three examples of the annotated multimodal bilingual dialogue in our MSCTD and the conversation is going from left to right.

tion.

In this work, we propose a new task named **M**ultimodal **C**hat **T**ranslation (MCT), with the goal to produce more accurate translations by taking the dialogue history and visual context into consideration. To this end, we firstly construct a **M**ultimodal **S**entiment **C**hat **T**ranslation **D**ataset (MSCTD). The MSCTD includes over 17k multimodal bilingual conversations (more than 142k English-Chinese and 30k English-German utterance pairs), where each utterance pair corresponds with the associated visual context indicating where it happens. In addition, each utterance is annotated with one sentiment label (*i.e.*, positive/neutral/negative).

Based on the constructed MSCTD, we benchmark the MCT task by establishing multiple Transformer-based (Vaswani et al., 2017) systems adapted from several advanced representative multimodal machine translation models (Ive et al., 2019; Yao and Wan, 2020) and textual chat translation models (Ma et al., 2020; Liang et al., 2021c). Specifically, we incorporate multimodal features and sentiment features into these models for a suitable translation under the current conversational scene. Extensive experiments on four language directions (English↔Chinese and English↔German) in terms of BLEU (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014) and TER (Snover et al., 2006), demonstrate the effectiveness of contextual and multimodal information fusion, and the positive impact of sentiment on MCT. Furthermore, experiments on the multimodal dialogue sentiment analysis task of the three languages show the added value of the proposed MSCTD.

In summary, our main contributions are:

- We propose a new task: multimodal chat translation named MCT, to advance multimodal chat translation research.
- We are the first that contributes the human-annotated multimodal sentiment chat translation dataset (MSCTD), which contains 17,841 multimodal bilingual conversations, totally 173,240 <English utterance, Chinese/German utterance, image, sentiment> quadruplets.
- We implement multiple Transformer-based baselines and provide benchmarks for the new

task. We also conduct comprehensive analysis and ablation study to offer more insights.

- As a by-product of our MSCTD, it also facilitates the development of multimodal dialogue sentiment analysis.

2 Tasks

In this section, we firstly clarify the symbol definition, and then define the proposed *Multimodal Chat Translation* task and the existing *Multimodal Dialogue Sentiment Analysis* task.

In a multimodal bilingual conversation (*e.g.*, Fig. 1 (a)), we assume the two speakers have alternatively given utterances in different languages for u turns, resulting in $X_1, X_2, X_3, X_4, ..., X_u$ and $Y_1, Y_2, Y_3, Y_4, ..., Y_u$ on the source and target sides, respectively, along with the corresponding visual context representing where it happens: $Z_1, Z_2, Z_3, Z_4, ..., Z_u$. Among these utterances, $X_1, X_3, X_5, ..., X_u$ are originally spoken by the first speaker and $Y_1, Y_3, Y_5, ..., Y_u$ are the corresponding translations in the target language. Similarly, $Y_2, Y_4, Y_6, ..., Y_{u-1}$ are originally spoken by the second speaker and $X_2, X_4, X_6, ..., X_{u-1}$ are the translated utterances in the source language. According to languages and modalities, we define three types of context: (1) the dialogue history context of X_u on the source side as $\mathcal{C}_{X_u}$=$\{X_1, X_2, X_3, ..., X_{u-1}\}$, and (2) that of Y_u on the target side as $\mathcal{C}_{Y_u}$=$\{Y_1, Y_2, Y_3, ..., Y_{u-1}\}$, and (3) the visual dialogue context $\mathcal{C}_{Z_u}$=$\{Z_1, Z_2, Z_3, ..., Z_{u-1}, Z_u\}$.[2]

Multimodal Chat Translation. When translating the u-th utterance X_u=$\{x_{u,1}, x_{u,2}, ..., x_{u,N}\}$, the goal of the MCT task is to generate Y_u=$\{y_{u,1}, y_{u,2}, ..., y_{u,T}\}$ with the guidance of bilingual dialogue history contexts $\mathcal{C}_{X_u}$ and $\mathcal{C}_{Y_u}$ and the associated visual context $\mathcal{C}_{Z_u}$. Formally, the probability distribution of the target utterance Y_u is defined as follows:

$$P(Y_u|X_u, \mathcal{C}_u) = \prod_{t=1}^{T} p(y_{u,t}|y_{u,<t}, X_u, \mathcal{C}_u), \quad (1)$$

where $y_{u,<t} = \{y_{u,1}, y_{u,2}, y_{u,3}, ..., y_{u,t-1}\}$ and $\mathcal{C}_u$=$\{\mathcal{C}_{X_u}, \mathcal{C}_{Y_u}, \mathcal{C}_{Z_u}\}$.

Multimodal Dialogue Sentiment Analysis. Taking the u-th utterance X_u for example, the task aims to predict a sentiment label $\ell \in$\{*Positive*, *Neutral*, *Negative*\} for it given the corresponding image Z_u and the dialogue history $\mathcal{C}_{X_u}$.

3 Dataset

In this section, we mainly introduce our MSCTD in five aspects: *Data Source* § 3.1, *Annotation Procedure* § 3.2, *Annotation Quality Assessment* § 3.3, *Dataset Statistics* § 3.4, and the introduction of *Related Datasets* § 3.5.

3.1 Data Source

We mainly select the multimodal dialogues from the public available OpenViDial dataset (Meng et al., 2021), where each monolingual (English) utterance corresponds to an image. Since the original English utterance in OpenViDial is automatically extracted from the corresponding movie image by optical character recognition (OCR)[3], it contains a lot of noises or errors. Furthermore, the lack of associated translations and sentiment labels for utterances, makes it impossible for directly conducting research on multimodal chat translation, sentiment-aware machine translation, and multimodal dialogue sentiment analysis with this data. Therefore, we further correct the wrong English utterances and annotate the corresponding Chinese/German translations and sentiment labels.

3.2 Annotation Procedure

To build the MSCTD, the annotation procedure includes two steps: automatic annotation and then human annotation according to the annotation rules.

Automatic Annotation. To improve the annotation efficiency, we firstly construct a paired English-Chinese subtitle database[4]. Then, we utilize the original English utterance to automatically select its Chinese translation by perfectly matching the English subtitle in the constructed bilingual database. As a result, about 78.57% original English utterances are paired with Chinese translations.

---

[2] For each item of $\{\mathcal{C}_{X_u}, \mathcal{C}_{Y_u}\}$, we add the special token '[CLS]' tag at the head of it and use another token '[SEP]' to delimit its included utterances, as in Devlin et al. (2019).

[3] https://github.com/JaidedAI/EasyOCR

[4] To build this database, we firstly crawl two consecutive English and Chinese movie subtitles (not aligned) from here `https://www.kexiaoguo.com/`. Then, we use several advanced technologies (*e.g.*, Vecalign (Thompson and Koehn, 2019) and LASER (Schwenk, 2018)) to align these subtitles. Finally, we obtain the large-scale bilingual dialogue dataset (28M). We will also release this dataset, together with the MSCTD, to facilitate subsequent research.

Table 1: Detailed Statistics of our MSCTD. #: number of the corresponding item, *i.e.*, Dial.: dialogues; Utter.: utterances; AvgTurns: Average turn length of each dialogue; AvgEn: Average length of each turn in English (word level); AvgZh/De: Average length of each turn in Chinese (character level) and in German (word level); Pos./Neu./Neg.: positive/neutral/negative sentiment label. The “T./A.” means the Total number or Average value of each column.

Human Annotation. Since the full data are large, we divide the data into three parts and employ three annotators who are Chinese postgraduate students highly proficient in English comprehension. Each annotator is responsible for annotating one part according to the following guidelines:

- Check and correct each English utterance;
- Check and correct the matched Chinese subtitle to suit the current conversational scene;
- For the remaining 21.43% (without Chinese subtitles), translate them according to the corrected English utterance, the corresponding image, and the dialogue history.

Additionally, we employ another three annotators to label sentiment polarity for each utterance independently (*i.e.*, each one annotates the full data) according to the current utterance, the associated image and the dialogue history. Following Firdaus et al. (2020), majority voting scheme is used for selecting the final sentiment label for each utterance.

Finally, having the conversations in both languages allows us to simulate bilingual conversations where one speaker speaks in English and the other responds in Chinese (Farajian et al., 2020; Liang et al., 2021a). Fig. 1 shows three bilingual conversations where the two speakers have alternatively given utterances, along with their corresponding translations. By doing so, we build the MSCTD[5].

3.3 Annotation Quality Assessment

To evaluate the quality of annotation, we use Fleiss’ Kappa to measure the overall annotation consistency among three annotators (Fleiss and Cohen, 1973). We measure this data from two aspects: translation quality and sentiment quality.

For translation quality, we measure the inter-annotator agreement on a subset of data (sample 50 dialogues with 504 utterances), and we ask the three annotators mentioned above to re-annotate this subset independently. Then, we invite another postgraduate student to measure the inter-annotator agreement on the re-annotated subset by the three annotators. Finally, the inter-annotator agreement calculated by Fleiss’ kappa are 0.921 for English↔Chinese and 0.957 for English↔German, respectively. They indicate “Almost Perfect Agreement” between three annotators.

For sentiment quality, we measure the inter-annotator agreement on the full dataset. The inter-annotator agreements calculated by Fleiss’ kappa is 0.695, which indicates “Substantial Agreement” between three annotators. The level is consistent with previous work (Firdaus et al., 2020) which can be considered as reliable.

3.4 Dataset Statistics

As shown in Tab. 1, the MSCTD contains totally 17,841 bilingual conversations and 142,871/30,370

---

[5] For English↔German, we firstly sample a small set of training data and apply the same test and validation set with the English↔Chinese version. Then, the German translations are collected from professional English-German workers contracted via a language service company (magicdatatech). The three crwodworkers are asked to translate them according to the English utterance, the corresponding image, and the dialogue history.

Dataset	Language Direction	Modality	Scene	Sentiment	#Dialogues			#Instances/Utterances		
					Train	Valid	Test	Train	Valid	Test
Multi30K (Elliott et al., 2016)	English→German/French	T,V	Caption	✗	-	-	-	29,000	1,014	1,000
BSD-AMI-ON (Rikters et al., 2020)	English↔Japanese	T	Dialogue	✗	2,643	69	69	84,800	2,058	2,104
BconTrasT (Farajian et al., 2020)	English↔German	T	Dialogue	✗	550	78	78	13,845	1,902	2,100
BMELD (Liang et al., 2021a)	English↔Chinese	T	Dialogue	✗	1,036	108	274	9,987	1,084	2,601
MSCTD (Ours)	English↔Chinese	T,V	Dialogue	✓	13,749	504	509	132,741	5,063	5,067
	English↔German	T,V	Dialogue	✓	2,066	504	509	20,240	5,063	5,067

Table 2: Comparison of (1) previous mulitmodal machine translation dataset: Multi30k, (2) textual chat translation datasets: BconTrasT, BSD-AMI-ON, and BMELD, and (3) our MSCTD. T/V: text/vision modality.

English-Chinese/English-German utterance pairs with two modalities (*i.e.*, text and image), where each utterance has been annotated with onesentiment label. For English-Chinese/English-German, we split the dialogues into 13,749/2,066 for train, 504/504 for valid, and 509/509 for test while keeping roughly the same distribution of the utterance pair/image, respectively. The detailed annotation of sentiment labels are also listed in Tab. 1, where three labels account for similar proportion.

Based on the statistics in Tab. 1, the average number of turns per dialogue is about 10, and the average numbers of tokens per turn are 8.2, 10.9, and 8.3 for English utterances (word level), Chinese utterances (character level), and German utterance (word level), respectively.

3.5 Related Datasets

The related datasets mainly involve three research fields: multimodal machine translation, textual chat translation, and multimodal dialogue sentiment analysis.

In **multimodal machine translation**, there exists one dataset: Multi30K (Elliott et al., 2016), where each image is paired with one English caption and two human translations into German and French. It is an extension of the original English description dataset: Flickr30K (Young et al., 2014). Afterwards, some small-scale multimodal test sets (about 3k instances) are released to evaluate the system, such as WMT18 test set (1,071 instances) (Barrault et al., 2018).

In **textual chat translation**, three datasets have been released: BSD-AMI-ON (Rikters et al., 2020), BconTrasT (Farajian et al., 2020), and BMELD (Liang et al., 2021a). The BSD-AMI-ON is a document-aligned Japanese-English conversation corpus, which contains three sub-corpora: Business Scene Dialogue (BSD (Rikters et al., 2019)), Japanese translation of AMI meeting corpus (AMI (McCowan et al., 2005)), and Japanese translation of OntoNotes 5.0 (ON (Marcus et al.)). The BconTrast and BMELD are two human-annotated datasets, which are extended from monolingual textual dialogue datasets Taskmaster-1 (Byrne et al., 2019) and MELD (Poria et al., 2019), respectively.

In **multimodal dialogue sentiment analysis**, the MELD (Poria et al., 2019) and MEISD (Firdaus et al., 2020) datasets are publicly available. The MELD dataset is constructed by extending the EmotionLines (Hsu et al., 2018) from the scripts of the popular sitcom *Friends*. It is similar to MEISD, which is also built from famous English TV shows under different genres (*e.g.*, *Friends*, *Grey's Anatomy*, *The Big Bang Theory*).

The resources mentioned above are extensively used in corresponding fields of research and they even cover some sub-tasks in MSCTD. However, our MSCTD is different from them in terms of both complexity and quantity.

Firstly, multimodal machine translation datasets and textual chat translation datasets are either in multimodal or textual dialogue, while ours includes both. It is obvious that conducting multimodal machine translation in conversations is more challenging due to the more complex scene. Furthermore, MSCTD covers four language directions and contains more than 17k human-annotated utterances-image triplets, which is more than the sum of the annotated ones in Multi30K, BSD-AMI-ON, BconTrasT, and BMELD. Tab. 2 provides information on the number of available modality, dialogues, and their constituent utterances for all the five datasets. What is more, our MSCTD is also annotated with sentiment labels while they are not.

Secondly, compared with two existing multimodal dialogue sentiment analysis datasets, MSCTD's quantity of English version is nearly ten-times of the annotated utterances in MEISD or MELD. More importantly, our MSCTD provides an equivalent Chinese multimodal dialogue senti-

Dataset	#Dialogues			#Utterances

ment analysis dataset and a relatively small German counterpart. Tab. 3 shows the comparison for all the five datasets, *i.e.*, MELD, MEISD, and our MSCTD on three languages.

4 Image Features

Following previous work (Wang et al., 2018; Ive et al., 2019; Meng et al., 2021), we focus on two types of image representation, namely the coarse-grained spatial visual feature maps and the fine-grained object-based visual features.

Coarse-grained Spatial Visual (CSV) Features. We use the ResNet-50 model (He et al., 2016) pre-trained on ImageNet (Deng et al., 2009) to extract a high-dimensional feature vector $\mathbf{f}_j \in \mathbb{R}^{d_c}$ for image Z_j. These features contain output activations for various filters while preserving spatial information. We refer to models that use such features as **CSV**.

Fine-grained Object-based Visual (FOV) Features. Since using coarse-grained image features may be insufficient to model fine-grained visual elements in images including the specific locations, objects, and facial expressions, we use a bag-of-objects representation where the objects are obtained using an off-shelf Faster R-CNNs (Ren et al., 2015) pre-trained on Visual Genome (Krishna et al., 2017). Specifically, for an input image Z_j, we obtain a set of detected objects from Faster R-CNNs, *i.e.*, $\mathbf{O}_j = \{\mathbf{o}_{j,1}, \mathbf{o}_{j,2}, \mathbf{o}_{j,3}, ..., \mathbf{o}_{j,m}\}$, where m is the number of extracted objects and $\mathbf{o}_{j,*} \in \mathbb{R}^{d_f}$. Each object is captured by a dense feature representation, which can be mapped back to a bounding box / region (*i.e.*, Region-of-Interest (ROI)). We refer to models that use such features as **FOV**.

Both types of features have been used in various vision and language tasks such as multimodal dialogue sentiment analysis (Firdaus et al., 2020), image captioning (Xu et al., 2015; Shi et al., 2021), and multimodal machine translation (Ive et al., 2019; Lin et al., 2020; Su et al., 2021).

5 Baseline Models

To provide convincing benchmarks for the MSCTD, we perform experiments with multiple Transformer-based (Vaswani et al., 2017) models for the multimodal chat translation task. Additionally, we provide several baselines for the multimodal dialogue sentiment analysis task.

5.1 Multimodal Chat Translation

According to different visual features, we divide the baselines into three categories: text only (**T**), text plus coarse visual features (**T + CSV**), and text plus fine-grained visual features (**T + FOV**).

T: Trans. (Vaswani et al., 2017): the standard transformer model, which is a sentence-level neural machine translation (NMT) model (Yan et al., 2020; Meng and Zhang, 2019; Zhang et al., 2019), *i.e.*, regardless of the dialogue history. TCT (Ma et al., 2020): A unified document-level NMT model based on Transformer by sharing the first encoder layer to incorporate the dialogue history, which is used as the Textual Chat Translation (TCT) model by (Liang et al., 2021c). CA-TCT (Liang et al., 2021c): A multi-task learning model that uses several auxiliary tasks to help model generate coherence-aware translations.

T+CSV: Trans.+Emb (Vaswani et al., 2017): it concatenates the image feature to the word embedding and then trains the sentence-level NMT model. Trans.+Sum (Ive et al., 2019): it adds the projected image feature to each position of the encoder output. Trans.+Att (Ive et al., 2019): this model utilizes an additional cross-attention sublayer to attend the image features in each decoder block. MCT: we implement the multimodal self-attention (Yao and Wan, 2020) in the encoder to incorporate the image features into the chat translation model. CA-MCT: similarly, we incorporate image features into the multitask-based chat translation model (Liang et al., 2021c) by the multimodal self-attention.

T+FOV: Trans.+Con (Vaswani et al., 2017): it concatenates the word sequence to the extracted object sequence and thus obtains a new sequence taken as the input of the sentence-level NMT model. Trans.+Obj (Ive et al., 2019): it is a translate-and-refine model (two-stage decoder) where the images are only used by a second-pass decoder. M-Trans. (Yao and Wan, 2020): it leverages a multimodal self-attention layer to encode multimodal information where the hidden representation of im-

Table 4: Test results of multimodal chat translation task in terms of BLEU, METEOR, and TER on our MSCTD. The best and the second results are **bold** and underlined, respectively. The symbol '*' denotes sentence-level multimodal machine translation models which do not use the dialogue history. '$\dagger$' indicates that statistically significant better than the M3 model with t-test $p < 0.01$. '$\ddagger$' indicates that statistically significant better than the sentence-level multimodal machine translation models (*i.e.*, M13 vs. M11 and M8 vs. M6) with t-test $p < 0.05$.

ages are induced from the text under the guidance of image-aware attention. MCT: here, we incorporate the object-level features into the model instead of coarse one. CA-MCT: similarly, we incorporate the object-level features into the multi-task learning model.

5.2 Multimodal Dialogue Sentiment Analysis

We perform several experiments with different models. text-CNN (Kim, 2014): it only applies CNNs to extract textual information for each utterance in a dialogue. In this approach, we do not use the dialogue history or the additional visual information. DialogueRNN (Majumder et al., 2019): this baseline is a powerful approach for capturing dialogue history with effective mechanisms for sentiment analysis. DialogueRNN + BERT (Firdaus et al., 2020): this model improves the performance of DialogueRNN by using BERT (Devlin et al., 2019) embeddings instead of Glove (Pennington et al., 2014) embeddings to represent the textual features. DialogueRNN + PLM: we propose a stronger baseline built upon the DialogueRNN for sentiment analysis. Specifically, we utilize RoBERTa (Liu et al., 2019) embeddings for English sentiment analysis, and ERNIE (Sun et al., 2019) embeddings for Chinese sentiment analysis, and XLM-R (Conneau et al., 2020) embeddings for German sentiment analysis.

Following Firdaus et al. (2020), we only use the coarse-grained image features (*i.e.*, **CSV**) when training above models with the visual information.

6 Experiments

6.1 Setup

For multimodal chat translation, we utilize the standard Transformer-Base architecture (Vaswani et al., 2017). Generally, we use the settings described in previous work (Ive et al., 2019; Yao and Wan, 2020; Liang et al., 2021c) to conduct experiments on our MSCTD.

For multimodal dialogue sentiment analysis, we mainly follow the settings of previous work (Poria et al., 2019; Firdaus et al., 2020).

Please refer to Appendix A for more details.

6.2 Metrics

For multimodal chat translation, following previous work (Liang et al., 2021c; Ive et al., 2019), we use the SacreBLEU[6] (Post, 2018), METEOR (Denkowski and Lavie, 2014) and TER (Snover et al., 2006) with the statistical significance test (Koehn, 2004) for fair comparison. Specifically, for Chinese→English, we report case-insensitive score. For English→Chinese, the reported score is at the character level. For English↔German, we report case-sensitive BLEU score.

For multimodal dialogue sentiment analysis, following Poria et al. (2019), we report weighted-average F-score.

6.3 Results of Multimodal Chat Translation

Results on English↔Chinese. (1) Among all only text-based models (M1∼M3), we find that M1

TCT (**T**)	20.78	24.39	60.87	64.65
CA-TCT (**T**)	21.15	24.73	60.74	64.78
MCT (**T+CSV**)	22.31	25.42	59.88	65.26
CA-MCT (**T+CSV**)	22.57	25.51	59.45	65.33

Table 6: Sentiment-aware translation results using predicted sentiment labels. The last column (*i.e.*, ACC.) is the corresponding predicted sentiment accuracy.

performs worse than M2, showing that the dialogue history indeed is beneficial for better translations. Furthermore, M3 can further improve the translation performance, which suggests that modeling the coherence characteristic in conversations is crucial for higher results. These can also be found in other settings (*e.g.*, M7 vs. M4∼6; M8 vs. M7). (2) The models with image features incorporated get higher results than corresponding text-based models (*i.e.*, M4∼M6&M9 vs. M1; M7&M12 vs. M2; M8&M13 vs. M3). (3) The dialogue history and the image features obtain significant cumulative benefits (M8 vs. M1 and M13 vs. M1) (4) Among these image-based models (M4∼M8 or M9∼M13), we observe that different fusion manners of text and image features reflect great difference on effects. It shows that there is much room for further improvement using other more advanced fusion methods. (5) Using **FOV** image features is generally better than the coarse counterpart **CSV** (M9∼M13 vs. M4∼M8), which demonstrates that the fine-grained object elements may offer more specific and effective information for better translations.

Results on English↔German. Similar findings are found on English↔German. This shows that our conclusions are solid and convincing on general datasets. All these results prove the value of our constructed MSCTD.

Furthermore, we provide some stronger baselines that we firstly train the model on the general-domain corpus and then fine-tune it on our chat translation dataset. The results are presented in Table Tab. 8 of Appendix B, which show similar findings observed in Table Tab. 4.

6.4 Effect of Sentiment on Multimodal Chat Translation

To evaluate the effect of sentiment, we conduct some experiments on several baselines including single-modality ones and double-modality ones. In terms of implementation, following Si et al. (2019), we append the sentiment label to the head of the source utterance. Tab. 5 shows the results. Comparing them with the results (M1∼M3 and M7∼M8) without using the sentiment in Tab. 4, we find that using the ground-truth sentiment label has a positive impact on the translation performance. Therefore, we believe that it is a topic worthy of research in the future.

We also conducted the experiments with automatically predicted sentiment labels rather than the gold ones as the reviewer suggested, where we used the mixed sentiment presentation by dot-multiplying the predicted sentiment distribution and the sentiment label representation. The results are shown in Tab. 6, where we find that the sentiment factor, as the inherent property of conversations, indeed has a positive impact on translation performance. We also observe that using the automatically predicted sentiment labels (actually the mixed sentiment representation) shows slightly lower results than using ground truth in terms of three metrics. The reason may be that the mixed sentiment representation has certain fault tolerance.

6.5 Results of Multimodal Dialogue Sentiment Analysis

In Tab. 7, we report the results of sentiment classification on three datasets under different settings.

Results on MSCTD-Zh. We can see that the text-based models perform much poorer than other multimodal systems, which shows that it is not enough to evaluate the sentiment based only on the text. It indicates that visual information and contextual embeddings are crucial for classifying sentiment polarities. Overall, we achieve weighted F1 score of 67.57% with the “DialogueRNN+ERNIE” model.

Results on MSCTD-En/MSCTD-De. On English/German, we observe the same findings on

Table 7: Test results of multimodal dialogue sentiment analysis task in terms of weighted F-score (%). The "W-avg." denotes weighted-average F-score and the best "W-avg." results are **bold**. The symbol '*' denotes that we use pre-trained language models ERNIE, RoBERTa and XLM-R for Chinese, English, and German, respectively.

Chinese. These show that it is beneficial to introduce the visual information and contextual embeddings into the multimodal dialogue sentiment analysis task for different languages. Overall, we achieve the best F1 score of 66.45% and 54.46% on English and German, respectively.

On this task, we obtain consistent results with previous work (Poria et al., 2019; Firdaus et al., 2020), which suggests the utility and reliability of our MSCTD. Additionally, MSCTD-Zh and MSCTD-De bridge the gap on multimodal dialogue sentiment analysis of Chinese and German.

7 Conclusion and Future Work

In this paper, we introduce a new multimodal machine translation task in conversations. Then, we construct a multimodal sentiment chat translation dataset named MSCTD. Finally, we establish multiple baseline systems and demonstrate the importance of dialogue history and multimodal information for MCT task. Additionally, we conduct multimodal dialogue sentiment analysis task on three languages of the MSCTD to show its added value.

MCT is a challenging task due to the complex scene in the MSCTD, leaving much room for further improvements. This work mainly focuses on introducing the new task and dataset, and we provide multiple models to benchmark the task. In the future, the following issues may be worth exploring to promote the performance of MCT:

- How to effectively perceive and understand the visual scenes to better assist multimodal machine translation in conversations?
- How to build a multimodal conversation representation model to effectively align, interact, and fuse the information of two modalities?

8 Ethical Considerations

In this section, we discuss the main ethical considerations of MSCTD: (1) Intellectual property protection. The English utterance and image of MSCTD is from OpenViDial dataset (Meng et al., 2021). For our translation and sentiments, its permissions are granted to copy, distribute and modify the contents under the terms of the Creative Commons AttributionShareAlike 3.0 Unported License and Creative Commons CC0 License, respectively. (2) Privacy. The data source are publicly available movies. Its collection and Chinese/German annotation procedure is designed for chat translation purpose, and does not involve privacy issues. (3) Compensation. During the sentiment annotation, Chinese and German translation, the salary for annotating each utterance is determined by the average time of annotation and local labor compensation standard. (4) Data characteristics. We refer readers to the content and Meng et al. (2021) for more detailed characteristics. (5) Potential problems. While principled measures are taken to ensure the quality of the dataset, there might still be potential problems with the dataset quality, which may lead to incorrect translations in applications. However, moderate noise is common in large-scale modern translators, even for human translated sentences, which should not cause serious issues.

A Implementation Details

For multimodal chat translation, we utilize the standard Transformer-Base architecture (Vaswani et al., 2017). Generally, we use the settings described in previous work (Ive et al., 2019; Yao and Wan, 2020; Liang et al., 2021c) to conduct experiments on our MSCTD. Specifically, we use 512 as hidden size, 2048 as filter size and 8 heads in multihead attention. Both the encoder and the decoder of all the models have 6 layers and are trained using THUMT (Tan et al., 2020). We set the training step to 100,000 steps. The dropout is set to 0.1. The batch size for each GPU is set to 4096 tokens. The experiments are conducted using 4 NVIDIA Tesla V100 GPUs, which gives us about 4*4096 tokens per update. The models are optimized using Adam (Kingma and Ba, 2014) with β_1=0.9 and β_2=0.998, and learning rate is set to 1.0. Label smoothing is set to 0.1. Following Liang et al. (2021c), we set the number of dialogue context to 3. During inference, the beam size is set to 4, and the length penalty is 0.6 in all experiments.

For the pre-training-then-fine-tuning setting, we firstly train our model on the WMT20 datasets for 100,000 steps. Then, we utilize the pre-trained model to initialize our all multimodal chat translation models.

For multimodal dialogue sentiment analysis, we mainly follow the settings of previous work (Poria et al., 2019; Firdaus et al., 2020). The experiments are conducted on an NVIDIA Tesla V100 GPU and the batch size is set to 64. The learning rate is set to 0.001.

B Pre-training-then-fine-tuning Results

In this section, we provide some stronger baselines that we firstly train the standard transformer (Vaswani et al., 2017) model on the general-domain corpus (WMT20 dataset of Appendix C) and then fine-tune it on our chat translation dataset (*i.e.*, using the pre-training-then-fine-tuning paradigm). In Tab. 8, the M1 denotes we directly evaluate the pre-trained model on the target chat test set (*i.e.*, without fine-tuning on chat translation dataset.). The M2∼M7 apply the pre-training-then-fine-tuning paradigm. From Tab. 8, we observe similar conclusions to § 6.3. This shows that our findings on the newly proposed dataset are solid even under the stronger baselines. Besides, we also find that, after pre-training on the general-domain corpus, the model obtains significant improvement (M2∼M7 vs. M1).

C WMT20 Dataset

For English↔Chinese, we combine News Commentary v15, Wiki Titles v2, UN Parallel Corpus V1.0, CCMT Corpus, and WikiMatrix. For English↔German, we combine six corpora including Euporal, ParaCrawl, CommonCrawl, TildeRapid, NewsCommentary, and WikiMatrix. First, we filter out duplicate sentence pairs and remove those whose length exceeds 80. To pre-process the raw data, we employ a series of open-source/in-house scripts, including full-/half-width conversion, unicode conversation, punctuation normalization, and tokenization (Wang et al., 2020). After filtering, we apply BPE (Sennrich et al., 2016) with 32K merge operations to obtain subwords. Finally, we obtain 22,244,006 sentence pairs for English↔Chinese and 45,541,367 sentence pairs

Learning Disentangled Textual Representations via Statistical Measures of Similarity

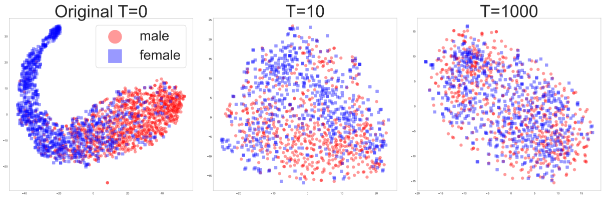
Abstract

When working with textual data, a natural application of disentangled representations is fair classification where the goal is to make predictions without being biased (or influenced) by sensitive attributes that may be present in the data (e.g., age, gender or race). Dominant approaches to disentangle a sensitive attribute from textual representations rely on learning simultaneously a penalization term that involves either an adversarial loss (e.g., a discriminator) or an information measure (e.g., mutual information). However, these methods require the training of a deep neural network with several parameter updates for each update of the representation model. As a matter of fact, the resulting nested optimization loop is both time consuming, adding complexity to the optimization dynamic, and requires a fine hyperparameter selection (e.g., learning rates, architecture). In this work, we introduce a family of regularizers for learning disentangled representations that do not require training. These regularizers are based on statistical measures of similarity between the conditional probability distributions with respect to the sensitive attributes. Our novel regularizers do not require additional training, are faster and do not involve additional tuning while achieving better results both when combined with pretrained and randomly initialized text encoders.



(a) (b) (c)

Fig. 1: PCA followed by a T-SNE projection of BERT embeddings of the sentences of `DIAL` corpus after T=0,10,1000 iterations of our framework (based on Sinkhorn divergence). Colors display the sensitive (i.e., binary gender) attribute.

1 Introduction

As natural language processing (NLP) systems are taken up in an ever wider array of sectors (e.g., legal system (Dale, 2019), insurance (Ly et al., 2020), education (Litman, 2016), healthcare (Basyal et al., 2020)), there are growing concerns about the harmful potential of *bias* in such systems (Leidner and Plachouras, 2017). Recently, a large body of research aims at analyzing, understanding and addressing *bias* in various applications of NLP including language modelling (Liang et al., 2021), machine translation (Stanovsky et al., 2019), toxicity detection (Dixon et al., 2018) and classification (Elazar and Goldberg, 2018). In NLP, current systems often rely on learning continuous embedding of the input text. Thus, it is crucial to ensure that the learnt continuous representations do not exhibit *bias* that could cause representational harms (Blodgett et al., 2020; Barocas et al., 2017), i.e., representations less favourable to specific social groups. One way to prevent the aforementioned phenomenon is to enforce disentangled representations, i.e., representations that are independent of a sensitive attribute (see Fig. 1 for a visualization of different degrees of disentangled representations). Learning disentangled representations has received a growing interest as it has been shown to be useful for a wide variety of tasks (e.g., style transfer (Fu et al., 2017), few shot learning (Karn et al., 2021), fair classification (Colombo et al., 2021d)). For text, the dominant approaches to learn such representations can be divided into two classes. The first one, relies on an adversary that is trained to recover the discrete sensitive attribute from the latent representation of the input (Xie et al., 2017). However, as pointed out by Barrett et al. (2019), even though the adversary seems to do a perfect job during training, a fair amount of the sensitive information can be recovered from the latent representation when training a new adversary from scratch. The second line of research involves a regularizer that is a train-

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2614 - 2630
May 22-27, 2022

able surrogate of the mutual information (MI) (e.g., CLUB (Cheng et al., 2020a), MIReny (Colombo et al., 2021d), KNIFE (Pichler et al., 2020), MINE (Belghazi et al., 2018; Colombo et al., 2021b)) and achieves higher degrees of disentanglement. However, as highlighted by recent works (McAllester and Stratos, 2020; Song and Ermon, 2019), these estimators are hard to use in practice and the optimization procedure (see App. D.4) involves several updates of the regularizer parameters at each update of the representation model. As a consequence, these procedures are both time consuming and involve extra hyperparameters (e.g., optimizer learning rates, architecture, number of updates of the nested loop) that need to be carefully selected which is often not such an easy task.

Contributions. In this work, we focus our attention on learning to disentangle textual representations from a discrete attribute. Our method relies on a novel family of regularizers based on discrepancy measures. We evaluate both the disentanglement and representation quality on fair text classification. Formally, our contribution is two-fold:

(1) *A novel formulation of the problem of learning disentangled representations.* Different from previous works–either minimizing a surrogate of MI or training an adversary–we propose to minimize a statistical measure of similarity between the underlying probability distributions conditioned to the sensitive attributes. This novel formulation allows us to derive new regularizers with convenient properties: (i) not requiring additional learnable parameters; (ii) alleviating computation burden; and (iii) simplifying the optimization dynamic.

(2) *Applications and numerical results.* We carefully evaluate our new framework on four different settings coming from two different datasets. We strengthen the experimental protocol of previous works (Colombo et al., 2021d; Ravfogel et al., 2020) and test our approach both on randomly initialized encoder (using RNN-based encoder) and during fine-tuning of deep contextualized pretrained representations[1]. Our experiments are conducted on four different main/sensitive attribute pairs and involve the training of over 280 deep neural networks. Our findings show that: (i) disentanglement methods behave differently when applied to randomly initialized or to deep contextualized pretrained encoder; and (ii) our framework offers a better accuracy/disentanglement trade-off than existing methods (i.e., relying on an adversary or on a MI estimator) while being faster and easier to train. Model, data and code are available at `https://github.com/PierreColombo/TORNADO`.

2 Related Work

Considering a tuple (X, S) where X is a random variable (r.v.) defined on the space of text $\mathcal{X}$ and S is a binary r.v. which corresponds to a sensitive attribute. Learning disentangled representations aims at learning the parameter θ of the encoder $f_\theta : \mathcal{X} \rightarrow \mathcal{Z} \subset \mathbb{R}^d$ which maps X to a latent representation $Z = f_\theta(X) \in \mathbb{R}^d$, where $d \in \mathbb{N}_*$ corresponds to the dimension of the embedding space. The goal is that Z retains as much useful information from X while being oblivious of S. Among the numerous possible applications for disentangled representations, we choose to focus on fair classification as it is a natural task to define the aforementioned useful information. In the fair classification task, we assume access to Y, a binary r.v., which corresponds to the main label/attribute. In order to learn disentangled representations for fair classification, we follow previous works (Beutel et al., 2017; Cheng et al., 2020b) and we will be minimizing the loss $\mathcal{L}(\phi, \psi, \theta)$, which is defined as follows:

$$\underbrace{\text{CE}\big(C_\phi(f_\theta(X)), Y\big)}_{\text{target task}} + \lambda \cdot \underbrace{R\big(f_\theta(X), S; \psi\big)}_{\text{regularizer}}, \quad (1)$$

where $C_\phi : \mathcal{Z} \rightarrow \mathcal{Y}$ refers to the main classifier; ϕ to its learnable parameters; CE to the cross-entropy loss; R denotes the disentanglement regularizer; ψ its parameters and λ controls the trade-off between disentanglement and success in the classification task. We next review the two main methods that currently exist for learning textual disentangled representations: *adversarial-based* and *MI-based*.

2.1 Adversarial-Based Regularizers

In the context of disentangled representation learning, a popular method is to rely on adding an adversary to the encoder (e.g., texts (Coavoux et al., 2018), images (Xie et al., 2017), categorical data (Beutel et al., 2017)). This adversary is competing against the encoder trying to learn the main task objective. In this line of work, $R(f_\theta(X), S; \psi) = -\text{CE}(C_\psi(f_\theta(X)), S)$ where $C_\psi : \mathcal{Z} \rightarrow \mathcal{S}$ refers to the adversarial classifier that is trained to minimize $\text{CE}(C_\psi(f_\theta(X)), S)$. Denoting by $\mathbb{P}_{Z|S=0}$

---

[1] Previous works (e.g., (Ravfogel et al., 2020)) do not fine-tune the pretrained encoder when testing their methods.

and $\mathbb{P}_{Z|S=1}$ the probability distribution of the conditional r.v. $Z|S=0$ and $Z|S=1$, respectively, these works build on the fact that if $\mathbb{P}_{Z|S=0}$ and $\mathbb{P}_{Z|S=1}$ are different, the optimal adversary will be able to recover sensitive information from the latent code Z. Although adversaries have achieved impressive results in many applications when applied to attribute removal, still a fair amount of information may remain in the latent representation (Lample et al., 2018).

2.2 MI-Based Regularizers

To better protect sensitive information, the second class of methods involves direct mutual information minimization. MI lies at the heart of information theory and measures statistical dependencies between two random variables Z and S and find many applications in machine learning (Boudiaf et al., 2020b,a, 2021). The MI is a non-negative quantity that is 0 if and only if Z and S are independent and is defined as follows:

$$I(Z;S) = \mathrm{KL}(\mathbb{P}_{ZS} \| \mathbb{P}_Z \otimes \mathbb{P}_S), \tag{2}$$

where the joint probability distribution of (Z,S) is denoted by $\mathbb{P}_{ZS}$; marginals of Z and S are denoted by $\mathbb{P}_Z$ and $\mathbb{P}_S$ respectively; and KL stands for the Kullback-Leibler divergence. Although computing the MI is challenging (Paninski, 2003; Pichler et al., 2020), a plethora of recent works devise new lower (Belghazi et al., 2018; Oord et al., 2018) and upper bounds (Cheng et al., 2020a; Colombo et al., 2021d) $\tilde{I}_\psi(f_\theta(X);S)$ where ψ denotes the trainable parameters of the surrogate of the MI. In that case, $R(f_\theta(X),S;\psi) = \tilde{I}_\psi(f_\theta(X);S)$. These methods build on the observation that if $I(Z;X) > 0$ then $\mathbb{P}_{Z|S=0}$ and $\mathbb{P}_{Z|S=1}$ are different and information about the sensitive label S remains in Z. Interestingly, these approaches achieve better results than adversarial training on various NLP tasks (Cheng et al., 2020b) but involve the use of additional (auxiliary) neural networks.

2.3 Limitations of Existing Methods

The aforementioned methods involve the use of extra parameters (i.e., ψ) in the regularizer. As the regularizer computes a quantity based on the representation given by the encoder with parameter θ, any modification of θ requires an adaptation of the parameter of R (i.e., ψ). In practice, this adaptation is performed using gradient descent-based algorithms and requires several gradient updates. Thus, a nested loop (see App. D.4) is needed. Additional optimization parameters and the nested loop both induce additional complexity and require a fine-tuning which makes these procedures hard to be used on large-scale datasets. To alleviate these issues, the next section describes a parameter-free framework to get rid of the ψ parameter present in R.

3 Proposed Method

This section describes our approach to learn disentangled representations. We first introduce the main idea and provide an algorithm to implement the general loss. We next describe the four similarity measures proposed in this approach.

3.1 Method Overview

As detailed in Section 2, existent methods generally rely on the use of neural networks either in the form of an adversarial regularizer or to compute upper/lower bounds of the MI between the embedding $Z = f_\theta(X)$ and the sensitive attribute S. Motivated by reducing the computational and complexity load, we aim at providing regularizers that are light and easy to tune. To this end, we need to get rid of the nested optimization loop, which is both time consuming and hard to tune in practice since the regularizer contains a large number of parameters (e.g., neural networks) that need to be trained by gradient descent. Contrarily to previous works in the literature, and following the intuitive idea that $\mathbb{P}_{Z|S=0}$ and $\mathbb{P}_{Z|S=1}$ should be as close as possible, we introduce similarity measures between $\mathbb{P}_{Z|S=0}$ and $\mathbb{P}_{Z|S=1}$ to build a regularizer R. It is worth noting that the similarity measures do not require any additional learnable parameters. For the sake of clarity, in the reminder of the paper we define $\mathbb{P}_i \triangleq \mathbb{P}_{Z|S=i}$ and $Z_i \triangleq f_\theta(X|S=i)$ for $i \in \{0,1\}$. Given a similarity measure defined as $\mathrm{SM} : \mathcal{M}_+^1(\mathcal{Z}) \times \mathcal{M}_+^1(\mathcal{Z}) \longrightarrow \mathbb{R}_+$ where $\mathcal{M}_+^1(\mathcal{Z})$ denotes the space of probability distributions on $\mathcal{Z}$, we propose to regularize the downstream task by $\mathrm{SM}(\mathbb{P}_0,\mathbb{P}_1)$. Precisely, the optimization problem boils down to the following objective:

$$\mathcal{L}(\phi,\theta) = \underbrace{\mathrm{CE}(C_\phi(f_\theta(X)),Y)}_{\text{target task}} + \lambda \cdot \underbrace{\mathrm{SM}(\mathbb{P}_0,\mathbb{P}_1)}_{\text{regularizer}}. \tag{3}$$

The proposed statistical measures of similarity, detailed in Section 3.2, have explicit and simple formulas. It follows that the use of neural networks is no longer necessary in the regularizer term which reduces drastically the complexity of the resulting learning problem. The disentanglement can be controlled by selecting appropriately the measure SM. For the sake of place, the algorithm we propose to solve (3) is deferred to the App. B.

3.2 Measure of Similarity between Distributions

In this work, we choose to focus on four different (dis-) similarity functions ranging from the most popular in machine learning such as the Maximum Mean Discrepancy measure (MMD) and the Sinkhorn divergence (SD) to standard statistical discrepancies such as the Jeffrey divergence (J) and the Fisher-Rao distance (FR).

3.2.1 Maximum Mean Discrepancy.

Let $k : \mathcal{Z} \times \mathcal{Z} \to \mathbb{R}$ be a kernel and $\mathcal{H}$ its corresponding Reproducing Kernel Hilbert Space with inner product $\langle ., . \rangle_{\mathcal{H}}$ and norm $\|.\|_{\mathcal{H}}$. Denote by $\mathcal{B}_{\mathcal{H}} = \{f \mid \|f\|_{\mathcal{H}} \leq 1\}$ the unit ball of $\mathcal{H}$. The Maximum Mean Discrepancy (MMD) (Gretton et al., 2007) between the two conditional distributions $\mathbb{P}_0, \mathbb{P}_1 \in \mathcal{M}_+^1(\mathcal{Z})$ associated with the kernel k, is defined as:

$$\begin{aligned}\mathrm{MMD}(\mathbb{P}_0,\mathbb{P}_1) &= \sup_{\Psi \in \mathcal{B}_{\mathcal{H}}} \left|\mathbb{E}_{\mathbb{P}_0}[\Psi(Z_0)] - \mathbb{E}_{\mathbb{P}_1}[\Psi(Z_1)]\right| \\ &= \mathbb{E}_{\mathbb{P}_0 \otimes \mathbb{P}_0}[k(Z_0, Z_0')] \\ &\quad + \mathbb{E}_{\mathbb{P}_1 \otimes \mathbb{P}_1}[k(Z_1, Z_1')] \\ &\quad - 2\,\mathbb{E}_{\mathbb{P}_0 \otimes \mathbb{P}_1}[k(Z_0, Z_1)].\end{aligned}$$

The MMD can be estimated with a quadratic computational complexity $\mathcal{O}(n^2)$ where n is the sample size. In this paper, MMD is computed using the Gaussian kernel $k : (z_0, z_1) \mapsto \exp(-\|z_0 - z_1\|^2/2\sigma^2)$, where $\|\cdot\|$ is the usual euclidean norm.

3.2.2 Sinkhorn Divergence.

The Wasserstein distance aims at comparing two probability distributions through the resolution of the Monge-Kantorovich mass transportation problem (see e.g. Villani (2003); Peyré and Cuturi (2019)):

$$\mathrm{W}^p(\mathbb{P}_0,\mathbb{P}_1) = \min_{\pi \,\in\, \mathcal{U}(\mathbb{P}_0,\mathbb{P}_1)} \int_{\mathcal{Z}\times\mathcal{Z}} \|z_0 - z_1\|^p d\pi(z_0, z_1), \tag{4}$$

where $\mathcal{U}(\mathbb{P}_0,\mathbb{P}_1) = \{\pi \in \mathcal{M}_+^1(\mathcal{Z} \times \mathcal{Z}) : \int \pi(z_0, z_1)dy = \mathbb{P}_0(z_0); \int \pi(z_0, z_1)dx = \mathbb{P}_1(z_1)\}$ is the set of joint probability distributions with marginals $\mathbb{P}_0$ and $\mathbb{P}_1$. For the sake of clarity, the power p in W^p is omitted in the remainder of the paper. When $\mathbb{P}_0$ and $\mathbb{P}_1$ are discrete measures, (4) is a linear problem and can be solved with a supercubic complexity $\mathcal{O}(n^3 \log(n))$, where n denotes the sample size. To overcome this computational drawback, Cuturi et al. (2013) added an entropic regularization term to the transport cost to obtain a strongly convex problem solvable using the Sinkhorn-Knopp algorithm (Sinkhorn, 1964) leading to a computational cost of $\mathcal{O}(n^2)$. The bias introduced by the regularization term, i.e., the quantity is not longer zero when comparing to the same probability distribution, have been corrected by Genevay et al. (2019) leading to the known Sinkhorn Divergence (SD) defined as:

$$\mathrm{SD}_\varepsilon(\mathbb{P}_0,\mathbb{P}_1) = \mathrm{W}_\varepsilon(\mathbb{P}_0,\mathbb{P}_1) - \frac{1}{2}\sum_{i=0}^{1} \mathrm{W}_\varepsilon(\mathbb{P}_i,\mathbb{P}_i),$$

where $\mathrm{W}_\varepsilon(\mathbb{P}_0,\mathbb{P}_1)$ is equal to

$$\min_{\pi \,\in\, \mathcal{U}(\mathbb{P}_0,\mathbb{P}_1)} \int_{\mathcal{Z}\times\mathcal{Z}} \|z_0 - z_1\|^p d\pi(z_0, z_1) + \varepsilon\,\mathrm{H}(\pi),$$

with $\mathrm{H}(\pi) = \int \pi(z_0, z_1)\log(\pi(z_0, z_1))dz_0 dz_1$.

3.2.3 Fisher-Rao Distance.

The Fisher-Rao distance (FR) (Rao, 1945) is a Riemannian metric defined on the space of parametric distributions relying on the Fisher information. The Fisher information matrix provides a natural Riemannian structure (Amari, 2012). It is known to be more accurate than popular divergence measures (Costa et al., 2015). Let $\mathcal{M}_+^1(\mathcal{Z}, \mathcal{P})$ be the family of parametric distributions with the parameter space $\mathcal{P} \subset \mathbb{R}^d$. The FR distance is defined as the geodesic distance [2] between elements (i.e., probability measures) on the manifold $\mathcal{M}_+^1(\mathcal{Z}, \mathcal{P})$. Parametrizing $\mathbb{P}_0, \mathbb{P}_1$ by parameters $p_1, p_2 \in \mathcal{P}$, respectively, such that $\mathbb{P}_0^{p_0} \triangleq \mathbb{P}_0$ and $\mathbb{P}_1^{p_1} \triangleq \mathbb{P}_1$, the FR distance between $\mathbb{P}_0^{p_0}$ and $\mathbb{P}_1^{p_1}$ is defined as:

$$\mathrm{FR}(\mathbb{P}_0^{p_0}, \mathbb{P}_1^{p_1}) = \min_{\gamma} \int |\sqrt{\gamma'(t)^\top G(p_0, p_1)\gamma(t)}|dt \tag{5}$$

where $\gamma(t)$ is the curve connecting p_0 and p_1 in the parameter space $\mathcal{P}$; and $G(p_0, p_1)$ is the Fisher information matrix of (p_0, p_1). In general, the optimization problem of (5) can be solved using the well-known Euler-Lagrange differential equations leading to computational difficulties. Atkinson and Mitchell (1981) have provided computable closed-form for specific families of distributions such as

---

[2] The geodesic is the curve that provides the shortest length.

Multivariate Gaussian with diagonal covariance matrix. Under this assumption, the parameters p_0 and p_1 are defined by $p_{i,j} = (\mu_{i,j}, \sigma_{i,j}) \in \mathbb{R}^2$ for $i \in \{0, 1\}$ and $1 \leq j \leq d$ with $\mu_i \in \mathbb{R}^d$ the mean vector and $\text{Diag}(\sigma_i)$ the diagonal covariance matrix of $\mathbb{P}_i$ where σ_i is the variance vector. The resulting FR metric admits the following closed-form (see e.g. Pinele et al. (2020):

$$\text{FR}(\mathbb{P}_0^{p_0}, \mathbb{P}_1^{p_1}) = \sqrt{\sum_{j=1}^{d} [d_{\text{FR}}(p_{0,j}, p_{1,j})]^2},$$

where $d_{\text{FR}}(p_{0,j}, p_{1,j})$ is the univariate Fisher-Rao detailed in the App. A.1 for the sake of space.

3.2.4 Jeffrey Divergence.

The Jeffrey divergence (J) is a symmetric version of the Kullback-Leibler (KL) divergence and measures the similarity between two probability distributions. Formally, it is defined as follow:

$$\text{J}(\mathbb{P}_0, \mathbb{P}_1) = \frac{1}{2}\big[\text{KL}(\mathbb{P}_0 \| \mathbb{P}_1) + \text{KL}(\mathbb{P}_1 \| \mathbb{P}_0)\big].$$

Computing the $\text{KL}(\mathbb{P}_0 \| \mathbb{P}_1)$ either requires to have knowledge of $\mathbb{P}_0$ and $\mathbb{P}_1$, or to have knowledge about the density ratio (Rubenstein et al., 2019). Without any further assumption on $\mathbb{P}_0$, $\mathbb{P}_1$ or the density ratio, the resulting inference problem is known to be provably hard (Nguyen et al., 2010). Although previous works have addressed the estimation problem without making assumptions on $\mathbb{P}_0$ and $\mathbb{P}_1$ (Oord et al., 2018; Hjelm et al., 2018; Belghazi et al., 2018), these methods often involve additional parameters (e.g., neural networks (Song and Ermon, 2019), kernels (McAllester and Stratos, 2020)), require additional tuning (Hershey and Olsen, 2007), and are time expensive. Motivated by speed, simplicity and to allow for fair comparison with FR, for this specific divergence, we choose to make the assumption that $\mathbb{P}_0$ and $\mathbb{P}_1$ are multivariate Gaussian distributions with mean vector μ_0 and μ_1 and diagonal covariance matrices: Σ_0 and Σ_1. Thus, $\text{KL}(\mathbb{P}_0, \mathbb{P}_1)$ boils down to:

$$\log\frac{|\Sigma_0|}{|\Sigma_1|} - d + \text{Tr}(\Sigma_0^{-1}\Sigma_1) + (\mu_0 - \mu_1)^T \Sigma_0^{-1} (\mu_0 - \mu_1),$$

where $\text{Tr}(\Sigma_0^{-1}\Sigma_1)$ is the trace of $\Sigma_0^{-1}\Sigma_1$.

Remark. *FR and J are computed under the multivariate Gaussian with diagonal covariance matrix assumption. In this case, the Sinkhorn approximation is not needed as (4) can be efficiently computed thanks to the following closed-form:*

$$\text{W}(\mathbb{P}_0, \mathbb{P}_1) = \|\mu_0 - \mu_1\|^2 + \text{Tr}\left(\Sigma_0 + \Sigma_1 - 2(\Sigma_0\Sigma_1)^{1/2}\right)$$

Remark. *Quantities defined in this section are replaced by their empirical estimate. Due to space constraints, the formula are described in App. A.2.*

4 Experimental Setting

In this section, we describe the datasets, metrics, encoder and baseline choices. Additional experimental details can be found in App. D. For fair comparison, all models were re-implemented.

4.1 Datasets

To ensure backward comparison with previous works, we choose to rely on the `DIAL` (Blodgett et al., 2016) and the `PAN` (Rangel et al., 2014) datasets. For both, main task labels (Y) and sensitive labels (S) are binary, balanced and splits follow (Barrett et al., 2019). Random guessing is expected to achieve near 50% of accuracy.

The `DIAL` corpus has been automatically built from tweets and the main task is either polarity[3] or mention prediction. The sensitive attribute is related to race (i.e., non-Hispanic blacks and non-Hispanic whites) which is obtained using the author geo-location and the words used in the tweet.

The `PAN` corpus is also composed of tweets and the main task is to predict a mention label. The sensitive attribute is obtained through a manual process and annotations contain the age and gender information from 436 Twitter users.

4.2 Metrics

For the choice of the evaluation metrics, we follow the experimental setting of Colombo et al. (2021d); Elazar and Goldberg (2018); Coavoux et al. (2018). To measure the success of the main task, we report the classification accuracy. To measure the degree of disentanglement of the latent representation we train from scratch an adversary to predict the sensitive labels from the latent representation. In this framework, a perfect model would achieve a high main task accuracy (i.e., near 100%) and a low (i.e., near 50%) accuracy as given by the adversary prediction on the sensitive labels. Following Colombo

Tab. 1: Results on the fair classification task: the main task (higher is better) accuracy corresponds to the column with $Y(\uparrow)$ and $S(\downarrow)$ denotes the sensitive task accuracy (lower is better). CE refers to a classifier trained with CE loss solely ($\lambda = 0$ in (1)).

et al. (2021d), we also report the disentanglement dynamic following variations of λ and train a different model for each $\lambda \in [0.001, 0.01, 0.1, 1, 10]$.

4.3 Models

Choice of the encoder. Previous works that aim at learning disentangled representations either focus on randomly initialized RNN-encoders (Colombo et al., 2021d; Elazar and Goldberg, 2018; Coavoux et al., 2018) or only use pretrained representations as a feature extractor (Ravfogel et al., 2020). In this work, we choose to fine-tune BERT during training as we believe it to be a more realistic setting.

Choice of the baseline models. We choose to compare our methods against adversarial training from Elazar and Goldberg (2018); Coavoux et al. (2018) (model named ADV) and the recently MI bound introduced in (Colombo et al., 2021d) (named MI) which has been shown to be more controllable than previous MI-based estimators.

5 Numerical Results

In this section, we gather experimental results for fair classification task. We study our framework when working either with RNN or BERT encoders. The parameter λ (see (3)) controls the trade-off between success on the main task and disentanglement for all models.

5.1 Overall Results

General observations. Learning disentangled representations is made more challenging when S and Y are tightly entangled. By comparing Fig. 2 and Fig. 3, we notice that the race label (main task) is easier to disentangled from the sentiment compared to the mention.

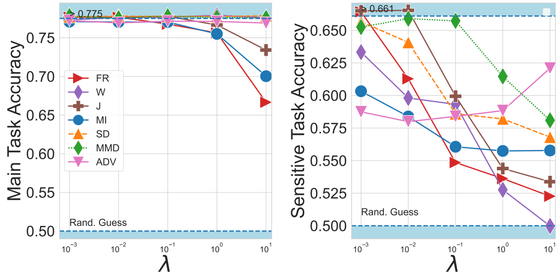
Randomly initialized RNN encoders. To allow a fair comparison with previous works, we start by testing our framework with RNN encoders on the `DIAL` dataset. Results are depicted in Fig. 2. It is worth mentioning that we are able to observe a similar phenomenon that the one reported in Colombo et al. (2021d). More specifically, we observe: (i) the adversary degenerates for $\lambda = 10$ and does not allow to reach perfectly disentangled representations nor to control the desirable degree of disentanglement; (ii) the MI allows better control over the desirable degree of disentanglement and achieves better-disentangled representations at a reduced cost on the main task accuracy. Fig. 2 shows that the encoder trained using the statistical measures of similarity–both with and without the multivariate Gaussian assumption–are able to learn disentangled representations. We can also remark that our losses follow an expected behaviour: when λ increases, more weight is given to the regularizer, the sensitive task accuracy decreases, thus the representations are more disentangled according to the probing-classifier. Overall, we observe that the W regularizer is the best performer with optimal performance for $\lambda = 1$ on both attributes. On the other hand, we observe that FR and J divergence are useful to learn to disentangle the representations but disentangling using these similarity measures comes with a greater cost as compared to W. Both MMD and SD also perform well[4] and are able to learn disentangled representations with little cost on the main task performance. However, on `DIAL`, they are not able to learn perfectly disentangled representations. Similar conclusions can be drawn on `PAN` and results are reported in App. C.1.

BERT encoder. Results of the experiment conducted with BERT encoder are reported in Fig. 3. As expected, we notice that on both tasks the main and the sensitive task accuracy for small values of λ is higher than when working with RNN encoders. When training a classifier without disentanglement constraints (i.e., case $\lambda = 0$ in (1)), which corresponds to the dash lines in Fig. 2 and Fig. 3, we observe that BERT encoder naturally preserves more sensitive information (i.e., measured

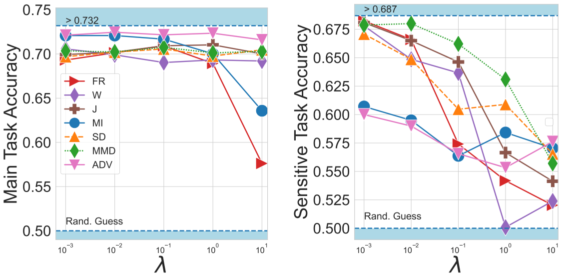
---

[4] For both losses when $\lambda > 10$ we did not remark any consistent improvements.

by the accuracy of the adversary) than randomly initialized encoder. Contrarily to what is usually undertaken in previous works (e.g., Ravfogel et al. (2020)), we allow the gradient to flow in BERT encoder while preforming fine-tuning. We observe a different behavior when compared to previous experiments. Our losses under the Multivariate diagonal Gaussian assumption (i.e., W, J, FR) can only disentangle the representations at a high cost on the main task (i.e., perfect disentanglement corresponds to performance on the main task close to a random classifier). When training the encoder with either SD or MMD, we are able to learn disentangled representations with a limited cost on the main task accuracy: $\lambda = 0.1$ achieves good disentanglement with less than 3% of loss in the main task accuracy. The methods allow little control over the degree of disentanglement and there is a steep transition between light protection with no loss on the main task accuracy and strong protection with discriminative features destruction.



(a) Y Mention (b) S Mention



(c) Y Sentiment (d) S Sentiment

Fig. 2: Results on `DIAL` with RNN. Dash lines correspond to model trained with CE loss solely (i.e., case $\lambda = 0$ in (1)). Figures on the left are dedicated to the mention attribute while the one on the rights reports results on the Sentiment attribute. The main task consists in predicting Y thus higher is better. The sensitive task accuracy is obtained by training a classifier to S on the final representation thus an ideal model would reach 50% of accuracy.

Takeaways. Our new framework relying on statistical Measures of Similarity introduces powerful methods to learn disentangled representations. When working with randomly initialized RNN encoders to learn disentangled representation, we advise relying on W. Whereas in presence of pretrained encoders (i.e., BERT), we observe a very different behavior [5] and recommend using SD.

Fig. 3: Results on `DIAL` for mention (left) and sentiment (right) attribute using a pretrained BERT.

5.2 Speed Gain and Parameter Reduction

We report in Table 2 the training time and the number of parameters of each method. The reduced number of parameters brought by our method is marginal, however getting rid of these parameters is crucial. Indeed, they require a nested loop and require a fined selection of the hyperparameters which complexify the global system dynamic.

Takeaways. Contrarily to MI or Adversarial based regularizer that are difficult (or even prohibitive) to be implemented on large-scale datasets, our framework is simpler and consistently faster which makes it a better candidate when working with large-scale datasets.

6 Further Analysis

Results presented in Section 5.1 have shown a different behaviour for RNN and BERT based encoders and, for different measures of similarity.

---

[5] To the best of our knowledge, we are the first to report such a difference in behavior when disentangling attributes with pretrained representations.

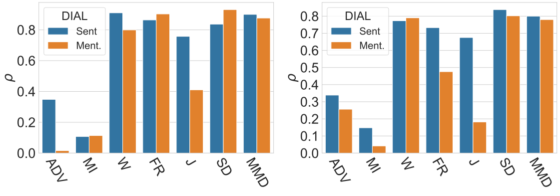
Tab. 2: Speed and number of model parameters (given in thousand) when working with `DIAL`. The runtime for 1 gradient update (denoted 1 upd.) or for 1 epoch is given for a batch of 64 when running our models on a single NVIDIA-V100. The relative improvements (in %) are given with respect to the MI model, which is our strongest baseline.

Here, we aim at understanding of this phenomena.

6.1 Training Dynamic

In the previous section, we examine the change of the measures during the training.

Takeaways. When using a RNN encoder, the system is able to maximize the main task accuracy while jointly minimizing most of the similarity measures. For BERT where the model is more complex, for measures relying on the diagonal gaussian multivariate assumption either the disentanglement *plateau* (e.g., FR or J) or the system fails to learn discriminative features and perform poorly on the main task (e.g., W). When combined with BERT both SD and MMD can achieve high main task accuracy while protecting the sensitive attribute.



(a) RNN (b) BERT

Fig. 5: Absolute Pearson correlation between the values of R and the sensitive task accuracy.

6.2 Correlation Analysis

In this experiment, we investigate how predictive of the disentanglement is each similarity measure, i.e., does a lower value of similarity measure indicates better disentangled representations? We gather for both the mention and sentiment attribute 5 checkpoints per model (i.e., each regularizer and each value of λ corresponds to one model). For each RNN model, we select one checkpoint after $5\text{k}, 10\text{k}, 15\text{k}, 20\text{k}, 25\text{k}$ gradient updates, and for BERT we select one checkpoint after $2\text{k}, 4\text{k}, 6\text{k}, 8\text{k}, 10\text{k}$ gradient updates to obtain the same number of models. For each type of loss, we ended with 50 models. For each model and each checkpoint, we train an adversary, compute the sensitive task accuracy and evaluate the Pearson correlation between the sensitive task accuracy and the corresponding similarity measure. Results are presented in Fig. 5.

Takeaways. Both ADV and MI poorly are correlated with the degree of disentanglement of the learned representations. We find this result not surprising at light of the findings of Xie et al. (2017) and Song and Ermon (2019). All our losses achieve high correlation ($\rho \geq 78$) except for J in the mention task with both encoders, and the FR with BERT on the mention task that achieves medium/low correlation. We believe, that the high correlation showcases the validity of the proposed approaches.

7 Summary and Concluding Remarks

We have introduced a new framework for learning disentangled representations which is faster to train, easier to tune and achieves better results than adversarial or MI-based methods. Our experiments on the fair classification task show that for RNN encoders, our methods relying on the closed-form of similarity measures under a multivariate Gaussian assumption can achieve perfectly disentangled representations with little cost on the main tasks (e.g. using Wasserstein). On BERT representations, our experiments show that the Sinkhorn divergence should be preferred. It can achieves almost perfect disentanglement at little cost but allows for fewer control over the degree of disentanglement.

A Additional details on Statistical Measures of Similarity

It is the purpose of this part to recall additional details on similarity measures defined in the core paper.

A.1 Univariate Fisher-Rao distance

Here, we recall the definition of the univariate Fisher-Rao distance used in the Section 3.2. Let $\mathbb{Q}_1, \mathbb{Q}_2$ be two univariate probability distributions with mean $m_1, m_2 \in \mathbb{R}$ and standard deviation $\sigma_1, \sigma_2 \in \mathbb{R}$. Thus, the univariate Fisher-Rao distance between the tuples (m_1, σ_1) and (m_2, σ_2) denoted by d_{FR} is defined as:

$$\sqrt{2} \log \frac{\sqrt{\frac{(m_1-m_2)^2}{2} + (\sigma_1+\sigma_2)^2} + \sqrt{\frac{(m_1-m_2)^2}{2} + (\sigma_1-\sigma_2)^2}}{\sqrt{\frac{(m_1-m_2)^2}{2} + (\sigma_1+\sigma_2)^2} - \sqrt{\frac{(m_1-m_2)^2}{2} + (\sigma_1-\sigma_2)^2}}.$$

A.2 Empirical versions of Statistical Measures of Similarity

Our experimental setting involves the tuple $\left(X^i, S^i, Y^i\right)_{i=1}^n$ where $X^1, \dots, X^n$ is a sample of texts drawn from the random variable $X \in \mathcal{X}$, $S^1, \dots, S^n$ is a sample of binary random variables corresponding to the sensitive attribute and $Y^1, \dots, Y^n$ is a sample of binary random variables coming from the classification task. Considering the embedding function f_θ, we denote by $Z^1, \dots, Z^n$ the embedding sample such that $Z^i = f_\theta(X^i)$ for every $1 \leq i \leq n$. Assume that $\{i_1, \dots, i_{n_0}\}$ and $\{j_1, \dots, i_{n_1}\}$ are two subsets of $\{1, \dots, n\}$ such that $S_{i_k} = 0$ and $S_{j_l} = 1$ for every $1 \leq k \leq n_0$ and $1 \leq l \leq n_1$. The empirical versions of the conditional measures $\mathbb{P}_0, \mathbb{P}_1$ are given by

$$\hat{\mathbb{P}}_0 = \frac{1}{n_0} \sum_{i \in \{i_1, \dots, i_{n_0}\}} \delta_{Z^i}, \; \hat{\mathbb{P}}_1 = \frac{1}{n_1} \sum_{j \in \{j_1, \dots, j_{n_1}\}} \delta_{Z^j}.$$

In practice, distances recalled in Section 3.2 are computed between $\hat{\mathbb{P}}_0$ and $\hat{\mathbb{P}}_1$ leading to the following distances.

Maximum Mean Discrepancy. The MMD is defined as:

$$\begin{aligned} \text{MMD}(\hat{\mathbb{P}}_0, \hat{\mathbb{P}}_1) = & \frac{1}{n_0(n_0-1)} \sum_{\substack{i,k \in \{i_1, \dots, i_{n_0}\} \\ i \neq k}} k(Z^i, Z^k) \\ & + \frac{1}{n_1(n_1-1)} \sum_{\substack{j,l \in \{j_1, \dots, j_{n_1}\} \\ j \neq l}} k(Z^j, Z^l) \\ & - \frac{2}{n_0 n_1} \sum_{\substack{i \in \{i_1, \dots, i_{n_0}\} \\ j \in \{j_1, \dots, j_{n_1}\}}} k(Z^i, Z^j). \end{aligned}$$

Sinkhorn divergence. Let $\mathbf{1}_{n_0}, \mathbf{1}_{n_1}$ denote the vectors of one with size n_0, n_1 respectively. Let $\mathcal{U}(\hat{\mathbb{P}}_0, \hat{\mathbb{P}}_1) = \{\Pi \in \mathbb{R}^{n_0 \times n_1} \mid \Pi \mathbf{1}_{n_1} = \mathbf{1}_{n_0}/n_0, \; \Pi^\top \mathbf{1}_{n_0} = \mathbf{1}_{n_1}/n_1\}$ be the set of joint probability distributions with marginals $\hat{\mathbb{P}}_0$ and $\hat{\mathbb{P}}_1$ where $/$ is the element-wise division. The Sinkhorn approximation of the 1-Wasserstein distance, denoted by $\text{W}_\varepsilon(\hat{\mathbb{P}}_0, \hat{\mathbb{P}}_1)$, is defined as the following optimization problem:

$$\min_{\Pi \in \mathcal{U}(\hat{\mathbb{P}}_0, \hat{\mathbb{P}}_1)} \sum_{\substack{i \in \{i_1, \dots, i_{n_0}\} \\ j \in \{j_1, \dots, j_{n_1}\}}} \Pi_{i,j} \text{D}_{i,j} + \varepsilon \sum_{\substack{i \in \{i_1, \dots, i_{n_0}\} \\ j \in \{j_1, \dots, j_{n_1}\}}} \Pi_{i,j} \log(\Pi_{i,j}),$$

where $\text{D}_{i,j}$ is the euclidean distance between Z^i and Z^j. We limit ourselves to the 1-Wasserstein for the sake of place. The Sinkhorn divergence is then:

$$\text{SD}_\varepsilon(\hat{\mathbb{P}}_0, \hat{\mathbb{P}}_1) = \text{W}_\varepsilon(\hat{\mathbb{P}}_0, \hat{\mathbb{P}}_1) - \frac{1}{2} \sum_{i=0}^{1} \text{W}_\varepsilon(\hat{\mathbb{P}}_i, \hat{\mathbb{P}}_i).$$

It is worth noticing that a robust version of the Wasserstein distance can be found in (Staerman et al., 2021a) (see also (Staerman et al., 2021b)).

Fisher-Rao distance. The Fisher-Rao distance is defined as

$$\text{FR}(\hat{\mathbb{P}}_0^{\hat{p}_0}, \hat{\mathbb{P}}_1^{\hat{p}_1}) = \sqrt{\sum_{j=1}^{d} [d_{\text{FR}}(\hat{p}_{0,j}, \hat{p}_{1,j})]^2},$$

where $d_{\text{FR}}(\hat{p}_{0,j}, \hat{p}_{1,j})$ is defined as in Section A.1, and m_1, m_2 and σ_1, σ_2 are replaced by $\hat{\mu}_{0,j}, \hat{\mu}_{1,j}$ and $\hat{\sigma}_{0,j}, \hat{\sigma}_{1,j}$ the classical (univariate) unbiased mean and standard deviation estimators respectively.

Jeffrey divergence. Let $(\hat{\mu}_0, \hat{\Sigma}_0)$ and $(\hat{\mu}_1, \hat{\Sigma}_1)$ be the mean and the covariance matrix estimators of the samples $Z^{i_1}, \ldots, Z^{i_{n_0}}$ and $Z^{j_1}, \ldots, Z^{j_{n_1}}$ respectively. Jeffrey divergence–under the multivariate Gaussian assumption–boils down to:

$$\log \frac{|\hat{\Sigma}_0|}{|\hat{\Sigma}_1|} - d + \mathrm{Tr}(\hat{\Sigma}_0^{-1}\hat{\Sigma}_1) + (\hat{\mu}_0 - \hat{\mu}_1)^T \hat{\Sigma}_0^{-1}(\hat{\mu}_0 - \hat{\mu}_1).$$

Furthermore, under the multivariate Gaussian assumption, the Wasserstein distance writes as follows:

$$\mathrm{W}(\hat{\mathbb{P}}_0, \hat{\mathbb{P}}_1) = \|\hat{\mu}_0 - \hat{\mu}_1\|^2 + \mathrm{Tr}\left(\hat{\Sigma}_0 + \hat{\Sigma}_1 - 2(\hat{\Sigma}_0\hat{\Sigma}_1)^{1/2}\right)$$

B Algorithm

The algorithm we propose to compute (3) involves a simple training loop and is described in Algorithm 1.

Algorithm 1 Training Algorithm

```
1: INPUT $\mathcal{D} = \{(x_j, s_j, y_j), \forall j \in [1, n]\}$, $\theta$ weights of the encoder network, $\phi$ parameters of the main classifier.
2: INITIALIZE parameters $\theta$, $\phi$.
3: while $(\theta, \phi)$ not converged do        ▷ Single loop
4:     Sample a batch $\mathcal{B}$ from $\mathcal{D}$
5:     Compute CE                  ▷ Classification Loss
6:     Compute SM                  ▷ Disentanglement Loss
7:     Update $\theta, \phi$ with $\mathcal{B}$ using AdamW.
8: end while
9: OUTPUT Encoder and main classifier weights $\theta, \phi$
```

C Additional Results

In this section, we gather additional experimental results.

C.1 Results on PAN

We report in Fig. 6 and Fig. 7 the results of the disentanglement analysis on the `PAN` dataset.

RNN encoders. We can make the same observations that the one done on `DIAL` in Section 5.1. We observe that the W regularizer performs well and is among the most controllable loss. It is worth noting the good performance of the SD and MMD losses which both work well on the RNN encoder.

BERT. For BERT encoder, we observe a similar steep transition than in Section 5.1 and we can draw similar conclusions. FR , W and J fail to disentangle BERT representation with little cost on the main task. SD and MMD achieve good results.

Takeaways. When working with randomly initialized RNN encoders to learn disentangled representation we advise relying on W and when working with pretrained encoder we advise to rely on the SD.

		`RNN`			`BERT`

Tab. 3: Results on the fair classification task: the main task (higher is better) accuracy is correspond to the column with $Y(\uparrow)$ and $S \downarrow$ denotes the sensitive task accuracy respectively (lower is better). λ (see Eq. 3 control the trade-off between success on the main task and disentanglement.

C.2 On the Diagonal Gaussian Assumption

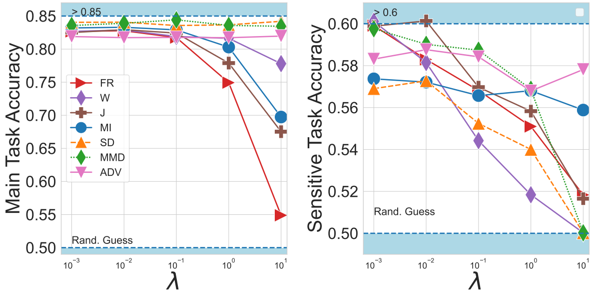
Our closed-form for the Fisher-Rao metric relies on the diagonal Gaussian assumption that we have also made for W and J for a fair comparison. In this experiment (see Fig. 8), we examine this assumption by evaluating the relative distance (using a L_2-norm) between the empirical covariance matrix and a diagonal matrix.

Takeaways. Interestingly, as λ increases, the empirical covariance matrix becomes closer to a diagonal matrix. For BERT, we observe that the W saturates and the distance for $\lambda > 0.1$ is higher than for RNN. This might be the result of the optimization problems identified in Fig. 4. Hence, we observe that our methods–when learning more disentangled representations–is that the covariance matrix becomes closer to a diagonal matrix.

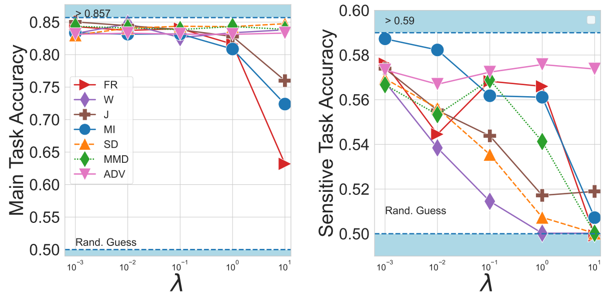
D Experimental Details

D.1 Replication

In this section we gather the model details we used in our experiments. All models rely on the tok-

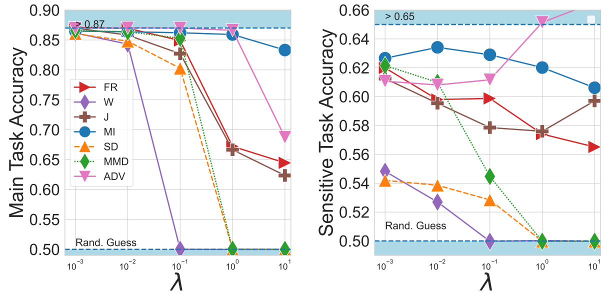


(a) Y RNN `PAN`-Age (b) S RNN `PAN`-Age

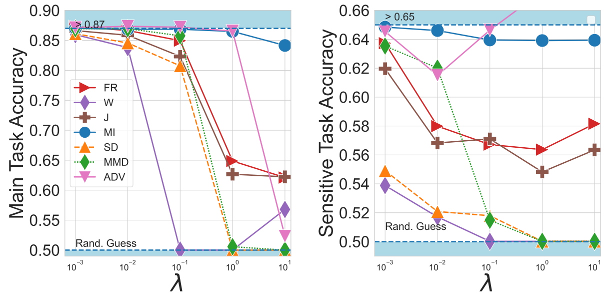


(c) Y RNN `PAN`-Gender (d) S RNN `DIAL`-Gender

Fig. 6: Results on `PAN` with randomly initialized RNN encoders. Dash lines correspond to model trained with CE loss solely (i.e case $\lambda = 0$ in (1)). Figures on the left are dedicated to the age attribute while the one on the rights reports results on the gender attribute. The main task consists in predicting Y thus higher is better. The sensitive task accuracy is obtained by training a classifier to S on the final representation thus an ideal model would reach 50% of accuracy



(a) Y BERT `PAN`-Age (b) S BERT `PAN`-Age



(c) Y BERT `PAN`-Gender (d) S BERT `PAN`-Gender

enizer based on Word Piece (Schuster and Nakajima, 2012) and is similar to the one used for BERT (*i.e* `bert-base-uncased`) and possess over $40k$ tokens.

Model Architecture for the RNN encoder. For the randomly initialized RNN encoder, we use a bidirectionnal GRU (Chung et al., 2014) that is composed of 2 layers with an hidden dimension of 128. For activation, we use LeakyReLU (Xu et al., 2015) and the classification head is composed of fully connected layers of input dimension 256. The learning rate of AdamW (Loshchilov and Hutter, 2017) is set to 0.0001 and the dropout (Srivastava et al., 2014) is set to 0.2. The number of warmup steps (Vaswani et al., 2017) is set to 1000.

Computational Resources. For all 140 models, we train on NVIDIA-V100 with 32GB of RAM. Each model is trained for 30k steps and the model with the best disentanglement accuracy is selected based on the validation set. Each model takes around 5 hours to train. Evaluation requires to train and adversary composed of 3 hidden layers of input 128-128-128-2. The evaluation which involves the training of the probing classifier takes below 1 hour of GPU time. Overall, we train 6 different classifiers per model which correspond to 840 models.

Model Architecture for the BERT encoder. For the BERT encoder, we add a classification head composed of one fully connected layer. We use a learning rate of 0.00001 for AdamW and he number of warmup steps is set to 1000.

Computational Resources. For all the 140 models, we train on NVIDIA-V100 with 32GB of RAM. Each model is trained for 10k steps, which correspond to the convergence of the model and the model with the best disentanglement accuracy is selected based on the validation set. Each model takes approximately 3 hours to train. Evaluation requires to train and adversary composed of 3 hidden layers and involes LeakyRely and dropout rate of 0.1 of input 768-768-768-2. The evaluation which involves the training of the probing classifier takes below 1 hour of GPU time. Overall, we train 6 different classifiers per model which correspond to 840 models.

D.2 Negative Results

We briefly describe a few ideas that did not look promising in our experiments to help future re-

Fig. 8: Relative distance as measured by a L_2 norm between the empirical covariance matrix and a diagonal matrix on `PAN` dataset for various values of S.

search. Specifically,

- We attempt to combine our work with MINE from Belghazi et al. (2018) and we observe high instability during the training.
- We additionally used the clozed-form of MMD under a multivariate Gaussian assumption which lead to poor results (there was no protection against the classifier).
- We also used the Hausdoff distance (Serra, 1998) which interpolates between the Iterative closest point (Chetverikov et al., 2002) loss and a kernel distance as well as MMD with Laplacian kernel (Kondor and Pan, 2016). For both case, we ended with optimization issues and poor trade-offs.

D.3 Dataset Examples

For completness, we gather in this section examples of the `DIAL` and `PAN` corpus. Note that this samples have been randomly selected. We report in Table 4 same randomly sampled examples text from the `DIAL` corpus and order them based on the sensitive attribute race. The polarity label is obtained through emojis. The goal of the mention task is to predict if a tweet is conversational (i.e., contains a @mentions tokens)

We report in Tab. 5 examples from the `PAN` corpus. The age attribute is obtained through birth-date published on the user's Linkedin profile whereas for the gender the authors rely on both the user's name and photograph.

D.4 Related Work General Algorithm

For completeness we provide in Algorithm 2 the algorithm used for training adversarial or MI-based regularizers. It is worth noting that these baselines require extra learnable parameters that need to be tuned using a Nested Loop.

Algorithm 2 Disentanglement using adversarial-based or MI-based regularizer

```

nomenon (Chapuis et al., 2020). Future research also include extending these losses to data augmentation (Dhole et al., 2021; Colombo et al., 2021e) and sentence generation (Colombo et al., 2021c,f) and study the trade-off using rankings (Colombo et al., 2022) or anomaly detection (Staerman et al., 2019, 2020).

D.6 Libraries used.

For this project among the library we used we can cite:

- Transformers from (Wolf et al., 2019).
- Pytorch (Paszke et al., 2017) for the GPU support.
- Geomloss (Feydy et al., 2019) for the SD and MMD. It can be found at `https://www.kernel-operations.io/geomloss`

On the Sensitivity and Stability of Model Interpretations in NLP

Fan Yin, Zhouxing Shi, Cho-Jui Hsieh, and Kai-Wei Chang
University of California, Los Angeles
{fanyin20, zshi, chohsieh, kwchang}@cs.ucla.edu;

Abstract

Recent years have witnessed the emergence of a variety of post-hoc interpretations that aim to uncover how natural language processing (NLP) models make predictions. Despite the surge of new interpretation methods, it remains an open problem how to define and quantitatively measure the *faithfulness* of interpretations, i.e., to what extent interpretations reflect the reasoning process by a model. We propose two new criteria, sensitivity and stability, that provide complementary notions of faithfulness to the existed removal-based criteria. Our results show that the conclusion for how faithful interpretations are could vary substantially based on different notions. Motivated by the desiderata of sensitivity and stability, we introduce a new class of interpretation methods that adopt techniques from adversarial robustness. Empirical results show that our proposed methods are effective under the new criteria and overcome limitations of gradient-based methods on removal-based criteria. Besides text classification, we also apply interpretation methods and metrics to dependency parsing. Our results shed light on understanding the diverse set of interpretations.

1 Introduction

As complex NLP models are widely deployed in real-world applications, there is an increasing interest in understanding how these models come to certain decisions. As a result, the line of research on interpretation techniques grows rapidly, facilitating a broad range of model analysis, from building user trust on models (Ribeiro et al., 2016; Hase and Bansal, 2020) to exposing subtle biases (Zhao et al., 2017; Doshi-Velez and Kim, 2017).

In this paper, we focus on *post-hoc interpretations* in NLP. Given a trained model and a specific input text, post-hoc interpretations assign an importance score to each token in the input which indicates its contribution to the model output. Current methods in this direction can be roughly divided into three categories: gradient-based methods (Simonyan et al., 2014; Li et al., 2016); reference-based methods (Sundararajan et al., 2017; Shrikumar et al., 2017); and perturbation-based methods (Zeiler and Fergus, 2014; Ribeiro et al., 2016).

Despite the emergence of new techniques, one critical issue is that there is little consensus on how to define and evaluate the faithfulness of these techniques, i.e., whether they reflect the true reasoning process by a model. A widely employed criterion, especially in NLP, is the *removal-based* criterion (DeYoung et al., 2020), which removes or only preserves a set of tokens given by interpretations and measures how much the model prediction would change. However, as pointed out in prior work (Bastings and Filippova, 2020; Ancona et al., 2018), the corrupted version of an input produced during evaluations falls out of the distribution that models are trained on, and thus results in an inaccurate measurement of faithfulness. This limitation prevents removal-based metrics from being used as the golden standard for evaluating interpretations. To remedy this, we complement the removal-based criterion with two other criteria, *sensitivity* and *stability*, which are overlooked in prior works.

Sensitivity is based on the notion that models should be more sensitive to perturbations on tokens identified by a faithful explanation. In contrast to the removal-based criterion, which completely removes important tokens, the sensitivity criterion adds small but adversarial perturbations in a local region of the token embedding, and thus preserves the structure of input sentences as well as interactions between context words. This criterion is recently discussed in Hsieh et al. (2020) in computer vision, while we provide comprehensive analyses on various NLP models and tasks. Note that while the removal-based criterion asks the question: *if some important tokens did not 'exist', what would happen*, the sensitivity criterion asks: *if some im-*

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2631 - 2647

portant tokens were 'changed' adversarially, what would happen.

Stability assumes that a faithful interpretation should not produce substantially different explanations for two inputs that the model finds similar. There are several attempts to generate such a pair of inputs. The most relevant one is Ghorbani et al. (2019). However, their method is only applicable to differentiable interpretations. Our work proposes a new paradigm based on adversarial word substitution that employs a black-box algorithm to generate a semantically related neighbor of the original input, which is specially designed for NLP and applicable to all interpretations techniques.

The above two metrics highlight the connection between interpretability and robustness. Experiments show that interpretations which perform well on the removal-based criterion might not do well on the new criteria. Motivated by the limitations of existing interpretations and the desiderata of sensitivity, we propose *robustness-based methods*, based on projected gradient descent (PGD) attacks (Madry et al., 2018) and certifying robustness (Jia et al., 2019; Huang et al., 2019; Shi et al., 2020; Xu et al., 2020). We demonstrate that the new methods achieve top performance under sensitivity and stability. Moreover, as a simple improvement to gradient-based methods, our methods avoid the gradient saturation issues of gradient-based methods under the removal-based criterion.

Another limitation of removal-based metrics emerges when interpreting dependency parsing – when input tokens are removed, the tree structure is drastically changed and a model might not be able to produce a meaningful parse tree. Thus, there are little discussion for dependency parsing interpretations. In this paper, we propose a new paradigm to interpret dependency parsers leveraging prepositional phrase (PP) attachment ambiguity examples. To our best knowledge, this is the first work to study interpretations on dependency parsing. We demonstrate that sensitivity does not change the output tree structure as much as removal-based ones do, and provide analyses for interpretation methods with our paradigm and metrics.

Our contributions can be summarized as follows.

1. We discuss two overlooked notions of faithfulness in NLP interpretations. Our notions emphasize the connection between interpretability and robustness. We systematically evaluate interpretations under these notions, including existed removal-based ones. The code for this paper could be found at `https://github.com/uclanlp/NLP-Interpretation-Faithfulness`.
2. We propose new robustness-based interpretations inspired by the sensitivity metric and demonstrate their effectiveness under both sensitivity and stability.
3. We propose a novel paradigm to evaluate interpretations on the dependency parsing task.

2 Faithfulness Evaluation Criteria

A faithful post-hoc interpretation identifies the important parts of the input a model prediction relies on. Let $x = [x_1; x_2; \ldots; x_n]$ be a sequence of tokens. $e(\cdot)$ denotes the token embedding function. An NLP model f takes the embedding matrix $e(x) \in \mathcal{R}^{n \times d}$ as input and provides its prediction $f(e(x)) = y$. Let $s_y(e(x))$ denote the output score of $f(e(x))$ on y. The exact form of $s_y(e(x))$ is defined in Appendix D. An interpretation assigns an importance score to each token which indicates its contribution to the model decision.

We first review the well-established *removal-based criterion* and emphasize its relation to the two criteria defined in this paper 1) *sensitivity*, and 2) *stability*, for which we propose novel paradigms to adapt them to various NLP tasks.

Removal-based Criterion A well-established notion of interpretation faithfulness is that the presence of important tokens should have more meaningful influence on the model's decision than random tokens, quantified by the removal-based criterion. We adopt the *comprehensiveness* and the *sufficiency* score in DeYoung et al. (2020). The comprehensiveness score measures how much the model performance would drop after the set of "relevant" tokens identified by an interpretation is removed. A higher comprehensiveness score suggests the tokens are more influential to the model output, and thus a more faithful explanation. The sufficiency score measures to what extent the original model performance is maintained when we solely preserve relevant tokens. A lower sufficiency score means less change in the model prediction, and thus a more faithful explanation. See DeYoung et al. (2020) for detailed definitions. Note that completely removing input tokens produces incomplete texts. Large perturbation of this kind lead to several issues as pointed out by prior studies (Feng et al., 2018; Bastings and Filippova, 2020).

Ours: Sensitivity Instead of removing important tokens, the sensitivity criterion adds *local* but adversarial noise to embedding vectors of the important tokens and measures the magnitude of the noise needed to change the model prediction. This is inspired by the notion that models should be more sensitive to perturbations being added to relevant tokens compared to random or irrelevant tokens. From the adversarial robustness perspective (Hsieh et al., 2020), this notion implies that by perturbing the most relevant tokens, we can reach the local decision boundary of a model with the minimum perturbation magnitude.

Given the sequence of relevant tokens r_k, sensitivity adds perturbation to its embedding $e\left(r_k\right)$ but keeps the remaining token embeddings unchanged. Then, it measures the minimal perturbation norm, denoted as ϵ_{r_k}, that changes the model prediction for this instance:

$$\epsilon_{r_k} = \min \|\boldsymbol{\delta}_{\boldsymbol{r_k}}\|_F \quad \text{s.t.} \quad f\left(e\left(x\right) + \boldsymbol{\delta}_{\boldsymbol{r_k}}\right) \neq y,$$

where $\|\cdot\|_F$ is the Frobenius norm of a matrix, and $\boldsymbol{\delta}_{\boldsymbol{r_k}} \in \mathcal{R}^{n\times d}$ denotes the perturbation matrix where only the columns for tokens in r_k have non-zero elements. Since the exact computation of ϵ_{r_k} is intractable, we use the PGD attack (Madry et al., 2018) with a binary search to approximate ϵ_{r_k}. A lower ϵ_{r_k} suggests a more faithful interpretation. In practice, we vary the size of r_k, compute multiple ϵ_{r_k}, and summarize them with the area under the curve (AUC) score.

Ours: Stability Another desired property of faithfulness is that a faithful interpretation should not give substantially different importance orders for two input points that the model finds similar. To construct a pair of similar inputs, we propose to generate contrast examples to the original one by synonym substitutions. A contrast example of x, $\tilde{x}$, satisfies (1) has at most k different but synonymous tokens with x; (2) the prediction score at $\tilde{x}$ changes less than τ compared to the score at x. The goal of these two conditions is to generate (almost) natural examples where the changes of model outputs are smaller than a threshold τ. Given all contrast examples, we search for the one that leads to the largest rank difference $\mathcal{D}$ between the importance order for x, $m\left(x\right)$ and the alternated order $m\left(\tilde{x}\right)$:

$$\begin{gathered}\arg\max_{\tilde{x}} \mathcal{D}\left(m\left(x\right), m\left(\tilde{x}\right)\right), \\ \text{s.t. } \left|s_y\left(e\left(x\right)\right) - s_y\left(e\left(\tilde{x}\right)\right)\right| \leq \tau,\ \|x - \tilde{x}\|_0 \leq k.\end{gathered}$$

Specifically, we first extract synonyms for each token x_i following Alzantot et al. (2018). Then, in the decreasing order of $m\left(x\right)$, we greedily search for a substitution of each token that induces the largest change in $m\left(x\right)$ and repeat this process until the model output score changes by more than τ or the pre-defined constraint k is reached. Finally, we measure the difference $\mathcal{D}$ between two importance ranks using Spearman's rank order correlation (Spearman, 1961). We call this criterion *stability*. A higher score indicates that the ranks between this input pair are more similar, and thus a more faithful interpretation.

Note that instead of using the gradient information of interpretation methods to perturb importance ranks like Ghorbani et al. (2019), our algorithm treats interpretations as black-boxes, which makes it applicable to non-differentiable ones. Also, compared to Ding and Koehn (2021), who manually construct similar input pairs, our method is a fully automatic one as suggested by their paper.

3 Interpretations via Adversarial Robustness Techniques

Experiments indicate that existing methods do not work well with the sensitivity and stability metrics (Sec. 4.2). In this section, we define a new class of interpretation methods by adopting techniques in adversarial robustness to remedy this. We first give a brief review of existing interpretation approaches and then introduce our new methods.

3.1 Existing Interpretation Methods

We roughly divide the existing methods into three categories: *gradient-based methods*, *reference-based methods*, and *perturbation-based methods*, and discuss the representatives of them.

Gradient-based methods The first class of methods leverage the gradient at each input token. To aggregate the gradient vector at each token into a single importance score, we consider two methods: 1) using the L_2 norm, $\left\|\frac{\partial s_y(e(x))}{\partial e(x_i)}\right\|_2$, referred to as **Vanilla Gradient** (VaGrad) (Simonyan et al., 2014), and 2) using the dot product of gradient and input, $\left(\frac{\partial s_y(e(x))}{\partial e(x_i)}\right)^\top \cdot e\left(x_i\right)$, referred to as **Gradient · Input** (GradInp) (Li et al., 2016).

Reference-based methods These methods distribute the difference between model outputs on a reference point and on the input as the importance score for each token. We consider **Inte-**

grated Gradient (IngGrad) (Sundararajan et al., 2017) and **DeepLIFT** (Shrikumar et al., 2017). IngGrad computes the linear intergral of the gradients from the reference point to the input. DeepLIFT decomposes the difference between each neuron activation and its 'reference activation' and back-propagates it to each input token. We use DeepLIFT with the Rescale rule. Note DeepLIFT diverges from IngGrad when multiplicative interactions among tokens exist (Ancona et al., 2018).

Perturbation-based methods Methods in this class query model outputs on perturbed inputs. We choose **Occlusion** (Zeiler and Fergus, 2014) and **LIME** (Ribeiro et al., 2016). Occlusion replaces one token at a time by a reference value and uses the corresponding drop on model performance to represent the importance of each token. LIME uses a linear model to fit model outputs on the neighborhood of input x and represents token importance by the weights in the trained linear model.

3.2 Proposed Robustness-based Methods

We propose two methods inspired from the PGD attack (Madry et al., 2018) and the certifying robustness algorithms (Xu et al., 2020) in adversarial robustness.

VaPGD and PGDInp The PGD attack in adversarial robustness considers a small vicinity of the input and takes several "mini-steps" within the vicinity to search for an adversarial example. Consider the token embeddings for the input x, we perform t iterations of the standard PGD procedure starting from $e^{(0)} = e\left(x\right)$:

$$e^{(j)} = \mathcal{P}\left(e^{(j-1)} - \alpha \nabla s_y\left(e^{(j-1)}\right)\right), \; j = 1, 2, \ldots, t.$$

$\mathcal{P}$ represents the operation that projects the new instance at each step back to the vicinity of $e\left(x\right)$, and α is the step size.

Intuitively, $e^{(t)} - e\left(x\right)$ tells us the descent direction of model confidence. Similar to the gradient-based methods, the importance of each token x_i can be either represented by $\left\|e_i^{(t)} - e\left(x_i\right)\right\|_2$, where $e_i^{(t)}$ is the i-th column in $e^{(t)}$, referred to as **Vanilla PGD** (VaPGD), or by $\left(e\left(x_i\right) - e_i^{(t)}\right)^\top \cdot e\left(x_i\right)$, referred to as **PGD** $\cdot$ **Input** (PGDInp)

Note that different from the PGD attack we use for approximating the sensitivity criterion, we manually decide the magnitude of the vicinity of $e\left(x\right)$ instead of using a binary search. We add perturbations to the whole sentence at the same time. Also, the final $e^{(t)}$ does not necessarily change the model prediction. See Appendix B for details.

Certify Certifying robustness algorithms also consider a vicinity of the original input and aim to provide guaranteed lower and upper bounds of a model output within that region. We use the linear relaxation based perturbation analysis (LiRPA) discussed in (Shi et al., 2020; Xu et al., 2020). LiRPA looks for two linear functions that bound the model. Specifically, LiRPA computes $\overline{\boldsymbol{W}}$, $\underline{\boldsymbol{W}}$, $\overline{\boldsymbol{b}}$, and $\underline{\boldsymbol{b}}$ that satisfy $\sum_i \underline{\boldsymbol{W_i}} e\left(x_i'\right) + \underline{\boldsymbol{b}} \leq s_y\left(e\left(x'\right)\right) \leq \sum_i \overline{\boldsymbol{W_i}} e\left(x_i'\right) + \overline{\boldsymbol{b}}$ for any point $e\left(x'\right)$ that lies within the L_2 ball of $e\left(x\right)$ with size δ. We use the IBP+backward method in Xu et al. (2020). It uses Interval Bound Propagation (Gowal et al., 2018; Mirman et al., 2018) to compute bounds of internal neurons of the model and then constructs the two linear functions with a bound back-propagation process (Zhang et al., 2018; Singh et al., 2019). Finally, the importance score of the i-th token in the input is represented by $\underline{\boldsymbol{W_i}} \cdot e\left(x_i\right)$, where $\underline{\boldsymbol{W_i}}$ is the i-th row of $\underline{\boldsymbol{W}}$. We call this method **Certify**.

Robustness-based vs. Gradient-based Gradient-based methods provide a linear approximation of the model decision boundary at the single input, which is not accurate for non-linear models. Robustness-based methods instead search multiple steps in neighbors and approximate the steepest descent direction better. We also empirically show that robustness-based methods avoid the saturation issue of gradient-based methods, i.e, gradient becomes zero at some inputs. See Appendix H. Note that VaPGD (PGDInp) degrades to VaGrad (GradInp) when the number of iterations is 1.

Robustness-based vs. IngGrad IngGrad leverages the average gradient in a segment between the input and a reference. It is likely to neglect local properties desired by the sensitivity criterion. Robustness-based methods instead search in the vicinity of the input, and thus local properties are better preserved. See results in Sec. 4.2.

4 Experiments on Text Classification

In this section, we present the results on text classification tasks under the three criteria. We find that the correlation between interpretation faithfulness based on different criteria are relatively low in some cases. Results verify the effectiveness of our new methods.

4.1 Experimental Setup

Datasets We conduct experiments on three text classification datasets: SST-2 (Socher et al., 2013), Yelp (Zhang et al., 2015), and AGNews (Zhang et al., 2015) following Jain and Wallace (2019)'s preprocessing approach. All of them are converted to binary classification tasks. SST-2 and Yelp are sentiment classification tasks where models predict whether a review is *negative* (0) or *positive* (1). AGNews is to discriminate between *world* (0) and *business* (1) articles. See Appendix A for statistics of the three datasets. When evaluating interpretation methods, for each dataset, we select 200 random samples (100 samples from class 0 and 100 samples from class 1) from the test set.

Models For text classification, we consider two model architectures: BERT (Devlin et al., 2019) and BiLSTM (Hochreiter and Schmidhuber, 1997).

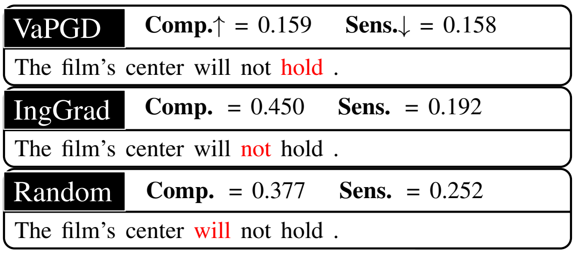
Interpretation Methods Besides our robustness-based interpretations **PGDInp**, **VaPGD**, and **Certify**, we experiment with six others from three existing categories: **VaGrad**, **GradInp** (gradient-based); **IngGrad**, **DeepLIFT** (reference-based); and **Occlusion**, **LIME** (perturbation-based). We also include a random baseline **Random** that randomly assigns importance scores. We use comprehensiveness (**Comp.**), sufficiency (**Suff.**), sensitivity (**Sens.**), and stability (**Stab.**) as metrics.

See Appendix A∼C for experimental details.

4.2 Results and Discussion

Overall Results Results of interpretations for BERT and BiLSTM are presented in Table 1 and 2. The interpretations' performance are averaged over three runs on models trained from different random seeds. Results verify the effectiveness of our proposed robustness-based methods. Specifically, VaPGD achieves the best performance under the sensitivity and the stability criteria for both BERT and BiLSTM. Our methods also outperform their gradient-based counterparts under removal-based criteria. Especially, when interpreting BERT on SST-2 and AGNews, GradInp has near random performance. PGDInp can avoid these unreasonable behaviors. See Appendix H for a qualitative study on this, where we find PGDInp does not suffer from the saturation issue as GradInp. Also notice that the superior performance of robsutness-based methods are consistent on BERT and BiLSTM+GloVe, which demonstrate that it is not influenced by the embeddings being used.

(a) Model Prediction: Negative



VaPGD **Comp.**↑ = 0.159 **Sens.**↓ = 0.158

The film's center will not hold .

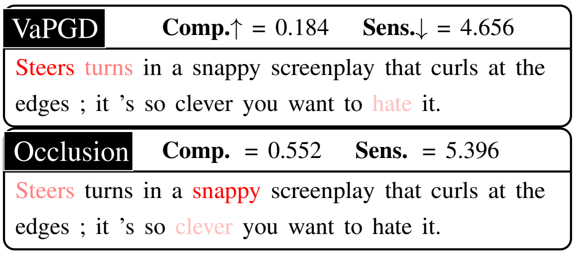
IngGrad **Comp.** = 0.450 **Sens.** = 0.192

The film's center will not hold .

Random **Comp.** = 0.377 **Sens.** = 0.252

The film's center will not hold .

(b) Model Prediction: Positive



VaPGD **Comp.**↑ = 0.184 **Sens.**↓ = 4.656

Occlusion **Comp.** = 0.552 **Sens.** = 5.396

Steers turns in a snappy screenplay that curls at the edges ; it 's so clever you want to hate it.

Figure 1: Two examples demonstrating different notions of faithfulness given by Comp. and Sens. A deeper red means the token is identified as more important. Comp. and Sens. scores are also shown.

However, the performance of other methods tend to be inconsistent under different measurements. For example, under the removal-based criterion, IngGrad performs well for BiLSTM, which gives four out of six best numbers. But, IngGrad has very limited performance under the sensitivity metric, especially for BiLSTM on SST-2 and Yelp. Similar issues exist for LIME and Occlusion. Also, one might fail to recognize the faithfulness of VaPGD by solely looking at the removal-based criterion. Thus, when deploying interpretation methods on real tasks, we advocate for a careful selection of the method you use based on the underlying faithfulness notion that aligned with your goal.

4.3 Discussion

Performance Curves To show how the size of the relevant set affects interpretation performance, we plot the comprehensiveness and the sensitivity curves when increasing the number of tokens being removed (perturbed). Consider interpreting BERT on Yelp as an example, we collect two groups of examples from the test set of Yelp based on input lengths, where examples in each group are of 30 ± 5 and 120 ± 5 tokens long, and remove (perturb) the top-k most important tokens given by interpretations. Results are shown in Figure 2.

As shown in the figure, Occlusion is able to discover a smaller set of impactful tokens, under both metrics. However, when the size of the relevant

Table 2: Results of evaluating different interpretation methods for BiLSTM. Same symbols as above.

set is increased, the performance of IngGrad under the comprehensiveness metric and the performance of VaPGD under the sensitivity metric gradually surpass Occlusion and other methods. This implies that the two methods are better at identifying a relevant set with more tokens.

Interpolation Analysis To check whether the comprehensiveness and sensitivity scores can reflect the relative importance of each token in the relevant set, we conduct an interpolation analysis that gradually replaces each token in the relevant set with a random token outside of the set.

Specifically, we select 50 examples from SST-2 and test on BERT with relevant sets given by LIME and VaPGD. For each example, we extract a relevant set consists of the top four most important tokens and gradually replace each token, from the least to the most important one, with a random token. We denote the relevant set at each step as $S_0, S_1, ..., S_4$, where S_0 is the original relevant set containing the top four tokens and S_4 is the set of four random tokens. The performance change at step i is represented by $f(i) = \frac{|M(S_0)-M(S_i)|}{|M(S_0)-M(S_4)|}$, where M is the comprehensiveness or sensitivity score. We expect that a good metric should induce a monotonically increasing function f. Further, f should be strictly convex as that indicates the importance of each token is different.

We plot the curve in Figure 3. Results show that both the comprehensiveness and sensitivity metrics generate a monotonically increasing function, which indicates that they fully consider each token in the relevant set. Also, notice that based on the comprehensiveness metric, the contribution of each token tends to distribute evenly within the relevant set, which contradicts the fact that tokens in the set have different contribution to the prediction, while the importance rank is better preserved based on the sensitivity metric,.

Different Notions of Faithfulness Finally, we qualitatively study the notions of faithfulness defined by comprehensiveness (*comp.*) and sensitivity (*sens.*), and discuss two main differences.

First, *comp.* removes important tokens during

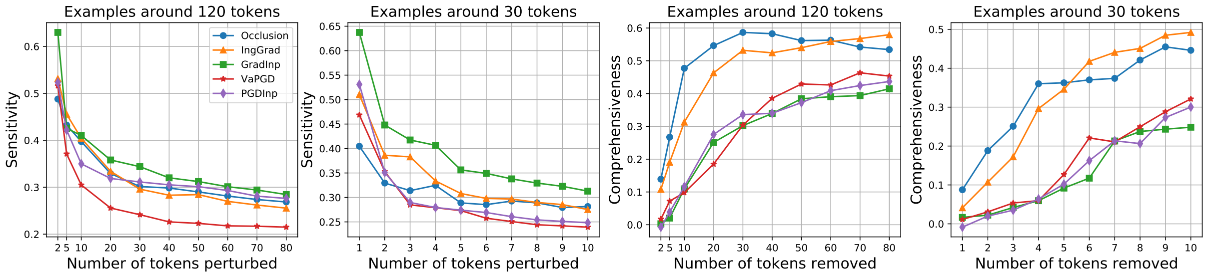

Figure 2: Evaluation curves of five interpretation methods. The title of each figure indicates the group of examples based on input lengths. The X-axis is the number of tokens being perturbed or removed for each instance, which varies in 1, 2, . . ., 10 for 30 tokens and 2, 5, 10, 20, . . ., 80 for 120 tokens. The Y-axis is the performance under the criterion. Results imply that IngGrad and VaPGD could be better at identifying a relevant set with more tokens.

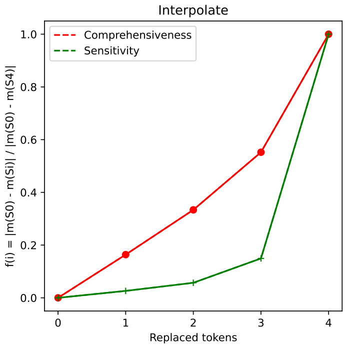

Figure 3: Interpolation between the relevant set and a random set. The relevant set for Comprehensiveness is given by LIME, and the set for Sensitivity is given by VaPGD. We find that Sensitivity better preserves the relative importance for each token in the relevant set.

evaluations, which could possibly break the interaction between removed tokens and context tokens, and underestimate the importance of context tokens. In Figure 1(a), the tokens ‘not’ and ‘hold’ together determine the negative sentiment of the sentence. *Sens.* considers both ‘not’ and ‘hold’ as important tokens as one expects. However, *comp.* regards ‘hold’ less important than ‘will’.

Second, *sens.* measures token importance by how much model performance would change after ‘adversarially perturbing’ that token. In this sense, both positive and negative pertinent tokens will be deemed important. In contrast, *comp.* only considers positive pertinent ones. In Figure 1(b), which is predicted as positive, removing the negative verb ‘hate’ would not influence model performance much. However, adversarially perturbing ‘hate’ (e.g. change ‘hate’ to a more negative verb) might change the model prediction from positive to negative. Thus, *sens.* prefers interpretations that identify ‘hate’ as an important token like VaPGD.

The full version of Figure 1(b) is in Appendix E. Some contrast examples generated for the stability criterion are presented in Appendix F.

5 Experiments on Structured Prediction

Structured prediction tasks are in the center of NLP applications. However, applying interpretation methods and criteria to these tasks are difficult because 1) the required output is a structure instead of a single score. It is hard to define the contribution of each token to a structured output, and 2) compared to text classification tasks, removing parts of the input like what removal-based criteria do, would cause more drastic changes to model predictions as well as the groundtruth. Therefore, existing works often conduct experiments only on binary or multi-class text classification tasks. To remedy these issues, we investigate interpretations for dependency parsing, with an special focus on analyzing how models resolve the PP attachment ambiguity, which avoids interpreting the structured output as a whole. We show that our sensitivity metric is a better metric for dependency parsing as it causes negligible changes to model outputs compared to removal-based metrics.

5.1 Evaluation Paradigm

Our paradigm focuses on the PP attachment ambiguity, which involves both syntactic and semantics considerations. A dependency parser needs to determine either the preposition in PP attaches to the preceding noun phrase NP (NP-attachment) or the verb phrase VP (VP-attachment) (Hindle and Rooth, 1993). The basic structure of ambiguity is VP – NP – PP. For example, in the sentence *I saw a cat with a telescope*, a parser uses the semantics of the noun phrase *a telescope* to predict the head of *with*, which is *saw*. If we change *a telescope* to

Method	PTB-SD Comp.	 Sens.
Random	0.051	10.928
VaGrad	0.156	3.373
GradInp	0.152	5.257
IngGrad	0.190	4.315
DeepLIFT	0.153	5.252
Occlusion	0.194	4.671
LIME	**0.195**	4.529
PGDInp	0.163	4.704
VaPGD	0.157	**3.358**
Certify	0.155	4.701

Table 3: Evaluating interpretations for DeepBiaffine under the comprehensiveness and the sensitivity metric on the dependency parsing task.

a tail, the head of *with* would become the preceding noun *cat*. We will later call nouns in PPs like *telescope* “disambiguating nouns", as they provide semantic information for a parser to disambiguate PP attachment ambiguity. The main advantage of this paradigm is that disambiguating nouns can be viewed as “proxy groundtruths” for faithfulness as parsers must rely on them to make decisions.

Experimental Setup We use DeepBiaffine, a graph-based dependency parser as the target model (Dozat and Manning, 2017). We extract 100 examples that contain the PP attachment ambiguity from the English Penn Treebank converted to Stanford Dependencies 3.5.0 (PTB-SD). We consider the same interpretation methods as before, and they assign an importance score to each token in the sentence to indicate how much it impacts the model prediction on PP attachment arcs. We test the faithfulness of the attributions using comprehensiveness and sensitivity. See Appendix A∼C for details.

5.2 Results and Discussion

Results are shown in Table 3. Similar to the results on text classification tasks, we find that perturbation-based methods like LIME and Occlusion perform well under the comprehensiveness score, while VaPGD performs the best under sensitivity. PGDInp and Certify are slightly better than GradInp under both the two metrics.

Qualitatively, we find that according to interpretation methods, important tokens for a PP-attachment decision converge tothe preposition itself, the preceding noun or verb, and the disambiguating noun. This is close to human expectations. An example is shown in Appendix E.

	PGD	Occlusion	IngGrad	GradInp
Comp.	0.82	0.81	0.81	0.79
Sens.	0.95	0.96	0.95	0.95

Table 4: Similarity between the parser outputs before and after applying the evaluation metric. We show that sensitivity changes the global model output less.

Metric Check Removing even a small piece of inputs breaks the dependency tree. It will be hard to distinguish either the decision process behind the model has changed or the removal of important tokens actually causes the performance drop. Thus, we expect a better metric to have less influence on the tree structure of a sentence. In Table 4, we show that evaluating interpretations with sensitivity leads to smaller changes in the output dependency tree compared to comprehensiveness, suggesting sensitivity a more compatible metric for the dependency parsing task interpretations.

Disambiguating Noun Analysis Disambiguating nouns are expected to be identified as important signals by faithful interpretations. We summarize how many times they are actually recognized as the top-k most important words by interpretation methods, where k is the interval varies in 10-20%, . . . , 90-100% of total tokens in an example.

Results in Figure 4 demonstrate that interpretation methods from the same category have high correlations when extracting disambiguating nouns. For example, VaGrad and VaPGD leveraging gradients only, tend to position disambiguating nouns on the top of their importance lists, which is consistent with human judgments. Likewise, the perturbation-based methods, Occlusion and LIME, also put the disambiguation words to very similar positions.

6 Related Work

Interpretation methods Various post-hoc interpretation methods are proposed to explain the behaviors of black-box models. These methods can be roughly categorized into three classes: gradient-based methods (Simonyan et al., 2014; Li et al., 2016), which leverage local gradient information; reference-based methods (Shrikumar et al., 2017; Sundararajan et al., 2017), which consider the model output difference between the original point and a reference point; and perturbation-based methods (Ribeiro et al., 2016; Zeiler and Fergus, 2014; Lundberg and Lee, 2017), which query model outputs on perturbed data. In our work, we propose

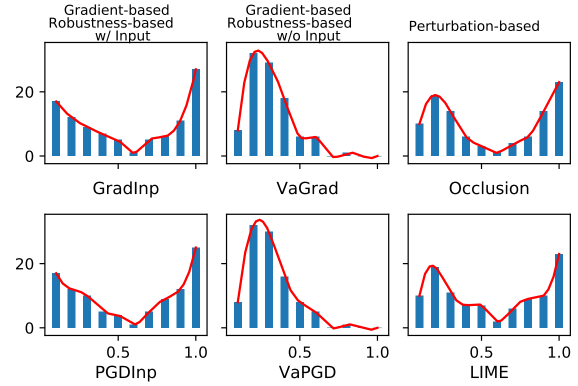

Figure 4: Where do interpretations place the disambiguating nouns. The results demonstrate obvious patterns in different categories. The X-axis is the top-k interval. Scales in {10%, 20%, . . ., 100%}. The Y-axis is the number of examples that an interpretation ranks the disambiguating noun within each top-k interval.

new interpretation methods called robustness-based methods, which adopt techniques in the adversarial robustness domain and bridge the gap between the gradient-based and the reference-based methods.

Evaluating interpretation methods One line of studies explores approaches to evaluate interpretations. Several studies propose measurements for faithfulness. A large proportion of them occlude tokens identified as important by interpretations and measure the confidence change of models (DeYoung et al., 2020; Jain and Wallace, 2019; Zaidan and Eisner, 2008; Serrano and Smith, 2019). Some other works propose to evaluate the faithfulness by checking to what extent they satisfy some desired axioms (Ancona et al., 2018; Sundararajan et al., 2017; Shrikumar et al., 2017). Besides, Alvarez-Melis and Jaakkola (2018); Ghorbani et al. (2019); Kindermans et al. (2019); Yeh et al. (2019) reveal limitations in interpretation faithfulness through testing the robustness of interpretations. Another group of studies measure the plausibility of interpretations, i.e., whether the explanations conform with human judgments (Doshi-Velez and Kim, 2017; Ribeiro et al., 2016), or assist humans or student models to predict model behaviors on new data (Hase and Bansal, 2020; Pruthi et al., 2020). Note that although there exist many hybrid works that evaluate both the faithfulness and the plausibility of interpretations by combining a suite of diagnostic tests (DeYoung et al., 2020; Atanasova et al., 2020; Liu et al., 2020), Jacovi and Goldberg (2020) advocate to explicitly distinguish between the two measurements. In our work, we focus on interpretation faithfulness but consider two new metrics. We apply them to the dependency parsing task. Also, notice that the stability could be regarded as an automatic input consistency tests suggested by Ding and Koehn (2021).

7 Conclusion

In our work, we enhanced the existed definition of interpretation faithfulness by two other notions and proposed corresponding quantitative metrics: sensitivity and stability, for each of them. We studied interpretations under the two notions along with the existed one. We found that interpretations have inconsistent performance regarding different criteria. We proposed a new class of interpretations, motivated by the adversarial robustness techniques, which achieves the best performance under the sensitivity and the stability criteria. We further proposed a novel paradigm to evaluate interpretations on the dependency parsing task, which moves beyond text classification in the literature. Our study shed light on understanding the behavior of model interpretations and suggested the community to put more efforts on defining an appropriate evaluation pipeline for interpretation faithfulness.

Ethical Considerations

This paper does not contain direct social influences. However, we believe the model analysis and interpretation techniques discussed in this paper are critical for deploying deep learning based models to real-world applications. Following previous work in this direction such as Jacovi and Goldberg (2020), we advocate to carefully consider the explanations obtained from interpretation methods as they may not always reflect the true reasoning process behind model predictions.

Besides the three notions of faithfulness discussed in this paper, there are other important aspects for measuring interpretations that could be applied to evaluate interpretations. Also, We are not claiming that the proposed paradigm are perfect as faithfulness measurements. For example, we recognize that it requires further and detailed analysis on either the model itself or the interpretation methods lead to a low performance on the *stability* metric, although we do try to make sure models behaviors do not change substantially between an input pair.

Moreover, experiments in this paper are all based on mainstream English corpora. Although our techniques are not language specific, there could be different conclusions given the varying properties of languages. For example, the discussion for dependency parsing could be easily affected by the language one considers.

A Dataset and Model Details

Datasets Statistics of the datasets are presented in Table 5.

Dataset	Train/Dev/Test	Avg Len
SST-2	67.3k/0.8k/1.8k	19.2
Yelp	447.9k/112.0k/1.2k	119.8
AGNews	51.0k/9.0k/3.8k	35.5
PTB-SD	39.8k/1.7k/2.4k	23.5

Table 5: Data Statistics

Models All models are implemented based on the PyTorch [1] library. All experiments are conducted on NVIDIA GeForce GTX 1080 Ti GPUs. For BERT, we use the bert-base-uncased model. We fine-tune BERT model on each dataset, using a unified setup: dropout rate 0.1, Adam (Kingma and Ba, 2015) with an initial learning rate of 1e-4, batch size 128, and no warm-up steps. We set the maximum number of fine-tuning to be 3. The fine-tuned BERT achieves 90.7, 95.4, and 96.9 accuracy on SST-2, Yelp and AGNews, respectively. When explaining BERT predictions, we only consider the contribution of word embeddings to the model output.

For BiLSTM classifier, we use an one-layer BiLSTM encoder with a linear classifier. The embedding is initialized with the 100-dimensional pre-trained GloVe word embedding. We use Adam with an initial learning rate of 1e-3, batch size 512, hidden size 100 and dropout rate 0.2 for training. We set the maximum number of epochs to be 20 but perform early stopping when the performance on the development set doesn't improve for three epochs. Our BiLSTM classifier receives 84.2, 93.3, 95.9 accuracy on SST-2, Yelp and AGNews, respectively.

For DeepBiaffine, we simplify the original architecture by using a one-layer BiLSTM encoder and a biaffine classifier. The word embedding is also initialized with the pre-trained 100-dimensional GloVe word embedding while the part-of-speech tag embeddings are initialized to all zero. The encoder hidden size is 100. The arc and dependency relation hidden size are both 500. We get an UAS of 95.1 with our model. Note that for DeepBiaffine, each input token is represented by the concatenation of its word embedding and its part-of-speech tag embedding. When applying the interpretation methods and the evaluation metrics, we only modify the word embeddings but keep the part-of-speech tag embeddings unchanged.

B Interpretation Methods Details

For VaGrad, GradInp, VaPGD, PGDInp, and IngGrad, we use the automatic differentiation mechanism of PyTorch. For LIME, we modify the code from the original implementation of Ribeiro et al. (2016) [1]. For DeepLIFT, we use the implementation in Captum [2]. For Certify, we modify the code in auto_LiRPA [3].

For the two reference-based methods IngGrad and DeepLIFT, we use all zero word embeddings as the reference point. To approximate the integral in IngGrad, we sum up 50 points along the linear path from the reference point to the current point. For the perturbation-based methods LIME and Occlusion, we also set the word embedding of a token to an all zero embedding when it is perturbed.

Hyper-parameter tuning For all interpretations that require hyper-parameter tuning, including LIME, PGDInp, VaPGD, we randomly select 50 examples from the development set and choose the best hyperparameters based on the performance on these 50 examples. Specifically, the number of perturbed examples around the original point for LIME to fit a linear regression model is selected from $\{100, 200, 500, 800\}$. For PGDInp and VaPGD, we select the best maximum perturbation norm ϵ as for BERT and BiLSTM classifier from $\{0.1, 0.5, 1.2, 2.2\}$. We set the number of iterations as 50, and the step size as $\epsilon/5$. Note that we might be able to achieve better performance of VaPGD and PGDInp by also tuning the number of iterations and the step size. However, to keep the computational burden comparable with other interpretations, we do not tune these hyperparameters.

C Evaluation Criteria Details

Sensitivity Details We use PGD with a binary search for the minimal perturbation magnitude. In practice, we set the number of iterations to be 100 and the step size to be 1.0. Then, we conduct a binary search to estimate the smallest vicinity of

[2] https://github.com/pytorch/captum

[3] https://github.com/KaidiXu/auto_LiRPA

the original point which contains an adversarial example that changes the model prediction.

Stability Details The synonyms in the stability metrics come from (Alzantot et al., 2018), where they extract nearest neighbors in the GloVe embeddings space and filter out antonyms with a counter-fitting method. We allow at most four tokens replaced by their synonyms for each input and at most 0.1 change in the output probability of the model prediction for BERT and 0.2 for BiLSTM.

Thresholds To compute the removal-based metrics and the AUC of sensitivity for text classification tasks, we vary the number of tokens being removed (preserved) or perturbed to be 10%, 20%, . . ., 50% of the total number of tokens in the input. For the dependency parsing task, the corresponding thresholds are 10%, 20% and 30%.

D Task Details

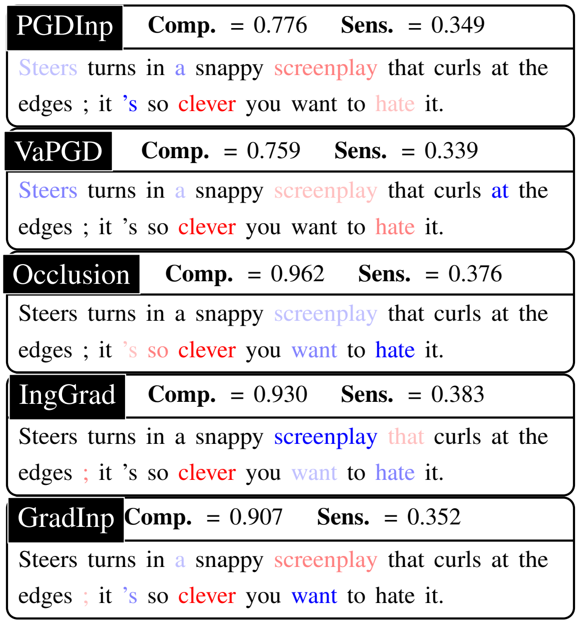
We evaluate the interpretation methods under both the text classification task and the dependency parsing task. Below, we cover implementation details for each task, respectively, including what is the specific model score interpretation methods explain, and what metrics we use for that task.

Text Classification Task $s_y(e(x))$ is the probability after the Softmax function corresponding to the original model prediction. We apply all the metrics mentioned in the main paper: removal-based metrics, including comprehensiveness and sufficiency scores, sensitivity score, and stability score. For removal-based metrics, we replace the important tokens with the pad token as a proxy for removing it.

Dependency Parsing Task $s(e(x))$ is the unlabeled arc log probability between the preposition and its head, i.e., unlabeled arc score after log_softmax, in the graph-based dependency parser. We discard the sufficiency score as it is unreasonable to remove a large proportion of tokens on a structured prediction task. We also discard the stability metric as there is little consensus on how to attack a structured model.

E An Example of Interpreting BERT and BiLSTM on the Text Classification Task

We showcase an example for interpreting BERT and BiLSTM in Figure 5 and 6. The example comes from the test set of SST-2. A deeper red color means the token is identified as more important to the model output by an interpretation while a deeper blue color stands for a less important token. Both the BiLSTM classifier and BERT classifier assign a positive label to this instance. Qualitatively, given an input, we observe that the most relevant or irrelevant sets of words identified by different interpretations are highly overlapped for BiLSTM, although the exact order of importance scores might be different. Whereas for BERT, different interpretations usually give different important tokens.



PGDInp **Comp.** = 0.776 **Sens.** = 0.349

Steers turns in a snappy screenplay that curls at the edges ; it 's so clever you want to hate it.

VaPGD **Comp.** = 0.759 **Sens.** = 0.339

Steers turns in a snappy screenplay that curls at the edges ; it 's so clever you want to hate it.

Occlusion **Comp.** = 0.962 **Sens.** = 0.376

Steers turns in a snappy screenplay that curls at the edges ; it 's so clever you want to hate it.

IngGrad **Comp.** = 0.930 **Sens.** = 0.383

Steers turns in a snappy screenplay that curls at the edges ; it 's so clever you want to hate it.

GradInp **Comp.** = 0.907 **Sens.** = 0.352

Steers turns in a snappy screenplay that curls at the edges ; it 's so clever you want to hate it.

Figure 5: An example of interpreting BERT with five interpretation methods. A deeper red color means the token is identified as more important while a deeper blue color stands for a less important token. Performance under Comp. and Sens. scores are shown.

H Case Study on Gradient Saturation

We qualitatively study some cases where PGDInp does well under the removal-based criterion while GradInp does not. In Figure 9, we show an example from explaining BERT on the SST-2 dataset, with the importance scores given by PGDInp, VaPGD, GradInp, VaGrad and the comprehensiveness score. For PGDInp and GradInp, we show the exponential of importance scores.

As shown in Figure 9, the importance score for each token given by GradInp is close to zero. VaGrad also gives near zero importance scores. At the same time, PGDInp and VaPGD have distinguishable and meaningful importance scores.

Based on the above observations, we suspect that the reason why PGD-based methods could avoid the failure of gradient-based methods is that they do not suffer from the gradient saturation issue. Gradient saturation refers to the cases where gradients are close to zero at some specific inputs and provide no information about the importance of different features of those inputs. Note that PGD-based methods consider not only a single input, but search on the vicinity of that input where the neighbors have none-zero gradients.

However, notice that VaGrad works better than GradInp. We suspect that is because although all elements in the gradient vector are close to zero, the **L-2 norm** of it is still distinguishable. However, GradInp takes the **dot-product** between embeddings and their gradients as the importance score. It is likely that negative and positive dimensions are neutralized, making the importance scores undistinguishable, and thus the behavior of GradInp corrupted. This hypothesis needs further explorations and demonstrations.

I Statistical Testing on the Performance of Robustness-based Methods

We use Student's t test to exam the superior performance of the best robustness-based methods against previous methods. The double checkmark represents a confidence level of 95% and a single checkmark for a confidence level of 90%.

VaPGD, BERT on SST-2	
Rank correlation = 0.346 **Model change = 0.00**	
Original	This is a film well worth seeing , talking and singing heads and all .

Abstract

Solving crossword puzzles requires diverse reasoning capabilities, access to a vast amount of knowledge about language and the world, and the ability to satisfy the constraints imposed by the structure of the puzzle. In this work, we introduce solving crossword puzzles as a new natural language understanding task. We release a corpus of crossword puzzles collected from the New York Times daily crossword spanning 25 years and comprised of a total of around nine thousand puzzles. These puzzles include a diverse set of clues: historic, factual, word meaning, synonyms/antonyms, fill-in-the-blank, abbreviations, prefixes/suffixes, wordplay, and cross-lingual, as well as clues that depend on the answers to other clues. We separately release the clue-answer pairs from these puzzles as an open-domain question answering dataset containing over half a million unique clue-answer pairs. For the question answering task, our baselines include several sequence-to-sequence and retrieval-based generative models. We also introduce a non-parametric constraint satisfaction baseline for solving the entire crossword puzzle. Finally, we propose an evaluation framework which consists of several complementary performance metrics.

1 Introduction

Recent breakthroughs in NLP established high standards for the performance of machine learning methods across a variety of tasks. However, even state-of-the-art models demonstrate fragility (Wallace et al., 2019) and exhibit sensitivity to shallow data patterns (McCoy et al., 2019; Zellers et al., 2019; Jin et al., 2020; Si et al., 2019; Sugawara et al., 2020; Yogatama et al., 2019; Niven and Kao, 2019). This has led to a growing demand for successively more challenging tasks.

One of the important tasks in natural language understanding is question answering (QA), with many recent datasets created to address different aspects of this task (Yang et al., 2018; Rajpurkar et al., 2016; Kwiatkowski et al., 2019a; Zellers et al., 2019; Dua et al., 2019; Rogers et al., 2021). There are two main forms of question answering (QA): extractive QA and open-domain QA. In extractive QA, a passage that answers the question is provided as input to the system along with the question. In open-domain QA, only the question is provided as input, and the answer must be generated either through memorized knowledge or via some form of explicit information retrieval over a large text collection which may contain answers.

The task of answering clues in a crossword is a form of open-domain question answering. Once a human or an open-domain QA system generates a few possible answer candidates for each clue, one of these candidates may form the correct answer to a word slot in the crossword grid, if the candidate meets the constraints of the crossword grid.

Solving a crossword puzzle is therefore a challenging task which requires (1) finding answers to a variety of clues that require extensive language and world knowledge, and (2) the ability to produce answer strings that meet the constraints of the crossword grid, including length of word slots and character overlap with other answers in the puzzle.

Our contributions in this work are as follows:

- We introduce a new natural language understanding task of solving crossword puzzles, along with a dataset of New York Times crosswords from Dec. 1, 1993 to Dec. 31, 2018.
- We propose an evaluation framework which consists of several complementary performance metrics.
- We release the collection of clue-answer pairs as a new open-domain QA dataset.
- We provide baselines for the proposed crossword task and the new QA task, including several sequence-to-sequence and retrieval-augmented generative Transformer models, with a constraint satisfaction crossword solver.

2 Related Work

Our work is in line with open-domain QA benchmarks. Examples of such tasks include datasets where each question can be answered using information contained in a relevant Wikipedia article (Yang et al., 2015; Kwiatkowski et al., 2019a; Yang et al., 2018). Several QA tasks have been designed to require multi-hop reasoning over structured knowledge bases (Berant et al., 2013; Bordes et al., 2015). The main limitation of such datasets is that their question types are mostly factual. Crossword clues differ from these efforts in that they combine a variety of different reasoning types.

Another line of research that is relevant to our work explores the problem of solving Sudoku puzzles since it is also a constraint satisfaction problem. Most sudoku puzzles can be efficiently solved by algorithms that take advantage of the fixed input size and do not rely on machine learning methods (Simonis, 2005). The machine learning attempts for solving Sudoku puzzles have been inspired by convolutional (Mehta, 2021) and recurrent relational networks (Palm et al., 2017). Unlike Sudoku, however, where the grids have the same structure, shape and constraints, crossword puzzles have arbitrary shape and internal structure and rely on answers to natural language questions that require reasoning over different kinds of world knowledge.

Several previous studies have treated crossword puzzle solving as a constraint satisfaction problem (CSP) (Littman et al., 2002; Ernandes et al., 2005; Ginsberg, 2011). Littman et al. (2002)'s Proverb system incorporates a variety of information retrieval modules to generate candidate answers. The Database module searches a large database of historical clue-answer pairs to retrieve the answer candidates. They find very poor crossword-solving performance in ablation experiments where they limit their answer candidate generator modules to not use historical clue-answer databases. WebCrow (Ernandes et al., 2005) builds upon Proverb and makes improvements to the database retriever module augmented with a new web module which searches the web for snippets that may contain answers. It allows partial matching to retrieve clues-answer pairs in the historical database that do not perfectly overlap with the query clue. Dr. Fill system proposed by Ginsberg (2011) treats each crossword puzzle as a singly-weighted CSP. Similarly to prior work, Dr. Fill relies on a large set of historical clue-answer pairs (up to 5M) collected over multiple years from the past puzzles by applying direct lookup and a variety of heuristics. One common design aspect of all these solvers is to generate answer candidates independently from the crossword structure and later use a separate puzzle solver to fill in the actual grid. In our work, we partition the task of crossword solving similarly.

Barlacchi et al. (2014) and Severyn et al. (2015) observe that the most important source of candidate answers for a given clue is a large database of historical clue-answer pairs and introduce methods to better search these databases. Barlacchi et al. (2014) apply a BM25 retrieval model to generate clue lists similar to the query clue from historical clue-answer database, where the generated clues get further refined through application of re-ranking models. Severyn et al. (2015) introduce a distributional neural network to compute similarities between clues trained over a large scale dataset of clues that they introduce.

In contrast to the previous work, our goal in this work is to motivate solver systems to generate answers organically, just like a human might, rather than obtain answers via the lookup in historical clue-answer databases. The answers could be generated either from memory of having read something relevant, using world knowledge and language understanding, or by searching encyclopedic sources such as Wikipedia or a dictionary with relevant queries.

3 Task and Dataset

For the purposes of our task, crosswords are defined as word puzzles with a given rectangular grid of white- and black-shaded squares. The goal is to fill the white squares with letters, forming words or phrases by solving textual clues which lead to the answers. The answer words and phrases are placed in the grid from left to right ("Across") and from top to bottom ("Down"). The shaded squares are used to separate the words or phrases. Usually, the white spaces and punctuation are removed from the answer phrases. A sample crossword puzzle is given in Figure 1. Note that the answers can include named entities and abbreviations, and at times require the exact grammatical form, such as the correct verb tense or the plural noun.

Solving a crossword puzzle is a complex task that requires generating the right answer candidates and selecting those that satisfy the puzzle constraints. Similar to prior work, we divide the task of solving a crossword puzzle into two subtasks, to be evaluated separately. The first subtask can be viewed as a question answering task, where a system is trained to generate a set of candidate answers for a given clue without taking into account any interdependencies between answers. The second subtask involves solving the entire crossword puzzle, i.e., filling out the crossword grid with a subset of candidate answers generated in the previous step.

The two tasks could be solved separately or in an end-to-end fashion. In contrast to prior work (Ernandes et al., 2005; Ginsberg, 2011), our clue-answer data is linked directly with our puzzle-solving data, so no data leakage is possible between the QA training data and the crossword-solving test data. In the present work, we propose a separate solver for each task. We provide details on the challenges of implementing an end-to-end solver in the discussion section.

3.1 NYT Crossword Collection

Our dataset is sourced from the New York Times, which has been featuring a daily crossword puzzle since 1942. We worked with daily puzzles in the date range from December 1, 1993 through December 31, 2018 inclusive. All the crossword puzzles in our corpus are available to play through the New York Times games website [1]. We release two separate specifications of the dataset corresponding to the subtasks described above: the NYT Crossword Puzzle dataset and the NYT Clue-Answer dataset.[2]

There are a few details that are specific to the NYT daily crossword. First, the clue and the answer must agree in tense, part of speech, and even language, so that the clue and answer could easily be substituted for each other in a sentence. Second, abbreviated clues indicate abbreviated answers. Further, clues that end in a question mark indicate a play on words in the clue or the answer. There are also a lot of short words that appear in crosswords much more often than in real life. These 3- and 4-letter words, referred to as crosswordese, can be very helpful in solving the puzzles. Finally, every Sunday through Thursday NYT crossword puzzle has a theme, something that unites the puzzle's longest answers. Theme answers are always found in symmetrical places in the grid.

Crossword Puzzle Dataset. The dataset consists of 9152 puzzles, split into the training, validation, and test subsets in the 80/10/10 ratio which give us 7293/922/941 puzzles in each set. We removed the total of 50/61 special puzzles from the validation

---

[1] `https://www.nytimes.com/crosswords`

[2] Details for dataset access will be made available at `https://github.com/text-machine-lab/xword_benchmark`. We are currently finalizing the agreement with the New York Times to release this dataset.

and test splits, respectively, because they used non-standard rules for filling in the answers, such as L-shaped word slots or allowing cells to be filled with multiple characters (called rebus entries).

Most NYT crossword grids have a square shape of 15×15 cells, with the exception of Sunday-released crosswords being 21×21 cells. Other shapes combined account for less than 3% of the data. The vast majority of both clues and answers are short, with over 76% of clues consisting of a single word. For traditional sequence-to-sequence modeling such conciseness imposes an additional challenge, as there is very little context provided to the model. In most puzzles, over 80% of the grid cells are filled and *every* character is an intersection of two answers. Such high answer interdependency suggests a high cost of answer misprediction, as errors affect a larger number of intersecting words. More detailed statistics on the dataset are given in Table 1.

Clue-Answer Dataset. We generate an open-domain question answering dataset consisting solely of clue-answer pairs from the respective splits of the Crossword Puzzle dataset described above (including the special puzzles). Within each of the splits, we only keep unique clue-answer pairs and remove all duplicates. However, certain clues may still be shared between the puzzles contained in different splits. We therefore remove from the training data the clue-answer pairs which are found in the test or validation data. This ensures that the model can not trivially recall the answers to the overlapping clues while predicting for the test and validation splits.

This produces the total of 578k clue-answer pairs, with 433k/72k/72k examples in the train/validation/test splits, respectively. Since certain answers consist of phrases and multiple words that are merged into a single string (such as "VERYFAST"), we further postprocess the answers by splitting the strings into individual words using a dictionary. Out of all the possible word splits of a given string we pick the one that has the smallest number of words. If there are multiple solutions, we select the split with the highest average word frequency. Examples of a variety of clues found in this dataset are given in the following section.

3.2 Clue types

To provide more insight into the diversity of the clue types and the complexity of the task, we categorize all the clues into multiple classes, which we describe below.

Factual. Clues that encode encyclopedic knowledge and typically can be answered using resources such as Wikipedia (e.g. *Clue: South Carolina State tree, Answer: PALMETTO*). This type of clue is the closest to the questions found in open-domain QA datasets. Note that the facts required to solve some of the clues implicitly depend on the date when a given crossword was released. For instance, the clue "*President of Brazil*" has a time-dependent answer.

Historical. Clues that require the knowledge of historical facts and temporal relations between events. (e.g. *Clue: Automobile pioneer, Answer: BENZ*).

Word meaning. Clues that exploit general vocabulary knowledge and can typically be resolved using a dictionary. (e.g. *Clue: Opposing sides, Answer: FOES*).

Synonyms/Antonyms. Clues that focus on paraphrasing and synonymy relations (e.g. *Clue: Prognosticators, Answer: SEERS*). In most cases, such clues can be solved with a thesaurus.

Fill in the blank. Clues formulated as a cloze task (e.g. *Clue: Magna Cum __, Answer: LAUDE*). Fill-in-the-blank clues are expected to be easy to solve for the models trained with the masked language modeling objective (Devlin et al., 2019).

Abbreviations. Clues answered with acronyms (e.g. *Clue: (Abbr.) Old Communist state, Answer: USSR*). Abbreviation clues are marked with "*Abbr.*" label.

Prefix/Suffix. Clues that suggest the answer is a suffix or prefix. (e.g. *Clue: Suffix with mountain, Answer: EER*)

Wordplay. Clues that rely on wordplay, anagrams, or puns / pronunciation similarities (e.g. *Clue: Consider an imaginary animal, Answer: BEAR IN MIND*). In a lot of cases, wordplay clues involve jokes and exploit different possible meanings and contexts for the same word.

Cross-lingual. Clues that either explicitly use words from other languages, or imply a specific language-dependent form of the answer. (e.g. *Clue: Sunrise dirección, Answer: ESTE*).

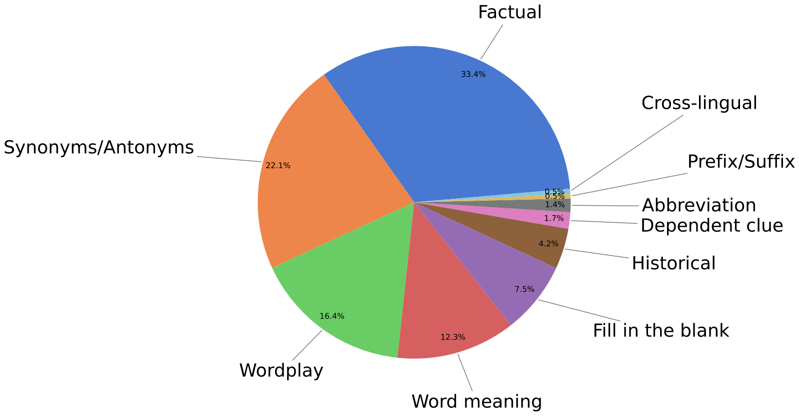

Figure 2: Class distribution of the 1000 manually annotated test examples.

Clues dependent on other clues. Clues the answer to which can be provided only after a different clue has been solved (e.g. *Clue: Last words of 45 Across*). Although rare, this category of clues suggests that the entire puzzle has to be solved in certain order.

To understand the distribution of these classes, we randomly selected 1000 examples from the test split of the data and manually annotated them. Figure 2 illustrates the class distribution of the annotated examples, showing that the Factual class covers a little over a third of all examples. The synonyms/antonyms, word meaning and wordplay classes taken together comprise 50% of the data. The remaining 20% are taken by fill-in-the-blank and historical clues, as well as the low-frequency classes (comprising less than or around 1%), which include abbreviation, dependent, prefix/suffix and cross-lingual clues. We illustrate each one of these classes in the Figure 1.

3.3 Evaluation metrics

In this section, we describe the performance metrics we introduce for the two subtasks.

Clue-Answer Task. For the clue-answer task, we use the following metrics:

- **Exact Match (EM)**. Model output matches the ground-truth answer exactly.
- **Contains (In)**. Model output contains the ground-truth answer as a contiguous substring

Since the ground-truth answers do not contain diacritics, accents, punctuation and whitespace characters, we also consider normalized versions of the above metrics, in which these are stripped from the model output prior to computing the metric. We will refer to them as $\mathbf{EM_{norm}}$ and $\mathbf{In_{norm}}$,

We report these metrics for top-k predictions, where k varies from 1 to 20.

	Train	**Validation**	**Test**
	Clue-Answer dataset		
# clues	4,33,033	72,303	72,939
avg/median clue length (words)	4.0/3	4.2/4	4.2/4
avg/median ans. length (chars)	5.5/5	5.7/5	5.6/5
avg/median ans. length (words)	1.3/1	1.3/1	1.3/1
	Crossword Puzzle dataset		
# puzzles	7,293	872	879
avg/median # of clues	83.5/76	83.6/76	82.9/76
avg cols×rows	15.9×15.9	15.9×15.9	15.8×15.8
% of cells filled	82.20%	80.20%	81.20%

Table 1: The full statistics on the two versions of the released datasets.

Crossword Puzzle Task. To evaluate the performance of the crossword puzzle solver, we propose to compute the following two metrics:

- **Character Accuracy ($\mathbf{Acc_{char}}$)**. Percentage of characters in the predicted crossword solution that match the ground-truth solution.
- **Word Accuracy ($\mathbf{Acc_{word}}$)**. Percentage of words in the predicted crossword solution that match the ground-truth solution.

Since the clue-answering system might not be able to generate the right answers for some of the clues, it may only be possible to produce a partial solution to a puzzle. The crossword puzzle solver will fail to produce a solution when the answer candidate list for a clue does not contain the correct answer. To prevent this from happening, the character cells which belong to that clue's answer must be removed from the puzzle grid, unless the characters are shared by other clues. We propose two additional metrics to track what percentage of the puzzle needs to be redacted to produce a partial solution:

- **Word Removal ($\mathbf{Rem}_{\mathbf{word}}$).** % of words that need to be removed from the puzzle to produce a partial solution.
- **Character Removal ($\mathbf{Rem}_{\mathbf{word}}$).** % of characters that need to be removed from the puzzle grid to produce a partial solution.

The motivation for introducing the removal metrics is to indicate the amount of constraint relaxation. For instance, a completely relaxed puzzle grid, where many character cells have been removed, such that the grid has no word intersection constraints left, could be considered "solved" by selecting any candidates from the answer candidate lists at random. However, this solution will mostly be incorrect when compared to the gold puzzle solution. As the word and character removal percentage increases, the potential for correctly solving the remaining puzzle is expected to decrease, since the under-constrained answer cells in the grid can be incorrectly filled by other candidates (which may not be the right answers). The removal metrics are thus complementary to word and character level accuracy.

4 Baselines

Our baseline approach is a two-step solution that treats each subtask separately. We first develop a set of baseline systems that solve the question answering problem, ignoring the grid-imposed answer interdependencies. We use seq-to-seq and retrieval-augmented Transformer baselines for this subtask. We feed generated answer candidates to a crossword solver in order to complete the puzzle and evaluate the produced puzzle solutions.

4.1 Clue-Answer Task Baselines

Sequence-to-sequence baselines. We fine-tune two sequence-to-sequence models on the clue-answer training data. We select two widely known models, BART (Lewis et al., 2019) and T5 (Raffel et al., 2019), which achieved state-of-the-art results on a set of generative tasks, including specifically abstractive QA involving commonsense and multi-hop reasoning (Fan et al., 2019; Khashabi et al., 2018; Zhang et al., 2018).

We train both models for 8 epochs with the learning rate of 5×10^{-5}, and a batch size of 60. [3]

Retrieval-augmented generation. T5 and BART store world knowledge implicitly in their parameters and are known to hallucinate facts (Maynez et al., 2020). Recently, a new method called retrieval-augmented generation (RAG) (Lewis et al., 2020) has been introduced for open-domain question answering. This method involves a Transformer encoder to encode the question and a decoder to generate the answer (Vaswani et al., 2017), but the encoded query is supplemented with relevant excerpts retrieved from an external textual corpus via Maximum Inner Product Search (MIPS); the entire neural network is trained end-to-end. Due to a built-in retrieval mechanism for performing a soft search over a large collection of external documents, such systems are capable of producing stronger results on knowledge-intensive open-domain question answering tasks than the vanilla sequence-to-sequence generative models and are more factually accurate (Shuster et al., 2021). Motivated by this, we train RAG models to extract knowledge from two separate external sources of knowledge:

(a) **RAG-wiki** uses a full Wikipedia dump from December 2018. Following existing work Lewis et al. (2020); Karpukhin et al. (2020); Lee et al. (2019), each Wikipedia article is split into disjoint 100-word chunks, resulting in a total of 21M passages.

(b) **RAG-dict** uses several English dictionaries and thesauri sources, including Wiktionary[4], Merriam-Webster[5], and Google's English dictionary by Oxford Languages.[6]

For both of these models, we use the retriever embeddings pretrained on the Natural Questions corpus Kwiatkowski et al. (2019b) in order to prime the MIPS retrieval to return meaningful entries (Lewis et al., 2020). We train with a batch size

---

[3] We use BART-large with approximately 406M parameters and T5-base model with approximately 220M parameters, respectively.

	Top-1				Top-10				Top-20			
	EM	**EM$_{\text{norm}}$**	**In**	**In$_{\text{norm}}$**	**EM**	**EM$_{\text{norm}}$**	**In**	**In$_{\text{norm}}$**	**EM**	**EM$_{\text{norm}}$**	**In**	**In$_{\text{norm}}$**
T5-base	8.4	9.5	8.7	9.9	18.7	20.8	19.8	22.0	22.2	24.6	23.8	26.3
BART-large	13.8	16.1	15.0	17.6	31.0	36.7	32.4	38.0	34.0	40.1	35.3	41.3
RAG wiki	24.2	26.0	24.9	26.7	46.8	49.8	48.6	51.6	50.6	53.9	53.4	56.7
RAG dict	24.0	25.8	24.6	26.5	46.0	48.9	48.0	50.9	50.0	53.2	53.0	56.2

Table 2: Performance of baseline systems on the Clue Answering dataset. *EM* and *In* stand for the "Exact-match" and "Contains" metrics as described in Section 3.3. The computed metrics are shown for top-1, top-10, and top-20 predictions for a given model.

of 8, label smoothing set to 0.1, dropout probability of 0.1, weight decay rate of 0.001, and a learning rate of 3×10^{-5} for 8 epochs.

4.2 Crossword Puzzle Task

A crossword puzzle can be cast as an instance of a satisfiability problem, and its solution represents a particular character assignment so that all the constraints of the puzzle are met. Under such formulation, three main conditions have to be satisfied: (1) the answer candidates for every clue must come from a set of words that answer the question, (2) they must have the exact length specified by the corresponding grid entry, and (3) for every pair of words that intersect in the puzzle grid, acceptable word assignments must have the same character at the intersection offset.

This class of problems can be modelled through Satisfiability Modulo Theories (SMT). SMT is a generalization of Boolean Satisfiability problem (SAT) in which some of the binary variables are replaced by first-order logic predicates over a set of non-binary variables. In the case of crosswords, a variable represents one character in the crossword grid which can be assigned a single letter of the English alphabet and 0 through 9 digit values. This is further subject to the constraints mentioned above which can be formulated with the equality operator and Boolean logical operators: `AND` and `OR`. For example, a word slot of length 3 where the candidate answers are "ESC", "DEL" or "CMD" can be formalised as:

$$\{v_1 = E \text{ AND } v_2 = S \text{ AND } v_3 = C\}$$
$$OR$$
$$\{v_1 = D \text{ AND } v_2 = E \text{ AND } v_3 = L\}$$
$$OR$$
$$\{v_1 = C \text{ AND } v_2 = M \text{ AND } v_3 = D\}$$

To solve the entire crossword puzzle, we use the formulation that treats this as an SMT problem. We modify an open source implementation[7] of this formulation based on Z3 SMT solver (de Moura and Bjørner, 2008). The answer length and intersection constraints are imposed on the variable assignment, as specified by the input crossword grid.

We take the top-k predictions from our baseline models and for each prediction, select all possible substrings of required length as answer candidates. For simplicity, we exclude from our consideration all the crosswords with a single cell containing more than one English letter in it.

Our current baseline constraint satisfaction solver is limited in that it simply returns "not-satisfied" (`nosat`) for a puzzle where no valid solution exists, that is, when *all* the hard constraints of the puzzle are not met by the inputs. Since the candidate lists for certain clues might not meet all the constraints, this results in a `nosat` solution for almost all crossword puzzles, and we are not able to extract partial solutions. To bypass this issue and produce partial solutions, we pre-filter each clue with an oracle that only allows those clues into the SMT solver for which the actual answer is available as one of the candidates.

5 Results

5.1 Clue-Answer Task

In Table 2 we report the Top-1, Top-10 and Top-20 match accuracies for the four evaluation metrics defined in Section 3.3.

Our results (Table 2) suggest a high difficulty of the clue-answer dataset, with the best achieved accuracy metric staying under 30% for the top-1 model prediction. Even top-20 predictions have an almost 40% chance of not containing the ground-truth answer anywhere within the generated strings. Generative Transformer models such as T5-base and BART-large perform poorly on the clue-answer task, however, the model accuracy across most

---

[7] `https://github.com/pncnmnp/Crossword-Solver`

Model	Solving Accuracy		Puzzle Removed	
	$\textbf{Acc}_{\textbf{word}}$	$\textbf{Acc}_{\textbf{char}}$	$\textbf{Rem}_{\textbf{word}}$	$\textbf{Rem}_{\textbf{char}}$
BART	16.6	28.4	55.6	43.4
RAG wiki	23.8	37.8	40.3	26.3
RAG dict	22.1	35.9	40.8	26.8

Table 3: Performance of baseline systems on the Crossword Puzzle dataset. We report the exact-match metric for top-20 predictions of the baseline models listed.

metrics almost doubles when switching from T5-base (with 220M parameters) to BART-large (with 400M parameter).

Our strongest baseline, RAG-wiki and RAG-dict, achieve 50.6 and 50.0 exact-match accuracies on the clue-answer dataset, respectively. The In_{norm} score, which looks at whether any substrings in the generated answer match the ground truth – and which can be seen an upper bound on the model's ability to solve the puzzle – is slightly higher, at 56.7 for RAG-wiki and 56.2 for RAG-dict.

Not surprisingly, these results show that the additional step of retrieving Wikipedia or dictionary entries increases the accuracy considerably compared to the fine-tuned sequence-to-sequence models such as BART which store this information in its parameters. The normalized metrics which remove diacritics, punctuation and whitespace bring the accuracy up by 2-6%, depending on the model.

We examined the top-20 exact-match predictions generated by RAG-wiki and RAG-dict and find that both models are in agreement in terms of answer matches for around 85% of the test set. In other words, both models either correctly predict the ground truth answer or both fail to do so.

5.2 Crossword Puzzle Task

The baseline performance on the entire crossword puzzle dataset shows there is significant room for improvement of the existing architectures (see Table 3). Our best model, RAG-wiki, correctly fills in the answers for only 26% (on average) of the total number of puzzle clues, despite having a much higher performance on the clue-answer task, i.e. measured independently from the crossword grid (Table 2). This is explained by the fact that the clues with no ground-truth answer present among the candidates have to be removed from the puzzles in order for the solver to converge, which in turn relaxes the interdependency constraints too much, so that a filled answer may be selected from the set of candidates almost at random. Despite that, the baseline solver is able to solve over a quarter of each the puzzle on average.

6 Qualitative analysis

Evaluation on the annotated subset of the data reveals that some clue types present significantly higher levels of difficulty than others (see Table 4). In particular, all of our baseline systems struggle with the clues requiring reasoning in the context of historical knowledge. As expected, all of the models demonstrate much stronger performance on the factual and word-meaning clue types, since the relevant answer candidates are likely to be found in the Wikipedia data used for pre-training. We observe the biggest differences between BART and RAG performance for the "abbreviation" and the "prefix-suffix" categories. The document retrieval step in RAG allows for more efficient matching of supporting documents, leading to generation of more relevant answer candidates. For instance, the clue *"Warehouse abbr."* results in *"pkg"* and *"bldg"* candidates among RAG predictions, whereas BART generates abstract and largely irrelevant strings.

Our manual inspection of model predictions suggest that both BART and RAG correctly infer the grammatical form of the answer from the formulation of the clue. For example, the clue *"Stitched"* produces the candidate answers *"Sewn"* and *"Made"*, and the clue *"Word repeated after "Que""* triggers mostly Spanish and French generations (e.g. *"Avec"* or *"Sera"*).

As previously stated RAG-wiki and RAG-dict largely agree with each other with respect to the ground truth answers. We qualitatively assessed instances where either RAG-wiki or RAG-dict predict the answer correctly in Appendix A.

7 Discussion and Future Work

The presented task is challenging to approach in an end-to-end model fashion. There are several reasons for this, which we discuss below.

Character-level outputs. Commonly used Transformer decoders do not produce character-level outputs and produce BPE and wordpieces instead, which creates a problem for a potential end-to-end neural crossword solver. One possible solution can be the modification of the loss term, designed with character-based output logits instead of BPE since the crossword grid constraints are at a single cell- (i.e. character-) level. There is

Model	Fact.	Hist.	Meaning	Syn./Ant.	Blank	Abbr.	Pref./Suf.	Wordplay	X-lingual	Dependent
BART	40.4	19.0	43.9	40.3	36.0	42.9	20.0	33.5	40.0	0.0
RAG-wiki	53.9	28.6	55.3	46.6	60.0	60.0	60.0	43.9	60.0	11.8
RAG-dict	54.2	35.7	52.8	48.9	61.3	85.7	60.0	46.3	40.0	11.8

Table 4: Performance of models across clue types in the exact match, top-20 setting. Evaluation performed on a 1000 clue subset of the test set which were manually annotated across clue categories.

some work done in the character-level output transformer encoders such as Ma et al. (2020). However, to our best knowledge there is no major generative Transformer architecture which supports character-level outputs yet, we intend to explore this avenue further in future work to develop an end-to-end neural crossword solver.

SMT solver constraints. As mentioned earlier, our current baseline solver does not allow partial solutions, and we rely on pre-filtering using the oracle from the ground-truth answers. Although this strategy is flawed for the obvious use of the oracle, the alternatives are currently either computationally intractable or too lossy. One such strategy is to remove k clues at a time, starting with $k = 1$ and progressively increasing the number of clues removed until the remaining relaxed puzzle can be solved – which has the complexity of O(2^n), where n is the total number of clues in the puzzle. Another approach we tried was to relax certain constraints of the puzzle grid, maximally satisfying as many constraints as possible, which is formally known as the maximal satisfaction problem (MAX-SAT). This is a NP-hard problem for which it is hard to find approximate solutions (Papadimitriou, 1994).

Our initial foray into such approximate solvers (Previti and Marques-Silva, 2013; Liffiton and Malik, 2013) produced severely under-constrained puzzles with garbage character entries. Further work needs to be done to extend this solver to handle partial solutions elegantly without the need for an oracle, this could be addressed with probabilistic and weighted constraint satisfaction solvers, in line with the work by Littman et al. (2002); Keim et al. (1999) and Ginsberg (2011), but without the dependency on the past crossword clues.

8 Conclusion

We present a new challenging task of solving crossword puzzles and present the New York Times Crosswords Dataset, which can be approached at a QA-like level of individual clue-answer pairs, or at the level of an entire puzzle, with imposed answer interdependency constraints. This new benchmark contains a broad range of clue types that require diverse reasoning components. We carry out a set of baseline experiments that indicate the overall difficulty of this task for the current systems, including retrieval-augmented SOTA models for open-domain question answering. We also discuss the technical challenges in building a crossword solver and obtaining partial solutions as well as in the design of end-to-end systems for this task. We hope that the NYT Crosswords task would define a new high bar for the AI systems.

9 Ethical Considerations

The New York Times daily crossword puzzles are a copyright of the New York Times. We have obtained preliminary approval from the New York Times to release this data under a non-commercial and research use license, and are in the process of finalizing the exact licensing terms and distribution channels with the NYT legal department.

10 Acknowledgments

We would like to thank the anonymous reviewers for their careful and insightful review of our manuscript and their feedback. We would like to thank Parth Parikh for the permission to modify and reuse parts of their crossword solver[7]. We are grateful to New York Times staff for their support of this project. This project is funded in part by an NSF CAREER award to Anna Rumshisky (IIS-1652742).

A Qualitative Analysis of RAG-wiki and RAG-dict Predictions

We examined top-20 exact-match predictions generated by RAG-wiki and RAG-dict. With some exceptions, both models predict similar results (in terms of answer matches) for around 85% of the test set.

Table 5 shows examples where RAG-dict failed to generate the correct predictions but RAG-wiki succeeded, and vice-versa. Most of the instances where RAG-dict predicted correctly and RAG-wiki did not are the ones where answer is closely related to the meaning of the clue. The instances where only RAG-wiki predicted correctly are where answer is not a direct meaning of the clue, and some more information is required predict.

Table 5: Examples where either RAG-dict or RAG-wiki predicts correctly and other fails.

Category	RAG-dict predicts correctly RAG-wiki fails		RAG-wiki predicts correctly RAG-dict fails	
	Clue	Answer	Clue	Answer
Factual	Asian nursemaid Pill alternative, for short	amah iud	Quisling's city Avatar of Vishnu	oslo rama

Abstract

Natural language processing models often exploit spurious correlations between task-independent features and labels in datasets to perform well only within the distributions they are trained on, while not generalising to different task distributions. We propose to tackle this problem by generating a debiased version of a dataset, which can then be used to train a debiased, off-the-shelf model, by simply replacing its training data. Our approach consists of 1) a method for training *data generators* to generate high-quality, label-consistent data samples; and 2) a filtering mechanism for removing data points that contribute to spurious correlations, measured in terms of *z-statistics*. We generate debiased versions of the SNLI and MNLI datasets,[1] and we evaluate on a large suite of debiased, out-of-distribution, and adversarial test sets. Results show that models trained on our debiased datasets generalise better than those trained on the original datasets in all settings. On the majority of the datasets, our method outperforms or performs comparably to previous state-of-the-art debiasing strategies, and when combined with an orthogonal technique, product-of-experts, it improves further and outperforms previous best results of SNLI-hard and MNLI-hard.

1 Introduction

Natural Language Processing (NLP) datasets inevitably contain biases that are unrelated to the tasks they are supposed to represent. These biases are usually artifacts of the annotation processes, task framing, or design decisions (Schwartz et al., 2017; Geva et al., 2019; Liu et al., 2021). Such biases often manifest as spurious correlations between simple features of the data points and their labels (Gardner et al., 2021). Trained models can exploit these spurious correlations to correctly predict the labels of the data points within the same distributions as those they are trained on, but fail to generalise to other distributions within the same tasks. Consequently, the models risk modelling the datasets, but not the tasks (Gururangan et al., 2018; Poliak et al., 2018; McCoy et al., 2019; Schuster et al., 2019).

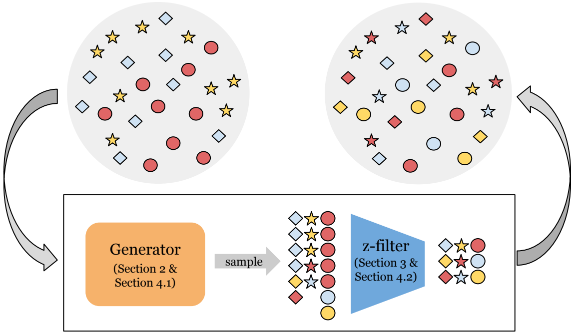

Figure 1: Overview of our dataset bias mitigation approach. We minimise spurious correlations between labels (represented by the shapes of data points) and task-independent features (represented by their colours) with our proposed data generation pipeline.

We address this issue by *adjusting* existing dataset distributions to mitigate the correlations between task-independent features and labels. First, we train *data generators* that generate high quality data samples in the distribution of existing datasets (Section 2). Then, we identify a set of simple features that are known to be task-independent, and use the theoretical framework (i.e., z-statistics) proposed by Gardner et al. (2021) to measure correlations between those features and the labels (Section 3.1). Finally, we adjust the distribution of the generated samples by post-hoc filtering (Section 3.2) to remove the data points that contribute to high z-statistics with task-independent features, or finetuning the data generator (Section 4.1) to make such data points less likely. Unlike prior *model-*

May 22-27, 2022

centric approaches to mitigate spurious correlations (Belinkov et al., 2019a,b; Clark et al., 2019; He et al., 2019; Karimi Mahabadi et al., 2020) that define new training objectives or model architectures, our approach has the advantage of keeping the objective and the model fixed, as we only alter the training data.

To evaluate our approach, we use the task of Natural Language Inference (NLI), which offers a wide range of datasets (including challenge datasets) for various domains. We generate debiased SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018) distributions and evaluate the generalisability of models trained on them to out-of-distribution hard evaluation sets (Gururangan et al., 2018; McCoy et al., 2019), and the adversarial attack suite for NLI proposed by Liu et al. (2020b). Furthermore, we compare our method to strong debiasing strategies from the literature (Belinkov et al., 2019b; Stacey et al., 2020; Clark et al., 2019; Karimi Mahabadi et al., 2020; Utama et al., 2020; Sanh et al., 2021; Ghaddar et al., 2021).

Our results show that models trained on our debiased datasets generalise better than those trained on the original datasets to evaluation sets targeting hypothesis-only biases (by up to 2.8 percentage points) and syntactic biases (by up to 13.3pp), and to a suite of adversarial tests sets (by up to 4.2pp on average). Since our contributions are orthogonal to model-centric approaches, we show that when combined with product-of-experts (Karimi Mahabadi et al., 2020), our method yields further improvements and outperforms previous state-of-the-art results of SNLI-hard and MNLI-hard. Finally, we train stronger and larger pretrained language models with our debiased datasets, and demonstrate that the performance gain by our method generalises to these larger models.

2 Generating High-Quality Data Samples

First, we need to train a data generator G to generate data samples automatically. Our goal for the data generator is to model the true distribution as well as possible so that we can generate valid and high-quality data samples.

2.1 Finetuning Pretrained Language Model to Generate NLI Samples

We finetune a pretrained language model on the NLI datasets to serve as our data generator. We choose GPT-2 because it is a powerful and widely-used autoregressive language model, and it can be easily adapted to generated the premise, label, and hypothesis of an instance sequentially.

Given an NLI dataset $\mathcal{D}_0$, the training objective is to minimise the following negative log-likelihood loss of generating the premise-label-hypothesis sequence, in that order:

$$\begin{aligned}\mathcal{L}_{MLE} &= -\sum_{i=1}^{|\mathcal{D}_0|} \log p(P^{(i)}, l^{(i)}, H^{(i)}) \\ &= -\sum_{i=1}^{|\mathcal{D}_0|} \log p(P^{(i)}) p(l^{(i)}|P^{(i)}) p(H^{(i)}|l^{(i)}, P^{(i)}),\end{aligned} \tag{1}$$

where $P^{(i)}$, $l^{(i)}$ and $H^{(i)}$ are the premise, label and hypothesis respectively.[2]

2.2 Improving Data Generation Quality

We find that samples generated by a generator trained with only $\mathcal{L}_{MLE}$ often contain ungrammatical text or incorrect label. In this section, we introduce two techniques to improve data quality.

2.2.1 Unlikelihood Training to Improve Label Consistency

We observe poor *label consistency* in samples generated by a generator trained with vanilla $\mathcal{L}_{MLE}$ objective – given a generated sample $(\tilde{P}, \tilde{H}, \tilde{l})$, the label $\tilde{l}$ often does not correctly describe the relationship between $\tilde{P}$ and $\tilde{H}$. To alleviate this issue, we apply *unlikelihood training* (Welleck et al., 2020) to make generating such label inconsistent instances less likely.

First we perturb the label to construct negative samples (P, H, l') where $l' \neq l$ for each sample in the dataset. Then we apply a token-level unlikelihood objective on the hypothesis tokens:

$$\mathcal{L}_{\text{consistency}} = -\sum_{i=1}^{|\mathcal{D}_0|} \sum_{t=1}^{|H|^{(i)}} \log(1 - p(H_t^{(i)}|l'^{(i)}, P^{(i)}, H_{<t}^{(i)})).$$

This objective decreases the probability of generating H when given an incorrect label l', hence improves the label consistency at generation time.

---

[2] In our preliminary study, we found the factorization order premise-label-hypothesis in Eq. (1) performs better than hypothesis-label-premise and premise-hypothesis-label.

We combine $\mathcal{L}_{MLE}$ and $\mathcal{L}_{\text{consistency}}$ to finetune our generator G with

$$\mathcal{L}_G = \mathcal{L}_{MLE} + \lambda \mathcal{L}_{\text{consistency}},$$

where λ is a hyperparameter that balances the two objectives. We can randomly sample from the trained generator to obtain a large amount of the synthetic data $\mathcal{D}_G \sim G$.

2.2.2 Filtering Based on Model Confidence

We add a consistency filtering step (Lewis et al., 2021; Bartolo et al., 2021) to further improve the quality of the generated dataset. We train an NLI model M with the original dataset $\mathcal{D}_0$ to filter out samples in which M has low confidence:

$$\hat{\mathcal{D}}_G = \{(P, H, l) \in \mathcal{D}_G \mid p_M(l|P, H) > \tau\},$$

where τ is a confidence threshold. We found that the filtered out data samples generally had ungrammatical text or incorrect labels.

3 Mitigating Spurious Correlations using *z-filtering*

We now define a method to reject samples that contribute to the high spurious correlations between task-independent features of the samples and their labels. Our approach is based on the theoretical framework proposed by Gardner et al. (2021) to measure these correlations, known as *z-statistics*. Our filtering method, called *z-filtering* (Section 3.2), will serve as the basis to construct debiased datasets in Section 4.

3.1 Identifying and Measuring Spurious Correlations

As a first step towards addressing spurious correlations, we need to be able to quantify them. We start by selecting a set of task-independent features – features that give away the labels and allow models to exploit them without actually solving the task. For NLI, we choose the following features: *1*) unigrams and bigrams; *2*) hypothesis length and hypothesis-premise length ratio; *3*) lexical overlap between hypothesis and premise; *4*) the predictions of a BERT-base (Devlin et al., 2019) hypothesis-only model.[3] These features capture various biases identified in prior work, including contradiction word biases, lexical overlap bias (McCoy et al., 2019), and hypothesis-only bias (Gururangan et al., 2018; Poliak et al., 2018). Note that our method does not rely on the specific choice of features, and one can easily add alternative features that should not be correlated with the labels.

Following Gardner et al. (2021), we assume there should be no correlation between each of these features and the class labels. More formally, for any feature x from our feature set $\mathcal{X}$, $p(l|x)$ should be uniform over the class labels l. We define $\hat{p}(l|x) = \frac{1}{n}\sum_{j=1}^{n} l^j$ to be the empirical expectation of $p(l|x)$ over n samples containing x. Then we compute the standardised version of *z-statistics* to quantify its deviation from the uniform distribution for each feature x and label l:

$$z^*(x, l) = \frac{\hat{p}(l|x) - p_0}{\sqrt{p_0(1 - p_0)/n}}, \qquad (2)$$

where p_0 is the probability of uniform distribution ($p_0 = 1/3$ in NLI tasks with three labels).

These z-statistics scores can be used to identify the most biased features for each label l – we select k features with the highest *z-statistic* to define the *biased features* set $\mathcal{B}_{\mathcal{D}}(l)$. Table 12 shows examples of these biased features on SNLI.

3.2 z-filtering

To mitigate the biases in the dataset, we propose *z-filtering*, an algorithm that iteratively selects and filters instances from a dataset $\mathcal{D}'$ to build a debiased dataset $\mathcal{Z}$. At each step, we find the set of biased features $\mathcal{B}_{\mathcal{Z}}(l)$ on the partially constructed $\mathcal{Z}$. We then select a new batch of samples from $\mathcal{D}'$ and filter out the samples that contain these biased features. This process is applied iteratively until it has exhausted all samples from $\mathcal{D}'$. It removes the samples that contribute to the spurious correlations in $\mathcal{D}'$, thus it finds a debiased subset $\mathcal{Z}(\mathcal{D}') \subset \mathcal{D}'$. We denote the removed samples as $\mathcal{Z}^-(\mathcal{D}')$. The full z-filtering algorithm is illustrated in Algorithm 1.

Optionally, one can initialise $\mathcal{Z}$ with a seed dataset $\mathcal{D}_{seed}$. In this case, the samples from $\mathcal{D}'$ are only added to $\mathcal{Z}$ when they do not contain the biased features of $\mathcal{D}_{seed}$. Thus it can be seen as a data-augmentation technique targeted to debias a given dataset. We refer to it as *conditional z-filtering* and denote the produced debiased dataset as $\mathcal{Z}(\mathcal{D}'|\mathcal{D}_{seed})$.

---

[3] See Appendix B for detailed descriptions of the features.

Algorithm 1: z-filtering algorithm.

```
Data: input dataset $\mathcal{D}'$ [with optional seed dataset $\mathcal{D}_{seed}$]
Result: debiased dataset $\mathcal{Z}$ and the rejected samples $\mathcal{Z}^-$
$\mathcal{Z} \leftarrow \emptyset$ (or $\mathcal{Z} \leftarrow \mathcal{D}_{seed}$);
$\mathcal{Z}^- \leftarrow \emptyset$;
for sample batch $\mathcal{D}'_t \subset \mathcal{D}'$ do
    compute or update z-statistics $z^*(x, l|\mathcal{Z}), \forall x \in \mathcal{X}$ of $\mathcal{Z}$;
    find the biased features $\mathcal{B}_{\mathcal{Z}}(l), \forall l \in \{\text{entailment}, \text{neutral}, \text{contradiction}\}$;
    foreach instance $I = (P, H, l) \in \mathcal{D}'_t$ do
        get the features $f$ of the instance $I$;
        if $f \cap \mathcal{B}_{\mathcal{Z}}(l) = \emptyset$ then
            $\mathcal{Z} \leftarrow \mathcal{Z} \cup \{I\}$;
        else
            $\mathcal{Z}^- \leftarrow \mathcal{Z}^- \cup \{I\}$;
        end
    end
end
```

4 Constructing Debiased NLI Datasets via Data Generation

We use z-filtering in two ways: *1*) to further finetune G (the one trained in Section 2.2.1 with consistency unlikelihood) with an objective that downweighs samples that should be rejected (Section 4.1); *2*) to post-hoc filter the generated samples to obtain debiased datasets (Section 4.2).

4.1 Learning to Generate Unbiased Samples

The generator G can learn to exploit task-independent features during its finetuning stage (Section 2), causing the synthetic data $\hat{\mathcal{D}}_G$ to contain many spurious correlations. While it is tempting to apply z-filtering to remove these spurious correlations from $\hat{\mathcal{D}}_G$, we find that this will lead to the removal of majority of the generated data. For example, when the generator is finetuned on SNLI, z-filtering removes around 85% of $\hat{\mathcal{D}}_{G_{SNLI}}$.[4] This leads to a very inefficient data generation process to mitigate the spurious correlations.

To alleviate this issue, we can incorporate the debiasing objectives into the training of the generator, so that the samples produced by the generator are more likely to be accepted by the z-filtering process. More specifically, we can encourage the model to generate $\mathcal{Z}(\mathcal{D}_0)$, while discouraging it from generating $\mathcal{Z}^-(\mathcal{D}_0)$. For the latter part, we again apply an unlikelihood training objective $\mathcal{L}_{UL}$ to *unlearn* $\mathcal{Z}^-(\mathcal{D}_0)$. Hence, the overall debiasing training objective is:

$$\mathcal{L}_{debias} = \mathcal{L}_{MLE}(\mathcal{Z}(\mathcal{D}_0)) + \alpha\mathcal{L}_{UL}(\mathcal{Z}^-(\mathcal{D}_0))$$

where α is a hyperparameter.

A naive use of an unlikelihood objective on all tokens gives the model mixed signals for good tokens and leads to ungrammatical, degenerate outputs. To avoid this degeneracy, we apply the unlikelihood loss only to tokens that contribute to biased features. Concretely, for each token I_t^- of instance $I^- \in \mathcal{Z}^-(\mathcal{D}_0)$, we define a mask m_t as

$$m_t = \begin{cases} 0, & \text{if } I_t^- \text{ contributes to } \mathcal{B}_{\mathcal{Z}}(l_{I^-}) \\ 1, & \text{otherwise.} \end{cases}$$

where $\mathcal{B}_{\mathcal{Z}}(l_{I^-})$ represent the biased features corresponding the label of I^-.

For biases towards unigram and bigram features (as defined in Section 3.1), we consider only the corresponding tokens to be relevant (i.e., $m_t = 0$ if I_t^- is part of the unigram or the bigram). For biases towards other features (e.g. length of the hypothesis), we consider all the tokens on the hypothesis to be relevant. The unlikelihood training objective is defined as follows:

$$\mathcal{L}_{UL}(\mathcal{Z}^-(\mathcal{D}_0)) = \sum_{I' \in \mathcal{Z}^-(\mathcal{D}_0)} \mathcal{L}_{UL}(I'),$$

$$\mathcal{L}_{UL}(I') = -\sum_{t=1}^{|I'|} \log(m_t p(I'_t|I'_{<t}) + (1 - m_t)(1 - p(I'_t|I'_{<t}))).$$

We further finetune G with $\mathcal{L}_{debias}$ to obtain a new generator G^*, that is trained to generate more unbiased data samples. We then randomly sample from G^* and conduct data filtering (Section 2.2.2) to obtain a large set of high-quality debiased data samples $\hat{\mathcal{D}}_{G^*}$.

4.2 Combining with z-filtering to Construct the Debiased NLI Datasets

Given the original dataset $\mathcal{D}_0$ and the synthetic dataset $\hat{\mathcal{D}}_{G^*}$, our goal is produce a large-scale unbiased dataset $\mathcal{D}^*$. There are various ways to do

---

[4] This is also strong confirmation that these biases are problematic, as the generative model easily finds them and relies on them during data generation. Conducting naive data augmentation with $\hat{\mathcal{D}}_{G_{SNLI}}$ will strengthen the spurious correlations.

this given that we can either apply conditional z-filtering, or simply z-filter both $\mathcal{D}_0$ and $\hat{\mathcal{D}}_{G^*}$ and merge them. We explore the following options:

1. **Z-Augmentation (Z-Aug)** $\mathcal{Z}(\hat{\mathcal{D}}_{G^*}|\mathcal{D}_0)$: we keep the original dataset as is, and augment it by conducting conditional z-filtering on $\hat{\mathcal{D}}_{G^*}$ using $\mathcal{D}_0$ as seed dataset.

2. **Parallel z-filter (Par-Z)** $\mathcal{Z}(\mathcal{D}_0) \cup \mathcal{Z}(\hat{\mathcal{D}}_{G^*})$: we conduct z-filtering on $\mathcal{D}_0$ and $\hat{\mathcal{D}}_{G^*}$ separately, and then merge them.

3. **Sequential z-filter (Seq-Z)** $\mathcal{Z}(\hat{\mathcal{D}}_{G^*}|\mathcal{Z}(\mathcal{D}_0))$: we first conduct z-filtering on $\mathcal{D}_0$, then conduct conditional z-filtering on $\hat{\mathcal{D}}_{G^*}$ with $\mathcal{Z}(\mathcal{D}_0)$ as seed dataset.

5 Experiments

5.1 Experimental Setup

Source Datasets We select the two most widely used NLI datasets SNLI (Bowman et al., 2015) and MNLI (Williams et al., 2018) as our original datasets. Prior work (Gururangan et al., 2018; Poliak et al., 2018; McCoy et al., 2019) found various annotation artifacts in them, hence they serve as good use cases for constructing debiased datasets.

Evaluation Datasets For the hypothesis-only bias, we use the challenge sets SNLI-hard (Gururangan et al., 2018) and MNLI-hard (Williams et al., 2018), which were produced by filtering the test set with a hypothesis-only model (Section 5.2). For syntactic biases, we follow previous work and use HANS (McCoy et al., 2019) for evaluation (Section 5.3). In addition, we evaluate on the adversarial test benchmark introduced by Liu et al. (2020b) (Section 5.4). This benchmark covers a wide range of adversarial attacks, which will give a more complete picture of what spurious correlations the debiasing methods tackle.

Generating Debiased Datasets We conduct debiased data generation for SNLI and MNLI *separately*. For SNLI, we use the proposed method described in Section 4.1 to train a generator G^*_{SNLI}. Then we randomly sample a large number of instances from the generator to construct $\mathcal{D}_{G^*_{\text{SNLI}}}$. The samples are filtered with a strong NLI model M trained on SNLI to obtain $\hat{\mathcal{D}}_{G^*_{\text{SNLI}}}$. Finally, different options (Section 4.2) can be adopted to merge the synthetic data with the original data $\mathcal{D}_{\text{SNLI}}$ to construct debiased versions of SNLI. The same procedure is used to produce debiased datasets for MNLI, by simply replacing the original dataset with MNLI. We choose GPT-2 large and Roberta-large as the pretrained language models for G^* and M respectively.[5] The size of the constructed debiased datasets are listed in Table 1.

Options	$\mathcal{D}_0 = \mathcal{D}_{\textbf{SNLI}}$	$\mathcal{D}_0 = \mathcal{D}_{\textbf{MNLI}}$
Original $\mathcal{D}_0$	549,367	382,702
Z-Aug $\mathcal{Z}(\hat{\mathcal{D}}_{G^*}\|\mathcal{D}_0)$	1,142,475	744,326
Par-Z $\mathcal{Z}(\mathcal{D}_0) \cup \mathcal{Z}(\hat{\mathcal{D}}_{G^*})$	933,085	740,811
Seq-Z $\mathcal{Z}(\hat{\mathcal{D}}_{G^*}\|\mathcal{Z}(\mathcal{D}_0))$	927,906	744,200

Table 1: Data size of the constructed debiased datasets for SNLI and MNLI.

NLI Model Training Since our method directly debiases the training data itself, we keep the model and training objective fixed and only replace the training data with our generated debiased datasets. For comparability with previous work (Karimi Mahabadi et al., 2020; Utama et al., 2020; Sanh et al., 2021), we train BERT-base (Devlin et al., 2019) on our debiased datasets. The NLI models are trained with ordinary *cross-entropy* classification loss, and the training hyperparameters are listed in Appendix A. We run our experiments five times and report the average and standard deviation of the scores.[6] We also conduct statistical significance testing using a 2-tailed t-test at 95% confidence level.

State-of-the-art Debiasing Models We compare our method with the following three state-of-the-art debiasing models on each of our evaluation datasets. **Product-of-Experts** (He et al., 2019; Karimi Mahabadi et al., 2020) ensembles a bias-only model's prediction b_i with the main model's p_i using $p'_i = softmax(\log p_i + \log b_i)$. This ensembling enforces that the main model focuses on the samples that the bias-only model does not predict well. **Learned-Mixin** (Clark et al., 2019) is a variant of PoE that introduces a learnable weight for the bias-only model's prediction. **Regularized-conf** (Utama et al., 2020) uses confidence regularisation to retain the in-distribution performance while conducting model debiasing.

---

[5] On one A100 GPU, training the generator takes around 24 hours and generating the samples takes roughly 35 hours for each dataset.

[6] With the exception of our PoE experiments which single run, as hyperparameter tuning for PoE is costlier.

Table 2: Accuracy on SNLI and SNLI-hard. $*$ are reported results and underscore indicates statistical significance against the baseline. Training on our debiased SNLI datasets significantly boosts the performance on SNLI-hard compared to the baseline, and it improves further when combined with PoE.

Combining PoE with Our Debiased Datasets Our approach changes the training data distribution instead of the model's training objective, and hence is orthogonal to prior work method-wise. We also report the results of combining PoE with our proposed method, simply by training a PoE model on our debiased datasets. We adapt the PoE implementation by Karimi Mahabadi et al. (2020), and we follow their approach to conduct hyperparameter tuning for PoE.[7] The hyperparameters of the PoE models are reported in Table 10 of Appendix A.

5.2 Hypothesis-only Bias in NLI

Gururangan et al. (2018) found that, on SNLI and MNLI, a model that only has access to the hypothesis can perform surprisingly well, which indicates that the datasets contain hypothesis-only bias. To alleviate this problem, SNLI-hard and MNLI-hard (Gururangan et al., 2018) subsets were constructed by filtering the test set with a hypothesis-only model and only accepting those that the hypothesis-only model predicts incorrectly. We examine whether our method successfully mitigates the hypothesis-only bias in NLI, by evaluating the models trained with our debiased datasets on SNLI-hard and MNLI-hard.

Results on SNLI-hard Table 2 shows the results of our method on SNLI and SNLI-hard. The results show that, compared to training on SNLI, training with our debiased datasets significantly improves the performance on SNLI-hard. The debiased dataset produced by Seq-Z achieves a 2.48% gain in accuracy on SNLI-hard compared to the SNLI baseline, whereas Z-Aug improves both SNLI and SNLI-hard accuracy.

Results on MNLI-hard Table 3 shows the results of our method on MNLI-matched (MNLI-m) and MNLI-mismatched (MNLI-mm), and their corresponding hard sets. We use the development sets of MNLI-hard reconstructed by (Karimi Mahabadi et al., 2020) to develop our methods. To comply with the submission limit of MNLI leaderboard system, we select the best checkpoint among the five runs using the development set, and report its test set performance in Table 3.

The results show that BERT-base models trained on our debiased MNLI datasets outperform the models trained on the original MNLI by a large margin on the MNLI-hard sets. In particular, the Z-Aug version of the debiased datasets gives a 2.72% and 2.76% gain in accuracy on MNLI-m hard and MNLI-mm hard respectively, and outperforms the previous state-of-the-art on MNLI-m, MNLI-mm, and MNLI-mm hard.

Combining PoE with Our Debiased Datasets We investigate the combination of our method and PoE, to see if the two orthogonal techniques can work together to achieve better performance. Since hyperparameter tuning of PoE is costly, we choose the best version of the debiased dataset (Seq-Z for SNLI and Z-Aug for MNLI) using the development set accuracy, and train PoE with it. The results are listed in the last rows of Table 2 and Table 3. We can find that, on both SNLI and MNLI, combining PoE with our debiased dataset yields further improvements on SNLI-hard, MNLI-m hard, and MNLI-mm hard, outperforming previous state-of-the-art results on all three datasets.

5.3 Syntactic Bias in NLI

McCoy et al. (2019) show that NLI models trained on MNLI can exploit syntactic heuristics present in the data, such as lexical overlap, subsequence, and constituent features. They introduce HANS, an evaluation dataset that contains examples where the syntactic heuristics fail. To test whether our method mitigates the syntactic biases in NLI, we evaluate models trained on our debiased datasets on HANS. If our debiased dataset contains less syntactic bias than the original dataset, the model would not exploit the syntactic heuristics and thus perform better on HANS. Due to the high variance

Table 4: Results on HANS (McCoy et al., 2019). ∗ are reported results and underscore indicates statistical significance against the baseline. BERT-base trained on our debiased MNLI datasets performs significantly better than the one trained on the original MNLI, and it improves further when combined with PoE. Roberta-large also benefits from training on our debiased dataset.

of the scores on HANS, we run five times for each experiment (except PoE), and report the average and standard deviation of the scores.

Results on HANS Table 4 shows the results on HANS. The results are categorised into three sections according to the training data: SNLI, MNLI, and our debiased datasets. The results of models trained on our debiased MNLI datasets show strong improvements: compared to the original MNLI, our debiased MNLI datasets obtain up to a 13.33% gain in HANS accuracy. Our Seq-Z variant achieves 67.69% accuracy, which is comparable with strong PoE baseline (Karimi Mahabadi et al., 2020; Sanh et al., 2021). Our method also further improves PoE models: the BERT-base PoE model trained on our Z-Aug MNLI outperforms the one trained on MNLI by 5.3%. Additionally, training Roberta-large (Liu et al., 2019) on our debiased dataset introduces 2.9 points accuracy gain on HANS, indicating that the performance gain by our debiased dataset can generalise to larger and stronger models (more on this in Section 5.5).

5.4 Adversarial Tests for Combating Distinct Biases in NLI

Liu et al. (2020b) find that debiasing methods often tie to one particular known bias and it is nontrivial to mitigate multiple NLI biases at the same time. They introduce a suite of test datasets for NLI models that targets various aspects of robustness, including partial input heuristics (PI), logical infer-

Table 5: Results on the NLI adversarial test benchmark (Liu et al., 2020b). We compare with the data augmentation techniques investigated by Liu et al. (2020b). ∗ are reported results and underscore indicates statistical significance against the baseline. Training on our debiased MNLI datasets significantly improves the performance on majority of the categories (PI-CD, PI-SP, IS-SD, IS-CS, LI-LI) and on average.

ence ability (LI), and stress test (ST).[8] Several data augmentation strategies were investigated by Liu et al. (2020b): 1) text swap: swapping the premise and hypothesis in the original data; 2) word substitution: replacing words in the hypothesis with synonyms or generations from a masked language model; 3) paraphrase: using back translation to paraphrase the hypothesis.

We compare our approach with their data-augmentation heuristics, and the results are shown in Table 5. Comparing with the MNLI baseline, our debiased MNLI datasets lead to better performance across all categories, which indicates that our method successfully mitigates various distinct biases simultaneously. All three variants of our debiased datasets outperform the data augmentation heuristics by Liu et al. (2021), which demonstrates the efficacy of our method when compared against manually designed heuristics.

5.5 Generalisation to Larger Pretrained Language Models

Since our method mitigates the spurious correlations in the dataset, not the model, our approach is model-agnostic and has the potential to benefit larger future models. To test this hypothesis, we train stronger and more modern models than BERT with our debiased datasets, and see if it can still improve the performance. More specifically, we choose Roberta-base, Roberta-large (Liu et al., 2019), and Albert-xxlarge (Lan et al., 2020), train them with Seq-Z SNLI and Z-Aug MNLI.

The results in Table 6 show that: 1) these larger models achieve better generalisation performance than BERT-base, which agrees with Bhargava et al. (2021); Bowman (2021); 2) training on our debiased datasets can still improve the performance of these models, yielding an average 2.30%, 1.23%, 1.13% gain for Roberta-base, Roberta-large and Albert-xxlarge respectively. This indicates that our method generalises to larger pretrained language models and could potentially enhance future models.

	Test data	Original	Debiased	Δ
Roberta-base	SNLI-hard	$82.02_{\pm 0.24}$	$\underline{\mathbf{83.71}}_{\pm 0.31}$	1.69
	MNLI-m hard	$81.74_{\pm 0.44}$	$\underline{\mathbf{83.14}}_{\pm 0.25}$	1.40
	MNLI-mm hard	$81.93_{\pm 0.30}$	$\underline{\mathbf{83.12}}_{\pm 0.24}$	1.19
	HANS	$71.17_{\pm 2.95}$	$\underline{\mathbf{76.15}}_{\pm 1.52}$	4.98
	Adv.Test avg	$77.63_{\pm 0.49}$	$\underline{\mathbf{79.89}}_{\pm 0.38}$	2.26
Roberta-large	SNLI-hard	$83.61_{\pm 0.31}$	$\underline{\mathbf{85.09}}_{\pm 0.32}$	1.48
	MNLI-m hard	$85.44_{\pm 0.62}$	$\mathbf{85.69}_{\pm 0.24}$	0.25
	MNLI-mm hard	$85.37_{\pm 0.63}$	$\mathbf{85.94}_{\pm 0.21}$	0.57
	HANS	$75.74_{\pm 2.82}$	$\mathbf{78.65}_{\pm 2.26}$	2.91
	Adv.Test avg	$80.92_{\pm 0.46}$	$\underline{\mathbf{81.86}}_{\pm 0.31}$	0.94
Albert-xxlarge	SNLI-hard	83.59	**84.82**	1.23
	MNLI-m hard	**86.42**	86.40	-0.02
	MNLI-mm hard	86.38	**86.82**	0.44
	HANS	76.32	**79.05**	2.73
	Adv.Test avg	81.91	**83.18**	1.27

Table 6: Performance gain when training larger models with our debiased datasets. Underscore indicates statistical significance against the baseline that is trained on the original datasets. For evaluation on SNLI-hard, the models are trained with SNLI or our debiased Seq-Z SNLI; for other evaluation datasets, the models are trained with MNLI or our debiased Z-Aug MNLI. Albert-xxlarge is experimented with one run due to its higher training cost.

---

[8] Details of the subcategories are described in Appendix C.

6 Related Work

Spurious Correlations in Datasets The issue of spurious correlations in datasets between labels and simple input features has recently received significant attention (Gururangan et al., 2018; Poliak et al., 2018; Belinkov et al., 2019a; Karimi Mahabadi et al., 2020). It has been shown that this issue is often inherent in the data annotation process, caused by biases in the framing of the task (Schwartz et al., 2017), noisy annotations (Chen et al., 2016), or personal (Geva et al., 2019) or group-level (Liu et al., 2021) annotator biases. Gardner et al. (2021) provide a theoretical framework for analyzing spurious correlations, which we use to define our filtering mechanism in Section 3.2.

Debiasing NLI Models Much prior work follows a *model-centric* approach towards mitigating biases in NLI models – they propose novel model architectures or training objectives to ensure that the models do not exploit the shortcuts presented by the dataset biases. At the representation level, Belinkov et al. (2019a,b) introduce an adversarial architecture to debias hypothesis representations to tackle hypothesis-only bias (Gururangan et al., 2018), and Stacey et al. (2020) strengthen the debiasing by using multiple adversarial classifiers. Zhou and Bansal (2020) use HEX projection to project the representation to the space orthogonal to the biased features to debias the model. At the model level, Clark et al. (2019); He et al. (2019); Karimi Mahabadi et al. (2020) propose methods based on Product-of-Expert (PoE) (Hinton, 2002) for mitigating biases by ensembling a biased-only model with a main model. Utama et al. (2020) propose the use of confidence regularization to improve out-of-distribution performance while retaining in-distribution accuracy.

Debiasing NLI Datasets Ross et al. (2021) introduce TAILOR, a semantically-controlled perturbation method for data augmentation based on a small number of manually defined perturbation strategies. Bras et al. (2020) propose AFLite, a dataset filtering method that learns feature representations with a model and conduct adversarial filtering based on model predictions. Unlike these approaches, our method requires no manually-written perturbation heuristics and is model-agnostic, hence it is more generally applicable.

Generative Data Augmentation Several works investigate generative data augmentation techniques to improve model robustness in other areas. Yang et al. (2020) conduct generative data augmentation for commonsense reasoning and show that it can improve out-of-domain generalisation. Lee et al. (2021) trains a generator to generate new claims and evidence for debiasing fact verification datasets like FEVER (Thorne et al., 2018). Schick and Schütze (2021) exploit large pretrained language models to generate semantic textual similarity datasets. Bartolo et al. (2021) improve robustness of question answering models by generating adversarial dataset.

7 Conclusions

To address the issue of spurious correlations between task-independent features and labels in NLI datasets, we propose methods to generate label-consistent data and then filter out instances from existing datasets that contribute to those spurious correlations; thereby generating debiased datasets. Models trained on our debiased versions of the SNLI and MNLI datasets generalise better than the equivalent model trained on the original datasets to a large suite of test sets focusing on various kinds of known biases. Future work in this direction includes investigating whether our techniques are applicable to tasks beyond NLI.

A Hyperparameters

A.1 Hyperparameters of Our Proposed Method

Hyperparameter	Value
learning rate	1e-5
batch size	24
epoch	5
optimiser	Adam
Adam ϵ	1e-6
Adam (β_1, β_2)	(0.9, 0.999)
learning rate scheduler	constant
max sequence length	128
pretrained model	GPT-2 large
device	Nvidia A100
λ	0.5
α	1.0

Table 7: Hyperparameters for training the generator G^*.

Hyperparameter	Value
number of samples from G^*_{SNLI}	5,000,000
number of samples from G^*_{MNLI}	4,000,000
data filtering threshold τ	0.95
data filtering model	Roberta-large
z-filtering number of biased features	20

Table 8: Hyperparameters of the data generation pipeline.

Hyperparameter	Value
learning rate	1e-5
batch size	32
epoch	5
optimiser	Adam
Adam ϵ	1e-6
Adam (β_1, β_2)	(0.9, 0.999)
learning rate scheduler	constant with warmup
warm up steps	2000
max sequence length	128
pretrained model	BERT-base
device	Nvidia A100
early stop patience	3 epochs

Table 9: Hyperparameters for training the NLI models.

A.2 Hyperparameter Tuning of PoE

The learning objective of PoE is defined as follows:

$$\mathcal{L}_{\text{PoE}} = \sum_{i=1}^{|\mathcal{D}|} CE(l_i, p_i') + \gamma CE(l_i, b_i),$$

where CE stands for cross-entropy loss, l_i is the label, and γ is a hyperparameter. $p_i' = softmax(\log p_i + \beta \log b_i)$ is the ensemble of the main model's prediction p_i, and the bias-only model's prediction b_i weighted by a hyperparameter β.

We find that the result of PoE is very sensitive to the hyperparameters β and γ. Following Karimi Mahabadi et al. (2020), we conduct grid search for the two hyperparameters, with $\beta \in \{0.05, 0.1, 0.2, 0.4, 0.8, 1.0, 2.0\}$ and $\gamma \in \{0.05, 0.1, 0.2, 0.4, 0.8, 1.0\}$. The best hyperparameters found for each evaluation dataset is listed in Table 10.

Train data	Eval. data	β	γ
SNLI	SNLI-hard	2.0	0.4
Seq-Z SNLI	SNLI-hard	2.0	0.4
MNLI	MNLI-m hard	0.8	1.0
	MNLI-mm hard	2.0	0.4
	HANS	2.0	0.8
Z-Aug MNLI	MNLI-m hard	2.0	0.4
	MNLI-mm hard	2.0	0.8
	HANS	2.0	1.0

Table 10: Best hyperparameters found for PoE models with different training and evaluation datasets.

B Task-independent Features

We list the chosen set of task-independent features that we aim to mitigate in this work in Table 11. Note that our method does not depend on the choice of task-independent features. One can easily add their own features in the future to mitigate newly-identified spurious correlations.

Table 12 shows the most salient task-independent features (ranked by z-statistics) in SNLI and our debiased SNLI dataset. It shows that the correlation between task-independent features and labels is massively reduced, dropping from over 400 to roughly 17. These results verify that our method successfully mitigates the spurious correlations in the dataset.

Feature	**Description**
Unigrams & Bigrams	All unigrams and bigrams. The n-grams from premise and hypothesis are treated separately.
Hypothesis length	Number of tokens in the hypothesis.
Hypothesis-premise length ratio	Number of tokens in hypothesis divided by number of tokens in the premise.
Lexical overlap	Ratio of tokens in the hypothesis that overlap with the premise.
Hypothesis-only model's prediction	We train a hypothesis-only model on the original dataset and use its prediction as a feature.
Null feature	A dummy feature added for *all* instances to avoid skewed label distribution.

Table 11: Descriptions of the features used to debias the datasets in Section 3.

SNLI		**Debiased SNLI (Seq-Z)**	
Biased feature	**z-statistics**	**Biased feature**	**z-statistics**
Entailment			
hypo-only-pred=0	422.1	theres@hypothesis	17.5
lex-overlap> 0.8	123.3	hypo-len< 5	17.4
full-lex-overlap	117.3	full-lex-overlap	17.4
outside@hypothesis	102.2	politician@hypothesis	17.4
lex-overlap> 0.9	90.4	speaking@hypothesis	17.4
Neutral			
hypo-only-pred=1	436.1	championship@hypothesis	15.3
for a@hypothesis	63.6	living room@hypothesis	15.2
his@hypothesis	56.8	many men@hypothesis	15.2
friends@hypothesis	55.6	green suit@hypothesis	15.2
tall@hypothesis	52.7	are wearing@hypothesis	15.2
Contradiction			
hypo-only-pred=2	433.9	nothing@hypothesis	17.0
sleeping@hypothesis	92.9	hypo-only-pred=2	16.9
is sleeping@hypothesis	68.7	at home@hypothesis	16.9
nobody@hypothesis	68.4	is no@hypothesis	16.9
no@hypothesis	62.7	york yankees@hypothesis	16.9

Table 12: Top-5 biased features with the highest z-statistics on SNLI (left) and debiased Seq-Z SNLI (right) for each label class.

C Description of Adversarial Test (Liu et al., 2020b) Subcategories

The adversarial test benchmark (Liu et al., 2020b) includes the following subcategories from various sources:

- PI-CD: classifier detected partial-input (Gururangan et al., 2018).
- PI-SP: HypoNLI (Liu et al., 2020a) dataset that tackles surface patterns heuristics.
- IS-SD: syntactic diagnostic dataset HANS (McCoy et al., 2019).
- IS-CS: lexically misleading instances constructed by Nie et al. (2019).
- LI-LI: lexical inference test by (Naik et al., 2018; Glockner et al., 2018).
- LI-TS: text-fragment swap test by swapping the premise and hypothesis (Wang et al., 2019; Minervini and Riedel, 2018).
- ST: an aggregation of word-overlap (ST-WO), negation (ST-NE), length mismatch (ST-LM), and spelling errors (ST-SE) tests in (Naik et al., 2018).

D Visualisation of z-statistics

Following Gardner et al. (2021), we visualise the statistics of the features on both SNLI and our debiased SNLI (Seq-Z) dataset in Fig. 2.[9] Comparing the two plots, it confirms that our method successfully suppresses the spurious correlations in the dataset.

E Ablation Study

Data	Size	SNLI	SNLI-hard
Seq-Z $\mathcal{Z}(\hat{\mathcal{D}}_{G^*} \mid \mathcal{Z}(\mathcal{D}_{\text{SNLI}}))$	928k	88.08	$82.82_{\pm 0.15}$
Seq-Z $\mathcal{Z}(\hat{\mathcal{D}}_{G^*} \mid \mathcal{Z}(\mathcal{D}_{\text{SNLI}}))$	549k	87.59	$82.35_{\pm 0.46}$
Seq-Z $\mathcal{Z}(\hat{\mathcal{D}}_{G} \mid \mathcal{Z}(\mathcal{D}_{\text{SNLI}}))$	549k	88.15	$82.20_{\pm 0.23}$
$\mathcal{D}_{\text{SNLI}} \cup \hat{\mathcal{D}}_{G^*}$	2577k	90.85	$81.99_{\pm 0.47}$
$\mathcal{D}_{\text{SNLI}} \cup \hat{\mathcal{D}}_{G}$	3717k	90.83	$80.82_{\pm 0.27}$
Z-Aug $\mathcal{Z}(\hat{\mathcal{D}}_{G^*} \mid \mathcal{D}_{\text{SNLI}})$	1142k	90.67	$81.78_{\pm 0.53}$
$\mathcal{D}_{\text{SNLI}} \cup \hat{\mathcal{D}}_{G^*}$	1142k	90.72	$81.45_{\pm 0.52}$
$\mathcal{D}_{\text{SNLI}} \cup \hat{\mathcal{D}}_{G}$	1142k	90.67	$80.85_{\pm 0.27}$
$\mathcal{Z}(\hat{\mathcal{D}}_{G^*})$	808k	88.44	$81.28_{\pm 0.57}$
$\mathcal{Z}(\hat{\mathcal{D}}_{G^*})$	549k	88.12	$80.67_{\pm 0.41}$
$\hat{\mathcal{D}}_{G^*}$ (w/ filter)	549k	88.59	$80.41_{\pm 0.50}$
$\mathcal{D}_{G^*}$ (wo/ filter)	808k	75.65	$76.67_{\pm 0.83}$
$\mathcal{D}_{G^*}$ (wo/ filter)	549k	75.43	$76.05_{\pm 0.49}$
$\mathcal{Z}(\mathcal{D}_{\text{SNLI}})$	127k	84.93	$80.52_{\pm 1.03}$
original SNLI $\mathcal{D}_{\text{SNLI}}$	549k	90.45	$80.34_{\pm 0.46}$

Table 13: Ablation study conducted on SNLI and SNLI-hard.

---

[9] We sample 10% of the points under the $z = 10.0$ curve to compress the figure, but it may still be slow to render the figures because the number of points is still large.

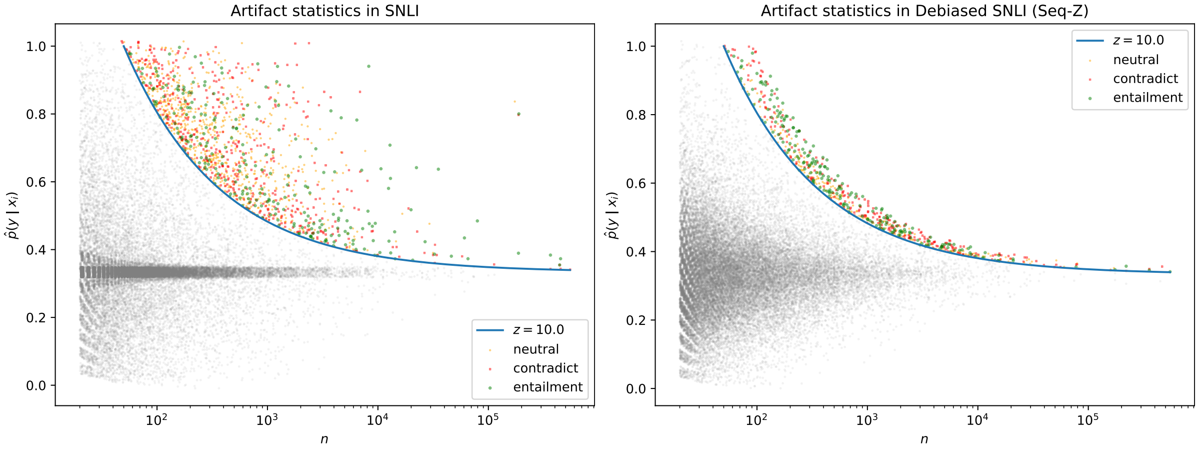

Figure 2: Statistics of the features on SNLI and our debiased SNLI (Seq-Z).

F Generated Samples of Debiased Dataset

Table 14 and Table 15 show generated samples in the debiased SNLI and MNLI datasets respectively. The samples are quite diverse and the quality is reasonably good, which demonstrates the effectiveness of our quality ensuring techniques presented in Section 2.2.

Premise	**Hypothesis**	**Label**
Thanksgiving dinner is a fun time for everyone.	The dinner is a fun event.	entailment
A father is letting his toddler drink from his glass.	A toddler is having a drink	entailment
Hair stylist performing a haircut.	A hailer is performing surgery	contradiction
Then there are two men in white shirts, one of which is holding a cigarette and the other an open book.	Two men sit at a conference table with a book and a cigarette.	neutral
Three men playing basketball on a court with an audience in the background.	Three people playing basketball	entailment
Six children, boys and girls, jumping into a swimming pool.	Six children are jumping into a pool	entailment
Three girls jump for joy in front of a building.	The kids are sitting on their front steps.	contradiction
The child in the green one piece suit is running in the playground.	The child is playing outside	entailment
View of an intersection with city buses and a police car.	The intersection is surrounded by vehicles.	entailment
The man on the yellow basketball team tries to score while the men on the opposing team try to block his shot.	Two men on different teams are competing in a game of a male is trying to score while other men on the opposing one defend his basket in basketball	entailment
Young child wearing orange shirt eating a ice cream cone.	A child eats ice cream at the ice cream stand.	neutral
Five people standing in front of a shopping center.	Five people outside the building	entailment
He's taking a break after a long workout.	He is taking a break from his workout	entailment
Two men are sitting on a couch, playing music together.	The two people play guitars.	neutral
Everyone is out enjoying the winter weather and having fun with their children.	Everyone is out enjoying the summer	contradiction
Many people walking through a city street.	There are a group of people in Times Square.	neutral
A woman in a black dress walks down the street.	a person in dresses walks	entailment
Four children, riding unicycles, are on a sidewalk in front of a brick building.	Four children ride unicycles on the sidewalk	entailment
Four kids playing soccer in a field.	The children played with bubbles.	contradiction
MADISON, Wis. (AP) — The man in the white jersey and orange visor threw the ball for the two boys in uniforms with blue jerseys.	A man in white is throwing a ball to two boys in blue uniforms.	entailment
Mikhail Kasyapkin, who plays Bart on The Simpsons, is talking to a woman.	The woman tells him to stop making couples sit	neutral
Shutterstock photo of a woman with a heart tattoo on her calf.	A woman with a pumpkin tattoo on her back	contradiction
Three women and a man sing their hearts out in the microphone.	A group singing	entailment
With so many people on the beach, the woman in yellow has to make a quick decision.	Many people are at a beach, one has to make a decision	entailment
Celebrants are walking with American flags.	People are walking.	entailment
Customer examines flowers at a market.	A customer examines flowers.	entailment
He is in the air on his skateboard.	A guy is in a tree.	contradiction
thousands of people enjoying a fireworks show.	There is an audience for a show.	entailment
Bicyclists in a race, with a blue bike leaving the ground in the lead.	Bikers resting after a long ride.	contradiction
He has a pet bird in a cage, and it is sleeping.	He is walking the dogs.	contradiction

Table 14: Generated samples in the debiased SNLI datasets.

Premise	**Hypothesis**	**Label**
As I noted earlier, the board and the auditors should have a strategic alignment of interests.	The board should align to increase efficiency.	neutral
This story was originally published in Slate. For more on the U.S. role in that war, subscribe to Slate's Subscribe now!	The U.S. played very little part in the war.	neutral
Via Newsday's a poll finds that 84 percent of Americans think Monica Lewinsky should tell the truth about her encounter with Clinton.	A majority of the public thinks Lewinsky should come forward.	entailment
Violence among theatrical people, on the other hand, can be entertainingly savage, cf, All About Eve (1884) and The Mousetrap (1928).	There aren, always hasn't usually been oancy situation with violence among theatrical people because they don't have to work because it isn't employment.	contradiction
Nowhere in the book does Hatfield warn the reader that he has altered details or created composite characters to protect his sources.	Hatfield didn't inform the readers in any part in the book that the details of the altered information was to protect his sources	entailment
The young inhabitants are brought up knowing nothing else.	The young inhabitants have been brought up knowing of nothing.	entailment
The 5th floor of the Royal Palace is open to the public, with restricted access for foreign guests.	Foreign guest have restricted access in the royal palace for visitors.	entailment
Pulitzer Prizes are given to books, magazines, paintings, and sculpture.	You won a prize when you eat blueberries at dinner.	contradiction
I admit I didn't have much reason to think that.	After all, most of the people don;t think that way.	neutral
In the past, Medicare's fiscal health has generally been gauged by the solvency of the HI trust fund projected over a 75-year period.	Medicare's soliesic fitness is displayed in the form of the surplus projected over a 50 year term.	contradiction
A case study where the only people interviewed were senior officials would be seen as a not-good case study, in contrast to one where the views of individuals at all levels affected was obtained.	If senior editors were interviewed they would not be considered the best examples for case studies.	entailment
If you've ever spent an evening plunging your wrists into ice water, you are an easy mark for devices that promise to relieve carpal tunnel syndrome.	People are easy marks for devices that may cure cat paral tunnel syndrome	entailment
It's a sign of a permanently altered world that natural blondness should have such sacred power no longer.	The people still believe blondness has a special significance.	contradiction
The Three-Arched Bridge, by Ismail Kadare, translated by John Hodgson (Arcade).	Ismail Marare translated The Three-Aral.	contradiction
Many of these organizations found themselves in an environment similar to the one confronting federal managers today-one in which they were called upon to improve performance while simultaneously reducing costs.	This was the only option for all their group.	neutral
The long-sought, the elusive, the elusive Jane Finn!	She is easily obtainable.	contradiction
And now, to-day, he puts forward a suggestion that he himself must have known was ridiculous.	He is making the ridiculous suggestion that himself must have been aware of.	entailment
Jupiter's moon, Callisto, has a thick atmosphere and is a good destination for a quiet tour.	Callisto's atmosphere makes for a pleasant journey to explore.	entailment
Founded in 1995, the Agora formed to address the enormous security challenges brought about by new computer, network, and Internet technologies.	The Agora was formed to address the challenge of nuclear proliferation.	contradiction
Just last week in The New Yorker, Malcolm Gladwell argued that Gen.	Just last week in Newsweek, Johnny Chung argued that Gen.	contradiction

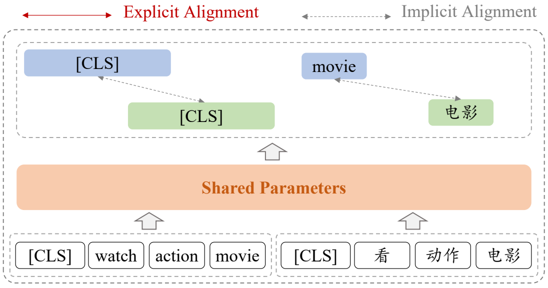
Abstract

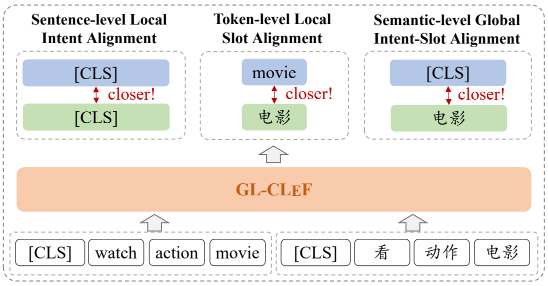
Due to high data demands of current methods, attention to zero-shot cross-lingual spoken language understanding (SLU) has grown, as such approaches greatly reduce human annotation effort. However, existing models solely rely on shared parameters, which can only perform implicit alignment across languages. We present **G**lobal–**L**ocal **C**ontrastive **LE**arning **F**ramework (GL-CLEF) to address this shortcoming. Specifically, we employ contrastive learning, leveraging bilingual dictionaries to construct multilingual views of the same utterance, then encourage their representations to be more similar than negative example pairs, which achieves to explicitly aligned representations of similar sentences across languages. In addition, a key step in GL-CLEF is a proposed `Local` and `Global` component, which achieves a fine-grained cross-lingual transfer (i.e., *sentence-level* `Local` intent transfer, *token-level* `Local` slot transfer, and *semantic-level* `Global` transfer across intent and slot). Experiments on MultiATIS++ show that GL-CLEF achieves the best performance and successfully pulls representations of similar sentences across languages closer.

1 Introduction

Spoken language understanding (SLU) is a critical component in task-oriented dialogue systems (Tur and De Mori, 2011; Qin et al., 2021b). It usually includes two sub-tasks: intent detection to identify users' intents and slot filling to extract semantic constituents from the user's query. With the advent of deep neural network methods, SLU has met with remarkable success. However, existing SLU models rely on large amounts of annotated data, which makes it hard to scale to low-resource languages that lack large amounts of labeled data. To address this shortcoming, zero-shot cross-lingual SLU generalization leverages the labeled training data in high-resource languages to transfer the trained model to a target, low-resource language, which gains increasing attention.



(a) Prior work.



(b) GL-CLEF

Figure 1: (a) Prior work (Implicit Alignment); (b) GL-CLEF (Explicit Alignment). Different color denotes representations across different languages. `[CLS]` represents the sentence representation.

To this end, many works have been explored for zero-shot cross-lingual SLU. Multilingual BERT (mBERT) (Devlin et al., 2019), a cross-lingual contextual pre-trained model from a large amount of multi-lingual corpus multi-lingual corpus, has achieved considerable performance for zero-shot cross-lingual SLU. Liu et al. (2020) further build an attention-informed mixed-language training by generating bi-lingual code-switched data to implicitly align keywords (e.g., slots) between source and target language. Qin et al. (2020) extend the idea to a multilingual code-switched setting, aligning the source language to multiple target languages. This approach currently achieves the

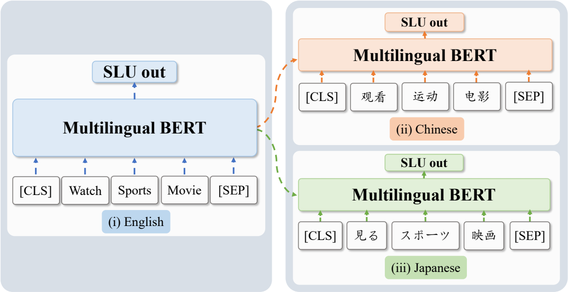
Volume 1: Long Papers, pages 2677 - 2686
May 22-27, 2022 ©2022 Association for Computational Linguistics

state-of-the-art performance for zero-shot cross-lingual SLU. Though achieving promising performance, as shown in Figure 1 (a), the above methods solely rely on shared parameters and can only perform implicit alignment across languages, which brings two challenges. First, such implicit alignment process seems to be a black box, which not only seriously affects the alignment representation but also makes it hard to analyze the alignment mechanism. Second, prior work do not distinguish between the varying granularities of the tasks: the intent detection is *sentence-level* and the slot filling is *token-level*, which does not offer fine-grained cross-lingual transfer for *token-level* slot filling.

To solve the aforementioned challenges, we propose a **G**lobal–**L**ocal **C**ontrastive **LE**arning **F**ramework (GL-CLEF) for zero-shot cross-lingual SLU. For the first challenge, as shown in Figure 1 (b), the key insight in GL-CLEF is to explicitly ensure that representations of similar sentences across languages are pulled closer together via contrastive learning (CL). Specifically, we leverage bilingual dictionaries to generate multi-lingual code-switched data pairs, which can be regarded as cross-lingual views with the same meaning. With the use of CL, our model is able to learn to distinguish the code-switched utterance of an input sentence from a set of negative examples, and thus encourages representations of similar sentences between source language and target language closer.

For the second challenge, SLU requires accomplishing tasks at two different levels: *token-level* slot filling and *sentence-level* intent detection. As such, simply leveraging ordinary *sentence-level* contrastive learning is ineffective for fine-grained knowledge transfer in *token-level* slot filling. Therefore, we first introduce a `Local` module in GL-CLEF to learn different granularity alignment representations (i.e., *sentence-level* `Local` intent CL and *token-level* `local` slot CL). To be specific, *sentence-level* `Local` intent CL and *token-level* `local` slot CL are introduced for aligning similar sentence and token representations across different languages for intent detection and slot filling, respectively. In addition, we further argue that slot and intent are highly correlated and have similar semantic meanings in a sentence. This phenomenon can serve as a signal for self-supervised alignment across intent and slots. Therefore, a `Global` module named *semantic-level* `global` intent–slot CL is further proposed to bring the representations of slot and intents within a sentence closer together.



(a) Training (b) Zero-shot Testing

Figure 2: Zero-shot cross-lingual SLU.

We conduct experiments on MultiATIS++ (Xu et al., 2020), which includes nine different languages. Our experiments show that GL-CLEF achieves state-of-the-art results of 54.09% sentence accuracy, outperforming the previous best by 10.06% on average. Besides, extensive analysis experiments demonstrate that GL-CLEF has successfully reduced the representation gap between different languages.

To facilitate further research, codes are publicly available at `https://github.com/LightChen233/GL-CLeF`.

2 Background

We first describe traditional SLU before the specifics of zero-shot cross-lingual version of SLU.

Traditional SLU in Task-oriented Dialogue. SLU in Task-oriented Dialogue contains two subtasks: *Intent Detection* and *Slot Filling*.

· *Intent Detection:* Given input utterance $\mathbf{x}$, this is a classification problem to decide the corresponding intent label o^I.

· *Slot Filling:* Often modeled as a sequence labeling task that maps an input word sequence $\mathbf{x} = (x_1, \ldots, x_n)$ to slots sequence $\mathbf{o}^S = (o^S_1, \ldots, o^S_n)$, where n denotes the length of sentence $\mathbf{x}$.

Since the two tasks of intent detection and slot filling are highly correlated, it is common to adopt a joint model that can capture shared knowledge. We follow the formalism from Goo et al. (2018), formulated as $(o^I, o^S) = f(\mathbf{x})$, where f is the trained model.

Zero-shot Cross-lingual SLU. This means that a SLU model is trained in a source language, e.g., English (*cf.* Figure 2 (a)) and directly applied to other target languages (*cf.* Figure 2 (b)).

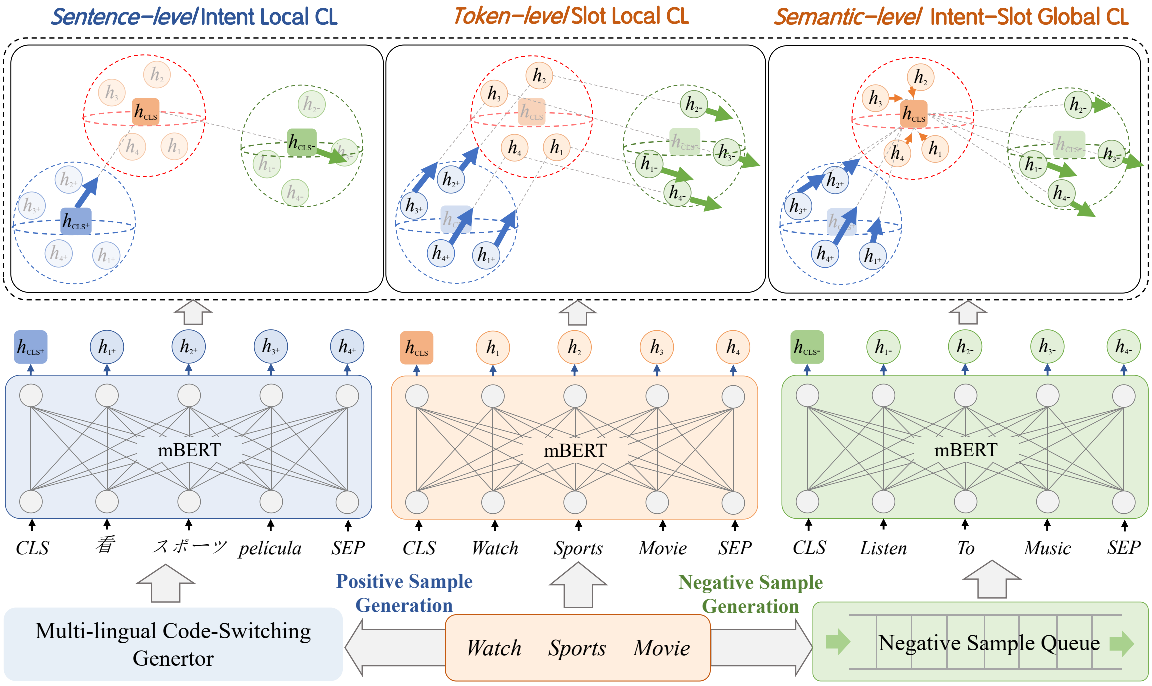


Figure 3: The main architecture of GL-CLEF. The boxes shown in figures are each sentence representation, while the circles are token representations. The dash lines and arrows in the top of the pictures on boxes and circles represent the direction of pushing in different levels made by contrastive learning. Different color denotes different representation spaces against anchor utterance, positive samples and negative samples. For simplicity, we only draw one case of *token-level* slot CL.

Formally, given each instance $\mathbf{x}_{tgt}$ in a target language, the model f which is trained on the source language is directly used for predicting its intent and slots:

$$(o^I_{tgt}, o^S_{tgt}) = f(\mathbf{x}_{tgt}), \tag{1}$$

where tgt represents the target language.

3 Model

We describe the general approach to general SLU task first, before describing our GL-CLEF model which explicitly uses contrastive learning to explicitly achieve cross-lingual alignment. The main architecture of GL-CLEF is illustrated in Figure 3.

3.1 A Generic SLU model

Encoder. Given each input utterance $x = (x_1, x_2, \ldots, x_n)$, the input sequence can be constructed by adding specific tokens $\mathbf{x} = (\texttt{[CLS]}, x_1, x_2, ..., x_n, \texttt{[SEP]})$, where `[CLS]` denotes the special symbol for representing the whole sequence, and `[SEP]` can be used for separating non-consecutive token sequences (Devlin et al., 2019). Then, we follow Qin et al. (2020) to first generate multi-lingual code-switched data. Then, we employ mBERT model to take code-switched data for encoding their representations $\mathbf{H} = (\boldsymbol{h}_{\texttt{CLS}}, \boldsymbol{h}_1, \ldots, \boldsymbol{h}_n, \boldsymbol{h}_{\texttt{SEP}})$.

Slot Filling. Since mBERT produces subword-resolution embeddings, we follow Wang et al. (2019) and adopt the first sub-token's representation as the whole word representation and use the hidden state to predict each slot: $\boldsymbol{o}^S_t = \mathrm{softmax}(\boldsymbol{W}^s \boldsymbol{h}_t + \boldsymbol{b}^s)$, where $\boldsymbol{h}_t$ denotes the first sub-token representation of word x_t; $\boldsymbol{W}^s$ and $\boldsymbol{b}^s$ refer to the trainable parameters.

Intent Detection. We input the sentence representation $\boldsymbol{h}_{\texttt{CLS}}$ to a classification layer to find the label o^I: $o^I = \mathrm{softmax}(\boldsymbol{W}^{\boldsymbol{I}} \boldsymbol{h}_{\texttt{CLS}} + \boldsymbol{b}^{\boldsymbol{I}})$, where $\boldsymbol{W}^{\boldsymbol{I}}$ and $\boldsymbol{b}^{\boldsymbol{I}}$ are tuneable parameters.

3.2 Global–local Contrastive Learning Framework

We introduce our global–local contrastive learning framework (GL-CLEF) in detail, which consists of three modules: 1) a *sentence-level* `local` intent contrastive learning (CL) module to align sentence representation across languages for intent detection, 2) a *token-level* `local` slot CL module to align token representations across languages for slot filling, and 3) *semantic-level* `global` intent–slot CL to align representations between a slot and an intent.

3.2.1 Positive and Negative Samples Construction

For contrastive learning, the key operation is to choose appropriate positive and negative pairs against to the original (anchor) utterance.

Positive Samples. Positive samples should preserve the same semantics compared against the anchor utterance. Therefore, given each anchor utterance $\mathbf{x} = (\texttt{[CLS]}, x_1, x_2, ..., x_n, \texttt{[SEP]})$, we follow Qin et al. (2020) to use bilingual dictionaries (Lample et al., 2018) to generate multi-lingual code-switched data, which is considered as the positive samples $\mathbf{x}_+$. Specifically, for each word x_t in $\mathbf{x}$, x_t is randomly chosen to be replaced with a translation provisioned from a bilingual dictionary to generate a positive sample. For example, given an anchor utterance *"watch sports movie"* in English, we can generate a positive multi-lingual code-switched sample *"看(watch/zh) スポツ (sports/ja) película (movie/es)"* (*cf.* Figure 3). Such a pair of anchor utterance and multi-lingual code-switched sample can be regarded as cross-lingual views of the same meaning across different languages. $\mathbf{x}_+$ is fed into mBERT to obtain the corresponding representations $\mathbf{H}_+ = (\boldsymbol{h}_{\texttt{CLS}+}, \boldsymbol{h}_{1+}, \ldots, \boldsymbol{h}_{n+}, \boldsymbol{h}_{\texttt{SEP}+})$.

Negative Samples. A natural approach for generating negative samples is randomly choosing other queries in a batch. However, this method requires the recoding of the negative samples, hurting efficiency. Inspired by He et al. (2020), in GL-CLEF, we maintain a negative sample queue, where the previously encoded original anchor utterance $\mathbf{x}$, positive samples $\mathbf{x}_+$ and previous negative samples $\mathbf{x}_-$ are also progressively reused as negative samples. This enables us to reuse the encoded samples from the immediate preceding batches, so as to eliminate the unnecessary negative encoding process. The negative sample queues for `[CLS]` and sentence representation are represented as: $\mathbf{H}_{\texttt{CLS}-}=\{\boldsymbol{h}^k_{\texttt{CLS}-}\}_{k=0}^{K-1}$, $\mathbf{H}_{S-}=\{\mathbf{H}^k_{S-}\}_{k=0}^{K-1}$, where K is the maximum capacity for negative queue.

3.2.2 `Local` Module

***Sentence-level* `Local` Intent CL.** Since intent detection is a *sentence-level* classification task, aligning sentence representation across languages is the goal of zero-shot cross-lingual intent detection task. Therefore, in GL-CLEF, we propose a *sentence-level* `local` intent CL loss to explicitly encourage the model to align similar sentence representations into the same local space across languages for intent detection. Formally, this is formulated as:

$$\mathcal{L}_{\mathrm{LI}} = -\log \frac{s(h_{\mathrm{CLS}}, h_{\mathrm{CLS^+}})}{s(h_{\mathrm{CLS}}, h_{\mathrm{CLS^+}}) + \sum_{\mathrm{k=0}}^{\mathrm{K\text{-}1}} s(h_{\mathrm{CLS}}, h^k_{\mathrm{CLS^-}})},$$

where $s(p, q)$ denotes the dot product between p and q; τ is a scalar temperature parameter.

***Token-level* `Local` Slot CL.** As slot filling is a token-level task, we propose a *token-level* `local` slot CL loss to help the model to consider token alignment for slot filling, achieving fine-grained cross-lingual transfer. We apply toke-level CL for all tokens in the query. Now, we calculate the ith token CL loss for simplicity:

$$\mathcal{L}^i_{\mathrm{LS}} = -\sum_{j=1}^{n} \log \frac{s(h_{\mathrm{i}}, h_{\mathrm{j^+}})}{s(h_{\mathrm{i}}, h_{\mathrm{j^+}}) + \sum_{k=0}^{\mathrm{K\text{-}1}} s(h_{\mathrm{i}}, h^k_{\mathrm{j^-}})} / n,$$

where the final $\mathcal{L}_{\mathrm{LS}}$ is the summation of all tokens CL loss.

3.2.3 `Global` Module

***Semantic-level* `Global` Intent-slot CL.** We noted that slots and intent are often highly related semantically when they belong to the same query. Therefore, we think that the intent in a sentence and its own slots can naturally constitute a form of positive pairings, and the corresponding slots in other sentences can form negative pairs. We thus further introduce a *semantic-level* `global` intent–slot CL loss to model the semantic interaction between slots and intent, which may further improve cross-lingual transfer between them. Formally:

$$\mathcal{L}_{\mathrm{GIS1}} = -\sum_{j=1}^{n} \log \frac{s(h_{\mathrm{CLS}}, h_{\mathrm{j}})}{s(h_{\mathrm{CLS}}, h_{\mathrm{j}}) + \sum_{k=0}^{\mathrm{K\text{-}1}} s(h_{\mathrm{CLS}}, h^k_{\mathrm{j^-}})} / n,$$
$$\mathcal{L}_{\mathrm{GIS2}} = -\sum_{j=1}^{n} \log \frac{s(h_{\mathrm{CLS}}, h_{\mathrm{j^+}})}{s(h_{\mathrm{CLS}}, h_{\mathrm{j^+}}) + \sum_{k=0}^{\mathrm{K\text{-}1}} s(h_{\mathrm{CLS}}, h^k_{\mathrm{j^-}})} / n,$$
$$\mathcal{L}_{\mathrm{GIS}} = \mathcal{L}_{\mathrm{GIS1}} + \mathcal{L}_{\mathrm{GIS2}},$$

where we consider CL loss from both anchor sentences ($\mathcal{L}_{\mathrm{GIS1}}$) and code-switched sentence ($\mathcal{L}_{\mathrm{GIS2}}$), and add them to do semantic-level contrastive learning ($\mathcal{L}_{\mathrm{GIS}}$) .

3.3 Training

3.3.1 Intent Detection Loss

$$\mathcal{L}_I \triangleq -\sum_{i=1}^{n_I} \hat{\mathbf{y}}_i^I \log\left(\mathbf{o}_i^I\right), \tag{2}$$

where $\hat{\mathbf{y}}_i^I$ are the gold intent label and n_I is the number of intent labels.

3.3.2 Slot Filling Loss

$$\mathcal{L}_S \triangleq -\sum_{j=1}^{n}\sum_{i=1}^{n_S} \hat{\mathbf{y}}_j^{i,S} \log\left(\mathbf{y}_j^{i,S}\right), \tag{3}$$

where $\hat{\mathbf{y}}_j^{i,S}$ are the gold slot label for jth token; n_S is the number of slot labels.

3.3.3 Overall Loss

The overall objective in GL-CLEF is a tuned linear combination of the individual losses:

$$\mathcal{L} = \lambda_I\mathcal{L}_I + \lambda_S\mathcal{L}_S + \lambda_{\text{LI}}\mathcal{L}_{\text{LI}} + \lambda_{\text{LS}}\mathcal{L}_{\text{LS}} + \lambda_{\text{GIS}}\mathcal{L}_{\text{GIS}}, \tag{4}$$

where λ_* are tuning parameters for each loss component.

4 Experiments

We use the latest multilingual benchmark dataset of MultiATIS++ (Xu et al., 2020) which consists of 9 languages including English (en), Spanish (es), Portuguese (pt), German (de), French (fr), Chinese (zh), Japanese (ja), Hindi (hi), and Turkish (tr).

4.1 Experimental Setting

We use the base case multilingual BERT (mBERT), which has $N = 12$ attention heads and $M = 12$ transformer blocks. We select the best hyperparameters by searching a combination of batch size, learning rate with the following ranges: learning rate $\{2 \times 10^{-7}, 5 \times 10^{-7}, 1 \times 10^{-6}, 2 \times 10^{-6}, 5 \times 10^{-6}, 6 \times 10^{-6}, 5 \times 10^{-5}, 5 \times 10^{-4}\}$; batch size $\{4, 8, 16, 32\}$; max size of negative queue $\{4, 8, 16, 32\}$; For all experiments, we select the best-performing model over the dev set and evaluate on test datasets. All experiments are conducted at TITAN XP and V100.

4.2 Baselines

To verify the effect of GL-CLEF, we compare our model with the following state-of-the-art baselines: 1) `mBERT`. mBERT[1] follows the same model architecture and training procedure as BERT (Devlin et al., 2019), but trains on the Wikipedia pages of 104 languages with a shared subword vocabulary. This allows mBERT to share embeddings across languages, which achieves promising performance on various cross-lingual NLP tasks;
2) `Ensemble-Net`. Razumovskaia et al. (2021) propose an `Ensemble-Net` where predictions are determined by 8 independent models through majority voting, each separately trained on a single source language, which achieves promising performance on zero-shot cross-lingual SLU;
3) `AR-S2S-PTR`. Rongali et al. (2020) proposed a unified sequence-to-sequence models with pointer generator network for cross-lingual SLU;
4) `IT-S2S-PTR`. Zhu et al. (2020) proposed a non-autoregressive parser based on the insertion transformer. It speeds up decoding and gain improvements in cross-lingual SLU transfer;
5) `CoSDA`. Qin et al. (2020) propose a data augmentation framework to generate multi-lingual code-switching data to fine-tune mBERT, which encourages the model to align representations from source and multiple target languages.

4.3 Main Results

Following Goo et al. (2018), we evaluate the performance of slot filling using F1 score, intent prediction using accuracy, and the sentence-level semantic frame parsing using overall accuracy which represents all metrics are right in an utterance.

From the results in Table 1, we observe that: (1) `CoSDA` achieves better performance than no alignment work `mBERT` and even outperforms the `Ensemble-Net`. This is because that such implicit alignment does align representations to some extent, compared against `mBERT`. (2) Our framework achieves the state-of-the art performance and beats `CoSDA` with 10.06% average improvements on overall accuracy. This demonstrates that `GL-CLEF` explicitly pull similar representations across languages closer, which outperforms the implicit alignment manner.

4.4 Analysis

To understand GL-CLEF in more depth, we perform comprehensive studies to answer the following research questions (RQs):
(1) Do the `local` intent and slot CLs benefit *sentence-* and *token-level* representation alignment? (2) Can *semantic-level* `global` intent-slot CL boost the overall sentence accuracy? (3) Are `local` intent CL and `local` slot CL complementary? (4) Does GL-CLEF pull similar representa-

tions across languages closer? (5) Does GL-CLeF improve over other pre-trained models? (6) Does GL-CLeF generalize to non pre-trained models? (7) Is GL-CLeF robust to the one-to-many translation problem?

Answer 1: `Local` intent CL and slot CL align similar sentence and token representations across languages. We investigate the effect of the `local` intent CL and `local` slot CL mechanism, by removing the `local` intent CL and slot CL, respectively (Figure 4, "– LI" and "– LS" (Col 1,2)). For the effectiveness of `local` intent CL, we find the performance of intent detection averaged on 9 languages drops by 3.52% against the full system (*ibid.* final, RHS column). This is because *sentence-level* intent CL loss can pull sentence representations closer across languages.

Similarly, considering the effectiveness of `local` slot CL, we find the performance of slot filling averaged on 9 languages drops by 2.44% against the full system. We attribute performance drops to the fact that `local` slot CL successfully make a fine-grained cross-lingual knowledge transfer for aligning token representation across languages, which is essential for *token-level* cross-lingual slot filling tasks.

Answer 2: *Semantic-level* `global` intent-slot successfully establishes a semantic connection across languages. We further investigate the effect of the *semantic-level* intent-slot CL mechanism when we remove the `global` intent-slot CL loss (Figure 4, "– GIS" (Col 3)). We find the sentence overall performance drops a lot (from 54.09% to 46.94%). Sentence overall metrics require model to capture the semantic information (intent and slots) for queries. Therefore, we attribute it to the proposed *semantic-level* `global` intent-slot CL. As it successfully establishes semantic connection across languages, it boosts overall accuracy.

Answer 3: Contribution from `local` intent CL and slot CL module are complementary. We explore whether `local` intent CL and slot CL module are complementary. By removing all the `Local` CL modules (including *sentence-level* `local` intent CL and *token-level* `local` slot CL), results are shown in Figure 4 (–Local Col 4). We find that the experiments are lowest compared with only removing any single `local` CL module, which demonstrates the designed two `local` CL module works orthogonally.

Answer 4: GL-CLeF pulls similar representations across languages closer. We choose test set and use representations of `[CLS]` of each sentence for visualization. Figure 5 (a, LHS) shows the t-SNE visualization of the `mBERT` output, where we observe that there very little overlap between different languages, which shows that the distance of the representations of different languages are distant. In contrast, the `GL-CLeF` representations (b, RHS) fine-tuned model in different languages are closer and largely overlap with each other. The stark contrast between the figures demonstrates

that `GL-CLeF` successfully aligns representations of different languages.

Answer 5: Contributions from contrastive learning and pre-trained model use are complementary. To verify the contribution from GL-CLeF is still effective when used in conjunction with other strong pre-trained models, we perform experiments with `XLM-R` (Conneau et al., 2020). `XLM-R` demonstrates significant gains for a wide range of cross-lingual tasks. From the results in Table 2, we find GL-CLeF enhances `XLM-R`'s performance, demonstrating that contributions from the two are complementary. This also indicates that CL-CLeF is model-agnostic, hinting that GL-CLeF may be applied to other pre-trained models.

Answer 6: GL-CLeF still obtains gains over BiLSTM. A natural question that arises is whether `GL-CLeF` is effective for non pre-trained models, in addition to transformers. To answer the question, we replace `mBERT` with `BiLSTM`, keeping other components unchanged. The results are shown in Table 2. We can see that GL-CLeF outperforms `BiLSTM` in all metrics, further demonstrating that `GL-CLeF` is not only effective over `mBERT` but also ports to general encoders for both pre-trained models and non pre-trained models.

Answer 7: GL-CLeF is robust. It is worth noting that words in the source language can have multiple translations in the target language. We follow Qin et al. (2020) to randomly choose any of the multiple translations as the replacement target language word. Their work verified that random selection effective method (Qin et al., 2020). A natural question that arises is whether GL-CLeF is robust over different translation selections. To answer the question, we choose 15 different seeds to perform experiment and obtain the standard deviation, which we take as an indicator of the stability and robustness of models' performance. in Figure 6 shows a lower standard deviation on each metric, indicating our model is robust to different translation. Finding and using the absolutely correct contextual word-to-word translation is an interesting direction to be explored in the future.

5 Related Work

Traditional Spoken Language Understanding. Since slot filling and intent detection are two correlated tasks, traditional SLU approaches mainly explore a joint model for capturing shared knowledge across the two tasks. Specifically, Zhang and Wang (2016); Liu and Lane (2016a,b); Hakkani-Tür et al. (2016) consider an implicit joint mechanism using a multi-task framework by sharing an encoder for both tasks. Goo et al. (2018); Li et al. (2018); Qin et al. (2019) consider explicitly leveraging intent detection information to guide slot filling. Wang et al. (2018); E et al. (2019); Zhang et al. (2020); Qin et al. (2021a) use a bi-directional connection between slot filling and intent detection.

Zero-shot Cross-lingual Spoken Language Understanding. Traditional SLU has largely been limited to high-resource languages. To solve this problem, zero-shot cross-lingual SLU has gained increasing attention. Recently, cross-lingual contextualized embeddings have achieved promising results (e.g., mBERT (Devlin et al., 2019)). Many works target improving mBERT at the pre-training stage (Conneau and Lample, 2019; Huang et al., 2019; Yang et al., 2020; Feng et al., 2020; Conneau et al., 2020; Xue et al., 2021; Chi et al., 2021a,b). Compared with their work, our focus is on enhancing mBERT at the fine-tuning stage.

In recent years, related work also considers aligning representations between source and target languages during fine-tuning, eschewing the need for an extra pre-training process. Specifically, Liu et al. (2020) propose code-mixing to construct training sentences that consist of both source and target phrases for implicitly fine-tuning mBERT. Qin et al. (2020) further propose a multi-lingual code-switching data augmentation to better align a source language and all target languages. In contrast to their work, our framework consider aligning similar representation across languages explicitly via a contrastive learning framework. In addition, in GL-CLEF, we propose a multi-resolution loss to encourage fine-grained knowledge transfer for token-level slot filling.

Contrastive Learning. Contrastive learning is now commonplace in NLP tasks. Wu et al. (2020) adopt multiple sentence-level augmentation strategies to learn a noise-invariant sentence representation. Fang and Xie (2020) apply back translation to create augmentations of original sentences for training transformer models. Wang et al. (2021) propose contrastive learning with semantically negative examples (CLINE) to improve the robustness under semantically adversarial attack. Inspired by the success of CL, we utilize contrastive learning to explicitly align similar representations across source language and target language.

6 Conclusion

We introduced a global–local contrastive learning (CL) framework (GL-CLEF) to explicitly align representations across languages for zero-shot cross-lingual SLU. Besides, the proposed `Local` CL module and `Global` CL module achieves to learn different granularity alignment (i.e., *sentence-level* local intent alignment, *token-level* local slot alignment, *semantic-level* global intent-slot alignment). Experiments on MultiATIS++ show that GL-CLEF obtains best performance and extensive analysis indicate GL-CLEF successfully pulls closer the representations of similar sentence across languages.

7 Ethical Considerations

Spoken language understanding (SLU) is a core component in task-oriented dialogue system, which becomes sufficiently effective to be deployed in practice. Recently, SLU has achieved remarkable success, due to the evolution of pre-trained models. However, most SLU works and applications are English-centric, which makes it hard to generalize to other languages without annotated data. Our work focuses on improving zero-shot cross-lingual SLU model that do not need any labeled data for target languages, which potentially is able to build multilingual SLU models and further promotes the globalization of task-oriented dialog systems.

Abstract

Recent advances in prompt-based learning have shown strong results on few-shot text classification by using cloze-style templates. Similar attempts have been made on named entity recognition (NER) which manually design templates to predict entity types for every text span in a sentence. However, such methods may suffer from error propagation induced by entity span detection, high cost due to enumeration of all possible text spans, and omission of inter-dependencies among token labels in a sentence. Here we present a simple demonstration-based learning method for NER, which lets the input be prefaced by task demonstrations for in-context learning. We perform a systematic study on demonstration strategy regarding what to include (entity examples, with or without surrounding context), how to select the examples, and what templates to use. Results on in-domain learning and domain adaptation show that the model's performance in low-resource settings can be largely improved with a suitable demonstration strategy (e.g., 4-17% improvement on 25 train instances). We also find that good demonstration can save many labeled examples and consistency in demonstration contributes to better performance. [1]

1 Introduction

Neural sequence models have become the *de facto* approach for named entity recognition (NER) and have achieved state-of-the-art results on various NER benchmarks (Lample et al., 2016; Ma and Hovy, 2016; Liu et al., 2018). However, these data-hungry models often rely on large amounts of labeled data manually annotated by human experts, which are expensive and slow to collect (Huang et al., 2020; Ding et al., 2021b), especially for specialized domains (*e.g.*, research papers). To improve NER performance on low-resource (label scarcity) settings, prior works seek auxiliary supervisions, such as entity dictionary (Peng et al., 2019; Shang et al., 2018; Yang et al., 2018; Liu et al., 2019) and labeling rules (Safranchik et al., 2020; Jiang et al., 2020), to either augment human-labeled data with pseudo-labeled data, or incorporate meta information such as explanation (Lin et al., 2020; Lee et al., 2020, 2021), context (Wang et al., 2021), and prompts (Ding et al., 2021a; Cui et al., 2021) to facilitate training. However, such methods have the following challenges: (1) human efforts to create auxiliary supervisions (e.g., dictionaries, rules, and explanations); (2) high computational cost to make predictions. For example, Ding et al. (2021a) shows effectiveness on entity type prediction given the entity span by constructing a prompt with the structure *"[entity span] is [MASK]"*. However, when the entity span is not given, cloze-style prompts need to be constructed over all the entity candidates in the sentence with the structure *"[entity candidate] is [MASK]"* to make a prediction (Cui et al., 2021). Such brute-force enumerations are often expensive.

In this paper, we propose *demonstration-based learning* (Gao et al., 2021; Liu et al., 2021), a simple-yet-effective way to incorporate automatically constructed auxiliary supervision. The idea was originally proposed in prompt-based learning to show some task examples before the cloze-style template so that the model can better understand and predict the masked slot (Gao et al., 2021). This paper proposes modified version of demonstration-based learning for NER task. Instead of reformatting the NER task into the cloze-style template, we augment the original input instances by appending automatically created task demonstrations and feed them into pre-trained language models (PTLMs) so that the model can output improved token representations by better understandings of the tasks. Unlike existing efforts which require additional hu-

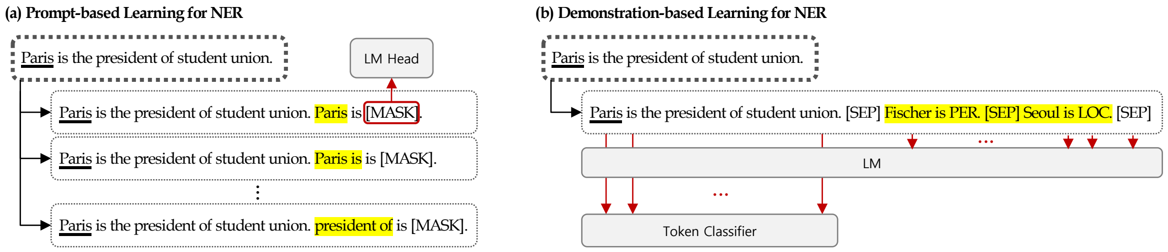

Figure 1: Prompt-based learning frameworks for NER mostly neglect entity span detection which leads to a huge time cost to generate prompts over all the entity candidates in the sentence, while our demonstration-based learning framework integrates prompt into the input itself to make better input representations for the token classification.

man labor to create such auxiliary supervisions, our model can be automatically constructed by picking up proper task examples from the train data. Moreover, unlike approaches that need to change the format of token classification into cloze-style mask-filling prediction which can neglect latent relationships among token labels, our approach can be applied to existing token classification module in a plug-and-play manner (See Figure 1 (a) vs (b)).

We investigate the effectiveness of task demonstration in two different low-resource settings: (1) in-domain setting which is a standard NER benchmark settings where the train and test dataset come from the same domain; and (2) domain-adaptation setting which uses sufficient labeled data in source domain to solve new tasks in a target domain. Here, we study which variants of task demonstration are useful to train an accurate and label-efficient NER model and further explore ways to adapt the source model to target domain with a small amount of target data. We propose two ways of automatic task demonstration construction: (1) *entity-oriented demonstration* selects an entity example per entity type from train data to construct the demonstration. It allows the model to get a better sense of entity type by showing its entity example; and (2) *instance-oriented demonstration* retrieves instance example similar to input sentence in train data. It allows the model to get a better sense of the task by showing similar instances and their entities.

We show extensive experimental results on CoNLL03, Ontonotes 5.0 (generic domain), and BC5CDR (biomedical domain) over 3 different templates and 5 selection/retrieval strategies for task demonstrations. For *entity-oriented demonstration*, we present 3 selection strategies to choose appropriate entity example per entity type: (1) `random` randomly selects entity example per entity type; (2) `popular` selects the entity example which occurs the most per entity type in the train data; and (3) `search` selects the entity example per entity type that shows the best performance in the development set. And for *instance-oriented demonstration*, we present 2 retrieval strategies to choose appropriate instance example (`SBERT` (Reimers and Gurevych, 2019) vs. `BERTScore` (Zhang et al., 2020)).

Our findings include: (1) good demonstration can save many labeled examples to reach a similar level of performance in low-resource settings. Our approach consistently outperforms standard fine-tuning by up to 3 points in terms of F1 score (p-value < 0.02); (2) demonstration becomes more effective when we also provide context. For example, not only showing 'Fischler is PER', but also the sentence that contains 'Fischler' as person, such as 'France backed Fischler's proposal'; and (3) consistency in demonstration contributes to better performance. Our experiments show that using consistent demonstration for all instances rather than varying per instance lead to better performance

2 Related Works

NER with additional supervision Recent attempts addressing label scarcity have explored various types of human-curated resources as auxiliary supervision. One of the research lines to exploit such auxiliary supervision is distant-supervised learning. These methods use entity dictionaries (Peng et al., 2019; Shang et al., 2018; Yang et al., 2018; Liu et al., 2019) or labeling rules (Safranchik et al., 2020; Jiang et al., 2020) to generate noisy-labeled data for learning a NER model. Although these approaches largely reduce human efforts in annotation, the cross-entropy loss may make the model be overfitted to the wrongly labeled tokens due to noisy labels (Meng et al., 2021). Another line of research is incorporating such auxiliary supervision during training and inference in a setting of supervised learning. These approaches usually

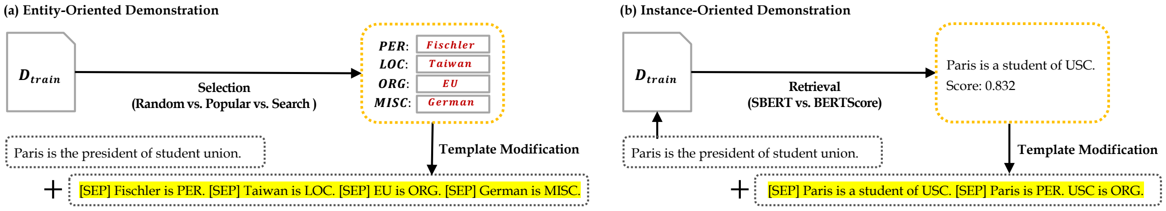

Figure 2: **Task Demonstration for NER.** (a) Entity-oriented demonstration selects an entity example per each entity type from the train data to append to the sentence; while (b) instance-oriented demonstration retrieves an instance from the train data to append to the sentence (along with the entities therein).

incorporate external information that is encoded including POS labels, syntactic constituents, dependency relations (Nie et al., 2020; Tian et al., 2020), explanations (Lin et al., 2020; Lee et al., 2020, 2021), retrieved context (Wang et al., 2021) and prompts (Ding et al., 2021a; Cui et al., 2021).

Demonstration-based Learning Providing a few training examples in a natural language prompt has been widely explored in autoregressive LMs (Brown et al., 2020; Zhao et al., 2021). Such prompt augmentation is called demonstration-based learning (Gao et al., 2021). This is designed to let prompt be prefaced by a few examples before it predicts label words for *[MASK]* in the cloze-style question. Recent works on this research line explore a good selection of training examples (Gao et al., 2021) and permutation of them as demonstration (Kumar and Talukdar, 2021).

3 Problem Definition

In this section, we introduce basic concepts of named entity recognition, standard fine-tuning for sequence labeling, and domain adaptation for sequence labeling. We then formally introduce our goal – generating task demonstration and then developing a learning framework that uses them to improve NER models.

3.1 Named Entity Recognition

Here, we let $\mathbf{x} = [x^{(1)}, x^{(2)}, \dots x^{(n)}]$ denote the sentence composed of a sequence of n words and $\mathbf{y} = [y^{(1)}, y^{(2)}, \dots y^{(n)}]$ denote the sequence of NER tags. The task is to predict the entity tag $y^{(i)} \in \mathcal{Y}$ for each word $x^{(i)}$, where $\mathcal{Y}$ is a pre-defined set of tags such as {B-PER, I-PER, …, O}. In *standard fine-tuning*, NER model $\mathcal{M}$ parameterized by θ is trained to minimize the cross entropy loss over token representations $\mathbf{h} = [h^{(1)}, h^{(2)}, \dots h^{(n)}]$ which are generated from the pre-trained contextualized embedder as follows:

$$\mathcal{L} = -\sum_{i=1}^{n} \log f_{i,y_i}(\mathbf{h}; \boldsymbol{\theta}) \tag{1}$$

where f is the model's predicted conditional probability that can be either from linear or CRF layers.

3.2 In-domain Low-resource Learning

We let $\mathcal{D}_{\text{train}}$ and $\mathcal{D}_{\text{test}}$ denote the labeled train and test dataset, respectively, consisting of $\{(\mathbf{x_i}, \mathbf{y_i})\}$. Here, we expect the number of labeled instances in $\mathcal{D}_{\text{train}}$ is extremely limited (e.g., $N < 50$). Given such small labeled instances, our goal is to train an accurate NER model with task demonstrations compared to standard fine-tuning and show the effectiveness of demonstration-based learning. We evaluate the trained models on $\mathcal{D}_{\text{test}}$.

3.3 Low-resource Domain Adaption

Domain adaptation aims to exploit the abundant data of well-studied source domains to improve the performance in target domains of interest. We consider two different settings: (1) *label-sharing* setting in which the label space $\mathbf{L} = \left\{l_1, \dots, l_{|L|}\right\}$ (e.g., $l_i = PERSON$) of source-domain data $\mathcal{S}$ and target-domain data $\mathcal{T}$ are equal; (2) *label-different* setting which $\mathbf{L}$ is different.

In domain adaptation, we first train a model $\mathcal{M}_s$ on source-domain data $\mathcal{S}$. Next, we initialize the weights of the new model $\mathcal{M}_t$ by weights of $\mathcal{M}_s$. Here, we can either transfer the whole model weights or only the weights of contextualized embedder from $\mathcal{M}_s$ to $\mathcal{M}_t$. Then, we further tune $\mathcal{M}_t$ on target-domain data $\mathcal{T}$. In our preliminary experiments, we find that transferring only the embedder from $\mathcal{M}_s$ to $\mathcal{M}_t$ is much more effective than transferring the whole model weights (See first rows in Table 2 and Table 3). For this paper, we focus on the effectiveness of our models to adapt to the target domain with a $\mathcal{T}$, for which the number of instances is extremely limited. We then

Given input $\mathbf{x}$ and label space $\mathbf{L}$, entity-oriented demonstration selects entity e per each label $l \in \mathbf{L}$ to construct three types of templates (`no-context`, `context`, `lexical`) while instance-oriented demonstration retrieve instance s to create two types of templates (`context`, `lexical`).

compare the results of tasks with demonstration to those without demonstration.

4 Demonstration-based NER

In this work, we focus on how to create effective task demonstration $\tilde{\mathbf{x}}$ to elicit better token representations for $\mathbf{x}$, and then we propose an efficient learning framework that can be improved by the effect of $[\mathbf{x}; \tilde{\mathbf{x}}]$. This section introduces the concepts of *demonstration-based learning*, and provides details of the approach. Here, we study example sampling strategies and templates to construct the demonstration (Sec 4.1) and how we can train the NER model with the demonstration (Sec 4.2).

4.1 Task Demonstration

Task demonstration $\tilde{\mathbf{x}} = [\textit{[SEP]}; \hat{\mathbf{x}}_1; \cdots; \hat{\mathbf{x}}_l]$ is constructed by selecting entity example e or retrieving instance example s from $\mathcal{D}_{\text{train}}$ ($\mathcal{T}_{\text{train}}$ for domain adaptation) and modifying by template T to form $\hat{\mathbf{x}}_i$. The demonstration sequence $\tilde{\mathbf{x}}$ is then appended to the original input $\mathbf{x}$ to create a demonstration-augmented input $[\mathbf{x}; \tilde{\mathbf{x}}]$. Here, *[SEP]* in front of $\tilde{\mathbf{x}}$ is to separate $\mathbf{x}$ and $\tilde{\mathbf{x}}$. The key challenge of constructing task demonstration is to choose appropriate e or s and template T that can be helpful to demonstrate how the model should solve the task. As shown in Figure 2, we categorize the demonstration into (1) *entity-oriented demonstration*; and (2) *instance-oriented demonstration* by whether we choose e or s respectively, for demonstration.

Entity-oriented demonstration. Given an entity type label set $\mathbf{L} = \{l_1, \ldots, l_{|L|}\}$, we select an entity example e per label l from $\mathcal{D}_{\text{train}}$. Then, we modify it using template T. To select e per each l, we first enumerate all the $e \in \mathcal{D}_{\text{train}}$ and create a mapping $\{l_i : [e_1, \ldots, e_n] \mid l_i \in \mathbf{L}\}$ between l and corresponding list of entities. Then for each label l, we select e by three selection strategies: (1) `random` randomly chooses e from the list; (2) `popular` chooses e that occurs the most frequently in the list; and (3) `search` conducts grid search over possible entity candidates per label. Here, we sample top-k frequent entities per label, and search over combinations of entity candidates ($= k^{|L|}$). We find the best combination that maximizes the F1 score on the dev set $\mathcal{D}_{\text{dev}}$. Here, $\tilde{\mathbf{x}}_\mathbf{i}$ for every $\mathbf{x}_\mathbf{i}$ is different in `random` while $\tilde{\mathbf{x}}_\mathbf{i}$ for every $\mathbf{x}_\mathbf{i}$ is same in `popular` and `search`.

Instance-oriented demonstration. Given an input $\mathbf{x}$, we retrieve an instance example s that is the most relevant to the input from $\mathcal{D}_{\text{train}}$. Then, we modify the s along with its $\{e, l\} \in s$ by template T. For retrieval, we present two strategies: (1) `SBERT` (Reimers and Gurevych, 2019) retrieves semantically similar sentence using pre-trained bi-encoder. It produces CLS embeddings independently for an input $\mathbf{x}$ and $s \in \mathcal{D}_{\text{train}}$, and compute the cosine similarity between them to rank $s \in \mathcal{D}_{\text{train}}$; (2) `BERTScore` (Zhang et al., 2020), which is originally used as a text generation metric, retrieves token-level semantically similar sentence by computing a sum of cosine similarity between token representations of two sentences. Since the NER task aims to token classification, sentence-level similarity may retrieve a sentence that is semantically relevant but has no relevant entities.

Fixed vs Variable demonstration. As described in previous sections, the demonstration in some strategies varies per instance while in others it stays fixed globally. We can divide the demonstration strategies into two categories: (1) Variable demonstration: `random`, `SBERT`, `BERTScore` (2) Fixed demonstration: `popular`, `search`

Demonstration template. As shown in Figure 3, we select three variants of template T:
(1) `no-context` shows selected e per l with a simple template "*e is l.*", without including the spe-

cific sentence where the entities show up. Between each pair of (e, l) (of different entity labels l), we concatenate with separator *[SEP]*. This template is only applied to the entity-oriented demonstration. (2) `context` in entity-oriented demonstration shows selected e per l along with an instance sentence s that contains e as a type of l. For each triple of (e, l, s), it is modified into "s. e *is* l." and concatenated with *[SEP]*. For instance-oriented demonstration, it shows the retrieved instance s along with all the entities mentioned in the sentence $e \in s$. It is modified into "s. e_1 *is* l_1. $\dots e_n$ *is* l_n.". (3) `lexical` in entity-oriented demonstration also shows selected e per l along with an instance sentence s. But here we only show s, which the entity span e is replaced by its label string l. For instance-oriented demonstration, we show retrieved s by replacing $e \in s$ with the corresponding l. We expect such templates can form labeling rules and let the model know how to label the sentence.

4.2 Model Training with Demonstration

Transformer-based standard fine-tuning for NER first feeds the input sentence $\mathbf{x}$ into a transfomer-based PTLMs to get the token representations $\mathbf{h}$. The token representations $\mathbf{h}$ are fed into a CRF layer to get the conditional probability $p_\theta(\mathbf{y} \mid \mathbf{h})$, and the model is trained by minimizing the conditional probability by cross entropy loss:

$$\mathcal{L} = -\sum_{i=1}^{n} \log p_\theta(\mathbf{y} \mid \mathbf{h}) \tag{2}$$

In our approach, we define a neural network parameterized by θ that learns from a concatenated input $[\mathbf{x}; \tilde{\mathbf{x}}]$. For both model training and inference, we feed the input and retrieve the representations:

$$[\mathbf{h}; \tilde{\mathbf{h}}] = [h^{(1)}, \dots h^{(n)}, \tilde{h}^{(1)}, \dots \tilde{h}^{(n)}] = \text{embed}([\mathbf{x}; \tilde{\mathbf{x}}]) \tag{3}$$

As shown in Figure 1, we then feed $\mathbf{h}$ into the CRF layer to get predictions and train by minimizing the conditional probability $p_\theta(\mathbf{y} \mid \mathbf{h})$ as Equation 2.

For domain adaptation, we first train $\mathcal{M}_s$ with standard fine-tuning. Then, transfer the weights of embedder of $\mathcal{M}_s$ to $\mathcal{M}_t$ and further fine-tune $\mathcal{M}_t$ with our approach.

5 Experimental Setup

5.1 Datasets

We consider three NER datasets as target tasks. We consider two datasets for a general domain (**CoNLL03** (Tjong Kim Sang, 2002), **Ontonotes 5.0** (Weischedel et al., 2013)) and one dataset for a bio-medical domain (**BC5CDR** (Li et al., 2016)). **CoNLL03** is a general domain NER dataset that has 22K sentences containing four types of general named entities: LOCATION, PERSON, ORGANIZATION, and MISCELLANEOUS entities that do not belong in any of the three categories. **Ontonotes 5.0** is a corpus that has roughly 1.7M words along with integrated annotations of multiple layers of syntactic, semantic, and discourse in the text. Named entities in this corpus were tagged with a set of general 18 well-defined proper named entity types. We split the data following (Pradhan et al., 2013). **BC5CDR** has 1,500 articles containing 15,935 Chemical and 12,852 Disease mentions.

Dataset	**Label**	**Train Data**	
		25	50
CoNLL03	PER (Person)	$16.0_{\pm 3.52}$	$29.2_{\pm 4.52}$
	LOC (Location)	$15.6_{\pm 3.92}$	$30.4_{\pm 4.07}$
	ORG (Organization)	$21.8_{\pm 2.31}$	$32.6_{\pm 3.77}$
	MISC (Miscellaneous)	$11.0_{\pm 2.52}$	$15.6_{\pm 2.33}$
Ontonotes 5.0	PER (Person)	$10.8_{\pm 2.22}$	$21.4_{\pm 4.02}$
	LOC (Location)	$16.0_{\pm 3.52}$	$25.0_{\pm 7.32}$
	ORG (Organization)	$13.8_{\pm 3.48}$	$24.2_{\pm 6.17}$
	MISC (Miscellaneous)	$23.8_{\pm 5.56}$	$62.6_{\pm 7.93}$
BC5CDR	Disease	$25.8_{\pm 6.01}$	$29.2_{\pm 4.52}$
	Chemical	$51.0_{\pm 7.49}$	$65.8_{\pm 7.12}$

Table 1: **Data statistics.** Average number of entities per each entity type over 5 different subsamples.

5.2 Baselines

To show its effectiveness in few-shot NER, we also show baselines of few-shot NER methods NNShot and StructShot (Yang and Katiyar, 2020). NNshot is simple token-level nearest neighbor classification system while StructShot extends NNshot with a decoding process using abstract tag transition distribution. Here, both the classification model and the transition distribution should be pre-trained on the source dataset. Thus, we consider this as domain adaptation setting.

5.3 Experiments and Implementation Details

We implement all the baselines and our frameworks using PyTorch (Paszke et al., 2019) and HuggingFace (Wolf et al., 2020). We set the batch size and learning rate to 4 and 2e-5, respectively, and use `bert-base-cased` model for all the experiments. For each variant, we run 50 epochs over 5 different sub-samples and 3 random seeds with early-stopping 20 and show its average and stan-

Table 3: **Domain adaptation performance comparison (F1-score)** on Ontonotes 5.0 and BC5CDR by different number of training instances. $\mathcal{M}_s$ is trained on CoNLL03 and $\mathcal{M}_t$ is initialized with embedder of $\mathcal{M}_s$. Scores are average of 15 runs (5 different sub-samples and 3 random seeds) and the backbone LM model is `bert-base-cased`.

dard deviation of F1 scores. Unlike existing sampling methods for few-shot NER (Yang and Katiyar, 2020), in which the training sample refers to one entity span in a sentence, we consider a real-world setting that humans annotate a sentence. We sub-sample data-points by random sampling with a constraint that sampled instances should cover all the BIOES labels (Chiu and Nichols, 2016) in the whole dataset. For Ontonotes, we aggregate all other entity types rather than person, location, and organization into miscellaneous to set the *label sharing* setting for domain adaptation experiments. Table 1 presents statistics of average number of entities per entity type over 5 different sub-samples.

6 Experimental Results

We first compare the overall performance of all baseline models and our proposed framework with the amount of training data 25 and 50 to show the impact of our approach in a low-resource scenario, assuming a task that needs to be annotated from scratch. Then, we show performance analysis to show the effectiveness of our approach and whether the model really learns from the demonstration.

6.1 Performance Comparison

In-domain setting In Table 2, we can observe that most variants of demonstration-based learning consistently and significantly (with p-value $<$ 0.02) outperform the baseline by a margin ranging from 1.5 to 7 F1 score in three low-resource NER datasets (25, 50 train instances respectively). It demonstrates the potential of our approach for serving as a plug-and-play method for NER models.

Domain adaptation setting First, we observe that simple domain adaptation technique can improve the performance (First rows of Table 2 vs. Table 3). Here, we only transfer the embedder weights of $\mathcal{M}_s$ to $\mathcal{M}_t$, and we expect the performance gain can be attributed to the embedder of $\mathcal{M}_s$, which is trained in task adaptive pre-training manner on NER task formats (Gururangan et al., 2020). In Table 3, we can see that the most variants of demonstration-based learning allow the source model $\mathcal{M}_s$ to be adapted to the target domain in fast with a small amount of target data $\mathcal{T}$, compared to baselines without demonstration including few-shot NER methods.

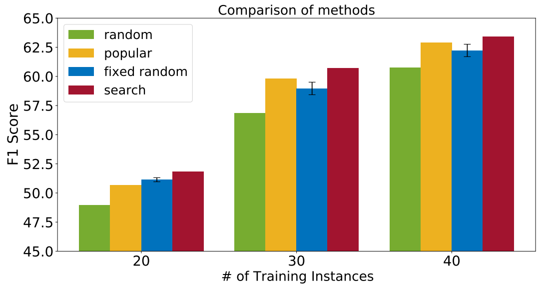

Figure 4: **Performance (F1-score) of randomly select one fixed entity per entity type for demonstration** (`fixed random`) on CoNLL03 by different numbers of train data (20, 30, 40). Error bars show standard deviation across 3 trials using 3 different random seeds for entity selection.

6.2 Performance Analysis

Entity vs. Instance-oriented demonstration. *instance-oriented demonstration* performs worse than *entity-oriented demonstration* due to the difficulty of finding an appropriate similar instance in a low resource train data. In our analysis, we find that the average cosine similarity between retrieved example s and input x is less than 0.4 which shows many of the retrieved examples are not appropriate similar examples to the input.

Fixed vs. Variable demonstration. As mentioned in section 4.1, `random` doesn't pick a fixed set of demonstrations the same way as `popular` and `search`. Instead, it picks random demonstrations for each input instance. In a low-resource setting, there are often no significantly popular entities. Therefore, the fact that `popular` outperforms `random` in our experiments might suggest that the consistency of demonstration selection, rather than popularity of selected entities, is a crucial factor in better few-shot learning. To test this, we randomly select one entity per entity type and attach it as the demonstration to all instances, we call it (`fixed random`). As shown in Figure 4, it outperforms `random` and is on par with `popular` and `search`. We believe this serves as evidence for two hypotheses: (1) consistency of demonstration is essential to performance, and (2) in low-resource settings, the effectiveness of combinations of entities as demonstrations might be a rather random function and not too affected by the combination's collective popularity in the training dataset, which further implies that the idea of `search` is on the right track.

LM	**Strategy**	**Template**	*In-domain*		*Label Sharing*	
			CoNLL03		**CoNLL03 -> Ontonotes**	
			25	50	25	50
`BL`	-	-	52.08 ±2.02	66.42 ±2.14	63.50 ±0.96	70.59 ±1.16
`RB`	-	-	59.67 ±4.65	70.17 ±3.93	68.43 ±2.09	74.11 ±1.19
`RL`	-	-	59.15 ±2.93	71.51 ±3.44	68.16 ±2.65	74.45 ±1.02

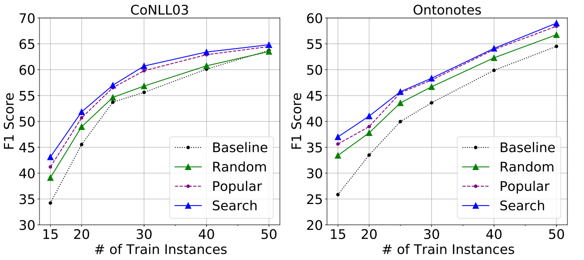
`RB`	`popular`	`context`	59.76 ±4.27	70.21 ±3.41	69.09 ±2.63	74.53 ±1.32
`RL`	`popular`	`context`	59.99 ±2.16	72.15 ±3.81	68.78 ±2.89	74.93 ±1.07

Table 4: **Performance comparison (F1-score)** with various backbone LMs: `bert-large-cased (BL)`; `roberta-base (RB)`; and `roberta-large (RL)`. Scores are average of 15 runs (5 different sub-samples and 3 random seeds).



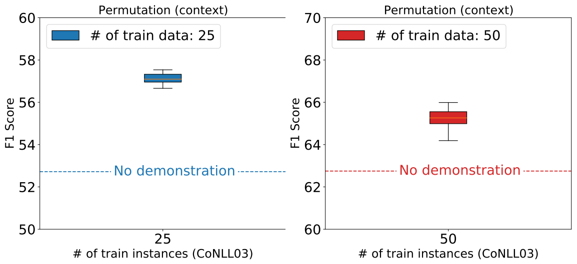
(a) CoNLL03 (b) Ontonotes

Figure 5: **Performance (F1-score) trend with entity-oriented demonstration** on CoNLL03 and Ontonotes by different numbers of train data (15, 20, 30, 40, 50).

Performance in other model variants To show the effectiveness of demonstration-based learning as plug-and-play method, we present performance in other model variants: `bert-large-cased`, `roberta-base` and `roberta-large`. As shown in Table 4, our method shows consistent improvement over baselines (p-value < 0.05). It shows that demonstration-based learning can be applied to any other model variants and output better contextualized representations for NER tasks and show its potential for scalability.

Effectiveness of `search`. `search` consistently outperforms all other strategies. It shows that not only the entity selection, but also the combination of entity examples per each entity type affects the performance. To see whether it consistently outperforms the baseline over various low-resource data points, we show the performance trend of *entity-oriented demonstration* in Figure 5.

Templates of entity-oriented demonstration. *entity-oriented demonstration* becomes more effective when not only showing the entity example per each entity type, but also the corresponding instance example as a context. `context` and `lexical` consistently outperform `no-context`. We explore other templates as well, and these three are the best among them. We present details on Appendix A. To see whether the order of entity type in *entity-oriented demonstration* affects the performance, we present analysis of entity type permutation, e.g., `person` - `organization` - `location` - `miscellaneous`. There is no



(a) 25 instances (b) 50 instances

Figure 6: **Performance (F1-score) variance by different permutation of entity type orders.** Performance is based on template `basic`, strategy `popular`, and CoNLL03.

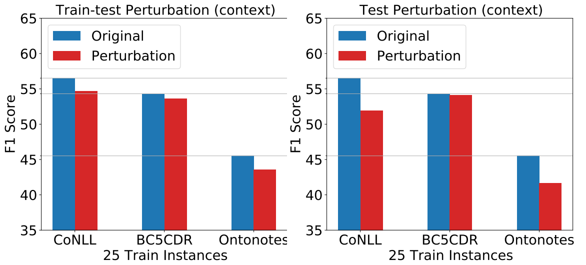
Train	Infer	CoNLL03		Ontonotes 5.0		BC5CDR	
		25	50	25	50	25	50
X	X	52.72 ±2.44	62.75 ±0.98	38.97 ±4.62	54.51 ±3.27	52.56 ±0.46	60.20 ±2.01
X	O	51.24 ±2.10	61.02 ±2.05	40.48 ±3.90	52.12 ±3.85	52.16 ±0.55	58.12 ±1.67
O	X	37.71 ±4.65	53.17 ±3.47	31.98 ±4.25	45.27 ±5.19	51.94 ±1.04	57.73 ±1.52
O	O	56.52 ±3.34	64.47 ±2.35	45.52 ±4.69	58.40 ±3.24	54.31 ±0.80	61.31 ±1.51

Table 5: **Effects of demonstration (F1-score)** with/without the demonstration (denoted by “O" and “X", respectively) at training and inference time.

clear pattern of which entity type order is better (spearman correlation between F1-scores over different entity type orders with 25 and 50 training instances < 0), but all the permutations outperform the baseline as shown in Figure 6, which show that *demonstration-based learning* can be effective regardless of the order (See Appendix Figure 8).

Demonstration perturbation. To investigate whether the model really learns from demonstration, we explore the performance of our approach with perturbed demonstration which selects random entities, labels, and context sentences as demonstration. Here, we present two studies: (1) *Test perturbation* which train with correct demonstration and test with perturbed demonstration; and (2) *Train-test perturbation* which both train and test with perturbed demonstration. Figure 7 shows perturbed demonstration disturbs the model in a large margin for both case. This shows that the model affects by demonstration, and proper demonstration can improve the model's performance. Full results are available in Appendix Table 9.

Effects of demonstration in train & inference. Table 5 shows the effects of demonstration in training and inference stage. A comparison of row 0 with row 3 shows that applying demonstration in the training stage but not in the inference stage would make the model perform worse than the fine-tuning baseline. This is another evidence that consistency of demonstration is essential to the method's performance.



(a) Test perturbation (b) Train-Test perturbation

Figure 7: **Performance (F1-score) difference between original and perturbed demonstration.** Performance is based on template `basic`, strategy `popular`, and CoNLL03 25 train instances.

Strategy	Template	CoNLL03		BC5CDR	
		50%	100%	50%	100%
-	-	91.24 ±0.13	91.82 ±0.12	84.58 ±0.17	85.89 ±0.32
`random`	`context`	90.60 ±0.13	91.22 ±0.38	84.32 ±0.07	85.58 ±0.14
`popular`	`context`	90.81 ±0.11	91.85 ±0.07	84.12 ±0.48	85.61 ±0.12

Table 6: **Performance (F1-score) in fully supervised setting** by different percentages of train data.

Fully supervised setting. Table 6 shows the performance in fully supervised setting, where the train data is sufficient. We can see that demonstration-based learning yields similar performance as baselines (p-value < 0.1), which shows that demonstrations are rather redundant when data is abundant.

7 Conclusion

In this paper, we propose *demonstration-based learning* for named entity recognition. Specifically, we present *entity-oriented demonstration* and *instance-oriented demonstration* and show that they successfully guide the model towards better understandings of the task in low-resource settings. We observe that *entity-oriented demonstration* is more effective than *instance-oriented demonstration*, and `search` strategy consistently outperforms all other variants. Moreover, we find that consistent demonstration for all the instances is crucial to the superior performance of our approach. We believe that our work provides valuable cost reduction when domain-expert annotations are too expensive and opens up possibilities for future work in automatic demonstration search for few-shot named entity recognition.

A Template Analysis

Here we present 4 other variants of templates that we have not presented in *entity-oriented demonstration*: (1) `context-all` shows selected e per l along with an instance sentence s that contains e as a type of l. Unlike `context`, it shows all the $e \in s$. For each triple of (e, l, s), it is modified into "s. e_1 *is* l_1. $\dots e_n$ *is* l_n." and concatenated with *[SEP]*. (2) `lexical-all` shows selected e per l in instance example s and further replaces the entity span e by its label string l. Unlike `lexical`, it replaces all the $e \in s$ by its label string l. (3) `structure` follows augmented natural language format, which is a structured format (Paolini et al., 2021). It shows selected e per l along with an instance sentence s that contains e as a type of l. For each triple of (e, l, s), e in s is replaced with *[e | l]* and concatenated with *[SEP]*. (4) `structure-all` also follows augmented natural language format, and shows selected e per l along with an instance sentence s that contains e as a type of l. Unlike `structure` it shows all the $e \in s$. For each triple of (e, l, s), for each e_i in s it is replaced with *[e_i | l_i]* and concatenated with *[SEP]*.done Table. 7 shows that `context` and `lexical` are more effective than others.

B Effects of Batch Size

Table 8 shows the main results in Table 2 with batch size 10. Overall performance is much lower than Table 2. It shows that choosing a lower batch size is important in a extremely low resource, where the number of train data is 25 or 50.

Abstract

How do masked language models (MLMs) such as BERT learn contextual representations? In this work, we analyze the learning dynamics of MLMs. We find that MLMs adopt sampled embeddings as anchors to estimate and inject contextual semantics to representations, which limits the efficiency and effectiveness of MLMs. To address these issues, we propose TACO, a simple yet effective representation learning approach to directly model global semantics. TACO extracts and aligns contextual semantics hidden in contextualized representations to encourage models to attend global semantics when generating contextualized representations. Experiments on the GLUE benchmark show that TACO achieves up to 5x speedup and up to 1.2 points average improvement over existing MLMs. The code is available at `https://github.com/FUZHIYI/TACO`.

1 Introduction

In the age of deep learning, the basis of representation learning is to learn distributional semantics. The target of distributional semantics can be summed up in the so-called distributional hypothesis (Harris, 1954): *Linguistic items with similar distributions have similar meanings*. To model similar meanings, traditional representation approaches (Mikolov et al., 2013; Pennington et al., 2014) (e.g., Word2Vec) model distributional semantics by defining tokens using *context-independent* (CI) dense vectors, i.e., word embeddings, and directly aligning the representations of tokens in the same context. Nowadays, pre-trained language models (PTMs) (Devlin et al., 2019; Radford et al., 2018; Qiu et al., 2020) expand static embeddings into contextualized representations where each token has two kinds of representations: *context-independent* embedding, and *context-dependent* (CD) dense representation that stems from its embedding and contains context information. Although language modeling and representation learning have distinct targets, masked language modeling is still the prime choice to learn token representations with access to large scale of raw texts (Peters et al., 2018; Devlin et al., 2019; Raffel et al., 2020; Brown et al., 2020).

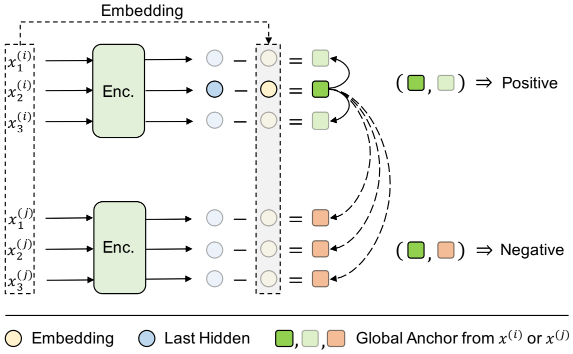

Figure 1: Illustration of the proposed token-alignment contrastive objective. It extracts and aligns the global semantics hidden in contextualized representations via the gap between contextualized representations and corresponding static embeddings.

It naturally raises a question: How do masked language models learn contextual representations? Following the widely-accepted understanding (Wang and Isola, 2020), MLM optimizes two properties, the alignment of contextualized representations with the static embeddings of masked tokens, and the uniformity of static embeddings in the representation space. In the alignment property, sampled embeddings of masked tokens play as an *anchor* to align contextualized representations. We find that although such local anchor is essential to model local dependencies, the lack of global anchors brings several limitations. First, experiments show that the learning of contextual representations is sensitive to embedding quality, which harms the efficiency of MLM at the early stage of

training. Second, MLM typically masks multiple target words in a sentence, resulting in multiple embedding anchors in the same context. This pushes contextualized representations into different clusters and thus harms modeling global dependencies.

To address these challenges, we propose a novel **T**oken-**A**lignment **C**ontrastive **O**bjective (**TACO**) to directly build global anchors. By combing local anchors and global anchors together, TACO achieves better performance and faster convergence than MLM. Motivated by the widely-accepted belief that contextualized representation of a token should be the mapping of its static embedding on the contextual space given global information, we propose to directly align global information hidden in contextualized representations at all positions of a natural sentence to encourage models to attend same global semantics when generating contextualized representations. Concerning possible relationships between context-dependent and context-independent representations, we adopt the simplest probing method to extract global information via the gap between context-dependent and context-independent representations of a token for simplification, as shown in Figure 1. To be specific, we define tokens in the same context (text span) as positive pairs and tokens in different contexts as negative pairs, to encourage the global information among tokens within the same context to be more similar compared to that from different contexts.

We evaluate TACO on GLUE benchmark. Experiment results show that TACO outperforms MLM with average 1.2 point improvement and 5x speedup (in terms of sample efficiency) on BERT-small, and with average 0.9 point improvement and 2x speedup on BERT-base.

The contributions of this paper are as follows.

- We analyze the limitation of MLM and propose a simple yet efficient method TACO to directly model global semantics.
- Experiments show that TACO outperforms MLM with up to 1.2 point improvement and up to 5x speedup on GLUE benchmark.

2 Understanding Language Modeling

2.1 Objective Analysis

The key idea of MLM is to randomly replace a few tokens in a sentence with the special token `[MASK]` and ask a neural network to recover the original tokens. Formally, we define a corrupted sentence as $\boldsymbol{x}_1$, $\boldsymbol{x}_2$, $\cdots$, $\boldsymbol{x}_L$, and feed it into a Transformers encoder (Vaswani et al., 2017), the hidden states from the final layer are denoted as $\boldsymbol{h}_1, \boldsymbol{h}_2, \cdots, \boldsymbol{h}_L$. We denote the embeddings of the corresponding original tokens as $\boldsymbol{e}_1$, $\boldsymbol{e}_2$, $\cdots$, $\boldsymbol{e}_L$. The MLM objective can be formulated as:

$$\mathcal{L}_{\mathrm{MLM}}(\boldsymbol{x}) = -\frac{1}{|\mathcal{M}|}\sum_{i\in\mathcal{M}} \log \frac{\exp(\boldsymbol{m}_i \cdot \boldsymbol{e}_i)}{\sum_{k=1}^{|\mathcal{V}|}\exp(\boldsymbol{m}_i \cdot \boldsymbol{e}_k)} \quad (1)$$

where $\mathcal{M}$ denotes the set of masked tokens and $|\mathcal{V}|$ is the size of vocabulary $\mathcal{V}$. $\boldsymbol{m}_i$ is hidden state of the last layer at the masked position, and can be regarded as a fusion of contextualized representations of surrounding tokens. Following the widely-accepted understanding (Wang and Isola, 2020), Eq.1 optimizes: (1) the alignment between contextualized representations of surrounding tokens and the context-independent embedding of the target token and (2) the uniformity of representations in the representation space.

In the alignment part, MLM relies on sampled contextual-independent embeddings of masked tokens as anchors to align contextualized representations in contexts, as shown in Figure 2. Local anchor is the key feature of MLM. Therefore, the learning of contextualized representations heavily relies on embedding quality. In addition, multiple local anchors in a sentence tend to pushing contextualized representations of surrounding tokens closer to different clusters, encouraging models to attend local dependencies where global semantics are neglected.

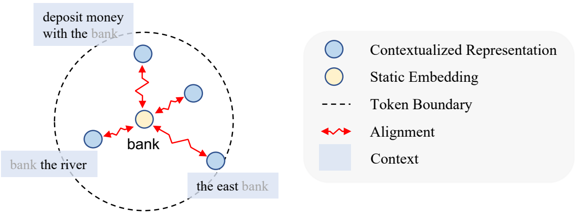

Figure 2: Illustration of the MLM objective. At the alignment part, it uses static embedding of masked tokens to align contextualized representations in the same context.

2.2 Empirical Analysis

To verify our understanding, we conduct comprehensive experiments to investigate: How does embedding anchor affect the learning dynamics of MLM? We re-train a BERT-small (Devlin et al., 2019) model with the MLM objective solely and analyze the changes in its semantic space during pre-training. The training details are described in Appendix A.

Contextualized representation evaluation. In general, if contextualized representations are well learned, the contextualized representations in a same context will have higher similarity than that of in different contexts. Naturally, we use the gap between intra-sentence similarity and inter-sentence similarity to evaluate contextual information in contextualized representations. We call this gap as *contextual score*. The similarity can be evaluated via probing methods like L2 distance, cosine similarity, etc. We observe similar findings on different probing methods and only report cosine similarity here for simplification. Figure 3(b) shows how contextual score changes during training. Other statistical results are listed in Appendix A.

Embedding similarity evaluation. To observe how sampled embeddings affect contextualized representation learning, we evaluate the embedding similarity between co-occurrent tokens. Motivated by the target that co-occurrent tokens should have similar representations, we use the similarity score calculated by cosine similarity between co-occurrent words labeled by humans (sampled from the WordSim353 dataset (Agirre et al., 2009)) as the evaluation metric. Figure 3(a) shows how embedding similarity between co-occurrent tokens changes during training.

The learning of contextualized representations heavily relies on embeddings similarity. As we can see from Figure 3(a), the embedding similarity between co-occurrent tokens first decreases during the earliest stage of pre-training. It is because all embeddings are randomly initialized with the same distribution and the uniformity feature in MLM pushes tokens far away from each other, thus resulting in the decrease of embedding similarity. Meanwhile, the contextual score, i.e., the gap between intra-context similarity and inter-context similarity in Figure 3(b), does not increase at the earliest stage of training. It shows that random embeddings provide little help to learn contextual semantics. During 5K-10K iterations, only when embeddings become closer, contextualized representations in the same context begin to have similar features. At this stage, the randomly sampled embeddings from the same sentence, i.e., the same context, usually have similar representations and thus MLM can push contextualized tokens closer to each other.

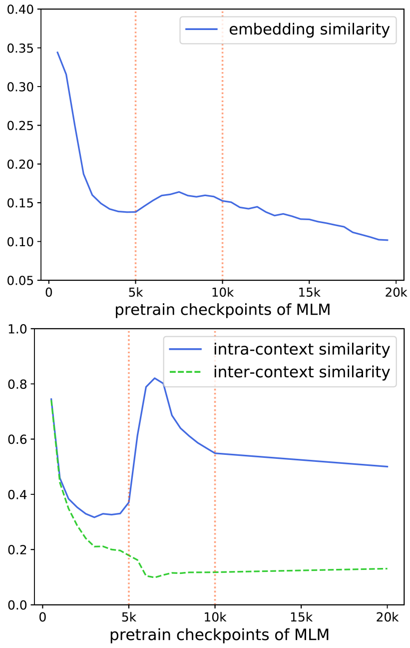

Figure 3: The learning dynamics of MLM. The top figure (a) illustrates the similarity between embeddings of frequently co-occurrent tokens (e.g., bank and money). The bottom figure (b) illustrates the similarity between contextualized representation of tokens from the same context and different contexts. These figures show an embedding bias problem where only the randomly selected target embeddings in MLM are similar, contextualized representations in the same context will be aligned with similar features.

We further verify the effects of embedding quality in Figure 4. To this end, we train two BERT models whose embedding matrices are frozen and initialized with the ones from different pre-training stage. We can see the model initialized with random embedding fails to teach contextualized representations to attend sentence meanings and representations from different contexts have almost the same similarity. However, the variant with well-trained but frozen embeddings learns to distinguish different contexts early at around 4k steps. These statistical observations verify that embedding anchors bring the efficiency and effectiveness problem.

Surprisingly, embedding anchors reduce global contextual information in contextualized representation at the later stage of training. Figure 3(a) shows that embedding similarity begins to drop after 8k steps. It shows that the model learns the specific meanings of co-occurrent tokens and begins to push them a little bit far away. Since MLM adopts local anchors, these local embeddings push contextualized representations into different clusters. The contextual score begins to decrease too. This phenomenon proves the embedding bias problem where the learning of contextualized representations is decided by the selected embeddings where the global contextual semantics are neglected.

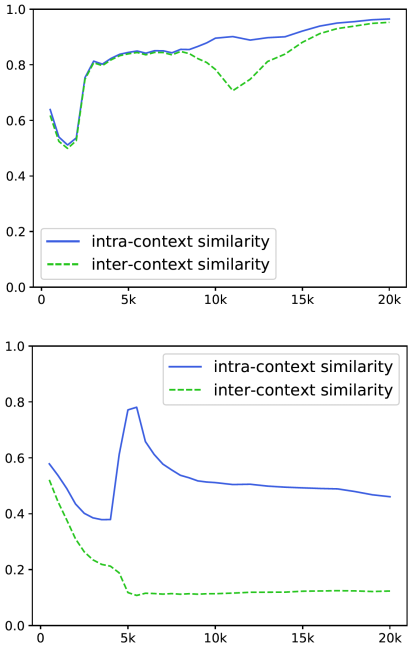

Figure 4: The impact of embedding quality for the learning of contextualized representations. We train two BERT-small variants from scratch, whose embedding is either (a) randomly initialized and frozen or (b) copied from normally pre-trained BERT at 250k steps and frozen.

3 Proposed Approach: TACO

To address the challenges of MLM, we propose a new method TACO to combine global anchors and local anchors. We first introduce TC, a token-alignment contrastive loss which explicitly models global semantics in Section 3.1, and combine TC with MLM to get the overall objective for training our TACO model in Section 3.2.

3.1 Token-alignment Contrastive Loss

To model global semantics, the objective is expected to be capable of explicitly capturing information shared between contextualized representation of tokens within the same context. Therefore, a natural solution is to maximize the mutual information of contextual information hidden in contextualized representations in the same context. To extract shared contextual information, we first define a rule to generate contextual representations of tokens by combining embeddings and global information. Formally,

$$\boldsymbol{h}_i = f(\boldsymbol{e}_i, \boldsymbol{g}). \tag{2}$$

where f is a probing algorithm and $\boldsymbol{e}_i$ is the embedding and $\boldsymbol{g}$ is the global bias of a concrete context. In this paper, we adopt a straightforward probing method to get global information hidden in contextualized representations, where

$$\boldsymbol{g}_i = \boldsymbol{h}_i - \boldsymbol{e}_i. \tag{3}$$

Given contextualized representations of an token $\boldsymbol{x}$ and its nearby tokens $\boldsymbol{c}$ in the same context, we use $\boldsymbol{g}_x$ and $\boldsymbol{g}_c$ to represent global semantics hidden in these representations. The mutual information between the two global bias $\boldsymbol{g}_x$ and $\boldsymbol{g}_c$ is

$$I(\boldsymbol{g}_x, \boldsymbol{g}_c) = \sum_{\boldsymbol{g}_x, \boldsymbol{g}_c} p(\boldsymbol{g}_x, \boldsymbol{g}_c) \log \frac{p(\boldsymbol{g}_x | \boldsymbol{g}_c)}{p(\boldsymbol{g}_x)} \tag{4}$$

According to van den Oord et al. 2019, the InfoNCE loss serves as an estimator of mutual information of $\boldsymbol{x}$ and $\boldsymbol{c}$:

$$I(\boldsymbol{g}_x, \boldsymbol{g}_c) \geq \log(K) - \mathcal{L}(\boldsymbol{g}_x, \boldsymbol{g}_c) \tag{5}$$

where $\mathcal{L}(\boldsymbol{g}_x, \boldsymbol{g}_c)$ is defined as:

$$\mathcal{L}(\boldsymbol{g}_x, \boldsymbol{g}_c) = -\mathbb{E}\left[\log \frac{f(\boldsymbol{g}_x, \boldsymbol{g}_c)}{f(\boldsymbol{g}_x, \boldsymbol{g}_c) + \sum_{k=1}^{K} f(\boldsymbol{g}_x, \boldsymbol{g}_{c_k^-})}\right] \tag{6}$$

where $\boldsymbol{c}_k^-$ is the k-th negative sample of $\boldsymbol{x}$ and K is the size of negative samples. Hence minimizing the objective $\mathcal{L}(\boldsymbol{g}_x, \boldsymbol{g}_c)$ is equivalent to maximizing the lower bound on the mutual information $I(\boldsymbol{g}_x, \boldsymbol{g}_c)$. This objective contains two parts: *positive pairs* $f(\boldsymbol{g}_x, \boldsymbol{g}_c)$ and *negative pairs* $f(\boldsymbol{g}_x, \boldsymbol{g}_{c_k^-})$.

Previous study (Chen et al., 2020) has shown that cosine similarity with temperature performs well as the score function f in InfoNCE loss. Following them, we take

$$f(\boldsymbol{g}_x, \boldsymbol{g}_c) = \frac{1}{\tau} \frac{\boldsymbol{g}_x \cdot \boldsymbol{g}_c}{\|\boldsymbol{g}_x\| \|\boldsymbol{g}_c\|} \tag{7}$$

where τ is the temperature hyper-parameter and $\| \cdot \|$ is ℓ_2-norm function.

Contextualized representation: To get global bias $\boldsymbol{g}_x$ and $\boldsymbol{g}_c$ following Eq. 3, we adopt the widely-used Transformer (Vaswani et al., 2017) as the encoder and take the last hidden states as the contextualized representations $\boldsymbol{h}_x$ and $\boldsymbol{h}_c$. Formally, suppose a batch of sequences $\{\boldsymbol{s}_i\}$ where $i \in \{1, \cdots, N\}$. We feed it into the Transformer encoder to obtain contextualized representations, $\boldsymbol{h}_1^i, \boldsymbol{h}_2^i, \cdots, \boldsymbol{h}_{|\boldsymbol{s}_i|}^i$ where $\boldsymbol{h}_j^i \in \mathbb{R}^d$.

Positive pairs: Given each token $\boldsymbol{x}$, we randomly sample a positive sample $\boldsymbol{c}$ from nearby tokens in the same context (sequence) within a window span where W is the window size.

Negative pairs: Given each token $\boldsymbol{x}$, we randomly sample K tokens from other sequences in this batch as negative samples $\boldsymbol{c}_k^-$.

To sum up, the **T**oken-alignment **C**ontrastive (**TC**) loss is applied to every token in a batch as:

$$\mathcal{L}_{\text{TC}} = \frac{1}{N}\sum_{i=1}^{N}\frac{1}{|\boldsymbol{s}_i|}\sum_{j=1}^{|\boldsymbol{s}_i|}\mathcal{L}(\boldsymbol{g}_j^i, \boldsymbol{g}_{jc}^i) \tag{8}$$

where N is the number of sequences of this batch; $\boldsymbol{s}_i$ is the i-th sequence; j and jc are tokens in $\boldsymbol{s}_i$ where $jc \neq j$; $\boldsymbol{g}^i$ is the global semantics hidden in contextualized representation of token $\boldsymbol{s}_i$. $\boldsymbol{g}_j^i$ and $\boldsymbol{g}_{jc}^i$ are generated via:

$$\boldsymbol{g}_j^i = \boldsymbol{h}_j^i - \boldsymbol{e}_j^i \tag{9}$$

$$\boldsymbol{g}_{jc}^i = \boldsymbol{h}_{jc}^i - \boldsymbol{e}_{jc}^i \tag{10}$$

where $\boldsymbol{h}_j^i$ and $\boldsymbol{e}_j^i$ are the contextualized representation and static embedding of the anchor token, respectively. $\boldsymbol{h}_{jc}^i$ and $\boldsymbol{e}_{jc}^i$ are the contextualized representation and static embedding of the sampled positive token in the same context.

3.2 Training Objective

As described before, the token-alignment contrastive loss $\mathcal{L}_{\text{TC}}$ is designed to model global dependencies while MLM is able to capture local dependencies. Therefore, we can better model contextualized representations by combining the token-alignment contrastive loss $\mathcal{L}_{\text{TC}}$ and the MLM loss to get our overall objective $\mathcal{L}_{\text{TACO}}$:

$$\mathcal{L}_{\text{TACO}} = \mathcal{L}_{\text{TC}} + \mathcal{L}_{\text{MLM}} \tag{11}$$

We implement it in a multi-task learning manner where all objectives are calculated within one forward propagation, which only introduces negligible extra computations.

4 Experiments

4.1 Experimental Settings

Training Following BERT (Devlin et al., 2019), we select the BooksCorpus (800M words after WordPiece tokenization) (Zhu et al., 2015) and English Wikipedia (4B words) as pre-training corpus. We pre-train two variants of BERT models: BERT-small and BERT-base. All models are equipped with the vocabulary of size 30,522, trained with 15% masked positions for MLM. The maximum sequence length is 256 and batch size is 1,280. We adopt optimizer AdamW (Loshchilov and Hutter, 2019) with learning rate 1e-4. All models are trained until convergence. To be specific, the small model is trained up to 250k steps with a warm-up of 2.5k steps. The base model is trained up to 500k steps with a warm-up of 10k steps. For TACO, we set the positive sample window size W to 5, the negative sample number K to 50, and the temperature parameter τ to 0.07 after a slight grid-search via preliminary experiments. More pre-training details can be found in Appendix A.

During fine-tuning models, we conduct a grid search over batch sizes of {16, 32, 64, 128}, learning rates of {1e-5, 2e-5, 3e-5, 5e-5}, and training epochs of {4, 6} with an Adam optimizer (Kingma and Ba, 2015). We use the open-source packages for implementation, including HuggingFace Datasets[1] and Transformers[2]. All the experiments are conducted on 16 GPU chips (32 GB V100).

Evaluation We evaluate methods on the GLUE benchmark (Wang et al., 2019). Specifically, we test on Microsoft Research Paraphrase Matching (MRPC) (Dolan and Brockett, 2005), Quora Question Pairs (QQP)[3] and STS-B (Conneau and Kiela, 2018) for Paraphrase Similarity Matching; Stanford Sentiment Treebank (SST-2) (Socher et al., 2013) for Sentiment Classification; Multi-Genre Natural Language Inference Matched (MNLI-m), Multi-Genre Natural Language Inference Mismatched (MNLI-mm) (Williams et al., 2018), Question Natural Language Inference (QNLI) (Rajpurkar et al., 2016) and Recognizing Textual Entailment (RTE) (Wang et al., 2019) for the Natural Language Inference (NLI) task; The Corpus of Linguistic Acceptability (CoLA) (Warstadt et al., 2019) for Linguistic Acceptability.

Following Devlin et al. (2019), we exclude WNLI (Levesque, 2011). We report F1 scores for QQP and MRPC, Spearman correlations for STS-B, and accuracy scores for the other tasks. For evaluation results on validation sets, we report the

Table 1: GLUE results on BERT-small. For validation results, we run 4 experiments with different seeds for each task and report the average score. For test results, we report the test scores of the checkpoint performing best on validation sets. TACO outperforms MLM with 1.2 point improvement and 5× speedup on validations sets. On test sets, TACO also obtains better results on 6 out of 8 tasks.

average score of 4 fine-tunings with different random seeds. For results on test sets, we select the best model on the validation set to evaluate.

Baselines We mainly compare TACO with MLM on BERT-small and BERT-base models. In addition, we also compare TACO with related contrastive methods: a sentence-level contrastive method BERT-NCE and a span-based contrastive learning method INFOWORD, both from Kong et al. (2020). We directly compare TACO with the results reported in their paper.

4.2 Results on BERT-Small

Table 1 and Figure 5 show the results of TACO on BERT-small. As we can see, compared with MLM with 250k training steps (convergence steps), TACO achieves comparable performance with only 1/5 computation budget. By modeling global dependencies, TACO can significantly improve the efficiency of contextualized representation learning. In addition, when pre-trained with the same steps, TACO outperforms MLM with 1.2 average score improvement on the validation set.

In addition to convergence, we also compare TACO and MLM on fewer training data. The results are shown in Table 2. We sample 4 tasks with the largest amount of training data for evaluation. As we can see, TACO trained on 25% data can achieve competitive results with MLM trained on full data. These results also verify the data efficiency of our method, TACO.

Approach	MNLI	QQP	QNLI	SST-2	**Avg.**
MLM-25%	77.8	85.7	85.8	87.2	84.1
MLM-100%	76.9	85.7	86.2	**89.0**	84.5
TACO-25%	77.8	85.7	86.1	88.4	84.5
TACO-100%	**77.9**	**86.1**	**86.5**	88.9	**84.9**

Table 2: TACO pre-trained on a quarter of data achieves competitive downstream results with MLM pre-trained on full data. All results are reported on GLUE validation sets with BERT-small. Here we sample 4 tasks with the largest amount of training data.

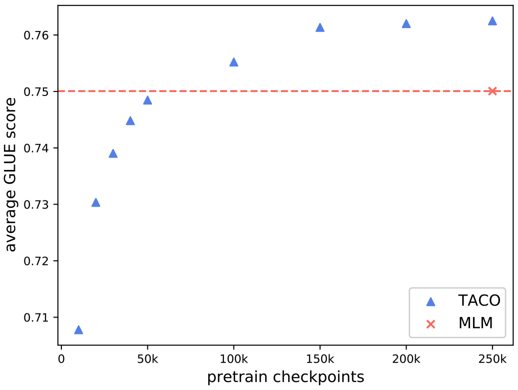

Figure 5: Average GLUE score during pre-training. All results are reported on validation sets with BERT-small. TACO achieves better results and 5× speedup than MLM.

4.3 Results on BERT-Base

We also compare TACO with MLM on base-sized models, which are the most commonly used models according to the download data from Huggingface[4] (Wolf et al., 2020). First, from Table 3, we can see that TACO consistently outperforms MLM under all pre-training computation budgets. Notably, TACO-250k achieves comparable performance with MLM-500k, which saves 2x computations. Similar results are observed on TACO-100k and BERT-250k. These results demonstrate that TACO can achieve better acceleration over MLM. It is also a significant improvement compared to previous methods (Gong et al., 2019) focusing on accelerating BERT but only with slight speedups. In addition, as shown in Table 4, TACO achieves competitive results compared to BERT-NCE and INFOWORD, two similar contrastive methods.

5 Discussion

5.1 TACO and MLM

To better understand how TACO works, we conduct a quantitative comparison on the learning dynamic for BERT and TACO. Similar to Section 2.2, we plot the Cosine similarity among contextualized representations of tokens in the same context (intra-context) and different contexts (inter-context) in Figure 6. We find that the learning dynamic of TACO significantly differs from that of MLM. Specifically, for TACO, the intra-context representation similarity remains high and the gap between intra-context similarity and inter-context similarity remains large at the later stage of training. This confirms that TACO can better fulfill global semantics, which may contribute to the superior downstream performance.

5.2 Ablation Study

TACO is implemented as a token-level contrastive (TC) loss along with the MLM loss. Therefore, the improvement of TACO might come from two aspects, including 1) denser supervision signals from the all-token objective and 2) the benefits of the contrastive loss to strengthen global dependencies. It is helpful to figure out which factor is more important. To this end, we design two variants for ablation. One is a *concentrated* TACO, where the contrastive loss is built on the 15% masked positions only, keeping the same density of supervision signal with MLM. The other is an *extended* MLM, where not only 15% masked positions are asked to predict the original token, so do the rest 85% unmasked positions. The extended MLM has the same dense supervision with TACO but loses the benefits of modeling the global dependencies. The results on small models are shown in Figure 6.

As we can see, the performance of TACO decreases if we sample a part of token positions to implement TC objectives. It shows that more supervision signals benefit the final performance of TACO. However, simply adding more supervision signals by predicting unmasked tokens does not help MLM too much. Even equipped with the extra 85% token prediction (TP) loss, MLM+TP does not show significant improvements and it is noticeable that the performance of MLM+TP starts to drop after 150k steps. This further confirms the effectiveness of TC loss by strengthening global dependencies.

6 Related Work

6.1 Language Representation Learning

Classic language representation learning methods (Mikolov et al., 2013; Pennington et al., 2014) aims to learn context-independent representation of words, i.e., word embeddings. They generally follow the distributional hypothesis (Harris, 1954). Recently, the pre-training then fine-tuning paradigm has become a common practice in NLP because of the success of pre-trained language models like BERT (Devlin et al., 2019). Context-dependent (or contextualized) representations are the basic characteristic of these methods. Many

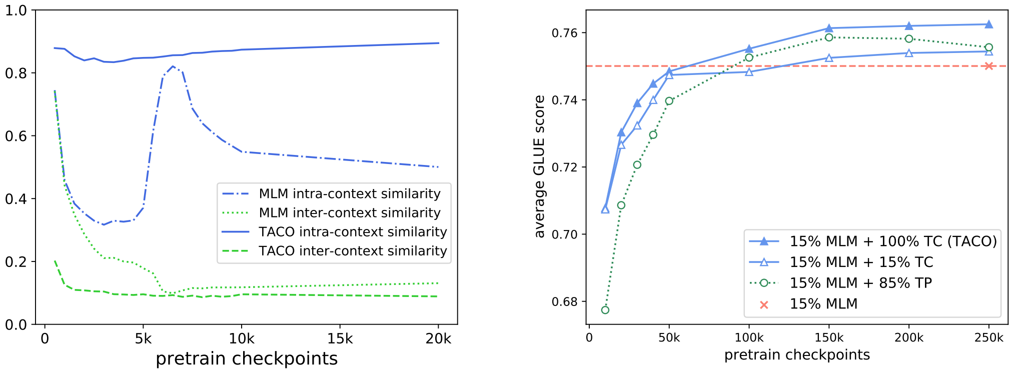

Figure 6: The left figure (a) shows the intra-context similarity and inter-context similarity change during pre-training. The right figure (b) shows two ablations of TACO: a concentrated TACO (15% MLM + 15% TC), where the MLM loss and the TC loss are both built on the same 15% masked positions, and an extended MLM (15% MLM + 85% TP), which masks 15% positions but predict original tokens on all positions.

existing contextualized models are based on the masked language modeling objective, which randomly masks a portion of tokens in a text sequence and trains the model to recover the masked tokens. Many previous studies prove that pre-training with the MLM objective helps the models learn syntactical and semantic knowledge (Clark et al., 2019). There have been numerous extensions to MLM. For example, XLNet (Yang et al., 2019) introduced the permutated language modeling objective, which predicts the words one by one in a permutated order. BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) investigated several denoising objectives and pre-trained an encoder-decoder architecture with the mask span infilling objective. In this work, we focus on the key MLM objective and aim to explore how MLM objective helps learn contextualized representation.

6.2 Contrastive-based SSL

Apart from denoising-based objectives, contrastive learning is another promising way to obtain self-supervision. In contrastive-based self-supervised learning, the models are asked to distinguish the positive samples from the negative ones for a given anchor. Contrastive-based SSL method was first introduced in NLP for efficient learning of word representations by negative sampling, i.e., SGNS (Word2Vec (Mikolov et al., 2013)). Later, similar ideas were brought into CV field for learning image representation and got prevalent, such as MoCo (He et al., 2020), SimCLR (Chen et al., 2020), BYOL (Caron et al., 2020), etc.

In the recent two years, there have been many studies targeting at reviving contrastive learning for contextual representation learning in NLP. For instance, CERT (Fang et al., 2020) utilized back-translation to generate positive pairs. CAPT (Luo et al., 2020) applied masks to the original sentence and considered the masked sentence and its original version as the positive pair. DeCLUTR (Giorgi et al., 2020) samples nearby even overlapping spans as positive pairs. INFOWORD (Kong et al., 2020) treated two complementary parts of a sentence as the positive pair. However, the aforementioned methods mainly focus on sentence-level or span-level contrast and may not provide dense self-supervision to improve efficiency. Unlike these approaches, TACO regards the global semantics hidden in contextualized token representations as the positive pair. The token-level contrastive loss can be built on all input tokens, which provides a dense self-supervised signal.

Another related work is ELECTRA (Clark et al., 2020). ELECTRA samples machine-generated tokens from a separate generator and trains the main model to discriminate between machine-generated tokens and original tokens. ELECTRA implicitly treats the fake tokens as negative samples of the context, and the unchanged tokens as positive samples. Unlike this method, TACO does not require architectural modifications and can serve as a plug-and-play auxiliary objective, largely improving pre-training efficiency.

7 Conclusion

In this paper, we propose a simple yet effective objective to learn contextualized representation. Taking MLM as an example, we investigate whether and how current language model pre-training objectives learn contextualized representation. We find that the MLM objective mainly focuses on local anchors to align contextualized representations, which harms global dependencies modeling due to an “embedding bias” problem. Motivated by these problems, we propose TACO to directly model global semantics. It can be easily combined with existing LM objectives. By combining local and global anchors, TACO achieves up to 5× speedups and up to 1.2 improvements on GLUE score. This demonstrates the potential of TACO to serve as a plug-and-play approach to improve contextualized representation learning.

A Experiment Details

A.1 Pre-training Hyper-parameters

All pre-training approaches involved in experiments use the same pre-training hyper-parameters but do not include BERT-NCE and INFOWORD. Results of BERT-NCE and INFOWORD are directly cited from the original paper (Kong et al., 2020). Following Liu et al. (2019), we do not use the next sentence prediction (NSP) objective and use dynamic masking for MLM with a 15% mask ratio, where the masked positions are decided on the fly.

TACO introduces three extra hyper-parameters, including negative sample size K, positive sample window size W and temperature τ. We set the temperature τ as a small value, 0.07, following Fang et al. (2020). By searching for the best K out of $\{10, 50\}$ and W out of $\{3, 5, 10, 50\}$ on the small TACO model, we found that TACO with K=50 and W=5 performs best, so we also apply these hyper-parameter choices for base-sized TACO. The full set of pre-training hyper-parameters are listed in Table 5. Actually, TACO outperforms MLM under most cases in our preliminary experiments. However, we still also find some extreme cases which might harm the effectiveness of TACO. If the size of negative samples K is too small, e.g., smaller than 10, the performance of TACO degenerates nearly to the level of BERT baseline. Similar conclusions are also mentioned in related works (He et al., 2020; Chen et al., 2020). Also, if the positive window size W is too large, e.g., bigger than 50, the performance of TACO degrades, too. We suspect the over-large positive window brings more false-positive samples, which makes the sequence meaning ambiguous, thus harms the performance.

A.2 Fine-tuning Details

For small-sized models, we fine-tune all saved checkpoints (5k, 10k, 20k, 30k, 40k, 50k, 100k, 150k, 200k, 250k-step) of different pre-trained models (TACO and its ablations) with the same hyper-parameters on each task. Considering the large amount of pre-training checkpoints, we just adopt the default fine-tuning hyper-parameters and repeat fine-tuning 4 times with different random seeds. Then the best performed fine-tuned models on validation sets are used for testing. This setting helps make a fair comparison among models and avoids a large amount of grid-search runs. The task-specific hyper-parameters for small-sized models

Pre-training	Hyper-parameters	Small	Base
Parameters Shared by All Approaches	Number of Layers	4	12
	Hidden Size	512	768
	Hidden Layer Activation Function	gelu	gelu

RTE	5e-5	32	4	100

Table 7: Task-specific hyper-parameters for small models during fine-tuning.

are listed in Table 7. The general fine-tuning hyper-parameters are listed in Table 6.

For base-sized models, we save checkpoints at 100k, 250k, and 500k steps, respectively. During fine-tuning, we also conduct multiple fine-tuning runs with different task-specific hyper-parameter combinations as shown in Table 8. Concretely, we randomly sample 6 different hyper-parameter combinations and report the average score for validation results. Then we select the best-performing run of 500k-step checkpoints (converged) for testing.

A.3 Statistic Details

Embedding Similarity We calculate cosine similarity of 20 randomly sampled pairs of frequently co-occurrent words from the WordSim353 dataset (Agirre et al., 2009) labeled by human annotators to plot the average similarity curve in Figure 3(b). Corresponding embeddings are obtained from the embedding layer of the BERT model and variant models mentioned in Section 2.2.

Intra-/Inter-context Similarity For every token w_i in the corpus, we randomly sample a positive token $w_{j \neq i}$ within the same context (sentence) and another token w_k from other sentences. As mentioned in Section 2.2, we take BERT (Devlin et al., 2019) as our encoder to get contextualized representations through the last hidden states $\boldsymbol{h}$. We mainly adopt the cosine similarity as the measurement and calculate the average intra-context similarity (between $\boldsymbol{h}_i$ and $\boldsymbol{h}_j$) and the average inter-context similarity (between $\boldsymbol{h}_i$ and $\boldsymbol{h}_k$) over all tokens in the corpus. It is worth noticing that we do use any masks here when generating a token's contextualized representation for statistics.

Other Measurements We observe the same findings for MLM under other measurements, though the statistics before are mainly based on cosine similarities. We tried other similarities or distances, e.g., L1 distance, L2 distance and L10 distance, to evaluate the discrepancy between contextualized representations from the same context and different contexts. Specifically, we make intra-context and inter-context statistics under specific measurement at different pre-training checkpoints, then calculate the ratio of intra-context measurement over the inter-context one. Table 9 shows the statistical results. As we can see, when the ratio of L1 distance decreases, the ratio of cosine similarity and the dot-production similarity increase, vice versa.

B Extra Experiments

In the standard implementation of BERT, the parameters of input embeddings are shared with output embeddings. All experiments and analyses in this paper are based on this assumption. To further

Table 9: The ratio of intra-context measurement over inter-context measurement during pre-training. We list two distance measurements and three similarity measurements here.

confirm the effectiveness of TACO, we conduct the extra experiments without embedding sharing on BERT-small. The results are showed in Table 10. It is unexpected that the variants without embedding sharing perform worse compared their counterparts due to lack of regularization of weight sharing. From the results, we can see that the TACO without embedding sharing performs slightly worse than TACO with embedding sharing. However, compared to the MLM, it is still better than MLM than 0.9 average GLUE score when convergence. These results prove the effectiveness of TACO even when embeddings are not sharing.

Approach	MNLI	QQP	QNLI	SST-2	CoLA	STS-B	MRPC	RTE	**Avg.**

Abstract

While hyper-parameters (HPs) are important for knowledge graph (KG) learning, existing methods fail to search them efficiently. To solve this problem, we first analyze the properties of different HPs and measure the transfer ability from small subgraph to the full graph. Based on the analysis, we propose an efficient two-stage search algorithm KGTuner, which efficiently explores HP configurations on small subgraph at the first stage and transfers the top-performed configurations for fine-tuning on the large full graph at the second stage. Experiments show that our method can consistently find better HPs than the baseline algorithms within the same time budget, which achieves 9.1% average relative improvement for four embedding models on the large-scale KGs in open graph benchmark. Our code is released in `https://github.com/AutoML-Research/KGTuner`. [1]

1 Introduction

Knowledge graph (KG) is a special kind of graph structured data to represent knowledge through entities and relations between the entities (Wang et al., 2017; Ji et al., 2021). Learning from KG aims to discover the latent properties from KGs to infer the existence of interactions among entities or the types of entities (Wang et al., 2017; Zhang and Yao, 2022). KG embedding, which encodes entities and relations as low dimensional vectors, is an important technique to learn from KGs (Wang et al., 2017; Ji et al., 2021). The existing models range from translational distance models (Bordes et al., 2013), tensor factorization models (Nickel et al., 2011; Trouillon et al., 2017; Balažević et al., 2019), neural network models (Dettmers et al., 2017; Guo et al., 2019), to graph neural networks (Schlichtkrull et al., 2018; Vashishth et al., 2020).

Hyper-parameter (HP) search (Claesen and De Moor, 2015) is very essential for KG learning. In this work, we take KG embedding methods (Wang et al., 2017), as a good example to study the impact of HPs to KG learning. As studied, the HP configurations greatly influence the model performance (Ruffinelli et al., 2019; Ali et al., 2020). An improper HP configuration will impede the model from stable convergence, while an appropriate one can make considerable promotion to the model performance. Indeed, studying the HP configurations can help us make a more scientific understanding of the contributions made by existing works (Rossi et al., 2021; Sun et al., 2020). In addition, it is also important to search for an optimal HP configuration when adopting KG embedding methods to the real-world applications (Bordes et al., 2014; Zhang et al., 2016; Saxena et al., 2020).

Algorithms for HP search on general machine learning problems have been well-developed (Claesen and De Moor, 2015). As shown in Figure 1(a), the search algorithm selects a HP configuration from the search space in each iteration, then the evaluation feedback obtained by full model training is used to update the search algorithm. The optimal HP is the one achieving the best performance on validation data in the search process. Representative HP search algorithms are within sample-based methods like grid search, random search (Bergstra and Bengio, 2012), and sequential model-based Bayesian optimization (SMBO) methods like Hyperopt (Bergstra et al., 2013), SMAC (Hutter et al., 2011), Spearmint (Snoek et al., 2012) as well as BORE (Tiao et al., 2021), etc. Recently, some subgraph-based methods (Tu et al., 2019; Wang et al., 2021) are proposed to learn a predictor with configurations efficiently evaluated on small subgraphs The predictor is then transferred to guide HP search on the full graph. However, these methods fail to efficiently search a good configuration of HPs for KG embedding models since the training

(a) Conventional methods

(b) KGTuner

Figure 1: The framework of conventional HP search algorithm and the proposed KGTuner.

cost of individual model is high and the correlation of HPs in the huge search space is very complex.

To address the limitations of existing HP search algorithms, we carry a comprehensive understanding study on the influence and correlation of HPs as well as their transfer ability from small subgraph to full graph in KG learning. From the aspect of performance, we classify the HPs into four different groups including *reduced options*, *shrunken range*, *monotonously related* and *no obvious patterns* based on their influence on the performance. By analyzing the validation curvature of these HPs, we find that the space is rather complex such that only tree-based models can approximate it well. In addition, we observe that the consistency between evaluation on small subgraph and that on the full graph is high, while the evaluation cost is significantly smaller on the small subgraph.

Above understanding motivates us to reduce the size of search space and design a two-stage search algorithm named as KGTuner. As shown in Figure 1(b), KGTuner explores HP configurations in the shrunken and decoupled space with the search algorithm RF+BORE (Tiao et al., 2021) on a subgraph in the first stage, where the evaluation cost of HPs are small. Then in the second stage, the configurations achieving the *top10* performance at the first stage are equipped with large batch size and dimension size for fine-tuning on the full graph.

Within the same time budget, KGTuner can consistently search better configurations than the baseline search algorithms for seven KG embedding models on WN18RR (Dettmers et al., 2017) and FB15k-237 (Toutanova and Chen, 2015). By applying KGTuner to the large-scale benchmarks ogbl-biokg and ogbl-wikikg2 (Hu et al., 2020), the performances of embedding models are improved compared with the reported results on OGB link prediction leaderboard. Besides, we justify the improvement of efficiency via analyzing the design components in KGTuner.

2 Background: HPs in KG embedding

We firstly revisit the important and common HPs in KG embedding. Following the general framework (Ruffinelli et al., 2019; Ali et al., 2020), the learning problem can be written as

$$\boldsymbol{P}^* = \arg\min\nolimits_{\boldsymbol{P}} L(F(\cdot,\boldsymbol{P}),D^+,D^-)+r(\boldsymbol{P}), \quad (1)$$

where F is the form of an embedding model with learnable parameters $\boldsymbol{P}$, D^+ is the set of positive samples from the training data, D^- represents negative samples, and $r(\cdot)$ is a regularization function. There are four groups of hyper-parameters (Table 1), i.e., the size of *negative sampling* for D^-, the choice of *loss function* L, the form of *regularization* $r(\cdot)$, and the *optimization* $\arg\min_{\boldsymbol{P}}$.

Embedding model. While there are many existing embedding models, we follow (Ruffinelli et al., 2019) to focus on some representative models. They are translational distance models TransE (Bordes et al., 2013) and RotatE (Sun et al., 2019), tensor factorization models RESCAL (Nickel et al., 2011), DistMult (Yang et al., 2015), ComplEx (Trouillon et al., 2017) and TuckER (Balažević et al., 2019), and neural network models ConvE (Dettmers et al., 2017). Graph neural networks for KG embedding (Schlichtkrull et al., 2018; Vashishth et al., 2020; Zhang and Yao, 2022) are not studied here for their scalability issues on large-scale KGs (Ji et al., 2021).

Negative sampling. Sampling negative triplets is important as only positive triplets are contained in the KGs (Wang et al., 2017). We can pick up m triplets by replacing the head or tail entity with uniform sampling (Bordes et al., 2013) or use a full set of negative triplets. Using the full set can be defined as the `1VsAll` (Lacroix et al., 2018) or `kVsAll` (Dettmers et al., 2017) according to the positive triplets used. The methods (Cai and Wang, 2018; Zhang et al., 2021) requiring additional models for negative sampling are not considered here.

Table 1: The HP space. Conditioned HPs are in parenthesize. "adv." and "reg." are short for "adversarial" and "regularization", respectively. Please refer to the Appendix A for more details.

component	name	type	range
negative sampling	# negative samples	cat	{32, 128, 512, 2048, `1VsAll`, `kVsAll`}
loss function	loss function	cat	{MR, BCE_(mean, sum, adv), CE}
	gamma (MR)	float	$[1, 24]$
	adv. weight (BCE_adv)	float	$[0.5, 2.0]$
regularization	regularizer	cat	{FRO, NUC, DURA, None}
	reg. weight (not None)	float	$[10^{-12}, 10^{2}]$
	dropout rate	float	$[0, 0.5]$
optimization	optimizer	cat	{Adam, Adagrad, SGD}
	learning rate	float	$[10^{-5}, 10^{0}]$
	initializer	cat	{uniform, normal, xavier_uniform, xavier_norm}
	batch size	int	{128, 256, 512, 1024}
	dimension size	int	{100, 200, 500, 1000, 2000}
	inverse relation	bool	{True, False}

Loss function. There are three types of loss functions. One can use margin ranking (MR) loss (Bordes et al., 2013) to rank the positive triplets higher over the negative ones, or use binary cross entropy (BCE) loss, with variants BCE_mean, BCE_adv (Sun et al., 2019) and BCE_sum (Trouillon et al., 2017), to classify the positive and negative triplets as binary classes, or use cross entropy (CE) loss (Lacroix et al., 2018) to classify the positive triplet as the true label over the negative triplets.

Regularization. To balance the expressiveness and complexity, and to avoid unbounded embeddings, the regularization techniques can be considered, such as regularizers like Frobenius norm (FRO) (Yang et al., 2015; Trouillon et al., 2017), Nuclear norm (NUC) (Lacroix et al., 2018) as well as DURA (Zhang et al., 2020b), and dropout on the embeddings (Dettmers et al., 2017).

Optimization. To optimize the embeddings, important optimization choices include the optimizer, such as SGD, Adam (Kingma and Ba, 2014) and Adagrad (Duchi et al., 2011), learning rate, initializers, batch size, embedding dimension size, and add inverse relation (Lacroix et al., 2018) or not.

3 Defining the search problem

Denote an instance $\mathbf{x} = (x_1, x_2 \dots, x_n)$, which is called an HP configuration, in the search space $\mathcal{X}$. Let $F(\boldsymbol{P}, \mathbf{x})$ be an embedding model with model parameters $\boldsymbol{P}$ and HPs $\mathbf{x}$, we define $\mathcal{M}(F(\boldsymbol{P}, \mathbf{x}), D_{\text{val}})$ as the performance measurement (the larger the better) on validation data D_{val} and $\mathcal{L}(F(\boldsymbol{P}, \mathbf{x}), D_{\text{tra}})$ as the loss function (the smaller the better) on training data D_{tra}. We define the problem of HP search for KG embedding models in Definition 1. The objective is to search an optimal configuration $\mathbf{x}^* \in \mathcal{X}$ such that the embedding model F can achieve the best performance on the validation data D_{val}.

Definition 1 (Hyper-parameter search for KG embedding). *The problem of HP search for KG embedding model is formulated as*

$$\mathbf{x}^* = \arg\max\nolimits_{\mathbf{x}\in\mathcal{X}} \mathcal{M}\big(F(\boldsymbol{P}^*, \mathbf{x}), D_{val}\big), \quad (2)$$

$$\boldsymbol{P}^* = \arg\min\nolimits_{\boldsymbol{P}} \mathcal{L}\big(F(\boldsymbol{P}, \mathbf{x}), D_{tra}\big). \quad (3)$$

Definition 1 is a bilevel optimization problem (Colson et al., 2007), which can be solved by many conventional HP search algorithms. The most common and widely used approaches are sample-based methods like grid search and random search (Bergstra and Bengio, 2012), where the HP configurations are independently sampled. To guide the sampling of HP configurations by historical experience, SMBO-based methods (Bergstra et al., 2011; Hutter et al., 2011) learn a surrogate model to select configurations based on the results that have been evaluated. Then, the model parameters $\boldsymbol{P}$ are optimized by minimizing the loss function $\mathcal{L}$ on D_{tra} in Eq. (3). The evaluation feedback $\mathcal{M}$ of $\mathbf{x}$ on the validation data D_{val} is used to update the surrogate.

There are three major aspects determining the efficiency of Definition 1: (i) the size of search space $\mathcal{X}$, (ii) the validation curvature of $\mathcal{M}(\cdot, \cdot)$

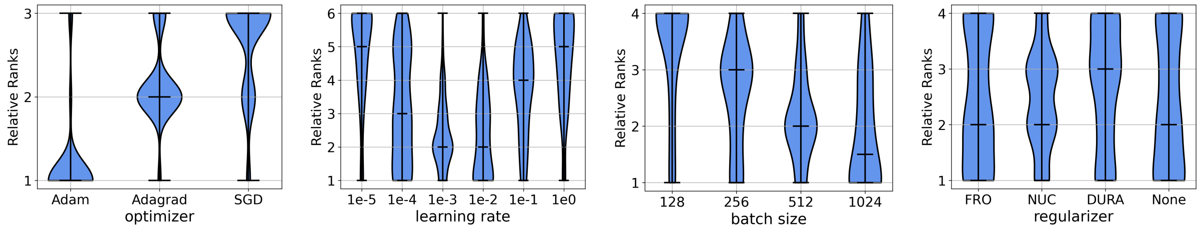

Figure 2: Ranking distribution of selected HPs. A value with larger area in the bottom indicates the higher ranking of this value. The four figures correspond to the four groups: reduced options, shrunken range, monotonously related, no obvious patterns. Full results are in the Appendix B.2.

in Eq. (2), and (iii) the evaluation cost in solving $\arg\min_{\boldsymbol{P}} \mathcal{L}$ in Eq. (3). However, the existing methods (Ruffinelli et al., 2019; Ali et al., 2020) directly search on a huge space with commonly used surrogate models and slow evaluation feedback from the full KG due to the lack of understanding on the search problem, leading to low efficiency.

4 Understanding the search problem

To address the mentioned limitations, we measure the significance and correlation of each HP to determine the feasibility of the search space $\mathcal{X}$ in Section 4.1. In Section 4.2, we visualize the HPs that determine the curvature of Eq. (2). To reduce the evaluation cost in Eq. (3), we analyze the approximation methods in Section 4.3. Following (Ruffinelli et al., 2019), the experiments run on the seven embedding models in Section 2 and two widely used datasets WN18RR (Dettmers et al., 2017) and FB15k-237 (Toutanova and Chen, 2015). The experiments are implemented with PyTorch framework (Paszke et al., 2017), on a machine with two Intel Xeon 6230R CPUs and eight RTX 3090 GPUs with 24 GB memories each. We provide the implementation details in the Appendix D.1.

4.1 Search space: $\mathbf{x} \in \mathcal{X}$

Considering such large amount of HP configurations in $\mathcal{X}$, we take the simple and efficient approach where HPs are evaluated under control variate (Hutter et al., 2014; You et al., 2020), which varies the i-th HP while fixing the other HPs. First, we discretize the continuous HPs according to their ranges. Then the feasibility of the search space $\mathcal{X}$ is analyzed by checking the ranking distribution and consistency of individual HPs. These can help us shrink and decouple the search space. The detailed setting for this part is in the Appendix B.1.

Ranking distribution. To shrink the search space, we use the ranking distribution to indicate what HP values perform consistently. Given an anchor configuration $\mathbf{x}$, we obtain the ranking of different values $\theta \in X_i$ by fixing the other HPs, where X_i is the range of the i-th HP. The ranking distribution is then collected over the different anchor configurations in $\mathcal{X}_i$, different models and datasets. According to the violin plots of ranking distribution shown in Figure 2, the HPs can be classified into four groups:

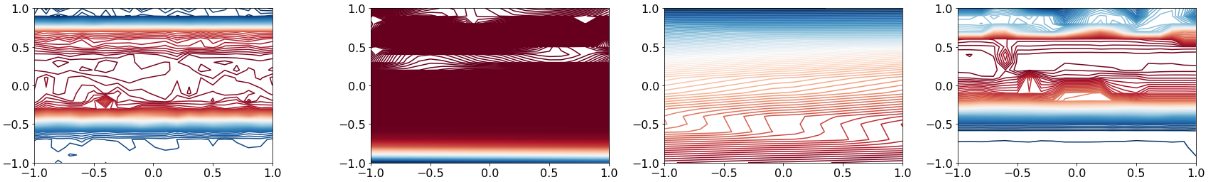
(a) *reduced options*, e.g., Adam is the best optimizer and inverse relation should not be introduced;
(b) *shrunken range*, e.g., learning rate, reg. weight and dropout rate are better in certain ranges;
(c) *monotonously related*: e.g., larger batch size and dimension size tend to be better;
(d) *no obvious patterns*: e.g., the remaining HPs.

Consistency. To decouple the search space, we measure the consistency of configurations' rankings when only a specific HP changes. For the i-th HP, if the ranking of configurations' performance is consistent with different values of $\theta \in X_i$, we can decouple the search procedure of the i-th HP with the others. We measure such consistency with the spearman's ranking correlation coefficient (`SRCC`) (Schober et al., 2018).

Given a value $\theta \in X_i$, we obtain the ranking $r(\mathbf{x}, \theta)$ of the anchor configurations $\mathbf{x} \in \mathcal{X}_i$ by fixing the i-th HP as θ. Then, the `SRCC` between the two HP values $\theta_1, \theta_2 \in X_i$ is computed as

$$1 - \frac{\sum_{\mathbf{x}\in\mathcal{X}_i} |r(\mathbf{x}, \theta_1) - r(\mathbf{x}, \theta_2)|^2}{|\mathcal{X}_i| \cdot (|\mathcal{X}_i|^2 - 1)}, \qquad (4)$$

where $|\mathcal{X}_i|$ means the number of anchor configurations in $\mathcal{X}_i$. `SRCC` indicates the matching rate of rankings for the anchor configurations in $\mathcal{X}_i$ with respect to $x_i = \theta_1$ and $x_i = \theta_2$. Then the consistency of the i-th HP is evaluated by averaging the `SRCC` over the different pairs of (θ_1, θ_2) for X_i, the different models and different datasets. The larger consistency (in the range $[-1, 1]$) indicates that changing the value of the i-th HP does not influence much on the other configurations' ranking.



(a) Ground truth (b) GP prediction (c) MLP prediction (d) RF prediction

Figure 3: Curvature of the search space and three surrogate models. The search space curvature is quite complex with many local maximum areas. The curvature of RF approximate the ground truth best.

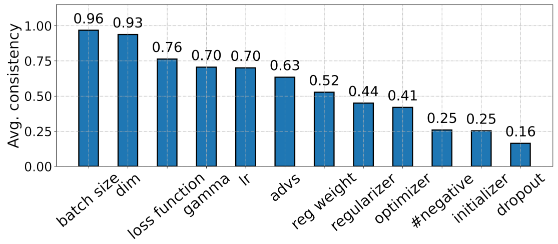


Figure 4: Consistency of each HP.

As in Figure 4, the batch size and dimension size show higher consistency than the other HPs. Hence, the evaluation of the configurations can be consistent with different choices of the two HPs. This indicates that we can decouple the search of batch size and dimension size with the other HPs.

4.2 Validation curvature: $\mathcal{M}(\cdot, \cdot)$

We analyze the curvature of the validation performance $\mathcal{M}(\cdot, \cdot)$ w.r.t $\mathbf{x} \in \mathcal{X}$. Specifically, we follow (Li et al., 2017) to visualize the validation loss' landscape by uniformly varying the numerical HPs in two directions (20 configurations in each direction) on the model ComplEx and dataset WN18RR. From Figure 3(a), we observe that the curvature is quite complex with many local maximum areas.

To gain insights from evaluating these configurations and guide the next configuration sampling, we learn a surrogate model as the predictor to approximate the validation curvature. The curvatures of three common surrogates, i.e., Gaussian process (GP) (Williams and Rasmussen, 1995), multi-layer perceptron (MLP) (Gardner and Dorling, 1998) and random forest (RF) (Breiman, 2001), are in Figures 3(b)-3(d). The surrogate models are trained with the evaluations of 100 random configurations in the search space. As shown, both GP and MLP fail to capture the complex local surface in Figure 3(a) as they tend to learn a flat and smooth distribution in the search space. In comparison, RF is better in capturing the local distributions. Hence, we regard RF as a better choice in the search space. A more detailed comparison on the approximation ability of different surrogates is in the Appendix B.3.

4.3 Evaluation cost: $\arg\min_{\boldsymbol{P}} \mathcal{L}$

The evaluation cost of the HP configuration on an embedding model is the majority computation cost in HP search. Thus, we firstly evaluate the HPs that have influence on the evaluation cost, including batch size, dimension size, number of negative samples loss function and regularizer. Then, we analyze the evaluation transfer ability from small subgraph to the full graph.

Cost of different HPs. The cost of each HP value $\theta \in X_i$ is averaged over the different anchor configurations in $\mathcal{X}_i$, different models and datasets. For fair comparsion, the time cost is counted per thousand iterations. We find that the evaluation cost increases significantly with larger batch size and dimension size, while the number of negative samples and the choice of loss function or regularizer do not have much influence on the cost. We provide two exemplar curves in Figure 5 and put the remaining results in the Appendix B.4.

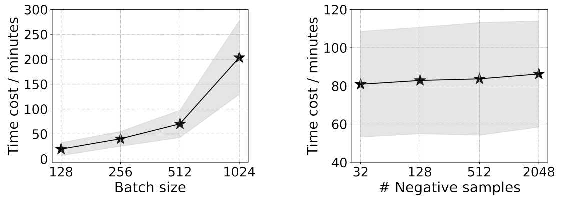

Figure 5: Computing time cost. The dots are the average and the shades are the standard deviation.

Transfer ability of subgraphs. Subgraphs can efficiently approximate the properties of the full graph (Hamilton et al., 2017; Teru et al., 2020). We evaluate the impact of subgraph sampling on HP search by checking the consistency between evaluations results on small subgraph and those on the full graph.

First, we study how to sample subgraphs. There are several approaches to sample small subgraphs from a large graph (Leskovec and Faloutsos, 2006). We compare four representative approaches in Figure 6, i.e., Pagerank node sampling (Pagerank), random edge sampling (Random Edge), single-start random walk (Single-RW) and multi-start random walk (Multi-RW). For a fair comparison, we constrain the subgraphs with about 20% of the full graph. The consistency between the sampled subgraph with the full graph is evaluated by the `SRCC` in (4). We observe that multi-start random walk is the best among the different sampling methods.

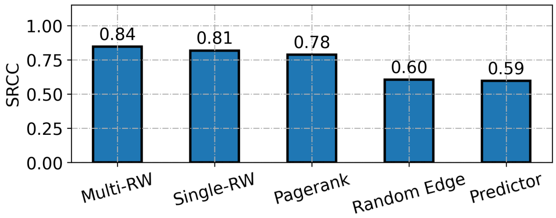

Figure 6: Comparison of the sampling methods.

Apart from directly transferring the evaluation from subgraph to full graph, we can alternatively train a predictor with observations on subgraphs and then transfers the model to predict the configuration performance on the full graph. From Figure 6, we find that directly transferring evaluations from subgraphs to the full graph is much better than transferring the predictor model.

In addition, we show the consistency and cost in terms of different subgraph sizes (percentage of entities compared to the full graph) in Figure 7. As shown, evaluation on subgraphs can significantly improve the efficiency. When the scale increases, the consistency increases but the cost also increases. To balance the consistency and cost, the subgraphs with 20% entities are the better choices.

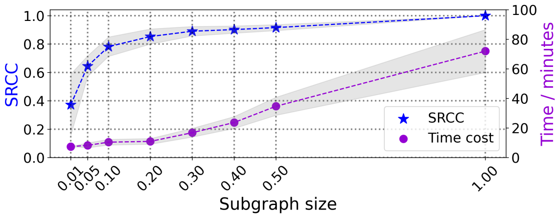

Figure 7: Consistency and cost of different subgraph sizes, where the shades are the standard deviation.

5 Efficient search algorithm

By analyzing the ranking distribution and consistency of HPs in Section 4.1, we observe that not all the HP values are equivalently good, and some HPs can be decoupled. These observations motivate us to revise the search space in Section 5.1. Based on the analysis in Section 4.2 and 4.3, we then propose an efficient two-stage search algorithm in Section 5.2.

5.1 Shrink and decouple the search space

To shrink the search space, we mainly consider groups (a) and (b) of HPs in Section 4.1. From the full results in the Appendix B.2, we observe that Adam can consistently perform better than the other two optimizers, the learning rate is better in the range of $[10^{-4}, 10^{-1}]$, the regularization weight is better in $[10^{-8}, 10^{-2}]$, dropout rate is better in $[0, 0.3]$, and add inverse relation is not a good choice.

To decouple the search space, we consider batch size and dimension size that have larger consistency values than the other HPs, and are monotonously related to the performance as in group (c). However, the computation costs of batch size and dimension size increase prominently as shown in Figure 5. Hence, we can set batch size as 128 and dimension size as 100 to search the other HPs with low evaluation cost and increase their values in a fine-tuning stage.

Given the full search space $\mathcal{X}$, we denote the shrunken space as $\mathcal{X}_{\text{S}}$ and the further decoupled space as $\mathcal{X}_{\text{S|D}}$. We achieve hundreds of times size reduction from $\mathcal{X}_{\text{S}}$ to $\mathcal{X}_{\text{S|D}}$ and we show the details of changes in the Appendix C.

5.2 Two-stage search algorithm (KGTuner)

As discussed in Section 4.3, the evaluation cost can be significantly reduced with small batch size, dimension size and subgraph. This motivates us to design a two-stage search algorithm, named KGTuner, as in Figure 1(b) and Algorithm 1.

Algorithm 1 KGTuner: two-stage search algorithm

```
Require: KG embedding model $F$, dataset $D$, and budget $B$;
shrink the search space $\mathcal{X}$ to $\mathcal{X}_{\text{S}}$ and decouple $\mathcal{X}_{\text{S}}$ to $\mathcal{X}_{\text{S|D}}$;
# state one: efficient evaluation on subgraph
sample a subgraph (with 20% entities) $G$ from $D_{\text{tra}}$ by multi-start random walk;
repeat
    sample a configuration $\hat{\mathbf{x}}$ from $\mathcal{X}_{S|D}$ by RF+BORE;
    evaluate $\hat{\mathbf{x}}$ on the subgraph $G$ to get the performance;
    update the RF with record $\left(\hat{\mathbf{x}}, \mathcal{M}(F(P^*, \hat{\mathbf{x}}), G_{\text{val}})\right)$;
until $^B/_2$ budget exhausted;
save the top10 configurations in $\mathcal{X}^*_{\text{S|D}}$;
# state two: fine-tune the top configurations
increase the batch/dimension size in $\mathcal{X}^*_{\text{S|D}}$ to get $\tilde{\mathcal{X}}^*$;
set $y^* = 0$ and re-initialize the RF surrogate;
repeat
    select a configuration $\tilde{\mathbf{x}}^*$ from $\tilde{\mathcal{X}}^*$ by RF+BORE;
    evaluate on full graph $G$ to get the performance;
    update the RF with record $\left(\tilde{\mathbf{x}}^*, \mathcal{M}(F(P^*, \tilde{\mathbf{x}}^*), D_{\text{val}})\right)$;
    if $\mathcal{M}(F(P^*, \tilde{\mathbf{x}}^*), D_{\text{val}}) > y^*$ then
        $y^* \leftarrow \mathcal{M}(F(P^*, \tilde{\mathbf{x}}^*), D_{\text{val}})$ and $\mathbf{x}^* \leftarrow \tilde{\mathbf{x}}^*$; end if
until the remaining $^B/_2$ budget exhausted;
return $\mathbf{x}^*$.
```

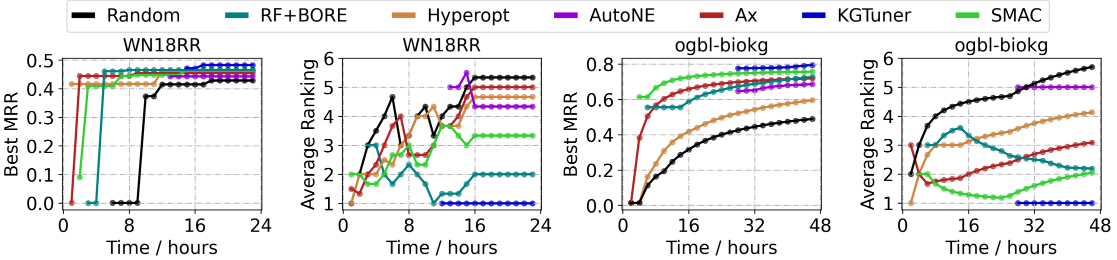

Figure 8: Search algorithm comparison (viewed in color). The dots are the results collected per hour.

- In the first stage, we sample a subgraph G with 20% entities from the full graph D_{tra} by multi-start random walk. Based on the understanding of curvature in Section 4.2, we use the surrogate model random forest (RF) under the state-of-the art framework BORE (Tiao et al., 2021), denoted as RF+BORE, to explore HPs in $\mathcal{X}_{\text{SID}}$ on the subgraph G in steps 3-7. The *top10* configurations evaluated in this stage are saved in a set $\mathcal{X}^*_{\text{SID}}$.
- In the second stage, we increase batch size and dimension size for configurations in $\mathcal{X}^*_{\text{SID}}$ to generate a new set $\tilde{\mathcal{X}}^*$. Then, the configurations in $\tilde{\mathcal{X}}^*$ are searched by the RF+BORE again in steps 11-16 until the remaining $B/2$ budget is exhausted.
- Finally, the configuration $\mathbf{x}^*$ achieving the best performance on the full validation data D_{val} is returned for testing.

5.3 Discussion

e now summarize the main differences of KGTuner with the existing HP search algorithms, i.e. Random (random search) (Bergstra and Bengio, 2012), Hyperopt (Bergstra et al., 2013), SMAC (Hutter et al., 2011), RF+BORE (Tiao et al., 2021), and AutoNE (Tu et al., 2019).

Table 2: Comparison of HP search algorithms.

	search space		surrogate model	fast evaluation
	shrink	decouple		
Random	×	×	×	×
Hyperopt	×	×	TPE	×
Ax	×	×	GP	×
SMAC	×	×	RF	×
RF+BORE	×	×	RF	×
AutoNE	×	×	GP	√
KGTuner	√	√	RF	√

The comparison is based on three aspects, i.e., search space, surrogate model and fast evaluation, in Table 2. KGTuner shrinks and decouples the search space based on the understanding of HPs' properties, and uses the surrogate RF based on the understanding on validation curvature. The fast evaluation on subgraph in KGTuner selects the *top10* configurations to directly transfer for fine-tuning, while AutoNE (Tu et al., 2019) just uses fast evaluation on subgraphs to train the surrogate model, and transfers the surrogate model for HP search on the full graph. In Figure 6, the transfer ability of the surrogate model is shown to be much worse than direct transferring.

6 Empirical evaluation

6.1 Overall performance

In this part, we compare the proposed algorithm KGTuner with six HP search algorithms in Table 2. For AutoNE, we allocate half budget for it to search on the subgraph and another half budget on the full graph with the transferred surrogate model. The baselines search in the full search space (in Table 1) with the same amount of budget as KGTuner. We use the mean reciprocal ranking (MRR, the larger the better) (Bordes et al., 2013) to indicate the performance.

Efficiency. We compare the different search algorithms in Figure 8 on an in-sample dataset WN18RR and an out-of-sample dataset ogbl-biokg. The time budget we set for WN18RR is one day's clock time, while that for ogbl-biokg is two days' clock time. For each dataset we show two kinds of figures. First, the best performance achieved along the clock time in one experiment on a specific model ComplEx. Second, we plot the the ranking of each algorithm averaged over all the models and datasets. Since AutoNE and KGTuner run on the subgraphs in the first stage, the starting points of them locate after 12 hours. The starting point of KGTuner is a bit later than AutoNE since it constrains to use large batch size and dimension size in the second stage, which is more expensive. As shown, random search is the worst. SMAC and RF+BORE achieve better performance than Hyperopt and Ax since RF can fit the space better than TPE and GP as in Section 4.2. Due to the weak transfer ability of the predictor (see Figure 6) and the weak approximation ability of GP (see Figure 3), AutoNE also performs bad. KGTuner is much better than all the baselines. We show the full search process of the two-stage algorithms AutoNE and KGTuner on WN18RR in Figure 9(a). By exploring sufficient number of configurations in the first stage, the configurations fine-tuned in the second stage can consistently achieve the best performance.

Effectiveness. For WN18RR and FB15k-237, we provide the reproduced results on TransE, ComplEx and ConvE with the original HPs, HPs searched by LibKGE and HPs searched by KGTuner in Table 3. The full results on the remaining four embedding models RotatE, RESCAL, DistMult and TuckER are in the Appendix D.2. Overall, KGTuner achieves better performance compared with both the original reported results and the reproduced results in (Ruffinelli et al., 2019). We observe that the tensor factorization models such as RESCAL, ComplEx and TuckER have better performance than the translational distance models TransE, RotatE and neural network model ConvE. This conforms with the theoretical analysis that tensor factorization models are more expressive (Wang et al., 2018).

Table 3: MRR of models with HPs tuned in different methods. The bold numbers mean the best performance of the same model.

source	models	WN18RR	FB15k-237
original	TransE	0.226	0.296
	ComplEx	0.440	0.247
	ConvE	0.430	0.325
LibKGE	TransE	0.228	0.313
	ComplEx	0.475	0.348
	ConvE	**0.442**	**0.339**
KGTuner	TransE	**0.233**	**0.327**
	ComplEx	**0.484**	**0.352**
	ConvE	0.437	0.335

To further demonstrate the advantage of KGTuner, we apply it to the Open Graph Benchmark (OGB) (Hu et al., 2020), which is a collection of realistic and large-scale benchmark datasets for machine learning on graphs. Many embedding models have been tested there by two large-scale KGs for link prediction, i.e., ogbl-biokg and ogbl-wikikg2. Due to their scale, the evaluation cost of a HP configuration is very expensive. We use KGTuner to search HPs for embedding models, i.e., TransE, RotatE, DistMult, ComplEx and AutoSF (Zhang et al., 2020a), on OGB. Since the computation costs of the two datasets are much higher, we set the time budget as 2 days for ogbl-biokg and 5 days for ogbl-wikikg2. All the embedding models evaluated here are constrained to have the same (or lower) number of model parameters[2]. More details on model parameters, standard derivation, and validation performance are in the Appendix D.3. As shown in Table 4, KGTuner consistently improves the performance of the four embedding models with the same or fewer parameters compared with the results on the OGB board.

Table 4: Performance in MRR in OGB link prediction board `https://ogb.stanford.edu/docs/leader_linkprop/` and those reproduced by KGTuner on ogbl-biokg and ogbl-wikikg2. Relative improvements are in parenthesize.

models		ogbl-biokg	ogbl-wikikg2
original	TransE	0.7452	0.4256
	RotatE	0.7989	0.2530
	DistMult	0.8043	0.3729
	ComplEx	0.8095	0.4027
	AutoSF	0.8320	0.5186
KGTuner	TransE	0.7781 (4.41%↑)	0.4739 (11.34%↑)
	RotatE	0.8013 (0.30%↑)	0.2944 (16.36%↑)
	DistMult	0.8241 (2.46%↑)	0.4837 (29.71%↑)
	ComplEx	0.8385 (3.58%↑)	0.4942 (22.72%↑)
	AutoSF	0.8354 (0.41%↑)	0.5222 (0.69%↑)
average improvement		2.23%	16.16%

6.2 Ablation study

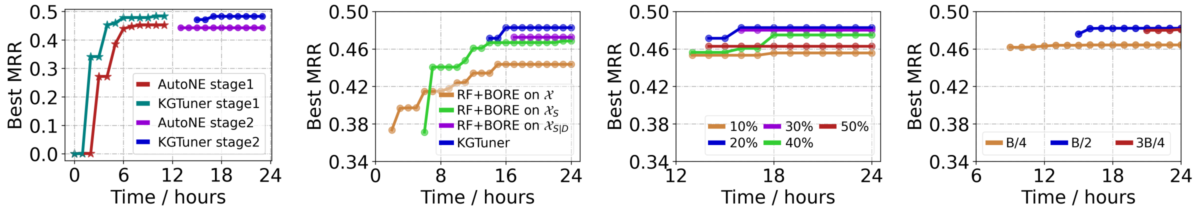
In this subsection, we probe into how important and sensitive the various components of KGTuner are.

Space comparison. To demonstrate the effectiveness gained by shrinking and decoupling the search space, we compare the following variants: (i) RF+BORE on the full space $\mathcal{X}$; (ii) RF+BORE on the shrunken space $\mathcal{X}_{\text{S}}$; (iii) RF+BORE on the decoupled space $\mathcal{X}_{\text{SID}}$, which differs from KGTuner by searching on the full graph in the first stage; and (iv) KGTuner in Algorithm 1. All the variants, i.e., RF+BORE, have one day's time budget. As in Figure 9(b), the size of search space matters for the search efficiency. The three components, i.e., space shrinkage, space decoupling, and fast evaluation on subgraph, are all important to the success of KGTuner.

Size of subgraphs. We show the influence of subgraph sizes with different ratios of entities (10%, 20%, 30%, 40%, 50%) from the full graph in Fig-

---

[2] We run all models on ogbl-wikikg2 with 100 dimension size to avoid out-of-memory, instead of 500 on OGB board.



(a) Full search processes (b) Search space (c) Subgraph size (d) First-stage budget

Figure 9: (a): full search processes of the two-stage algorithms. (b-d): ablation studies on KGTuner. Model ComplEx and dataset WN18RR are used in these experiments.

ure 9(c). Using subgraphs with too large or too small size is not guaranteed to find good configurations. Based on the understanding in Figure 7, the subgraph with small size have poor transfer ability and those with large size are expensive to evaluate. Hence, we should balance the transfer ability and evaluation cost by sampling subgraphs with $20\% \sim 30\%$ entities.

Budget allocation. In Algorithm 1, we allocate $B/2$ budget for both the first and second stage. Here, we show the performance of different allocation ratios, i.e., $B/4$, $B/2$, and $3B/4$ in the first stage and the remaining budget in the second stage. As in Figure 9(d), allocating too many or too few budgets to the first stage is not good. It either fails to explore sufficient configurations in the first stage or only fine-tunes a few configurations in the second stage. Allocating the same budget to the two stages is in a better trade-off.

7 Related works

In analyzing the performance of KG embedding models, Ruffinelli et al. (2019) pointed out that the earlier works in KG embedding only search HPs in small grids. By searching hundreds of HPs in a unified framework, the reproduced performance can be significantly improved. Similarly, Ali et al. (2020) proposed another unified framework to evaluate different models. Rossi et al. (2021) evaluated 16 different models and analyzed their properties on different datasets. All of these works emphasize the importance of HP search, but none of them provide efficient algorithms to search HPs for KG learning. AutoSF (Zhang et al., 2020a) evaluates the bilinear scoring functions and set up a search problem to design bilinear scoring functions, which can be complementary to KGTuner.

Understanding the HPs in a large search space is non-trivial since many HPs only have moderate impact on the model performance (Ruffinelli et al., 2019) and jointly evaluating them requires a large number of experiments (Fawcett and Hoos, 2016; Probst et al., 2019). Considering the huge amount of HP configurations (with 10^5 categorical choices and 5 continuous values), it is extremely expensive to exhaustively evaluate most of them. Hence, we adopt control variate experiments to efficiently evaluate HPs' properties instead of the quasi-random search in (Ruffinelli et al., 2019; Ali et al., 2020).

Technically, we are similar to AutoNE (Tu et al., 2019) and e-AutoGR (Wang et al., 2021) by leveraging subgraphs to improve search efficiency on graph learning. Since they do not target at KG embedding methods, directly adopt them is not a good choice. Besides, based on the understanding in this paper, we demonstrate that transferring the surrogate model from subgraph evaluation to the full graph is inferior to directly transferring the top configurations for KG embedding models.

8 Conclusion

In this paper, we analyze the HPs' properties in KG embedding models with search space size, validation curvature and evaluation cost. Based on the observations, we propose an efficient search algorithm KGTuner that efficiently explores configurations in a reduced space on small subgraph and then fine-tunes the top configurations with increased batch size and dimension size on the full graph. Empirical evaluations show that KGTuner is robuster and more efficient than the existing HP search algorithms and achieves competing performance on large-scale KGs in open graph benchmarks. In the future work, we will understand the HPs in graph neural network based models and apply KGTuner on them to solve the scaling limitations in HP search.

A Details of the search space

Denote a knowledge graph as $\mathcal{G} = \{E, R, D\}$, where E is the set of entities, R is the set of relations, and D is the set of triplets with training/validation/test splits $D = D_{\text{tra}} \cup D_{\text{val}} \cup D_{\text{tst}}$.

Basically, the KG embedding models use a scoring function f and the model parameters $\boldsymbol{P}$ to measure the plausibility of triplets. We learn the embeddings such that the positive and negative triplets can be separated by f and $\boldsymbol{P}$. In Table 5, we provide the forms f of the embedding model we used to evaluate the search space $\mathcal{X}$ in Section 3.

Table 5: Definitions of the embedding models. $\circ$ is a rotation operation in the complex value space; $\otimes$ is the Hermitian dot product in the complex value space; Re$(\cdot)$ returns the real part of a complex value; $\mathcal{W}_{i,j,k}$ is the ijk-th element in a core tensor $\mathcal{W} \in \mathbb{R}^{d \times d \times d}$; and conv is a convolution operator on the head and relation embeddings. For more details, please refer to the corresponding references.

A.1 Negative sampling

Since KG only contains positive triplets in D_{tra} (Wang et al., 2017), we should rely on the negative sampling to avoid trivial solutions of the embeddings. Given a positive triplet $(h, r, t) \in D_{\text{tra}}$, the corresponding set of negative triplets is represented as

$$D^-_{(h,r,t)} = \left\{(\tilde{h}, r, t) \notin D_{\text{tra}} : (h, r, t) \in D_{\text{tra}}, \tilde{h} \in E\right\} \cup \left\{(h, r, \tilde{t}) \notin D_{\text{tra}} : (h, r, t) \in D_{\text{tra}}, \tilde{t} \in E\right\}.$$

A common practice is to sample m negative triplets from $D^-_{(h,r,t)}$. The value of m can be any integer smaller than the number of entities. We follow (Sun et al., 2019) to sample from the range of m in $\{32, 128, 512, 2048\}$ for simplicity.

An alternative choice is to use all the negative triplets in $D^-_{(h,r,t)}$, leading to the `1VsAll` (Lacroix et al., 2018) and `kVsAll` (Dettmers et al., 2017) settings.

- In `1VsAll`, (h, r, t) is in the positive part and all the triplets in the set $\{(\tilde{h}, r, t) \notin D_{\text{tra}} : (h, r, t) \in D_{\text{tra}}, \tilde{h} \in E\}$ or $\{(h, r, \tilde{t}) \notin D_{\text{tra}} : (h, r, t) \in D_{\text{tra}}, \tilde{t} \in E\}$ are in the negative part;
- In `kVsAll`, the positive part contains all the triplets sharing the same head-relation pair or tail-relation part, i.e. $\{(h, r, t') \in D_{\text{tra}}\}$ or $\{(h', r, t) \in D_{\text{tra}}\}$, with the corresponding negative part $\{(h, r, \tilde{t}) \notin D_{\text{tra}} : (h, r, t) \in D_{\text{tra}}, \tilde{t} \in E\}$ or $\{(\tilde{h}, r, t) \notin D_{\text{tra}} : (h, r, t) \in D_{\text{tra}}, \tilde{h} \in E\}$.

Hence, the choice of negative sampling can be set in the range $\{32, 128, 512, 2048, \texttt{1VsAll}, \texttt{kVsAll}\}$.

A.2 Loss function

For simplicity, we denote D^+ and D^- as the sets of positive and negative triplets, respectively. Then, we summarize the commonly used loss functions as follows:

- Margin ranking (MR) loss. This loss ranks the positive triplets to have larger score than the negative triplets. Hence, the ranking loss is defined as

$$\mathcal{L} = \sum\nolimits_{(h,r,t) \in D^+} \sum\nolimits_{(\tilde{h},r,\tilde{t}) \in D^-} -\left|\gamma - f(h, r, t) + f(\tilde{h}, r, \tilde{t})\right|_+,$$

where $\gamma > 0$ is the margin value and $|a|_+ = \max(a, 0)$. The MR loss is widely used in early developed models, like TransE (Bordes et al., 2013) and DistMult (Yang et al., 2015). The value of γ, conditioned on MR loss, is another HP to search.

- Binary cross entropy (BCE) loss. It is typical to set the positive and negative triplets as a binary classification problem. Let the labels for the positive and negative triplets as $+1$ and -1 respectively, the BCE loss is defined as

  $$\mathcal{L} = \sum\nolimits_{(h,r,t)\in D^+} \log\left(\sigma(f(h,r,t))\right) + \sum\nolimits_{(\tilde{h},r,\tilde{t})\in D^-} w_{(\tilde{h},r,\tilde{t})} \log\left(1-\sigma(f(\tilde{h},r,\tilde{t}))\right),$$

  where $\sigma(x) = \frac{1}{1+\exp(-x)}$ is the sigmoid function. The choice of $w_{(\tilde{h},r,\tilde{t})}$ leads to three different loss functions

  - BCE_mean (Sun et al., 2019), with $w_{(\tilde{h},r,\tilde{t})} = {}^1\!/_{|D^-_{(h,r,t)}|}$.
  - BCE_sum (Dettmers et al., 2017), with $w_{(\tilde{h},r,\tilde{t})} = 1$.
  - BCE_adv (Sun et al., 2019), with

    $$w_{(\tilde{h},r,\tilde{t})} = \frac{\exp(\alpha \cdot f(\tilde{h},r,\tilde{t}))}{\sum_{(h',r,t')\in D^-} \exp(\alpha \cdot f(h',r,t'))},$$

    where $\alpha > 0$ is the adversarial weight conditioned on BCE_adv loss.

- Cross entropy (CE) loss. Since the number of negative triplets is fixed, we can also regard the (h, r, t) as the true label over the negative ones. The loss can be written as

  $$\mathcal{L} = \sum\nolimits_{(h,r,t)\in D^+} -f(h,r,t) + \log\left(\sum\nolimits_{(h',r,t')\in\{(h,r,t)\cup D^-\}} \exp(f(h',r,t'))\right),$$

  where the left part is the score of positive triplet and the right is the log sum scores of the joint set of positive and negative triplets.

A.3 Regularization

To avoid the embeddings increasing to unlimited values and reduce the model complexity, regularization techniques are often used. Denote $\boldsymbol{P}'$ as the embeddings participated in one iteration,

- the Frobenius norm is defined as the sum of L2 norms $r_{\text{FRO}} = \|\boldsymbol{P}'\|_2^2 = \sum_{ij} P'^2_{ij}$ (Yang et al., 2015);
- the NUC norm is defined as sum of L3 norms $r_{\text{FRO}} = \|\boldsymbol{P}'\|_3^3 = \sum_{ij} |P_{ij}|^3$ (Lacroix et al., 2018);
- DURA operates on triplets (Zhang et al., 2020b). Denote $\boldsymbol{h}, \boldsymbol{r}, \boldsymbol{t}$ as the embeddings for the triplet (h, r, t), DURA constrains the composition of $\boldsymbol{h}$ and $\boldsymbol{r}$ to approximate $\boldsymbol{t}$ with $r_{\text{DURA}} = \|c(\boldsymbol{h}, \boldsymbol{r}) - \boldsymbol{t}\|_2^2$, where the composition function $c(\boldsymbol{h}, \boldsymbol{r})$ depends on corresponding scoring functions.

The regularization functions are then weighted by the regularization weight in the range $[10^{-12}, 10^2]$.

Apart from using explicit forms of regularization, we can also add dropout on the embeddings (Dettmers et al., 2017). Specifically, each dimension in the embeddings $\boldsymbol{h}, \boldsymbol{r}, \boldsymbol{t}$ will have a probability to be deactivated as 0 in each iteration. The probability is controlled by the dropout rate in the range $[0, 0.5]$. In some cases, working without regularization can also achieve good performance (Ali et al., 2020).

A.4 Optimization

To solve the learning problem, we should setup an appropriate optimization procedure. First, we can directly use the training set or add inverse relations to augment the data (Kazemi and Poole, 2018; Lacroix et al., 2018). This will not influence the training data, but will introduce additional parameters for the inverse relations. Second, we should choose the dimension of embeddings in small sizes $[100, 200]$ or large sizes $[500, 1000, 2000]$. Then, the embeddings are initialized by the initialization methods such as uniform, normal, xavier_norm, and xavier_uniform (Goodfellow et al., 2016). The optimization is conducted with optimizers like standard SGD, Adam (Kingma and Ba, 2014) and Adagrad (Duchi et al., 2011) with learning rate in the range $[10^{-5}, 0]$ Since the training is conducted on mini-batch, a batch size is determined in the range $\{128, 256, 512, 1024\}$.

B Details of HP understanding

In this part, we provide the details of configuration generation and the full results related to the HP understanding.

B.1 Configure generation

Since there are infinite numbers of values for a continuous HP, it is intractable to fully evaluate their ranges. To better analyze the continuous HPs, we discretize them in Table 6 according to their ranges. Then, for each HP $i = 1 \dots n$ with range X_i, we sample a set $\mathcal{X}_i \subset \mathcal{X}$ of s anchor configurations through quasi random search (Bergstra and Bengio, 2012) and uniformly distribute them to evaluate the different embedding models and datasets.

Table 6: Discretized HP values.

name	original range	discretized range
gamma	[1, 24]	$\{1, 6, 12, 24\}$
adv. weight	[0.5, 2.0]	$\{0.5, 1, 2\}$
reg. weight	$[10^{-12}, 10^{2}]$	10^{2} in log scale
dropout rate	$[0, 0.5]$	0.1 in linear scale
learning rate	$[10^{-5}, 10^{0}]$	10^{1} in log scale

We use the control variate experiments to evaluate each HP. For the i-th HP, we enumerate the values $\theta \in X_i$ for each anchor configuration $\mathbf{x} \in \mathcal{X}_i$, while fix the other HPs. In this way, we can observe the influence of x_i without the influence of the other HPs. For example, when evaluating the optimizers, we enumerate the optimizers Adam, Adagrad and SGD for the anchor configurations in $\mathcal{X}_i$. This generates a set of $|\mathcal{X}_i| \cdot |X_i|$ configurations. In this paper, the number of anchor configurations $|\mathcal{X}_i|$ is 175 for each HP.

B.2 Details for search space understanding

In this part, we add the ranking distribution of all the HPs. In addition, we also show the normalized MRR of each HP as a complementary. The normalization is conducted on each dataset with $\frac{y - y_{\min}}{y_{\max} - y_{\min}}$ such that the results of the HPs can be evaluated in the same value range.

The full results for the four types of HPs in Section 4.1 are provided in Figures 10-13. The larger area in the bottom in the voilin plots and the top area in the box plots indicate better performance. The HPs can be classified into four types:

(a). *fixed choices*: Adam is the fixed optimizer, and inverse relation is not preferred. See Figure 10.

(b). *limited range*: Learning rate, regularization weight and dropout rate should be limited in the ranges $[10^{-4}, 10^{-1}]$, $[10^{-12}, 10^{-2}]$ and $[0, 0.3]$, respectively. See Figure 11

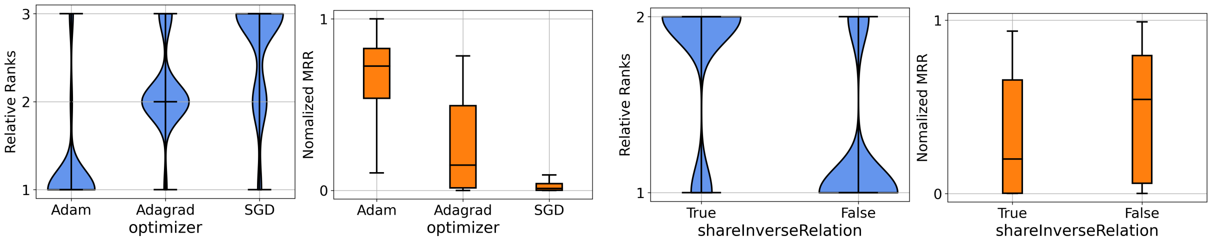
(c). *monotonously related*: Batch size and dimension size have monotonic performance. The larger value tends to lead better results. See Figure 12.

(d). *no obvious patterns*: The choice of loss function, value of gamma, adversarial weight, number of negative samples, regularizer, initializer do not have obvious patterns. See Figure 13.

In addition, we provide the details of Spearman's ranking correlation coefficient (`SRCC`). Given a set of anchor configurations $\mathcal{X}_i$ to analyze the i-th HP, we denote $r(\mathbf{x}, \theta)$ as the rank of different $\mathbf{x} \in \mathcal{X}_i$ with fixed $x_i = \theta$. Then, the `SRCC` between two HP values $\theta_1, \theta_2 \in X_i$ is

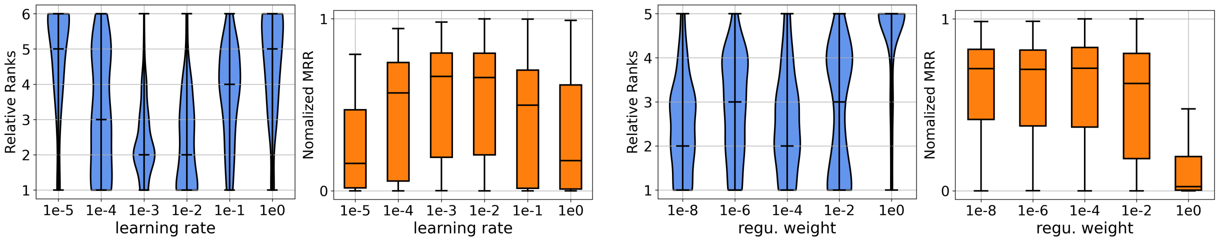
$$\texttt{SRCC}(\theta_1, \theta_2) = 1 - \frac{\sum_{\mathbf{x} \in \mathcal{X}_i} |r(\mathbf{x}, \theta_1) - r(\mathbf{x}, \theta_2)|^2}{|\mathcal{X}_i| \cdot (|\mathcal{X}_i|^2 - 1)}, \tag{5}$$

where $|\mathcal{X}_i|$ means the number of anchor configurations in $\mathcal{X}_i$. We evaluate the consistency of the i-th HP by averaging the `SRCC` over the different pairs of $(\theta_1, \theta_2) \in X_i \times X_i$, the different models and datasets.

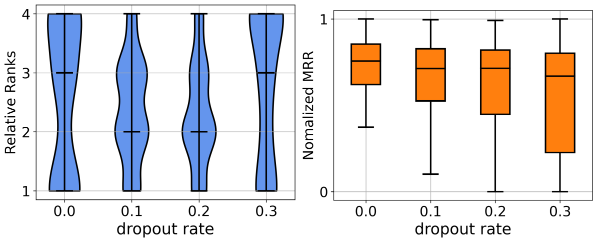


(a) optimizer (b) add inverse relation

Figure 10: HPs that have fixed choice since one configure has significant advantage.



(a) learning rate (b) reg. weight



(c) dropout rate

Figure 11: HPs that have limited ranges since they only perform well in certain ranges.

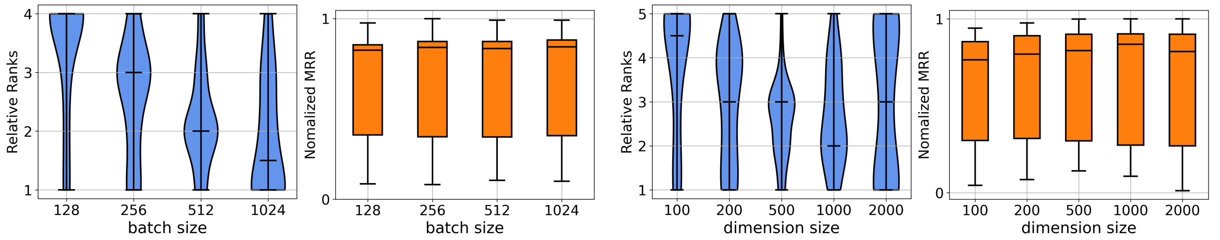
B.3 Approximation ability of surrogate models

In Section 4.2, we have shown that the curvature of a learned random forest (RF) model is more similar with the real curvature of the ground truth. Here, we further demonstrate this point through a synthetic experiment.

Specifically, 100 random configurations with evaluated performance are sampled. We use 10/20/30 random samples from them to train the surrogates since only a small number of HP configurations are available for the surrogate during searching. The remaining configurations are used for testing. Then, we evaluate the fitting ability of each model by the mean square error (MSE) of the estimated prediction to the target prediction. For GP (Rasmussen, 2003), we show the prediction with the Matern kernel used in AutoNE (Tu et al., 2019). For RF (Breiman, 2001), we build 200 tree estimators to fit the training samples. The MLP here (Gardner and Dorling, 1998) is designed as a three-layer feed-forward network with 100 hidden units and ReLU activation function in each layer. The average value and std of MSE over five different groups of configurations are shown in Table 7. As can been seen, random forest show much lower prediction error than GP and MLP with different number of training samples. This further demonstrates that RF can better fit such a complex HP search space.

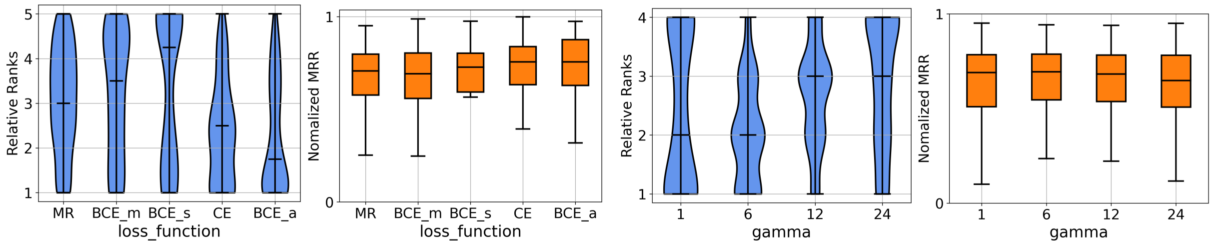
Table 7: Comparison of different surrogate models in MSE.

# train configurations	10	20	30
GP	0.0693±0.02	0.029±0.01	0.019±0.01
MLP	2.121±0.4	2.052±0.3	0.584±0.1
RF	**0.003±0.002**	**0.002±0.001**	**0.001±0.001**

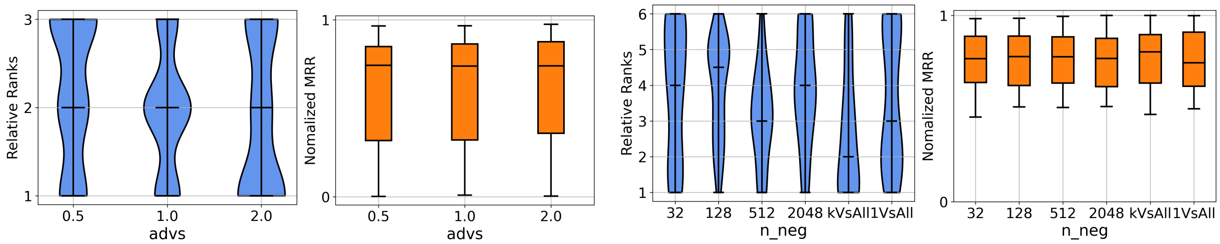


(a) batch_size (b) dimension

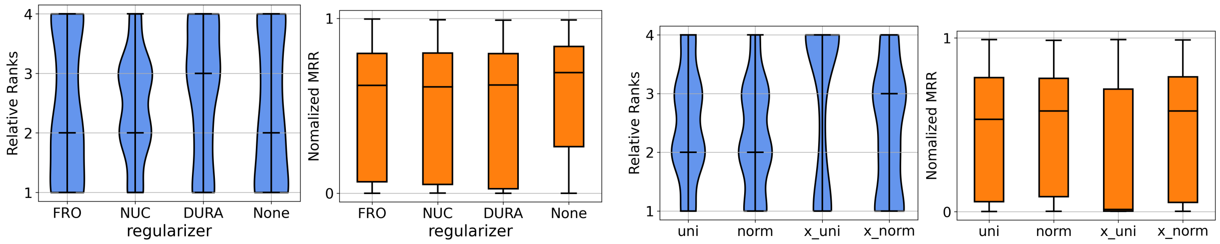
Figure 12: HPs that is monotonic with different choices of values.



(a) loss (b) gamma (MR)



(c) adv weight (BCE_adv) (d) # negative sample



(e) regularizer (f) initializer

Figure 13: HPs that do not have obvious patterns. All of the values should be searched.

B.4 Results of cost evaluation

We show the average cost and standard derivation of five HPs, i.e. batch size, dimension size, number of negative samples, loss functions, and regularizer, in Figure 14. As can be seen, the cost of batch size and dimension size increase much when the size increases. But for the number of negative samples, choices of loss functions and regularizers, the influence on cost is not strong as indicated by the average cost.

C Detail for the search algorithm

C.1 Search space

We show the shrunken and decoupled search space compared with the full space in Table 8. To evaluate the ratio of space change after shrinkage and decoupling, we measure the learning rate and regularization weight in log scale. The size of the whole space $\mathcal{X}$ compared with the decoupled $\mathcal{X}_{S|D}$ is

$$3 \times \frac{14}{6} \times \frac{5}{3} \times \frac{5}{3} \times 2 \times 4 \times 5 = 777.8.$$

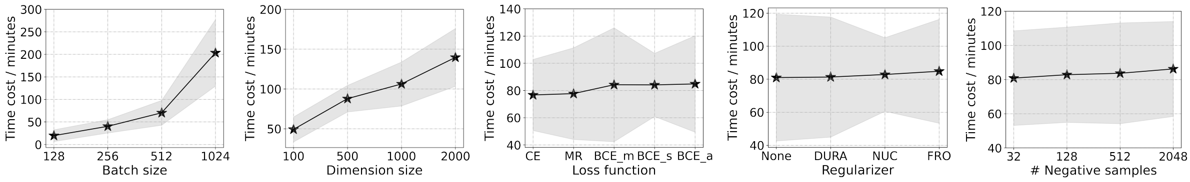


Figure 14: Computing time cost. The dots are the average and the shades are the standard deviation.

Hence, the reduced and decoupled space is hundreds times smaller than the full space.

Table 8: The revised HP values in the reduced and decoupled search space compared with the full space.

name	ranges in the whole space	revised ranges
optimizer	{Adam, Adagrad, SGD}	Adam
learning rate	$[10^{-5}, 10^{0}]$	$[10^{-4}, 10^{-1}]$
reg. weight	$[10^{-12}, 10^{2}]$	$[10^{-8}, 10^{-2}]$
dropout rate	[0, 0.5]	[0, 0.3]
inverse relation	{True, False}	{False}
batch size	{128, 256, 512, 1024}	128
dimension size	{100, 200, 500, 1000, 2000}	100

C.2 Search algorithm

We visualize the searching process of the traditional one-stage method and the proposed two-stage method in Figure 15. Since the evaluation cost on the full graph is rather high, the one-stage method can only take a few optimization trials. Thus the search space remains unexplored for a large proportion, and the performance of the optimal configuration is hard to be guaranteed. As for the proposed two-stage method KGTuner, it efficiently explores the search space on the sampled subgraph at the first stage, and then fine-tunes the top-K configurations on the full graph.

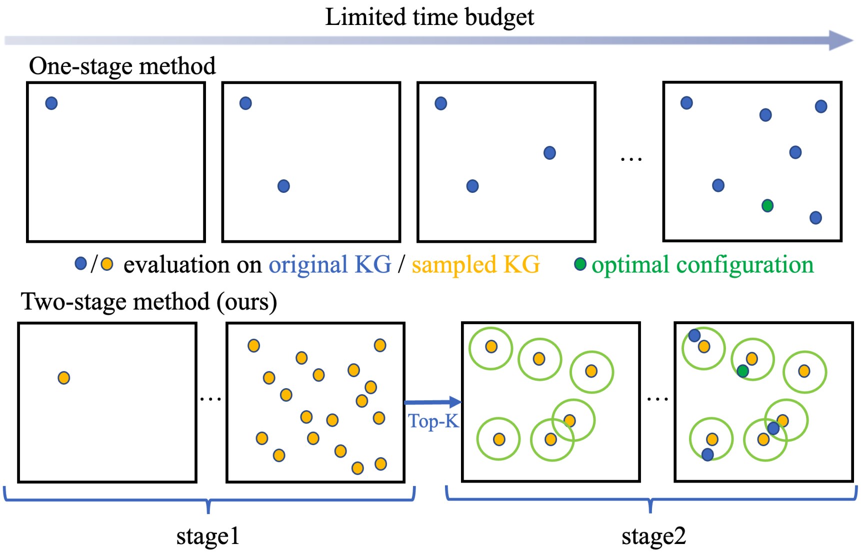

Figure 15: Diagram of one-stage search method and the proposed two-stage method.

In Algorithm 1, we increase the batch size and dimension size in stage two. We set the searched range for batch size in stage two as $[512, 1024]$ and dimension size as $[1000, 2000]$. There are some exceptions due to the memory issues, i.e., dimension size for RESCAL is in $[500, 1000]$; dimension size for TuckER is in $[200, 500]$. For ogbl-wikikg2, since the used GPU only has 24GB memory, we cannot run models with 500 dimensions which requires much more memory in the OGB board. Instead, we set the dimension as 100 to be consistent with the smaller models in OGB board with 100 dimensions, and increase the batch size in $[512, 1024]$ in the second stage. In addition, we show the details for the search procedure by RF+BORE in Algorithm 2.

Algorithm 2 Full procedure of HP search with RF+BORE (in stage one)

```
Require: KG embedding $F$, dataset $G$, search space $\mathcal{X}_{S|D}$, budget $B/2$, RF model $y = c(\mathbf{x})$, threshold $\tau = 0.8$.
initialize the RF model and $\mathcal{H} = \emptyset$;
split triplets in $G$ with ratio $9 : 1$ into $G_{\text{tra}}$ and $G_{\text{val}}$;
repeat
    randomly sample a set of configurations $\mathcal{X}_{\overline{S|D}} \subset \mathcal{X}_{S|D}$;
    select $\hat{\mathbf{x}} = \arg\max_{\mathbf{x} \in \mathcal{X}_{\overline{S|D}}} y(\mathbf{x})$;
    train embedding model into converge
    $\boldsymbol{P}^* = \arg\min_{\boldsymbol{P}} \mathcal{L}\big(F(\boldsymbol{P}, \hat{\mathbf{x}}), G_{\text{tra}}\big)$;
    evaluate the performance $\hat{y}_{\hat{\mathbf{x}}} = \mathcal{M}\big(F(\boldsymbol{P}^*, \hat{\mathbf{x}}), G_{\text{val}}\big)$;
    record $\mathcal{H} \leftarrow \mathcal{H} \cup \{(\hat{\mathbf{x}}, \hat{y}_{\hat{\mathbf{x}}})\}$;
    % BORE:
    set label 0 for configuration in $\mathcal{H}$ with $\hat{y}_{\hat{\mathbf{x}}} < \tau$, and label 1 for $\hat{y}_{\hat{\mathbf{x}}} \geq \tau$;
    update RF model $y = c(\mathbf{x})$ to classify the two labels;
until $B/2$ exhausted.
```

D Additional experimental results

D.1 Implementation details

Evaluation metrics. We follow (Bordes et al., 2013; Wang et al., 2017; Ruffinelli et al., 2019) to use the filtered ranking-based metrics for evaluation. For each triplet (h, r, t) in the validation or testing set, we take the head prediction $(?, r, t)$ and tail prediction $(h, r, ?)$ as the link prediction task. The filtered rankings on the head and tail are computed as

$$\text{rank}_h = \Big|\big\{e \in \mathcal{E} : \big(f(e, r, t) \geq f(h, r, t)\big) \wedge \big((e, r, t) \notin D_{\text{tra}} \cup D_{\text{val}} \cup D_{\text{tst}})\big)\big\}\Big| + 1,$$

$$\text{rank}_t = \Big|\big\{e \in \mathcal{E} : \big(f(h, r, t) \geq f(h, r, e)\big) \wedge \big((h, r, e) \notin D_{\text{tra}} \cup D_{\text{val}} \cup D_{\text{tst}})\big)\big\}\Big| + 1,$$

respectively, where $|\cdot|$ is the number of elements in the set. The the two metrics used are:

- Mean reciprocal ranking (MRR): the average of reciprocal of all the obtained rankings.
- Hit@k: the ratio of ranks no larger than k.

For both the metrics, the large value indicates the better performance.

Dataset statistics. We summarize the statistics of different benchmark datasets in Table 9. As shown, ogbl-biokg and ogbl-wikikg2 have much larger size compared with WN18RR and FB15k-237.

Table 9: Statistics of the KG completion datasets.

dataset	#entity	#relation	#train	#validate	#test
WN18RR (Dettmers et al., 2017)	41k	11	87k	3k	3k
FB15k-237 (Toutanova and Chen, 2015)	15k	237	272k	18k	20k
ogbl-biokg (Hu et al., 2020)	94k	51	4,763k	163k	163k
ogbl-wikikg2 (Hu et al., 2020)	2,500k	535	16,109k	429k	598k

Baseline implementation. All the baselines compared in this paper are based on their own original open-source implementations. Here we list the source links:

- Hyperopt (Bergstra et al., 2013), `https://github.com/hyperopt/hyperopt`;
- Ax, `https://github.com/facebook/Ax`;
- SMAC (Hutter et al., 2011), `https://github.com/automl/SMAC3`;
- BORE (Tiao et al., 2021), `https://github.com/ltiao/bore`;
- AutoNE (Tu et al., 2019), `https://github.com/tadpole/AutoNE`.

Searched hyperparameters. We list the searched hyperparameters for each embedding model on the different datasets in Tables 10-13 for reproduction.

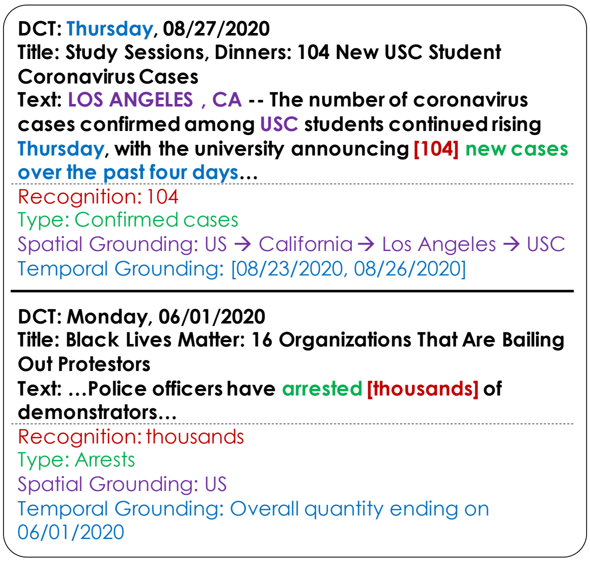
Abstract

News events are often associated with *quantities* (e.g., the number of COVID-19 patients or the number of arrests in a protest), and it is often important to extract their type, time, and location from unstructured text in order to analyze these quantity events. This paper thus formulates the NLP problem of spatiotemporal quantity extraction, and proposes the first meta-framework for solving it. This meta-framework contains a formalism that decomposes the problem into several information extraction tasks, a shareable crowdsourcing pipeline, and transformer-based baseline models. We demonstrate the meta-framework in three domains—the COVID-19 pandemic, Black Lives Matter protests, and 2020 California wildfires—to show that the formalism is general and extensible, the crowdsourcing pipeline facilitates fast and high-quality data annotation, and the baseline system can handle spatiotemporal quantity extraction well enough to be practically useful. We release all resources for future research on this topic.[1]



DCT: Thursday, 08/27/2020
Title: Study Sessions, Dinners: 104 New USC Student Coronavirus Cases
Text: LOS ANGELES , CA -- The number of coronavirus cases confirmed among USC students continued rising Thursday, with the university announcing [104] new cases over the past four days...
Recognition: 104
Type: Confirmed cases
Spatial Grounding: US → California → Los Angeles → USC
Temporal Grounding: [08/23/2020, 08/26/2020]

DCT: Monday, 06/01/2020
Title: Black Lives Matter: 16 Organizations That Are Bailing Out Protestors
Text: ...Police officers have arrested [thousands] of demonstrators...
Recognition: thousands
Type: Arrests
Spatial Grounding: US
Temporal Grounding: Overall quantity ending on 06/01/2020

Figure 1: Given document creation time (DCT), title, and text, the STEQE problem is to do quantity recognition, typing, spatial grounding, and temporal grounding according to the proposed formalism (Sec. 2). Above are two examples from our COVID-19 dataset and BLM protest dataset.

1 Introduction

Events are often associated with *quantities* – how many COVID-19 patients are on ventilators, how many people are injured during protests, or how large is the extent of a wildfire. We often need to figure out the type of an event, and where and when it happened for these quantities for coherent discussion of public policy on sociopolitical events in rapidly evolving situations: *"19 deaths"* is different from *"19 recoveries;" "19 deaths in a small city yesterday"* apparently describes a more severe situation than *"19 deaths in the whole country last month."* However, until dedicated channels are established, these quantities are typically first reported on social media and local news articles, which then have to slowly make their way to some aggregate location for decision-makers to use. This calls for a general framework to extract and analyze quantities associated with events, so that we can automatically summarize quantitative information from news streams, rapidly respond to emergencies, investigate incidents, and potentially combat misinformation through comparisons with trusted sources.

Prior work on *events* focused on extracting event mentions, attributes, and relationships (ACE, 2005; Chen and Ji, 2009; Do et al., 2011; UzZaman et al., 2013; Glavaš et al., 2014; Zhou et al., 2019; Chen et al., 2021), and paid little attention to quantities associated with those events, which presents an opportunity to perform targeted information extraction on these *quantity events*.

This paper studies spatiotemporal quantity extraction (STEQE): finding quantities of certain

types and extracting their associated times and locations. We develop a general meta-framework to help researchers overcome challenges and extend to new domains easily. Specifically, the contributions of this meta-framework are:

Task Formulation We draw on ideas from existing NLP tasks to create the first formalism that defines STEQE as four information extraction tasks: quantity recognition, typing, spatial grounding, and temporal grounding. While each of these has analogues in the literature, our combination of them into a complete picture of quantity events is novel.

Annotation Collection We release a shareable and extensible crowdsourcing pipeline on CROWDAQ (Ning et al., 2020a) that facilitates fast and reliable data annotation. We show how this pipeline facilitates fast and high-quality annotations for three sociopolitical events: the COVID-19 pandemic, Black Lives Matter (BLM) protests, and 2020 California wildfires. These practical STEQE datasets are also released to foster future research.

Modeling We propose a T5 baseline model for its flexibility across tasks and easy domain transfer. This model shows that, while the end-to-end STEQE problem remains challenging in all domains, temporal grounding is typically the most difficult task, pointing out a research focus next.

2 STEQE

The STEQE problem aims to extract information about quantity events in text, consisting of four parts: determining which numerical expressions actually correspond to events (§2.1), the type of the event that a quantity is referring to (§2.2), where that event happened (§2.3), and the temporal extent to which the quantity refers (§2.4).

Note that for each of these subparts, there could have been other definition and formulation choices. We describe our formalism's design choices, and discuss why they would lead to better-defined learning problems and more reliable data collection, along with their limitations and how to extend our formalism for more specialised applications.

2.1 Quantity Recognition

Similar to named entity recognition (NER) (Tjong Kim Sang and De Meulder, 2003), quantity recognition is defined as a text span detection problem. We discuss two questions regarding the definition of *quantities*: (1) how to distinguish between quantities and non-quantities; (2) how to define the span for quantities to avoid misalignment.

First, quantities are a special type of numbers that are associated with events, either in digits (e.g., *"123"*) or in words (e.g., *"one hundred twenty three"*). Some non-quantity examples are:

1. Date and time: *"May 8, 2020"* and *"5:30 pm"*
2. Duration: *"3 months"* and *"60 years old"*
3. Part of an entity name: *"COVID-19"*, *"Porsche 911"*, and *"502 Main Street"*

Article words, *"a"* and *"an"*, require more attention. When we say *"a man died,"* the *"a"* does mean *"1"* death, while in *"a large number of people died,"* the *"a"* itself does not have the meaning of *"1,"* and we thus do not consider it a quantity.

Ordinal numbers can also indicate events, but their spatiotemporal extent can be understood differently: *"the fifth case in Seattle"* implies that there had been 5 cases, and the spatiotemporal extent of *"fifth"* can be that of the fifth case only, or all of the five cases. Ordinal-number events are rare in our study, so comparing to the extra annotation requirement, we decide to consider ordinal numbers as non-quantities, although the definition is easily extensible to cover them in the future.

Second, we need to define the boundaries of these quantity spans. For instance, in *"five cases in Seattle,"* should one label the text span of *"five"* or *"five cases"*? What about *"4.8 billion"* and *"\$4.8 billion"*? Similar to labeling an event using its predicate only, our choice is to keep the span minimal while keeping the *numerical* semantics: we will mark *"five"* (i.e., drop *"case"*), *"4.8 billion"* (i.e., keep *"billion"*), and *"4.8 billion"* (i.e., drop *"\$"*) in these examples. Minimising the span does not lose information about the quantity—only marking *"five"* in *"five cases"* does not prevent us from identifying its type, unit, and spatiotemporal extent in subsequent annotation tasks. Below are some tricky cases, and quantities are in brackets.

1. Rate: *"[20 percent] of the tenants were infected"*, *"the positive rate is now [200] per [100,000]"*, *"[1000] tests per day"*
2. Approximation: *"[4 or 5] are missing"*
3. Range: *"the positive rate is [2 to 3 percent] / at least [2%] / at most [3%]"*

2.2 Quantity Typing

Again, similar to NER, recognized quantities can have an associated type from a predefined set of classes.[2] A clear event type is important for subsequent spatiotemporal grounding, but some quantities can have multiple types, and some can have multiple interpretations for their spatiotemporal extent. This work thus makes two design choices to mitigate these issues.

Enforce single-typing In this work, we allow quantities to have only one single type. This ensures annotation quality since multiple types for a single quantity may complicate the spatiotemporal extent. For instance, in *"[three] men were hospitalized 5 days after being tested positive,"* the time span of hospitalization and that of tested positive are different. We enforce single-typing by providing an *order* of importance. For instance, hospitalization is more important than tested positive, so the spatiotemporal extent of *"three"* will be that of hospitalizations.

Ignore rate and money quantities Rate and money quantities are excluded in all of our typing labels, because their spatiotemporal extent can be interpreted in different ways. For instance, the spatiotemporal extent of *"a bill of $4.8 billion"* can be interpreted either as when and where this bill was passed, or as when and where the bill will be used; similarly, to define the time span of the rate quantity *"[20%] of the tenants were infected"*, we can either use the time span from the very first case to the last case that brought the infection rate from 0% to 20%, or use the time span when the infection rate was holding at 20%. For applications where one needs to spatiotemporally ground rate and money quantities, one could extend our instructions to clarify the ambiguities above.

2.3 Spatial Grounding

The spatial grounding problem of STEQE is to ground real-world events to a locale (see Fig. 7 in Appendix), avoiding complications in applications like human-robot interactions (e.g., *"turn left and go to the kitchen, and then pick up the fruit on the table"*). Thus we do not need to handle the nuances of relative spatial relationships like *"the kitchen is on our left"* and *"the table is in the kitchen."* We describe our formalism in terms of the format, granularity, and multi-location handling.

Title: Six COVID-19 cases emerge in South Portland

Text: SOUTH PORTLAND, Maine -- A facility for people with cognitive disabilities reports having [six] COVID-19 cases...

Spatial grounding for [six]: US → Maine → South Portland → A facility for people with cognitive disabilities

Figure 2: The desired spatial grounding annotation is the most specific location mentioned in the text that contains all individual cases of a quantity event.

Format An important decision for spatial grounding is the *format*: we can use natural language to describe the locale, select text spans from the original text, or select from a map directory. In this work, we use a combination of all three for spatial grounding to balance between flexibility and consistency: we choose from a predefined set of questions to determine the country (U.S. vs non-U.S.) and state, use free text for the name of the city, and span selection for more granular locale information (e.g., *"a pork plant"*). We leave it for future work if one wants to extend to other countries, or if one can provide a detailed map directory.

Granularity We define spatial grounding annotation to be the most specific location mentioned in the text that contains all individual cases of a quantity event. For instance, in Fig. 2, the title mentions 6 cases in "South Portland," but later we will see that the 6 cases are all from "a facility for people with cognitive disabilities." The annotation should specify that facility instead of stopping at "South Portland." This design choice requires annotators to check the context in addition to the sentence containing the quantity, and is important for downstream tasks because it is likely that there are cases in South Portland but not in that facility.

Multi-location We handle events in multiple locations by broadening the granularity of the spatial location, as mentioned above. However, there are cases where the same quantity is explicitly mentioned with two or more separate locations:

1. *"Both Seattle and Tacoma had [10] new cases."*
2. *"Seattle and Tacoma together had more than [10] new cases."*

The *"10"* in both sentences above are associated with two cities, Seattle and Tacoma. The semantics are also different: being shared by two locales, or the events from both locales combine to make this quantity. In our pilot studies, we tried to consider

---

[2] The set of types in a STEQE problem will be domain-specific. We will explain the label set for typing for each of the 3 domains studied in this work later in §3.2.

these details in multi-location quantities, but found that they were very rare and crowd workers could not capture them reliably. We thus decide to ignore these cases in this work and only allow crowd workers to select a single location.

2.4 Temporal Grounding

The temporal grounding problem of STEQE is to ground each real-world quantity event to a single time span, which reduces the complexities in temporal semantics often encountered in prior datasets (Pustejovsky et al., 2003; Cassidy et al., 2014; O'Gorman et al., 2016; Ning et al., 2018a, 2020b) and improves practicality.

Format A time span consists of two time points, and the key is the format for time points. In this work, we allow a time point to be UNKNOWN if the text is unclear. For a specific time point, there are two general ways to describe it: (1) use absolute date and time (e.g., *"Feb 1st, 2021"*); (2) use relative time Δ based on a reference time point T (e.g., *"3 days before lockdown"*).

We have chosen the first format in this study, and when a time point is unclear based on the text, we allow annotators to simply select *"Unknown"*. The second method above is strictly more expressive, but also comes with many degrees of freedom: the reference point T can be either an absolute date and time T_{time} or another event T_{event} (e.g., *"lockdown"*), and the relative time difference Δ can be either a specific duration Δ_{spec} like *"3 days before/after"* or a rough description Δ_{rough} like *"a few days before/after."* In our pilot studies allowing for $T_{time} + \Delta_{rough}$, $T_{event} + \Delta_{spec}$, or $T_{event} + \Delta_{rough}$, we found the $T + \Delta$ method too flexible to achieve annotation agreement; in the meantime, using absolute date and time could reliably estimate those time spans in practice. This is why we recommend the first format above.

Granularity Given the nature of news events, it is often enough to be specific up to *days*. We define the time span of a quantity to be from the day of first event to the day of the last,[3] but this exact time span may not always exist in the text, so STEQE uses the best over-estimate of this gold time span based on information in the text (see Table 3).

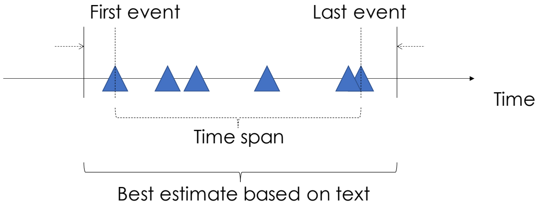

Figure 3: We define the time span of a quantity to start from the first event and end at the last; the desired temporal grounding annotation is the tightest estimate based on the text that covers all 6 events.

This work also addresses common ambiguities. (1) Some time expressions are not critical and thus less specific in text, e.g., *"March 2020,"* for which we will simply use the entire span of that range, e.g., [03/01/2020, 03/31/2020]. (2) For time expressions like *"mid September"* and *"end of 2020"*, we choose the closest dates, e.g., *"09/15"* and *"12/31/2020"*. (3) Depending on the actual publication date and the content of an article, there can be different interpretations for *"today,"* thus leading to a one-day disagreement among people regarding time expressions like *"yesterday"* or *"in the last three days."* We allow our annotators to use their best judgment in these cases.

Multi-span Similar to spatial grounding, we handle events in multiple time spans by broadening the granularity of the time span, as mentioned above, and as with spatial grounding, we do not label multiple time spans separately in rare cases like *"10 arrests on Monday and Wednesday."*

Overall quantity A special type of temporal grounding phenomenon is *overall quantities*. Strictly speaking, this notion exists for spatial grounding as well (e.g., the overall COVID-19 case number around the world or the U.S.). While humans easily agree on the spatial extent of these overall quantities, their time spans are often ambiguous, especially the start time. For instance, in *"there have been [3 million] cases so far,"* the start time is supposed to be *"the beginning of the pandemic,"* but people do not always agree on when that was. The disagreement comes from (1) the pandemic started at different times in different regions of the world; (2) one may argue that the pandemic started either since the first confirmed case, or since the lockdown. This debate over start-time is not an NLP problem, so instead of inventing a new mechanism to resolve this, we simply allow "overall" as a label for the start time of a quantity.

---

[3] If these events are durative, then accordingly, the time span should change to the day when the first event *started* to the day when the last event *ended*, although we did not find it necessary to point this out in our data collection guidelines for crowd workers.

Domain, DCT	Quantity	Type	Spatial Grd.	Temporal Grd.
COVID-19 Sat, 2020-08-15	*Tennessee has conducted 1,757,690 tests with 1,631,297 negative results.*	*Tested negative*	Tennessee	Overall number at DCT
Wildfires Tue, 2020-09-22	*The blaze had more than doubled in size over the past week to 170 square miles (440 square kilometers), ... from Los Angeles.*	*Measurements*	Los Angeles, California	2020-09-15 to 2020-09-22
BLM Protests Tue, 2020-06-16	*Black Lives Matter demonstrators in a tiny Ohio town...Sunday. The small demonstration has about 80 people, organized by local Bethel residents.*	*Participants*	Bethel, Ohio	2020-06-14 to 2020-06-14

Table 1: Example annotations with quantity span highlighted. Texts are truncated.

3 Data Annotation

We have walked through the definition of the tasks in our STEQE framework, with discussions on various design choices. Next we explain how to collect annotations via this framework in practice. Table 1 shows some example annotations from our datasets.

3.1 Input Document Filtering

We worked with NewsBreak Inc., a local news aggregation company, to obtain raw newswire texts from publicly available news outlets.[4] We then made use of NewsBreak's internal tools to determine the topic of these news articles, i.e., whether an article is about COVID-19, Black Lives Matter protests in 2020, or the 2020 California wildfires. The data also comes with meta information including each article's source domain and publication time. Altogether, we obtain 1M articles on COVID-19 between 01/01/2020 and 12/31/2020, 100k on protests from 05/22/2020 to 12/31/2020, and 90k on California fires from 08/01/2020 to 12/31/2020 as source articles.

3.2 Domain-specific Typing

Following the general guidelines in §2.2, we used the following domain-specific types in this study.

1. COVID-19 pandemic: deaths caused by COVID-19, deaths likely caused by COVID-19, recoveries, confirmed cases, tests, tested negative, hospitalizations, patients on ventilators, and in ICUs.
2. BLM protests: protests, participants, order maintainers, arrests, deaths, injuries, and shootings.
3. California fires: fires, physical measurements, people impacted, items impacted, and resources.

These domain-specific types can be very specific (see those for the COVID-19 pandemic) or generic (see those for California fires), which demonstrates the flexibility of our framework.

3.3 Shareable CROWDAQ Pipeline

CROWDAQ (Ning et al., 2020a) is an open-source platform that standardizes data annotation pipelines and provides a customizable annotation interface, automated annotator qualification exams, progress monitoring, and annotation agreement monitoring.[5] CROWDAQ pipelines have four components: instruction, tutorial, exam, and main task: an annotator will read the instruction and tutorial, and then work on a set of multiple-choice exam questions. CROWDAQ automatically checks their scores and assigns qualifications. Qualified annotators will then be able to work on the main task. For each of the four tasks defined in Sec. 2, we have designed CROWDAQ pipelines that are general enough to be used for annotating in all domains.[6] We release the CROWDAQ pipelines for public use.[7]

3.4 Data statistics

We first show statistics of our qualification exams in Table 2. We can see quantity recognition expectedly has the fewest hard questions and highest passing rate, and spatial and temporal grounding have more hard questions. Note that typing for California fires seems harder than typing for the other two domains, likely due to our choice of more generic types for California wildfires.

We then launched main annotation tasks on Amazon Mechanical Turk (MTurk) that were available

---

[5] `http://www.crowdaq.com/`

[6] The only change for a new domain is instructions and exams for quantity typing, which have to be domain-specific.

[7] Please see the description at `https://dev2.crowdaq.com/w/instruction/steqe/readme`.

Qual ID	Qual Name	Hard (%)	Passed (%)
$\mathcal{Q}$	Recognition	18	94
$\mathcal{SG}$	Sp. Grd.	47	62
$\mathcal{TG}$	Temp. Grd.	50	57
$\mathcal{T}$-C	Typing (COVID)	27	60
$\mathcal{T}$-B	Typing (BLM)	36	60
$\mathcal{T}$-F	Typing (Fire)	50	53

Table 2: The difficulty of the qualification exams in this work. **Hard**: exam questions where less than 70% attempts were correct. **Passed**: the ratio of passed in all attempts. See Table 5 in the appendix for more details.

only to qualified workers. We also required 3 different workers for each single annotation job and used majority voting to aggregate multiple workers' annotations. Since quantity recognition is a relatively easy task and our quantity recognition system based on BERT (Devlin et al., 2019) for the COVID domain was reliable enough to be applied to other domains, we did not further collect quantity recognition data. Table 3 and Table 6 (Appendix) show more statistics of these datasets.

Task	QID	#W	#Q	WAWA	Expert
Recog.					
- COVID	$\mathcal{Q}$	58	2.6k	92%	98%
Typing					
- COVID	$\mathcal{Q}$, $\mathcal{T}$-C	52	1.5k	95%	100%
- BLM	$\mathcal{Q}$, $\mathcal{T}$-B	74	4k	87%	94%
- Fire	$\mathcal{Q}$, $\mathcal{T}$-F	68	2k	91%	96%
Sp. Grd.					
- COVID	$\mathcal{T}$-C, $\mathcal{SG}$	91	3.4k	91%	98%
- BLM	$\mathcal{T}$-B, $\mathcal{SG}$	50	1.5k	80%	96%
- Fire	$\mathcal{T}$-F, $\mathcal{SG}$	63	2k	92%	90%
Temp. Grd.					
- COVID	$\mathcal{T}$-C, $\mathcal{TG}$	132	4.3k	86%	100%
- BLM	$\mathcal{T}$-B, $\mathcal{TG}$	57	1.6k	77%	96%
- Fire	$\mathcal{T}$-F, $\mathcal{TG}$	63	1.6k	82%	96%

Table 3: The required qualifications (QID), numbers of actual annotators (#W) and annotated quantities (#Q), worker agreement with aggregate (WAWA), and expert evaluation on 50 random samples after worker aggregation. The WAWA metric is for the "state" choice in spatial grounding, and the "overall number" judgment in temporal grounding (reported by CROWDAQ directly). The expert evaluation scores are all accuracy, except for F_1 for quantity recognition.

Note that we did not enforce full annotation for all quantities (i.e., one quantity may only receive typing annotations, and another may only receive spatial annotations) to cover more documents (Ning et al., 2019a). Within those reported in Table 3, 500 quantities in each domain are fully labeled with both typing and spatiotemporal extent, and we use these as our test sets.

We paid \$0.05 for each job in quantity recognition, and \$0.15 for those in typing, spatial grounding, and temporal grounding; in the COVID-19 data collection, the average hourly pay of the top 5 annotation contributors was \$25 (typing), \$13 (spatial grounding), and \$12 (temporal grounding). In total, the cost of 3 datasets was \$11k (including 20% overhead paid to MTurk).

We developed our CROWDAQ pipeline for COVID-19 and applied it on other domains. When we received news articles in BLM protests and California wildfires from NewsBreak Inc., it only took us about 2 weeks to obtain the annotations used in this work, including designing domain-specific typing instructions and exams, launching tasks to MTurk, and waiting for crowd workers to finish. This fast and reliable data collection is appealing for responding to emerging events in the future.

4 Model

Quantity recognition is a typical span selection problem and we use the standard token classification model based on BERT (large, cased) (Devlin et al., 2019) that comes with HuggingFace (Wolf et al., 2020). For typing, spatial, and temporal grounding, we use the T5-large language model (Raffel et al., 2020) for its flexibility across tasks and easy domain transfer. We format data from each task to fit into T5's sequence to sequence (seq-to-seq) nature. Specifically, for each quantity, the input sequence to T5 is the string of the previous 3 sentences, the current sentence with a special marker token right before the quantity span, the next 3 sentences, the title, and document creation time (DCT). For typing, the output sequence is a single token representing each label mapped from a reserved vocabulary. For spatial grounding, the output sequence is the location names from the highest hierarchy to the lowest ended by an end-of-sentence (EOS) marker. For temporal grounding, the output sequence is the start time followed by the end time. Both times are either *"unknown"* or a date string in ISO 8601 format (e.g., *"2021-01-15"*). We view the start time of an overall quantity as *"unknown"*. To get complete date predictions, we enforce the decoding length to be at least 12 and use a date parser to find *"unknowns"* or dates.

System	Task	Typing	Spatial Grounding		Temporal Grounding			End-to-end
		Acc	EM-city	EM-state	Binary	S-N	E-N	EM-city, Binary
Naive	COVID	44	68	84	68	0	24	3
	BLM	38	74	82	32	0	32	0
	Fire	27	58	92	86	0	31	20
T5 (in-domain)	COVID	89	81	90	74	53	52	**56**
	BLM	89	77	89	57	49	43	41
	Fire	87	70	94	**83**	1	32	**55**
T5 (all domains)	COVID	89	81	**91**	74	**54**	**57**	55
	BLM	89	**80**	**91**	**65**	**62**	**57**	**48**
	Fire	87	**71**	94	76	**46**	**61**	52

Table 4: System performances on typing, spatial grounding, and temporal grounding (averaged from 3 different runs). **EM-city/-state**: exact match scores up to the city-/state-level. **Binary**: judging if a quantity is an overall-quantity ending on DCT. **S-N/E-N**: EM scores when the start/end time is non-trivial. **End-to-end**: quantities receiving correct predictions on all steps based on "EM-city" (spatial) and "Binary" (temporal). **T5 (all domains)** uses the same typing systems trained in-domain, but combine the spatiotemporal grounding data from all domains in training. **Bold** values are best results with respect to each domains and metrics.

5 Experiments

In our evaluation of **quantity recognition** using the aforementioned BERT model on a random set of 300 sentences (100 from each domain), we find the precision 99% for all domains, and the recall 95% (COVID), 87% (BLM), and 87% (Fire). The recall is slightly lower because of poor performance on article words (*"a"* and *"an"*). However, since most missed quantities are not associated with event types that we are interested in (e.g., *"[a] post office"* or *"[a] comment"*), the adjusted recall is 98% (COVID), 94% (BLM), and 93% (Fire) if we do not consider those irrelevant quantities.

Table 4 shows system performances on **typing**, **spatial**, and **temporal grounding** on extracted quantities. Our test set in each domain consists of 500 fully annotated quantities. The rest of the data is split into 80% for training and 20% for development, that we use to acquire the learning rate (5e-3) and batch size (32). We compare T5 with a naive method, which always predicts the majority type in each domain for "typing," the location mention closest to the quantity in text for "spatial grounding,"[8] and overall quantity ending on DCT for "temporal grounding." For **spatial grounding**, we report two exact match (EM) scores, up to the state-level and city-level, respectively. For **temporal grounding**, we report the accuracy for judging whether a quantity is *an overall quantity ending on DCT* ("Binary" in Table 4), and two EM scores for cases where the gold start time is a specific date ("S-N" for "Start-Nontrivial") and where the end time is not DCT ("E-N" for "End-Nontrivial").

T5 (in-domain) On quantity typing, T5 improves by a large margin over the naive baseline in all domains. The naive baseline performs reasonably well on spatial grounding at the state level (82-92% EM-state across three domains), but often fails to provide more granular information at the city level (58-74% EM-city). This is expected because a city mentioned close to the quantity does not necessarily mean that the quantity is for the city.[9] This phenomenon also varies across domains: BLM protests were in a few major cities, the EM-city score of the naive method is thus relatively high (74%), while for Calfornia wildfires, there were more cities to choose from, leading to a low EM-city of 58%. In contrast, T5 can produce more granular information at the city level, and maintain a relatively stable score across domains (70-81% EM-city). As for temporal grounding, due to the nature of news articles, the naive baseline that treats all quantities as an overall quantity ending on DCT yields reasonably good performances in all domains; but for quantities with a non-trivial start time or end time, the naive baseline largely fails.

T5 (all domains) We also combine the training data for spatiotemporal grounding from all domains and train a single T5 system (but keep T5 in-domain systems for typing), which achieves the best scores for almost all metrics in Table 4. One outlier is the Fire domain, where the Binary score

---

[8] This assumes world knowledge of geo-hierarchies, e.g., "L.A." is in California.

[9] *"The State Department of Public Health in Springfield reports a total case of [268]."* is a quantity for the state.

for temporal grounding drop, probably due to most temporal annotations being overall quantities. This suggests that spatiotemporal phenomena can be generally transferred across different domains.

Finally, the **end-to-end** column in Table 4 shows how many of these quantities have received correct predictions on typing, spatial grounding (based EM-city), and temporal grounding (based on "Binary"). The reported performance does not count for quantities that are not recognized, so we view this as the precision of the system. We see that the naive baseline has very low performance due to errors propagated at each step, while with this framework, T5 is trained to produce significantly better results. Note that depending on the use case, one can simply collect more training data, or focus on only a few important event types, to further improve the end-to-end performance.

6 Related works

Existing NLP works on events have focused on detection (e.g., detecting LIFE and BUSINESS events; ACE (2005)), common sense (e.g., Rashkin et al. (2018); Sap et al. (2019); Zhang et al. (2020a)), and relationships (e.g., coreferential Chen and Ji (2009), temporal UzZaman et al. (2013), causal Do et al. (2011), and parent-child relations Glavaš et al. (2014)). There is also a line of recent works specifically on temporal semantics: time expression extraction and normalization (Laparra et al., 2018), temporal relation extraction (Ning et al., 2018a, 2019b, 2020b), temporal common sense (Zhou et al., 2019, 2020), temoral slot filling (Surdeanu, 2013), and timeline construction (Do et al., 2012; Ning et al., 2018b; Li et al., 2019). These tasks may help understanding the temporal aspects of events in general, but they cannot directly associate temporal values with quantities, and calls for a dedicated framework such as STEQE. Prior works on *quantities* either focus on math calculations (Roy et al., 2015; Roy and Roth, 2018) or common sense reasoning (e.g., mass distribution of animals; Elazar et al. (2019)), and not on *quantity events* and the associated spatiotemporal extent studied in this work.

Existing works on spatial semantics have focused on natural language navigation (Chen et al., 2019; Kim et al., 2020), human-machine interaction (Landsiedel et al., 2017; Roman Roman et al., 2020), dialogue systems (Udagawa et al., 2020), and clinical analysis (Kordjamshidi et al., 2015; Datta and Roberts, 2020). Works on geocoding (Gritta et al., 2018; Kulkarni et al., 2020) map spatial mentions to coordinates, which can be applied to our work for finer geolocation mapping. Zhang and Choi (2021) proposes a QA dataset that considers time and location of the question when judging answer correctness, which may benefit from our information extraction framework.

A recent work from Zong et al. (2020), which extracts COVID-19 related events from tweets, is closely related to our work. Besides that they worked on tweets instead of news articles, the key differences are: (1) instead of span selection used in Zong et al. (2020), we propose formalisms deeper into the spatiotemporal extent of quantity events and capture more nuances in spatiotemporal semantics; (2) we show that our STEQE framework generally applies to multiple domains and not only for the COVID-19 pandemic; (3) we release our entire data collection pipeline on CROWDAQ for public use and extension.

7 Discussion

As §5 shows, the performance bottleneck of STEQE is mainly at temporal grounding: with almost perfect quantity recognition and very good typing and spatial grounding results, temporal grounding performance is typically much lower than the other tasks. While typing and spatial grounding are ready for practical research into few- and zero-shot settings along the lines of what is done in entity typing (Zhou et al., 2018; Obeidat et al., 2019; Zhang et al., 2020b), temporal grounding still requires more investigation even in in-domain settings.

Why is temporal grounding so challenging? First, news articles tend to mention many overall quantities ending on publication time, leading to imbalanced datasets. For instance, 86% in Fire fall into this category, leaving little training data for other quantities; in contrast, this number is only 32% in BLM, and the S-N and E-N scores are much higher in BLM than those in Fire. Second, temporal grounding often requires reasoning, an effect known to be difficult in many works on temporal semantics (Ning et al., 2020b; Zhou et al., 2021). For instance in Fig. 4, to figure out the time span of *"80,"* we need to understand that (1) it happened on *"Sunday"* (2) the *"Sunday"* is a Sunday in the past instead of in the future, and (3) it is most likely the most recent Sunday instead of earlier ones.

DCT: Tuesday, 06/16/2020
Text: Black Lives Matter demonstrators in a tiny Ohio town...Sunday. The small demonstration has about [80] people, organized by local Bethel residents.

Figure 4: The start time of *"80"* needs reasoning.

Another direction to improve on STEQE is to aggregate from multiple articles, given that the same quantity or similar quantities are typically covered by multiple sources. Cross-document event coreference has many unique difficulties (e.g., see Upadhyay et al. (2016); Bugert et al. (2020)), but knowing the quantity event type, location, and time span may make it relatively easy to find coreference to strengthen one's belief in its prediction, or demote outliers that are likely wrong predictions.

The proposed STEQE framework may also be used to detect misinformation and perhaps in social science studies too. For instance, we have anecdotes where a website mistakenly reported Virginia's COVID-19 case number on Apr 2, 2020 to be 17k, while the correct number was 1.7k; we also found signs that news agencies might have mentioned case numbers in New York city less frequently after a sharp increase, but turned to report case numbers in New Jersey in April 2020. These social science analyses are beyond the scope of this work, but the examples above point to interesting potential uses of these information extraction systems.

8 Conclusion

Many important news events are associated with quantities. With practicality in mind, we dive deep into the semantics of quantity events and propose a meta-framework for spatiotemporal quantity extraction: we formulate the problem as four information extraction tasks which lead to quick and reliable data annotation via crowdsourcing; we also build a T5 baseline to study the difficulties of the task and discuss transfer learning opportunities. We use this meta-framework to build datasets on three separate sociopolitical events: the COVID-19 pandemic, BLM protests, and California fires. Our meta-framework is shown to be readily extensible to different domains of quantity events, an appealing feature for quick response to future events. The new datasets we collect as examples of this framework can also directly contribute to future studies on spatiotemporal quantity extraction.

A Qualification setups

Note that exams for quantity recognition, spatial & temporal grounding are domain-agnostic, and exams for quantity typing are domain-specific. The way exams work on Crowdaq is that we provide a pool of questions and Crowdaq will randomly select a specified number of them. We also do not allow a crowd worker to make too many attempts. Table 5 shows the setup and statistics of those exams.

Crowdaq provides diagnostic information on each question too. In Table 5, we also show the number of questions where less than 70% examinees were correct (i.e., "Hard"). The total number of attempts in each exam and how many of them got scores higher than the passing score are also reported.

Qual ID	Qual Name	Question Pool		Crowdaq Configuration			Workers' Performance	
		#Total	#Hard	#Questions	#Attempts	Passing Grade	#Attempts	#Succeeded
$\mathcal{Q}$	Recognition	11	2	10	3	90	952	895
$\mathcal{SG}$	Spa. Grd.	17	8	12	3	90	1454	897
$\mathcal{TG}$	Temp. Grd.	12	6	10	3	90	1180	674
$\mathcal{T}$-C	Typing-COVID	11	3	10	3	90	1156	698
$\mathcal{T}$-B	Typing-BLM	11	4	8	3	85	760	457
$\mathcal{T}$-F	Typing-Fire	14	7	12	3	90	905	476

Table 5: The qualification exam setups in this study. **Question Pool**: All the questions we provided to Crowdaq; hard questions are those where less than 70% attempts were correct. **Crowdaq Configuration**: #questions to display each time, #attempts allowed, and the required passing grade. **Workers' Performance**: the total number of attempts and succeeded.

B Corpus statistics

Table 6 shows a more complete version of our earlier Table 3. The extra columns are the total number of qualified workers for each task, the Gini index, and the total number of sentences/documents annotated here. Gini is a metric proposed by TORQUE (Ning et al., 2020b) to measure the skewness of crowdsourcing data collection. Our Gini is significantly higher and we think the reason is that many crowd workers only attempted a couple our HITs. Regarding the definition of WAWA, we realize that Ning et al. (2020b) has provided a very good explanation about it; please refer to the appendix E of Ning et al. (2020b) about it.

Task	Worker Pool				Size			Quality	
	Req. Qual ID(s)	#Qualified	#Actual	Gini	#Quant.	#Sent.	#Doc.	WAWA	Expert
Typ-COVID	$\mathcal{Q}$, $\mathcal{T}$-C	299	52	0.74	1.5k	1.5k	1.3k	95%	100%
Typ-BLM	$\mathcal{Q}$, $\mathcal{T}$-B	291	74	0.53	4k	3.9k	3k	87%	94%
Typ-Fire	$\mathcal{Q}$, $\mathcal{T}$-F	231	68	0.62	2k	2k	1.4k	91%	96%
Spa-COVID	$\mathcal{T}$-C, $\mathcal{SG}$	258	91	0.74	3.4k	3.3k	2.9k	91%	98%
Spa-BLM	$\mathcal{T}$-B, $\mathcal{SG}$	141	50	0.68	1.5k	1.5k	1.2k	80%	96%
Spa-Fire	$\mathcal{T}$-F, $\mathcal{SG}$	160	63	0.71	2k	2k	1.3k	92%	90%
Temp-COVID	$\mathcal{T}$-C, $\mathcal{TG}$	399	132	0.81	4.3k	4.2k	3.5k	86%	100%
Temp-BLM	$\mathcal{T}$-B, $\mathcal{TG}$	190	57	0.71	1.6k	1.6k	1.2k	77%	96%
Temp-Fire	$\mathcal{T}$-F, $\mathcal{TG}$	215	63	0.74	1.6k	1.6k	1.1k	82%	96%

Table 6: Corpus statistics. The required qualifications (QID), numbers of actual annotators (#W) and annotated quantities (#Q), worker agreement with aggregate (WAWA), and expert evaluation on 50 random samples after worker aggregation. The WAWA metric is for the "state" choice in spatial grounding, and the "overall number" judgment in temporal grounding (reported by Crowdaq directly). The expert evaluation scores are all accuracy, except for F_1 for quantity recognition.

C Example annotations

Figure 7 shows two examples in each of the three domains in this study.

Domain, DCT	Quantity	Type	Spatial Grd.	Temporal Grd.
COVID-19 Sat, 2020-08-15	*Tennessee has conducted 1,757,690 tests with 1,631,297 negative results .*	*Test performed for COVID-19: result is negative*	US, Tennessee	Overall number ends at DCT
COVID-19 Wed, 2020-08-12	*Wyandotte County is reporting 4,895 confirmed cases...The county said on Tuesday that 99 people have died from the coronavirus since the start of the outbreak*	*Deaths: definitely caused by COVID-19*	US, Kansas, Wyandotte County	Overall number ends on 2020-08-11
Wildfires Mon, 2020-09-14	*...large fires across 10 states...At least 35 people have died in California , Oregon and Washington.*	*People impacted*	US	Overall number ends at DCT
Wildfires Tue, 2020-09-22	*The blaze had more than doubled in size over the past week to 170 square miles (440 square kilometers), ... from Los Angeles.*	*Physical measurements*	US, California, Los Angeles	2020-09-15 to 2020-09-22
Protests Tue, 2020-06-16	*Black Lives Matter demonstrators in a tiny Ohio town...Sunday. The small demonstration has about 80 people, organized by local Bethel residents.*	*Number of participants in protests or relevant activities*	US, Ohio, Bethel	2020-06-14 to 2020-06-14
Protests Sun, 2020-05-31	*A CNN analysis found about 80% of the 51 people booked into a Minneapolis jail during two days of protests are actually from Minnesota .*	*Number of arrests due to the protests or following skirmishes*	US, Minnesota, Minneapolis	unknown

Table 7: Example annotations of quantity typing, spatial grounding, and temporal grounding across three domains. Quantity span is highlighted. Text snippets are cut short to only keep the sentence with the quantity and other relevant information.

D Reproducibility

For T5-based experiments related to model performances in Table 4, we choose the learning rate from [5e-2, 5e-3, 5e-4] and select 5e-3 for final experiments. We use a batch size of 32 and run 20 epochs for each setting. All parameters are tuned on the development set as described in §5. Experiments on average finish in 3 hours on a single Nvidia RTX 8000 GPU. Spatial and temporal results are averaged from 3 runs with seeds [10, 20, 30].

Leveraging Visual Knowledge in Language Tasks: An Empirical Study on Intermediate Pre-training for Cross-modal Knowledge Transfer

Abstract

Pre-trained language models are still far from human performance in tasks that need understanding of properties (e.g. appearance, measurable quantity) and affordances of everyday objects in the real world since the text lacks such information due to reporting bias. In this work, we study whether integrating visual knowledge into a language model can fill the gap. We investigate two types of knowledge transfer: (1) *text knowledge transfer* using image captions that may contain enriched visual knowledge and (2) *cross-modal knowledge transfer* using both images and captions with vision-language training objectives. On 5 downstream tasks that may need visual knowledge to solve the problem, we perform extensive empirical comparisons over the presented objectives. Our experiments show that visual knowledge transfer can improve performance in both low-resource and fully supervised settings. [1]

1 Introduction

Pre-trained language models (PTLMs) such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and T5 (Raffel et al., 2020) have shown impressive results in various conventional natural language understanding (NLU) tasks by capturing syntactic and semantic knowledge from the pre-training tasks of *masked language modeling* and *masked span infilling* tasks on massive text corpora.

Though yielding good performance on various NLU downstream tasks, these pre-training objectives suffer from a lack of out-of-domain knowledge that is not explicitly present in the pre-training corpus (Gururangan et al., 2020a; Petroni et al., 2021; Schick and Schütze, 2020). Specifically, one type of knowledge that models often struggle with is the visual knowledge of common objects such as attributes (e.g. appearance, measurable quantity) and affordances. This is because this kind of knowledge is rarely explicitly described in the training text due to reporting bias. For example, as shown in Figure 1, people tend to report what interests them rather than general facts such as a shape or color of oranges they already know.

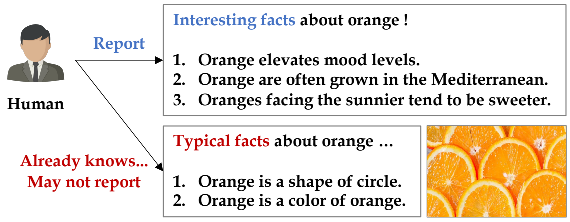

Figure 1: **Reporting Bias.** People tend to report what interests them rather than typical and general facts.

Towards better knowledge-enhanced PTLMs, recent works incorporate external knowledge bases (e.g., knowledge graph, dictionary) to inject entity knowledge into PTLMs (Zhang et al., 2019; Peters et al., 2019; Wang et al., 2021; Yu et al., 2021) or retrieve knowledge from external knowledge bases to solve the problem (Lin et al., 2019; Wang et al., 2020). However, these approaches still suffer from a lack of visual knowledge that is important to understand the real world.

In this paper, we conduct systematic experiments to understand whether such visual knowledge can be transferred into LMs, and if so, how to perform effective knowledge transfer. Specifically, we look into a series of analysis question as follows: (1) Can intermediate pre-training (Pruksachatkun et al., 2020a) on image-caption pairs help transfer the knowledge? (2) What types of knowledge sources are more helpful? To answer questions, we explore various intermediate pre-training tasks (Pruksachatkun et al., 2020a) on two different sources: text-only (*text knowledge transfer* from visual domains) and image-caption pairs (*cross-modal knowledge transfer*).

For the text knowledge transfer, we utilize text

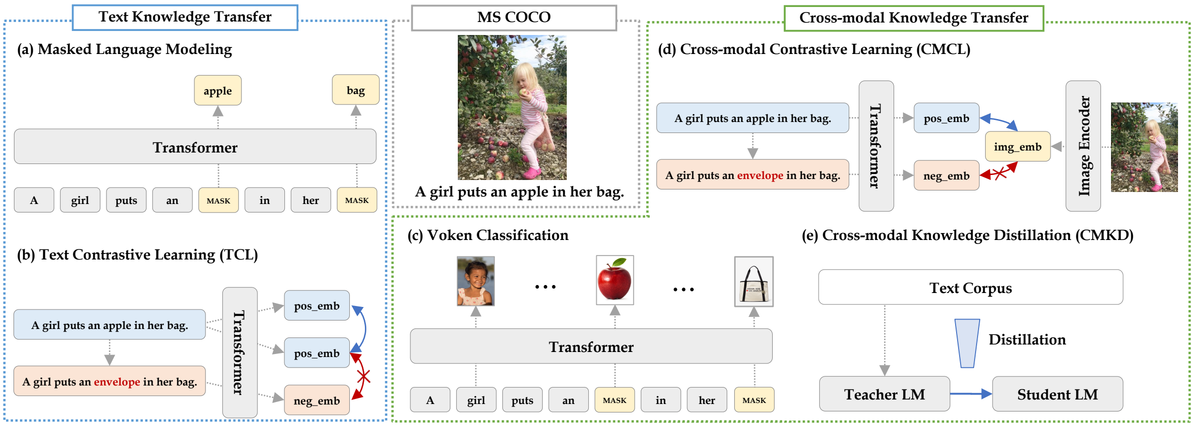

Figure 2: **Illustration of different methods for transferring visual knowledge into transformer-based language model.** In this example, we assume image-caption pair as an input. (a) *masked language model* (Devlin et al., 2019) on image captions. (b) *text contrastive learning* obtains positive example by dropout representation to learn better sentence representation while negative augmentation is optional. (c) *voken classification* employs token-level text-to-image retrieval to transfer visual knowledge. (d) *cross-modal contrastive learning* aims to train correct paring of images and captions. (e) *cross-modal knowledge distillation* transfers knowledge from the teacher model, which is trained by cross-modal contrastive learning, into student model.

corpus from visual domain, e.g., image captions. We leverage two training objectives for the language model: (1) *masked language modeling* follows the domain adaptive pre-training scheme (Gururangan et al., 2020a), assuming the corpus contains enriched visual knowledge or physical commonsense knowledge; (2) *text contrastive learning* augments the sentence representation with dropout to create positive samples while considering all others in the batch as negative samples for the contrastive learning (Gao et al., 2021), assuming training better sentence representations leads to better understanding of the corpus.

For the cross-modal knowledge transfer, we explore multiple methods to transfer visual-related knowledge to LMs: (1) *masked language modeling with visual clues* incorporates visual clues to capture dependencies between visual and linguistic contents (Su et al., 2020); (2) *voken classification* contextually aligns language tokens to their related images (called "vokens") to transfer visual knowledge into LMs (Tan and Bansal, 2020); (3) *cross-modal contrastive learning* aims to improve text representations by maximizing the agreement between correct image-text pairs versus random (in-batch) and adversarial negative pairs by contrastive learning between image and text modalities; and (4) *cross-modal knowledge distillation* transfers the knowledge from the teacher model, which is trained by cross-modal contrastive learning on image and text modalities, to the student language model using knowledge distillation.

We perform comprehensive comparisons on five downstream tasks that may require visual or physical commonsense knowledge, including PIQA (Bisk et al., 2020), Visual Paraphrasing (VP) (Lin and Parikh, 2015), CSQA (Talmor et al., 2019), OBQA (Mihaylov et al., 2018), and RiddleSense (Lin et al., 2021). Results suggest that: (1) Simple intermediate pre-training on captions can help improving performance on commonsense reasoning that needs physical or visual knowledge. (2) Cross-modal knowledge transfer approaches consistently improve the performance in a large margin when only few train examples are available. (3) Cross-modal contrastive learning shows that it is best for packaging visual knowledge into LMs.

2 Analysis Setup

In this work, we study how to transfer the visual knowledge into language models. For this study, we introduce our analysis setup: problem formulation, analysis questions, and knowledge corpora.

2.1 Problem Formulation

We focus on a pre-trained text encoder f_L and an image encoder f_V if images are available. f_L and f_V are initialized with pre-trained model and we continue to pre-train the models on different sources and tasks, which we call *intermediate pre-training* (Gururangan et al., 2020b; Pruksachatkun et al., 2020b). After the intermediate pre-training, we fine-tune f_L on downstream NLU tasks. Existing NLU benchmarks have been trained against standard supervised learning paradigms that typically require a large number of question answering examples which need a large annotation efforts. However, in scenarios where the number of labeled examples is small, the model tends to overfit the training examples and shows poor generalization performance on test set. Here, we evaluate the intermediate pre-training objective's generalization ability on test set in both fully supervised and low-resource settings.

2.2 Analysis Questions

In this paper, we provide a comprehensive study for transferring the visual knowledge into LMs. Visual knowledge transfer can be done in two approaches, depending on the source to be trained: (1) *Text knowledge transfer* using the text corpus in the visual domain, e.g., image captions and (2) *cross-modal knowledge transfer* which passes visual knowledge about common objects to LMs by training over paired image and captions. By evaluating the model on 5 downstream datasets that require physical and visual commonsense knowledge, we explore following three research questions.

Q1: Can intermediate pre-training on external knowledge sources help transfer visual knowledge to augment text encoders? We investigate diverse intermediate pre-training methods with external knowledge sources including caption data to inject visual information from images and captions into LMs. We first analyze the performance of text and cross-modal knowledge transfer methods with a image-caption dataset, and we additionally study text knowledge transfer methods with other text corpora such as GenericsKB (Bhakthavatsalam et al., 2020), Wiki103 (Merity et al., 2017) and BookCorpus (Zhu et al., 2015a).

Q2: What types of knowledge sources are more helpful for visual knowledge transfer? As mentioned above, we have two categories to exploit visual information: (1) *text knowledge transfer* and (2) *cross-modal knowledge transfer*. Here, we explore which type of knowledge transfer is more useful to transfer the visual knowledge into LMs.

Q3: What intermediate pre-training objectives are effective for cross-modal knowledge transfer? We present three pre-training objectives for cross-modal knowledge transfer: (1) voken classification, (2) contrastive learning, and (3) knowledge distillation. Here, we want to present which strategy is best suited for cross-modal knowledge transfer. Furthermore, we study how to enhance cross-modal contrastive learning with adversarial negative samplings.

Dataset	# Train	# Dev	# Test	# choices
PIQA	14,113	1,838	2,000	2
VP	21,988	2,000	6,057	2
CSQA	8,500	1,221	1,241	5
OBQA	4,957	500	500	4
RiddleSense	3,510	1,021	1,202	5

Table 1: **Downstream task data statistics.** We create in-house test set for PIQA and CSQA, and in-house dev set for VP by splitting the train set.

2.3 Pre-training Data

To transfer the visual knowledge, we collect 250K image-caption pairs from MS COCO (Lin et al., 2014; Chen et al., 2015). MS COCO contains images reflecting the composition of actual everyday scenes and corresponding captions which describe contextual reasoning between objects in the scene. We only use captions for text knowledge transfer while we use both images and captions for cross-modal knowledge transfer. As an ablation study, we explore other text corpora such as GenericsKB (Bhakthavatsalam et al., 2020), Wiki103 (Merity et al., 2017) and BookCorpus (Zhu et al., 2015a).

2.4 Downstream Tasks and Datasets

For downstream benchmarks, we find tasks that can benefit from visual knowledge: multiple choice question answering tasks including PIQA (Bisk et al., 2020) which requires physical commonsense reasoning, CSQA (Talmor et al., 2019) for general understanding of commonsense reasoning, OBQA (Mihaylov et al., 2018) that needs elemenatry-level science knowledge, and RiddleSense (RS) (Lin et al., 2021) for complex understanding of figurative language, and binary classification task including Visual Paraphrasing (VP) (Lin and Parikh, 2015) that needs scene understanding. We use in-house test sets made from training sets for PIQA and CSQA since test set is not provided to public. We list the data statics in Table 1. Moreover, We additionally test on GLUE (Wang et al., 2019) to evaluate the general text understanding.

2.5 Evaluation Protocol

We evaluate the models in both fully supervised and low-resource settings. For both settings, we consider accuracy for 5 different classification tasks and get average performance over tasks to check the final performance. In the fully supervised setting, we evaluate models with 3 different random seeds and report the average accuracy. In the low-resource setting, we set the size of the train data to 64 or 128. For each experiment, we run over 5 different sub-samples and show the average accuracy.

3 Method

In this section, we introduce the following two approaches to integrate visual knowledge into LMs: (1) *text knowledge transfer*; and (2) *cross-modal knowledge transfer*. Throughout this section, we assume the data is a collection of image x^v and caption x^l pairs $\{(x_i^v, x_i^l)\}_{i=1}^m$ (m is the size of the pairs) and image encoder f_V and text encoder f_L are given. Note that we use the same text encoder.

3.1 Text Knowledge Transfer

For text knowledge transfer, we investigate following pre-training objectives: (1) *masked language modeling*; and (2) *text contrastive learning*.

Masked Language Modeling (MLM) Following BERT (Devlin et al., 2019), we select 15% of input tokens and replace them with `[MASK]`. Of the selected tokens, 80% are replaced, 10% are not changed and 10% are replaced by random vocabulary token. Here, we employ dynamic masking, which performs random masking and replacement during training to prevent the same masking for the same examples (Liu et al., 2019). MLM objective is the cross-entropy loss for masked token predictions :

$$\ell_{\mathrm{MLM}}(x_i^l) = -\log p(x_i^l | x^{\mathrm{masked}}), \tag{1}$$

where x_i is the i-th token and x^{masked} is a mask.

Text Contrastive Learning (TCL) Contrastive learning aims to learn representations by pulling positive pairs closer and pushing negative pairs apart. Here, we employ the contrastive framework with cross-entropy objective and in-batch negatives (Chen et al., 2020a; Gao et al., 2021). Given a text encoder f_L, and a caption x_i^l, we first get text representations using the encoders $h_i^l = f_L(x_i^l)$. Following Gao et al. (2021), we create identical positive sample h_i^{l+} by different dropout representations. The contrastive loss is defined as follows:

$$\ell_i^l = -\log \frac{e^{\mathrm{sim}(h_i^l, h_i^{l^+})/\tau}}{\sum_{j=1}^{N} e^{\mathrm{sim}(h_i^l, h_j^l)/\tau}}, \tag{2}$$

where N is a batch size and $\mathrm{sim}(\cdot)$ represents cosine similarity, i.e., $\mathrm{sim}(u, v) = u \cdot v / \|u\| \|v\|$. τ represents a temperature parameter.

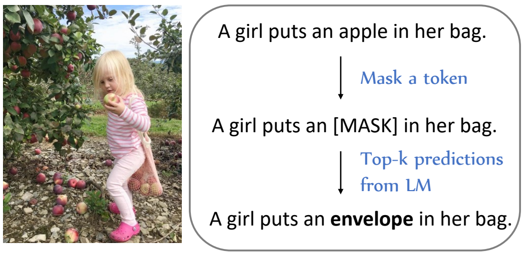

Figure 3: **LM perturbation.** We create adversarial negatives using language models.

3.2 Cross-modal Knowledge Transfer

Language models might learn additional information from visual sources such as images and captions. So we include a variety of vision-based approaches and investigate the approaches whether they can benefit from visual sources. We introduce vision-based approaches as follows.

Voken Classification Vokenization (Tan and Bansal, 2020) employs token-level text-to-image retrieval to transfer visual knowledge. It aligns language tokens to their related images (called "vokens") to transfer visual knowledge into LMs, and call it "voken classification". Given text x and a voken v_i for the i-th token, the loss is defined as

$$\ell_i^{\mathrm{voken}} = -\log(p(v_i|x)). \tag{3}$$

Similar to masked language modeling, it classifies each token to a corresponding voken. Vokenization trains language models with the voken classification task and MLM.

Masked Language Modeling with Visual Clues VL-BERT (Su et al., 2020) adopts masked language modeling with visual clues in which models are given a caption with masked tokens and an image and predict the masked tokens using visual clues. VL-BERT is pre-trained on Conceptual Captions (Sharma et al., 2018) as an image-caption corpus, and BooksCorpus (Zhu et al., 2015b) and English Wikipedia as text-only corpora. It shows its effectiveness in many vision-language tasks. We investigate whether this model also succeed in NLP tasks and compare it with others.

Cross-modal Contrastive Learning (CMCL) To harness the visual knowledge from image-caption datasets, we adopt contrastive loss on image and text vectors. Given an image encoder f_V, a text encoder f_L, and an image-caption pair (x_i^v, x_i^l), we first get image and text representations using the encoders $h_i^v = f_V(x_i^v), h_i^l = f_L(x_i^l)$. Then the contrastive learning objective contains two loss functions: an image-to-text contrastive loss $\ell^{(v,l)}$ and a text-to-image contrastive loss $\ell^{(l,v)}$. The image-to-text contrastive loss is defined as follows:

$$\ell_i^{(v,l)} = -\log \frac{e^{\mathrm{sim}(h_i^v,h_i^l)/\tau}}{\sum_{j=1}^{N} e^{\mathrm{sim}(h_i^v,h_j^l)/\tau}}, \tag{4}$$

where N is a batch size and $\mathrm{sim}(\cdot)$ represents cosine similarity. This loss encourages a closer distance between representations of aligned image-caption pairs than unaligned pairs given an image and multiple captions. Similarly, the text-to-image contrastive loss $\ell^{(l,v)}$ is defined as follows:

$$\ell_i^{(l,v)} = -\log \frac{e^{\mathrm{sim}(h_i^l,h_i^v)/\tau}}{\sum_{j=1}^{N} e^{\mathrm{sim}(h_i^l,h_j^v)/\tau}}. \tag{5}$$

The final loss is defined as

$$L = \frac{1}{N} \sum_{i=1}^{N} (\ell_i^{(v,l)} + \ell_i^{(l,v)}). \tag{6}$$

CLIP (Radford et al., 2021) and ConVIRT (Zhang et al., 2020) also adopt contrastive learning, but we freeze the image encoder in training and use the trained text encoder for downstream tasks.

CMCL with Adversarial Negative Samples (ANS) As in-batch negatives in CMCL are not challenging enough for models to distinguish, we present adversarial negative sampling strategy to improve CMCL. Given an image-caption pair (x_i^v, x_i^l), we define a LM-perturbed sentence $x_i^{l^-}$, which is a hard negative where n is replaced with a different word n' from a probability distribution of PTLMs. We expect the l^- is syntactically correct and plausible sentence even the word n is replaced to n', while it does not semantically match to the corresponding image x_i^v. With such hard negative, we try to make more challenging task so that models can effectively learn from the task. For example, we choose a word 'girl' in the sentence 'A girl puts an apple in her bag.' in Figure 3. Then we mask the word with `[MASK]` token to do masked token predictions by PTLMs. Then we get top-k predictions from language models and replace the masked tokens with one of the predicted ones. To avoid false negative sentences which may have the same semantics as the original sentence, we introduce an additional filtering step: if the masked predictions are synonyms or hypernyms of the original tokens, we discard the predictions. We use WordNet (Miller, 1992) to find synonyms and hypernyms. The contrastive loss with hard negative is defined as follows:

$$-\log \frac{e^{\mathrm{sim}(h_i^v,h_i^l)/\tau}}{\sum_{j=1}^{N} e^{\mathrm{sim}(h_i^v,h_j^l)/\tau} + \sum_{k=1}^{M} e^{\mathrm{sim}(h_i^v,h_j^{l^-})/\tau}}, \tag{7}$$

where M is the number of hard negative samples per positive pair. This formula is only for image-to-text contrastive loss $\ell^{(v,l)}$ and final loss is defined to same as equation (6).

CMCL with Positive Sample Augmentation (PSA) In ANS, we filter perturbed sentences where the masked predictions are synonyms or hypernyms of the original tokens. Instead of excluding these perturbed sentences, another option is to include them as additional positive samples l^+ to the paired images. We name this as positive sample augmentation (PSA). It also adopts LM-perturbed negative samples as in ANS.

Cross-modal Knowledge Distillation (CMKD) Cross-modal knowledge distillation is to transfer knowledge between different modalities, e.g., image modality and text modality. In this category, CMKD is to transfer knowledge from a teacher model which is knowledgeable about visual information. VidLanKD (Tang et al., 2021) also utilizes a cross-modal knowledge distillation method to help with general language understanding. A teacher model is first trained using contrastive learning on a video-text dataset, and then it transfers its knowledge to a student language model using KD on a text corpus. Their contrastive learning loss (hinge loss) is defined as

$$L = \sum_{i}^{N} [\max(0, \alpha - \mathrm{sim}(h_i^v, h_i^l) + \mathrm{sim}(h_i^{v'}, h_i^l)) + \max(0, \alpha - \mathrm{sim}(h_i^v, h_i^l) + \mathrm{sim}(h_i^v, h_i^{l'}))], \tag{8}$$

where v' and l' are a random image and caption text, respectively. α is the margin between the similari-

Table 2: **Performance (accuracy) in low-resource setting.** We test models on diverse datasets with low-resource learning (64 and 128 training samples). We use captions in the MS COCO dataset for text knowledge transfer methods and images and captions for cross-modal knowledge transfer methods. We get average performance on 64 and 128 training samples. **Bold** and underlined numbers refer to the best and second-best performance, respectively.

ties of a positive pair and a negative pair. Instead of video datasets, we use a MS COCO dataset to train a teacher model and use two versions of contrastive learning, equations (6) and (8).

As another version of CMKD, we consider distilling visual knowledge from a pre-trained vision-language model, VL-BERT, which is knowledgeable about grounded language. We adopt masked language modeling on Wikitext103 (Merity et al., 2017), a subset of English Wikipedia, in the knowledge distillation step. For knowledge distillation, we adopt Neuron Selectivity Transfer (NST) (Huang and Wang, 2017), which proves the effectiveness in VidLanKD (Tang et al., 2021).

4 Experimental Settings

For all the approaches, we use `bert-base-uncased` (Devlin et al., 2019) as text encoder f_L and ResNeXt101 (Xie et al., 2017) as an image encoder f_V. We continue to pre-train the encoders in our experiments. For text knowledge transfer, (1) MLM follows the exact setting of codebase in huggingface[2] which uses dynamic masking strategy to conduct language modeling task. (2) TCL conducts contrastive learning with f_L. We choose the best checkpoint by the best spearman correlation on STSb (Cer et al., 2017). For cross-modal knowledge transfer, (1) CMKD explores VL-BERT, Vokenization, and VidLanKD approaches. Here, we use VL-BERT-large model to do CMKD. We use the VL-BERT and Vokenization checkpoints from their official codebases[3]. VidLanKD trains a teacher model by two versions of contrastive learning (equations (6) and (8)) on MS COCO dataset. We set $\alpha = 1$ in VidLanKD (equation (8)). (2) CMCL conducts contrastive learning with f_L and f_V. Here, we set $\tau = 0.05$ (equations (2) and (4)). (3) CMCL with ANS chooses three noun words or verb words to do masked prediction and use top-5 predictions from f_L as replacement. We filter out synonyms and hypernyms of original words using WordNet (Miller, 1992). (4) CMCL with PSA includes the perturbed sentences with synonyms and hypernyms as additional positive samples. In CMCL, we adopt ResNeXt101 (Xie et al., 2017) as an image encoder f_V and BERT as a text encoder f_L. TCL and CMCL train with batch size 64, maximum sequence length 20, learning rate 1e-4 for 3 epochs. For fine-tuning on downstream tasks, we do grid search on learning rates {5e-5, 1e-4, 3e-4, 4e-4, 5e-4, 6e-4} and choose the best learning rate. We set maximum epochs to 30 in low-resource and 15 in fully supervised settings.

5 Results and Analysis

We analyze the main results of intermediate pre-training. Tables 2 and 3 show the main results of low-resource learning and fully supervised learning with the MS COCO captioning dataset, respectively. We train the models with a few training examples, 64 and 128, to understand the better initialization. We argue that if a model obtains better performance in the low-resource setup, then it is a faster learner and has better generalization on downstream tasks.

Table 4: **Performance (accuracy) on GLUE benchmark. Bold** and underlined numbers refer to the best and second-best performance, respectively.

Can text intermediate pre-training help improve text encoders? Text intermediate pre-training using MLM and TCL on a caption corpus improves the performance on downstream tasks in both low-resource and fully supervised settings. In particular, TCL shows significant improvement on OBQA and RiddleSense over BERT (p-value < 0.01). These results suggest that text intermediate pre-training on visual-related datasets helps performance on commonsense reasoning tasks.

Can cross-modal intermediate pre-training help transfer visual knowledge to augment text encoders? We observe that cross-modal intermediate pre-training is helpful in both fully supervised and low-resource settings (See Table 2 and 3). Specifically, CMKD with VidLanKD variant outperforms the baseline by 1.6% point on the PIQA dataset in fully supervised setting. CMCL also shows its effectiveness. However, we could find that it becomes more powerful when equipped with PSA and ANS. It suggests that data augmentation for positive and negative sampling is an important factor for CMCL. In low-resource setting, we find that cross-modal knowledge transfer helps better initialization and lets models learn new tasks faster.

What intermediate pre-training objectives are effective for cross-modal knowledge transfer? Among various cross-modal knowledge transfer methods, we study which method is the most effective for cross-modal knowledge transfer. Overall, CMCL with PSA and ANS shows the best performance among all cross-modal methods. Interestingly, VL-BERT also shows better performance than BERT-base on all datasets in the low-resource setting. This suggests that exploiting images in masked language modeling task help transfer the knowledge to language models.

What types of knowledge sources are most helpful? Here, we investigate whether using an image source in addition to a text source can further improve the model. To answer this question, we analyze methods from different types of sources: text-only and text-image pair sources. We focus on the methods that use the contrastive learning objective: TCL and CMCL. Note that these two methods share the same objective but CMCL trains on cross modalities which are images and captions while TCL only trains on captions. Overall, TCL performs slightly better than CMCL in low-resource and fully supervised settings. Interestingly, additional negative samples (ANS) and positive samples in TCL decreases the performance while they help CMCL to improve the performance. We conjecture that perturbed sentences in ANS might not be semantically negative to the original sentence so models learn from wrong labels.

5.1 Ablation Study

How do models perform on general NLU tasks? Table 4 presents results on GLUE benchmark. In GLUE, text intermediate pre-training methods slightly underperform the original BERT-base. We conjecture that the intermediate pre-training on caption data might sacrifice knowledge of general language understanding.

Analysis on diverse text corpora Table 5 represents text approaches with different pre-training corpora: MS COCO captions (Lin et al., 2014; Chen et al., 2015), GenericsKB (Bhakthavatsalam et al., 2020), BooksCorpus (Zhu et al., 2015a), and WikiText103 (Merity et al., 2017). We sample 250k sentences from each corpus for a fair comparison. We notice that caption datasets are useful on OBQA and RiddleSense datasets while GenericsKB are the most helpful on PIQA datasets. Results are expected since GenericsKB contains a lot of everyday

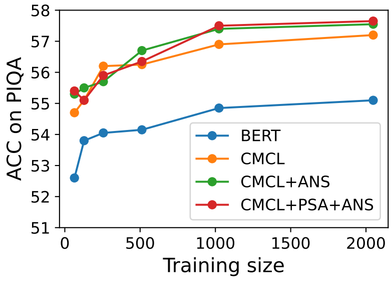

Figure 4: **Results on varying training sizes.** We test methods with different training sizes.

statements that contain various types of commonsense.

Different training sizes. We test different training sizes on PIQA in Fig. 4. In the experiment, we observe that CMCL consistently outperforms BERT on all training sizes. Additional negative sample (ANS) improves the CMCL on different training sizes, and positive sample augmentation boosts the performance of CMCL further. This suggests including perturbed sentences as positive and negative samples are useful to cross-modal knowledge transfer.

6 Related Work

Text Knowledge enhanced methods. Recently, huge efforts on integrating knowledge into PTLMs have been made. One typical form of knowledge is a knowledge graph. There have been efforts of using knowledge graph to inject entity and relation representations, which are pre-computed from external source, into PTLMs (Zhang et al., 2019; Xu et al., 2021a; Peters et al., 2019; He et al., 2020; Xu et al., 2021b). Some other works try to retrieve or generate the sub-graph from the graph to solve the problem (Lin et al., 2019; Wang et al., 2020). Another existing form of knowledge is extra large-scale corpus. Works that use such corpus present knowledge-related pre-training objectives such as concept order recovering (Zhou et al., 2021), entity category prediction (Yu et al., 2020) and source of knowledge prediction (Wang et al., 2021; Calixto et al., 2021). They are mostly focused on injecting world knowledge presented in text, rather than physical and visual commonsense knowledge that can be found in images.

Cross-modal knowledge enhanced methods. There is a extensive line of works for a variety of vision-language tasks, such as VL-BERT (Su et al., 2020), VisualBert (Li et al., 2019), and Uniter (Chen et al., 2020b). These models aim to improve vision-language tasks, e.g., VQA (Goyal et al., 2017) and event understanding (Li et al., 2022), and they are found to be not effective in improving language tasks (Tan and Bansal, 2020). Another line of works is to transfer visual knowledge to language models: Vokenization (Tan and Bansal, 2020) and VidLanKD (Tang et al., 2021). Vokenization employs token-level text-to-image retrieval to transfer visual knowledge to language models. For this, Vokenization introduces 30k vokens and matches each token into the limited voken space. VidLanKD adopts contrastive learning to train a teacher model on video datasets and uses distillation approaches to distill visual knowledge from the teacher to a student model.

7 Conclusion

We study whether intermediate pre-training on visual knowledge can help transfer visual knowledge into LMs. We investigate text knowledge transfer and cross-modal knowledge transfer using images and captions. In our empirical analysis, we observe that intermediate pre-training on captions can help improving performance and cross-modal knowledge transfer approaches consistently improve performance. When the transfer methods are equipped with additional positive and negative samples, they show better performance. Future works include improving both commonsense reasoning and general language understanding.

A Dataset Properties

PIQA is a multiple-choice question answering task, which chooses the most appropriate solution for physical commonsense questions, which may need illustration or description of physical interaction in the real world. VP is to tell if two descriptions are describing the same scene or two different scenes. While they seem like purely textual tasks, they require visual common sense to answer. CSQA is a multiple-choice question answering task that requires commonsense reasoning to answer. It is built from ConceptNet (Speer et al., 2017). OBQA is a multiple-choice question answering task, which is modeled after open book exams on elementary-level core science questions. The task generally requires open book fact but also additional commonsense which can be learnt from scientific illustration. RiddleSense is a multiple-choice riddle-style question answering which requires complex commonsense reasoning ability and understanding of figurative language which may benefit from visual knowledge.

A Good Prompt Is Worth Millions of Parameters:
Low-resource Prompt-based Learning for Vision-Language Models

Abstract

Large pre-trained vision-language (VL) models can learn a new task with a handful of examples and generalize to a new task without fine-tuning. However, these VL models are hard to deploy for real-world applications due to their impractically huge sizes and slow inference speed. To solve this limitation, we study prompt-based low-resource learning of VL tasks with our proposed method, FEWVLM, relatively smaller than recent few-shot learners. For FEWVLM, we pre-train a sequence-to-sequence transformer model with prefix language modeling (PrefixLM) and masked language modeling (MaskedLM). Furthermore, we analyze the effect of diverse prompts for few-shot tasks. Experimental results on VQA show that FEWVLM with prompt-based learning outperforms Frozen (Tsimpoukelli et al., 2021) which is 31× larger than FEWVLM by 18.2% point and achieves comparable results to a 246× larger model, PICa (Yang et al., 2021). In our analysis, we observe that (1) prompts significantly affect zero-shot performance but marginally affect few-shot performance, (2) models with noisy prompts learn as quickly as hand-crafted prompts given larger training data, and (3) MaskedLM helps VQA tasks while PrefixLM boosts captioning performance. Our code is publicly available at `https://github.com/woojeongjin/FewVLM`

1 Introduction

Fine-tuning large pre-trained language models (PLMs) have led to strong results in various domains including vision-language tasks (Devlin et al., 2019; Raffel et al., 2020; Brown et al., 2020; Radford et al., 2021). Such large PLMs can learn a new task with a few examples or generalize to a new task without fine-tuning on any training examples, i.e., few-shot and zero-shot learning (Brown et al., 2020; Radford et al., 2021; Tsimpoukelli et al., 2021). Few-shot learning overcomes the challenges of data-hungry supervised learning, where collecting human-labeled data is costly and slow. However, recent few-shot models such as GPT3 (Brown et al., 2020), Frozen (Tsimpoukelli et al., 2021), and PICa (Yang et al., 2021) are too large to deploy in small or moderate computing machines due to their gigantic model sizes

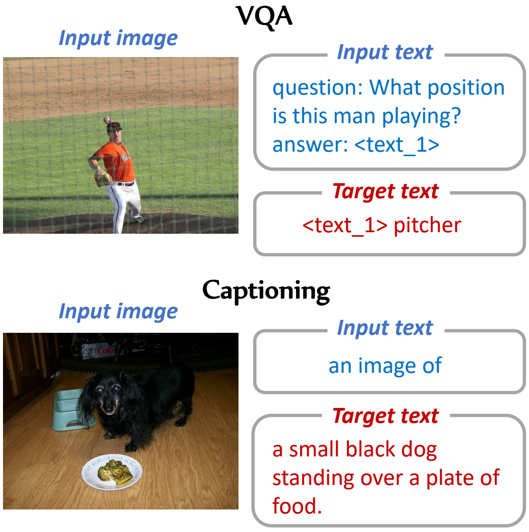

Figure 1: **Examples of VQA and Captioning tasks.** In our setup, we convert the tasks into generative tasks in which models need to generate target text given input text and an image.

In this paper, we study low-resource learning of VL tasks with our proposed method, FEWVLM, a moderate-sized vision-language model, in which we fine-tune the model with no or a handful of training examples. For FEWVLM, we pre-train a sequence-to-sequence transformer model (Cho et al., 2021; Raffel et al., 2020) with prefix language modeling (PrefixLM) and masked language modeling (MaskedLM). This setup is more practical in that training and inference can be run economically using standard computing hardware and

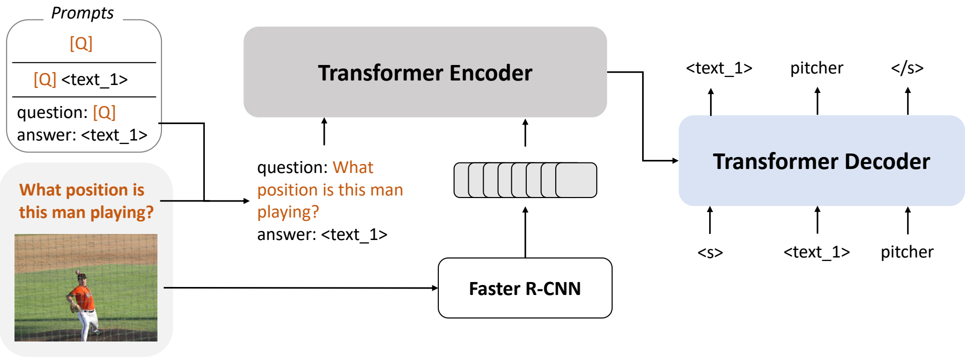

Figure 2: **Illustration of FEWVLM.** This shows inference of FEWVLM with prompt-based learning. Given a prompt template, we convert the question text into input text. The prompt helps the model generate correct answers.

it is expensive to obtain a large number of quality training examples in the real world. In such a few-shot setting, task-specific prompts or task descriptions are important and have shown effectiveness in few-shot NLP tasks (Gao et al., 2021; Radford et al., 2021; Schick and Schütze, 2021a,b; Brown et al., 2020).

To extend the success to VL tasks, we aim to answer the following questions for prompt-based low-resource VL learning. Q1) How does prompt design affect zero/few-shot learning on new tasks? Q2) Does prompt design still matter given larger training? Q3) How do different pre-training objectives affect zero/few-shot learning? To answer these questions, we explore various prompt formats including hand-crafted and noisy prompts on zero/few-shot VL learning datasets. In addition, we study pre-training objectives on few-shot tasks inspired by Raffel et al. (2020): prefix language modeling (PrefixLM) inspired by Raffel et al. (2020) and masked language modeling (MaskedLM). To this end, we investigate the model's performance on few-shot VL tasks including visual question answering (Goyal et al., 2017; Marino et al., 2019; Hudson and Manning, 2019), captioning (Agrawal et al., 2019; Young et al., 2014) (Fig. 1), and miniImageNet (Vinyals et al., 2016).

In our empirical analysis, our FEWVLM with prompt-based learning outperforms Frozen (Tsimpoukelli et al., 2021) which is 31× larger than FEWVLM by 18.2% point on zero-shot VQAv2 and achieves comparable results to a 246× larger model, PICa (Yang et al., 2021). Furthermore, we observe that (1) prompts significantly affect zero-shot performance but marginally affect few-shot performance on new tasks (§6.2 and §6.3), (2) models with noisy prompts learn as quickly as hand-crafted prompts given larger training data (§6.5), and (3) MaskedLM helps few-shot VQA tasks while PrefixLM boosts captioning performance (§6.6).

2 Related Work

Vision-language few-shot learning. Recently, several few-shot learners on vision-language tasks were proposed including GPT (Radford et al., 2019; Brown et al., 2020), Frozen (Tsimpoukelli et al., 2021), PICa (Yang et al., 2021), and SimVLM (Wang et al., 2021). Frozen (Tsimpoukelli et al., 2021) is a large language model based on GPT-2 (Radford et al., 2019), and is transformed into a multimodal few-shot learner by extending the soft prompting to incorporate a set of images and text. Their approach shows the few-shot capability on visual question answering and image classification tasks. Similarly, PICa (Yang et al., 2021) uses GPT-3 (Brown et al., 2020) to solve VQA tasks in a few-shot manner by providing a few in-context VQA examples. It converts images into textual descriptions so that GPT-3 can understand the images. SimVLM (Wang et al., 2021) is trained with prefix language modeling on weakly-supervised datasets. It demonstrates its effectiveness on a zero-shot captioning task. While these models achieve improvement on few-shot tasks, they are impractical to use in real-world applications due to their model sizes.

Language model prompting. Providing prompts or task descriptions play an vital role in improving pre-trained language models in many tasks (Gao et al., 2021; Radford et al., 2021; Schick and Schütze, 2021a,b; Brown et al., 2020). Among them, GPT models (Radford et al., 2019; Brown et al., 2020) achieved great success in prompting

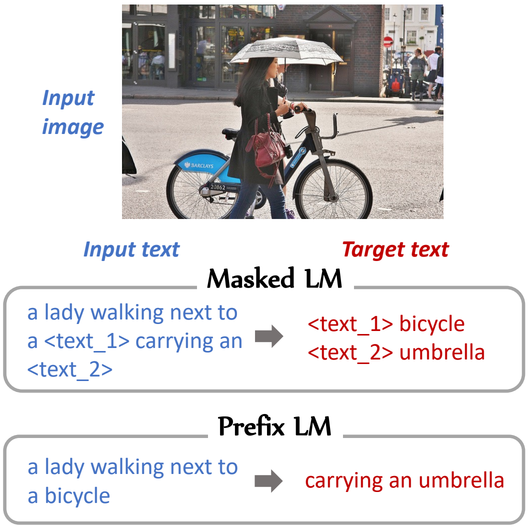

Figure 3: **Pre-training objectives.** We pre-train FewVLM with masked language modeling (MaskedLM) and prefix language modeling (PrefixLM).

or task demonstrations in NLP tasks. In light of this direction, prompt-based approaches improve small pre-trained models in few-shot text classification tasks (Gao et al., 2021; Schick and Schütze, 2021a,b). CLIP (Radford et al., 2021) also explores prompt templates for image classification which affect zero-shot performance. We follow these core ideas so we aim to improve zero-shot and few-shot performance using prompts in vision-language tasks.

3 Analysis Setup

In this work, we study the zero-shot and few-shot performance of vision-language models $\mathcal{L}$. We introduce our analysis setup: problem formulation, analysis questions, downstream tasks and datasets, evaluation metrics, and baselines.

3.1 Problem Formulation

For zero-shot tasks, a pre-trained VL model $\mathcal{L}$ have no access to training set $\mathcal{D}_{train}$ and development set $\mathcal{D}_{dev}$, and directly makes inference on the test instances $\mathcal{D}_{test}$. For few-shot tasks, we compose a dev set $\mathcal{D}_{dev}$ from training data and ensure that $|\mathcal{D}_{train}| = |\mathcal{D}_{dev}|$ following Perez et al. (2021); Gao et al. (2021) to tune the hyper-parameters and select the model. We limit the sizes of training and development sets to meet the goal of learning from limited data. The size of $\mathcal{D}_{train}$ and $\mathcal{D}_{dev}$ are small — i.e., we set the size of both to 16 in our study.

3.2 Analysis Questions

We aim to answer the following questions in this study through experiments on multiple VL datasets.

Q1) How does prompt design affect zero/few-shot learning on new tasks? Providing a pre-trained language model with task-specific prompts or significantly improves zero-shot and few-shot performance on NLP domains (Gao et al., 2021; Schick and Schütze, 2021a,b; Brown et al., 2020). For this question, we test several ad-hoc prompts on vision-language tasks and analyze how large zero-shot and few-shot performance is affected by different prompts, hand-crafted and noisy prompts, in Sec. 6.5.

Q2) Does prompt design still matter given larger training data? As we will see in our experiments, prompts affect the zero/few-shot performance. However, prompts may have different effects when models are given different sizes of training data. To answer this question, we train models with different sizes of training data and various prompts, and compare the performance between different prompts.

Q3) How do different pre-training objectives affect zero/few-shot performance? We study two different pre-training objectives on few-shot performance: prefix language modeling (PrefixLM) inspired by Raffel et al. (2020) and masked language modeling (MaskedLM). In this setup, we pre-train our model with different objectives and test the model on zero-shot and few-shot tasks in Sec. 6.6.

3.3 Downstream Tasks and Datasets

In this work, we mainly focus on three tasks: visual question answering, captioning, and categorical learning. The visual question answering task requires models to answer a question to a given context image. We convert the visual question answering task into a generation task so that the model can generate answers in the zero-shot setting. The captioning task requires a model to generate descriptions for a given context image. The categorical learning requires a model to choose the correct category or class. We evaluate our model in an open-ended fashion to quantify fast learning of categories, in which it must generate correct labels unlike other classification methods.

We include VQAv2 (Goyal et al., 2017), OK-VQA (Marino et al., 2019), and GQA (Hudson

Table 1: **Hand-crafted prompts.** We study hand-crafted prompts on zero-shot and few-shot tasks. `[Q]` and `[A]` refer to question text and answer text, respectively. `<text_1>` is a sentinel token. We append image features to input text. Target prompts are "`[A]`" and "`<text_1> [A]`" in VQA. We use caption text as a target prompt in captioning.

Task	**ID**	**Input prompt**	**Example**
VQA	P1	`[Q] <text_1>`	**input:** What position is this man playing? `<text_1>` **output:** `<text_1>` pitcher
	P2	*question:* `[Q]` *answer:*	**input:** question: What position is this man playing? answer: **output:** `<text_1>` pitcher
	P3	*question:* `[Q]` *answer:* `<text_1>`	**input:** question: What position is this man playing? answer: `<text_1>` **output:** `<text_1>` pitcher
Captioning	Q1	*a picture of*	**input:** a picture of **output:** a small black dog standing over a plate of food.
	Q2	*a photo of*	**input:** a photo of **output:** a small black dog standing over a plate of food.
	Q3	*an image of*	**input:** an image of **output:** a small black dog standing over a plate of food.

and Manning, 2019) for visual question answering tasks, and NoCaps (Agrawal et al., 2019), and Flickr30k (Young et al., 2014) for image captioning.[1] We use Karpathy split (Karpathy and Li, 2015) for Flickr30k, which re-splits train and val images into 29,000 / 1,014 / 1,000 for train / validation / test. For categorical learning, we include miniImageNet (Vinyals et al., 2016), a meta learning dataset. Following (Tsimpoukelli et al., 2021), we use only meta test data to evaluate FEWVLM in a few-shot manner and test on 5-way k-shot setup, where 5 classes and k examples *per class* are given.[2]

3.4 Evaluation Metrics

To evaluate few-shot performance, we randomly sample 5 different training and dev splits and measure average performance on the 5 splits. We fine-tune the vision-language models with 200 epochs for the few-shot setup and choose the best checkpoint on the dev set. For NoCaps task, it does not have training data. Thus we use the training data from COCO captioning in the experiments following Wang et al. (2021). We evaluate on the VQAv2 validation set, GQA test-dev, OK-VQA test set, test set of Karpathy split for Flickr30k captioning, and NoCaps validation set. We adopt accuracy for VQA datasets and miniImageNet, and CIDEr (Vedantam et al., 2015) and SPICE (Anderson et al., 2016) as evaluation metrics for captioning.

3.5 Baselines

We evaluate strong zero/few-shot vision-language learners for comparison: Frozen (Tsimpoukelli et al., 2021), PICa (Yang et al., 2021) for VQA datasets and SimVLM (Wang et al., 2021) for captioning datasets. We include Unified VLP (Zhou et al., 2020) for few-shot VQAv2 and Flickr30k. Also, we compare them with fully fine-tuned models $\mathcal{L}_{full}$ as upper bounds of few-shot models for each task; these models are fine-tuned on the entire datasets while few-shot models can access a small amount of data. For fully fine-tuned models $\mathcal{L}_{full}$, we borrow numbers from Uniter$_{large}$ (Chen et al., 2019) for VQAv2, Oscar (Li et al., 2020b) for GQA, SimVLM (Wang et al., 2021) and VinVL (Zhang et al., 2021) for NoCaps CIDER and SPICE respectively, and Unified VLP (Zhou et al., 2020) for Flickr30k captioning. We include VL-T5$_{\text{no-vqa}}$ as a baseline which is pre-trained without visual question answering datasets (Cho et al., 2021). For miniImageNet, we include Frozen and AFHN (Li et al., 2020a). Frozen is designed for few-shot learning while AFHN is for meta learning, which is smaller and faster.

4 Method

Before diving into the analysis, we introduce our model, FEWVLM, to do zero/few-shot learning on VL tasks and answer the analysis questions we raised. We introduce FEWVLM architecture and pre-training objectives.

4.1 Encoder-decoder Vision-language Model

We adopt an encoder-decoder architecture (Cho et al., 2021; Vaswani et al., 2017), to encode visual and text inputs and generate target text. We represent an input image with 36 object regions from a Faster R-CNN (Ren et al., 2015) trained on Visual Genome (Krishna et al., 2017). The sets of region representations are fed into the encoder by appending them to the text Cho et al. (2021). We train the model parameters θ by minimizing the negative

---

[1] We include COCO captioning results on Sec. B of Appendix.

[2] For VQA and captioning, we include k samples in total, not per class.

log-likelihood of target text y tokens given input text x and image v:

$$L_\theta = -\sum_{i=1}^{|y|} \log P_\theta(y_i | y_{<i}, x, v). \qquad (1)$$

The model is not task-specific, so it is a good option for zero/few-shot settings.

4.2 Pre-training Objectives

We pre-train the models with both prefix language modeling (PrefixLM) and masked language modeling (MaskedLM). Fig. 3 illustrates the PrefixLM and MaskedLM.

Prefix language modeling. We include prefix language modeling (PrefixLM) following Raffel et al. (2020). Given an image and a span of text, this objective randomly splits the text into two separate components; the former component with the given image is used as inputs to the encoder and the latter component is used as target text to be generated by the decoder.

Masked language modeling. We follow Cho et al. (2021) to do masked language modeling. This objective is to replace random spans with numbered sentinel tokens, e.g., `<text_1>`, and then the masked text is fed into the encoder. Then the decoder generates the masked spans as target text. We randomly mask 15% of input text tokens and replace them with sentinel tokens.

Pre-training data. To pre-train FEWVLM, we collect image-caption data from MS COCO (Lin et al., 2014; Chen et al., 2015) and Visual Genome (VG) (Krishna et al., 2017). The pre-training datasets contains 9.18M image-text pairs and 180K distinct images.

5 Low-resource Adaptation

In downstream tasks, we train our model with few-shot examples. Fig. 2 shows an illustration of FEWVLM in inference time. Given a prompt template $\mathcal{P}$, we first get input text and target text using the template $x, y = \mathcal{P}(\text{input}, \text{label})$. Then we train model parameters by minimizing the negative log-likelihood in Eq. (1). In inference, we use the same prompt and the model generates the label text. Here we obtain the final label by removing the target prompt template.

5.1 Prompt Design

Prompts affect the performance of the vision-language model (Cho et al., 2021); we study the effect of different prompts on the zero-shot and few-shot performance on downstream tasks. Tables 1 and 11 show prompts we used in our experiments.

5.1.1 Visual Question Answering

The visual question answering tasks (VQA, OK-VQA, and GQA) require models to answer a question to a given context image. Recent approaches (Chen et al., 2019; Tan and Bansal, 2019; Su et al., 2020; Li et al., 2019, 2020b) tackle visual question answering tasks as multi-label classification over a predefined set of answer candidates. Instead, we approach the visual question answering tasks as a generation task so that the model can produce the answers without introducing any task-specific heads. In this setup, prompts act as constraints to guide the models to generate proper formats of answers; models might generate a sentence for VQA, which is not the correct format, without prompts.

Therefore, we study several prompts for input and output as shown in Tables 1 and 11; we explore hand-crafted prompts (Table 1) and noisy prompts for ablation study (Table 11).

Hand-crafted prompts. For input prompts, we explore three different templates: "*question:* `[Q]` *answer:*" and with the `<text_1>` sentinel token at the end. Similarly to masked language modeling, we expect models to generate words thanks to the sentinel token. For target prompts, we explore two different templates: "`[A]`" (an answer) and "`<text_1> [A]`" (an answer with a sentinel token). Here, we aim to mimic MaskedLM's target text format, so the similar format helps the model quickly adapt to the new task. We call each prompt ID as in Table 1.

Noisy prompts. To understand the effect of noisy prompts in zero/few-shot learning, we include irrelevant prompts, noisy tokens, and random sentences as in Table 11. Irrelevant prompts are random questions or instructions that mislead models to answer wrong questions or follow irrelevant instructions. Noisy tokens are randomly selected from T5's vocabulary, so we test how robust our model is to random tokens. Finally, random sentences are captions from MS COCO and this gives false information to models.

5.1.2 Captioning

In NoCaps and Flickr30k, we explore three hand-crafted input prompts: "*a picture of*", "*a photo of*", and "*an image of*". We study the effect of different

Table 2: **Zero-shot VQA results.** We test models without any training examples. VL-T5$_{\text{no-vqa}}$ is pre-trained without VQA datasets. Compared to larger models, Frozen and PICa-Full, our models outperform them or show the comparable results.

Model	**Model size**	**VQAv2**	**OK-VQA**	**GQA**
Unified VLP	122M	0.0	-	-
VL-T5$_{\text{no-vqa}}$	224M	13.5	5.8	6.3
Frozen	7B	29.5	5.9	-

SimVLM$_{huge}$	-	**101.4**	-	-	-
FewVLM$_{base}$	224M	42.2	8.5	31.0	10.0
FewVLM$_{large}$	740M	*47.7*	**9.1**	**36.5**	**10.7**

Table 5: **Few-shot captioning results.** We report average performance over 5 different splits. We use the CIDEr and SPICE metrics for evaluation.

Model	**Model size**	**NoCaps**		**Flickr30k**	
		CIDEr	**SPICE**	**CIDEr**	**SPICE**
Unified VLP	122M	-	-	28.8	9.4
VL-T5$_{\text{no-vqa}}$	224M	22.0	6.8	12.8	8.3
FewVLM$_{base}$	224M	48.6	10.0	32.6	12.8
FewVLM$_{large}$	740M	**53.1**	**10.4**	**37.0**	**13.5**
Fine-tuned $\mathcal{L}_{full}$	-	112.2	13.1	67.4	17.0

word choices in this captioning task. While the three different words have similar meanings, they show different performance in zero-shot and few-shot tasks as we will see in our experiments.. For target prompts, we just train the model with the original caption without any additional prompts.

5.1.3 MiniImageNet

In miniImageNet, we train our model with a hand-crafted input prompt, "*This is* `<text_1>`," and target prompt, "`<text_1> [A]`." We compare our model with and without prompts in this dataset to study whether prompts are helpful in categorical learning.

6 Results and Discussion

In this section, we first discuss our main results on zero-shot and few-shot tasks and then answer the questions we raised: does prompt design matter in zero/few-shot learning?

6.1 Experiment Details

For pre-training, we set batch size 1,280 and 800 for FewVLM$_{base}$ and FewVLM$_{large}$, respectively and pre-train them with 30 epochs. We use learning rate 1e-4 with 5% linear warmup. For few-shot learning, we train models with 200 epochs, learning rate 5e-5 and 5% linear warmup and choose the best checkpoint on the dev set. For FewVLM, we use "question: `[Q]` answer `<text_1>`" (P3) as an input prompt and "`<text_1> [A]`" as a target prompt for visual question answering, and "an image of" (Q3) as an input prompt for captioning, which show the best performance. We will study the effect of different prompts in Sec. 6.5. The sizes of of $\mathcal{D}_{train}$ and $\mathcal{D}_{dev}$ are 16 on VQA and captioning tasks. For miniImageNet, we use 'This is `<text_1>`,' and "`<text_1> [A]`" as input and target prompts. In this data, we test with {1, 3, 5}-shots per class.

6.2 Performance on Zero-shot Learning

We evaluate the existing models in a zero-shot manner, in which models do not have access to any training data. Tables 2 and 4 show the results on VQA and captioning datasets, respectively. First, FewVLM with the hand-crafted prompt (P3) achieves better performance than other baselines on VQA datasets. In particular, our FewVLM$_{base}$ significantly outperforms Frozen

Table 6: **5-way miniImageNet results.** We evaluate FewVLM in a generative manner. The shot represents the number of training examples per class.

Model	**Model size**	**1 shot**	**3 shots**	**5 shots**
Frozen	7B	14.5	34.7	33.8
FewVLM$_{base}$ (no prompt)	224M	48.0	75.0	82.6
FewVLM$_{base}$	224M	57.0	78.0	84.2
FewVLM$_{large}$	740M	57.1	78.3	84.4
AFHN	-	62.3	-	78.1

which is about 31× larger than ours. Also, PICa based on GPT3 (Brown et al., 2020) shows the best performance on OK-VQA. It is noticeable that our FewVLM$_{large}$, the 246× smaller model, achieves the comparable result to PICa. Compared to VL-T5$_{\text{no-vqa}}$ which is the same architecture as ours, FewVLM$_{base}$ improves VQAv2 performance by about 30% point. As we will see in the later section, our pre-training objectives and the prompts boost the VQA performance. On NoCaps, SimVLM$_{huge}$ shows the best performance. Our FewVLM$_{base}$ significantly improves the performance compared to VL-T5$_{\text{no-vqa}}$. As we will see in the later section, our pre-training objectives and the prompts boost the VQA and captioning performance.

6.3 Performance on Few-shot Learning

Tables 3 and 5 show the few-shot performance on VQA and captioning datasets. Sizes of training and validation sets are 16 for FewVLM, VL-T5$_{\text{no-vqa}}$, and Unified VLP; and Frozen and PICa use 4 and 16 in-context demonstration examples, respectively.

On VQAv2 and OK-VQA, PICa shows the best performance while our FewVLM$_{large}$ achieves the comparable result on VQAv2. OK-VQA requires external knowledge to answer unlike other VQA datasets, so larger models and large pre-training data (prior knowledge) are necessary to improve. Interestingly, FewVLM$^{*}_{base}$, which is trained with 4 training examples, outperforms Frozen. On captioning data, FewVLM$_{base}$ notably outperforms VL-T5$_{\text{no-vqa}}$ by 31.1% point on NoCaps CIDEr.

Unified VLP slightly underperforms FewVLM on Flickr30k captioning task. We conjecture that their architecture is based on a encoder-decoder transfomer and it is pre-trained with a captioning task (Zhou et al., 2020).

Table 7: **Zero-shot results of hand-crafted prompts.** We test different input prompts in zero-shot predictions. We use a CIDEr metric for Flickr30k. Note that zero-shot setting does not require target prompts.

	no prompt	**P1**	**P2**	**P3**
VQAv2	3.7	9.9	19.0	43.4
	no prompt	**Q1**	**Q2**	**Q3**
Flickr30k	9.6	15.2	25.6	31.0

6.4 MiniImageNet

Table 6 shows results on miniImageNet, where models must choose the correct class for each image. We train and evaluate FewVLM in an generative manner; the model must generate correct label text to get the credit. FewVLM significantly outperforms Frozen in all shots. Note that we train FewVLM with a few training samples while Frozen uses them as in-context demonstration. Interestingly, FewVLM with a hand-crafted prompt improves performance a lot on the 1-shot case, while it marginally improves on the 5-shot case.

6.5 Study of Prompt Design

Here we examine the effect of different prompts on FewVLM$_{base}$ in Table 7 and Figs. 6, 5, and 4. We test the model on VQAv2 and Flickr30k datasets.

6.5.1 Zero-shot Predictions

Table 7 shows the zero-shot performance on VQAv2 and Flickr30k. We observe that zero-shot results are remarkably affected by input prompts on both datasets. For input prompts, `<text_1>` in P1 and P3 helps the zero-shot predictions significantly compared to "no prompt" and P2. We conjecture that `<text_1>` guides the model to predict masked spans similarly to MaskedLM, so it improves the performance.

On Flickr30k, we examine different word choices of prompts: "a picture of" (Q1), "a photo of" (Q2), and "an image of" (Q3). For instance, using "an image of" outperforms using no prompt by 21.4 point. It is noticeable that different word choices significantly affect the zero-shot results.

6.5.2 Few-shot Predictions

We study various input prompts including irrelevant prompts, noisy tokens, and random sentences on VQAv2 (Fig. 4). First, noisy prompts and no prompt achieve near 0 accuracy on the zero-shot setting. In few-shot predictions, FewVLM with

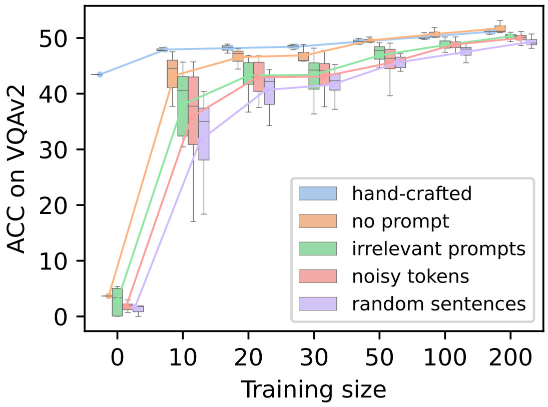

Figure 4: **VQAv2 results on noisy prompts.** We investigate different prompts on various training sizes. FEWVLM is trained with our best hand-crafted prompt (P3), irrelevant prompts, noisy tokens and random sentences. We list the prompt templates in Table 11 of appendix. We use "`<text_1> [A]`" as our target prompt.

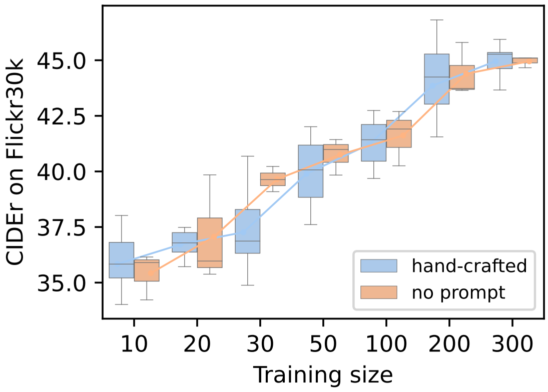

Figure 5: **Flickr30k results on hand-crafted prompts.** We investigate different hand-crafted prompts (Q1, Q2, and Q3) on various training sizes.

noisy prompts learns as quickly as hand-crafted prompts given larger data. For example, our model with noisy prompts achieves comparable results to the best hand-crafted prompt. Among all different types of noisy prompts, random sentences deteriorate performance the most. This is because the random sentences come from captions in MS COCO, so the model might choose the answer from wrong captions not from images. Interestingly, no prompt outperforms the other noisy prompts and even shows similar to or better than the hand-crafted prompt with larger training data. We also observe a similar phenomenon on Flickr30k; no prompt performs similar to hand-crafted prompts in Fig. 5.

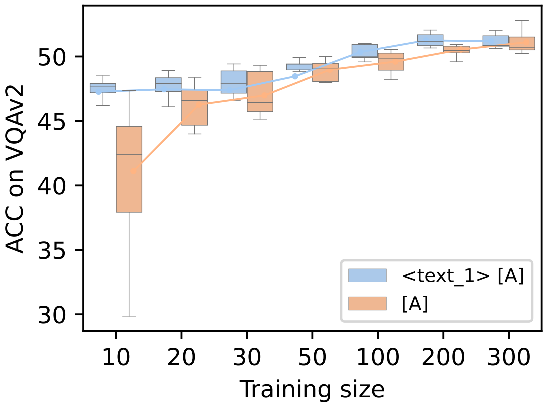

Figure 6: **VQAv2 results on different target prompts.** We investigate different target prompts with hand-crafted input prompts on various training sizes.

Table 8: **Results on different pre-training objectives.** We test our pre-training objectives to investigate how it affects zero-shot and few-shot performance. We train FEWVLM$_{base}$ with 16 training and validation examples.

Objective	VQAv2	GQA	Flickr30k CIDEr
Zero-shot			
MaskedLM	42.4	25.1	4.6
PrefixLM	11.9	6.7	26.8
MaskedLM + PrefixLM	**43.4**	**27.0**	**31.0**
Few-shot			
MaskedLM	46.0	31.4	18.5
PrefixLM	40.8	27.6	31.8
MaskedLM + PrefixLM	**48.2**	**32.2**	**32.6**

In addition, we explore two different target prompts, "`<text_1> [A]`" and "`[A]`." We try to mimic the MaskedLM's target text format, so we add "`<text_1>`" to target prompt on VQA. This might help the model's fast adaptation to a new task since they share the same target prompt. In Fig. 6, we notice an interesting phenomenon; the target prompt "`[A]`" shows a larger variance than the other suggesting that introducing "`<text_1>`" helps the model quickly adapt to a new task. However, both prompts show similar results given larger training data, e.g., 300.

6.6 Pre-training Objectives

We investigate how pre-training objectives affect different tasks. We pre-train FEWVLM with different pre-training objectives: masked language modeling (MaskedLM) and prefix language modeling (PrefixLM).

In Table 8, we observe that MaskedLM helps

VQA tasks while PrefixLM helps captioning tasks in zero-shot and few-shot settings. We conjecture that MaskedLM is to predict spans, which is analogous to predict correct answers to questions, and PrefixLM is to generate the rest of the given prefix, which is similar to captioning tasks. In other words, if the pre-training task is similar to the downstream tasks, then it will help performance further. When pre-training with both objectives, they create a synergetic effect and thus improve cross-task generalization.

7 Conclusion

In this work, we present FEWVLM, a few-shot prompt-based learner on vision-language tasks. On diverse datasets, FEWVLM outperforms baselines and shows comparable results to PICa which is 246× larger than ours. We observe that prompts are vital in zero-shot and few-shot tasks and each pre-training objective helps different few-shot tasks. Also, we find out that models with larger training data are not significantly affected by noisy prompts. Future work includes exploring automatic prompt generation and diverse formats of few-shot tasks such as multiple-choice VQA. Finding optimal prompts require exhaustive engineering to achieve the best performance and leads to impressive results. We leave the exploration of these directions to future investigations.

Continual Few-shot Relation Learning via Embedding Space Regularization and Data Augmentation

Chengwei Qin♣ and Shafiq Joty♣♠

Abstract

Existing continual relation learning (CRL) methods rely on plenty of labeled training data for learning a new task, which can be hard to acquire in real scenario as getting large and representative labeled data is often expensive and time-consuming. It is therefore necessary for the model to learn novel relational patterns with very few labeled data while avoiding catastrophic forgetting of previous task knowledge. In this paper, we formulate this challenging yet practical problem as continual few-shot relation learning (CFRL). Based on the finding that learning for new emerging few-shot tasks often results in feature distributions that are incompatible with previous tasks' learned distributions, we propose a novel method based on embedding space regularization and data augmentation. Our method generalizes to new few-shot tasks and avoids catastrophic forgetting of previous tasks by enforcing extra constraints on the relational embeddings and by adding extra relevant data in a self-supervised manner. With extensive experiments we demonstrate that our method can significantly outperform previous state-of-the-art methods in CFRL task settings.[1]

1 Introduction

Relation Extraction (RE) aims to detect the relationship between two entities in a sentence, for example, predicting the relation *birthdate* in the sentence "*Kamala Harris* was born in Oakland, California, on *October 20, 1964*." for the two entities *Kamala Harris* and *October 20, 1964*. It serves as a fundamental step for downstream tasks such as search and question answering (Dong et al., 2015; Yu et al., 2017). Traditionally, RE methods were built by considering a fixed static set of relations (Miwa and Bansal, 2016; Han et al., 2018a). However, similar to entity recognition, RE is also an open-vocabulary problem (Sennrich et al., 2016), where the relation set keeps growing as new relation types emerge with new data.

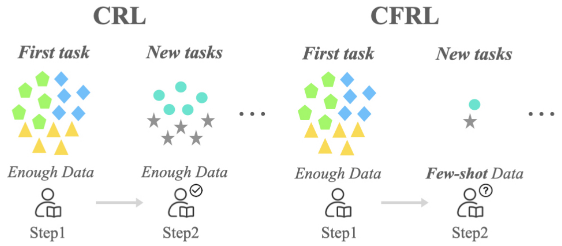

Figure 1: Difference between Continual Relation Learning (CRL) and Continual Few-shot Relation Learning (CFRL). Except for the first task which has enough training data, the subsequent new tasks are all *few-shot* in CFRL. In contrast, CRL assumes enough training data for every task.

A potential solution is to formalize RE as Continual Relation Learning or CRL (Wang et al., 2019). In CRL, the model learns relational knowledge through a sequence of tasks, where the relation set changes dynamically from the current task to the next. The model is expected to perform well on both the novel and previous tasks, which is challenging due to the existence of *Catastrophic Forgetting* phenomenon (McCloskey and Cohen, 1989; French, 1999) in continual learning. In this phenomenon, the model forgets previous relational knowledge after learning new relational patterns.

Existing methods to address catastrophic forgetting in CRL can be divided into three categories: (*i*) regularization-based methods, (*ii*) architecture-based methods, and (*iii*) memory-based methods. Recent work shows that memory-based methods which save several key examples from previous tasks to a memory and reuse them when learning new tasks are more effective in NLP (Wang et al., 2019; Sun et al., 2020). Successful memory-based CRL methods include EAEMR (Wang et al., 2019), MLLRE (Obamuyide and Vlachos, 2019), EMAR (Han et al., 2020), and CML (Wu et al., 2021).

Despite their effectiveness, one major limitation

---

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2776 - 2789
May 22-27, 2022

of these methods is that they all assume plenty of training data for learning new relations (tasks), which is hard to satisfy in real scenario where continual learning is desirable, as acquiring large labeled datasets for every new relation is expensive and sometimes impractical for quick deployment (*e.g.,* RE from news articles during the onset of an emerging event like Covid-19). In fact, one of the main objectives of continual learning is to quickly adapt to new environments or tasks by exploiting previously acquired knowledge, a hallmark of human intelligence (Lopez-Paz and Ranzato, 2017). If the new tasks are *few-shot*, the existing methods suffer from over-fitting as shown later in our experiments (§4). Considering that humans can acquire new knowledge from a handful of examples, it is expected for the models to generalize well on the new tasks with few data. We regard this problem as Continual Few-shot Relation Learning or CFRL (Fig. 1). Indeed, in relation to CFRL, Zhang et al. (2021), Zhu et al. (2021) and Chen and Lee (2021) recently introduce methods for incremental few-shot learning in Computer Vision.

Based on the observation that the learning of emerging few-shot tasks may result in distorted feature distributions of new data which are incompatible with previous embedding space (Ren et al., 2020), this work introduces a novel model based on Embedding space Regularization and Data Augmentation (ERDA) for CFRL. In particular, we propose a multi-margin loss and a pairwise margin loss in addition to the cross-entropy loss to impose further relational constraints in the embedding space. We also introduce a novel contrastive loss to learn more effectively from the memory data. Our proposed data augmentation method selects relevant samples from unlabeled text to provide more relational knowledge for the few-shot tasks. The empirical results show that our method can significantly outperform previous state-of-the-art methods. In summary, our main contributions are:

- To the best of our knowledge, we are the first one to consider CFRL. We define the CFRL problem and construct a benchmark for the problem.
- We propose ERDA, a novel method for CFRL based on embedding space regularization and data augmentation.
- With extensive experiments, we demonstrate the effectiveness of our method compared to existing ones and analyse our results thoroughly.

2 Related Work

Conventional RE methods include supervised (Zelenko et al., 2002; Liu et al., 2013; Zeng et al., 2014; Miwa and Bansal, 2016), semi-supervised (Chen et al., 2006; Sun et al., 2011; Hu et al., 2020) and distantly supervised methods (Mintz et al., 2009; Yao et al., 2011; Zeng et al., 2015; Han et al., 2018a). These methods rely on a predefined relation set and have limitations in real scenario where novel relations are emerging. There have been some efforts which focus on relation learning without predefined types, including open RE (Shinyama and Sekine, 2006; Etzioni et al., 2008; Cui et al., 2018; Gao et al., 2020) and continual relation learning (Wang et al., 2019; Obamuyide and Vlachos, 2019; Han et al., 2020; Wu et al., 2021).

Continual Learning (CL) aims to learn knowledge from a sequence of tasks. The main problem CL attempts to address is *catastrophic forgetting* (McCloskey and Cohen, 1989), *i.e.,* the model forgets previous knowledge after learning new tasks. Prior methods to alleviate this problem can be mainly divided into three categories. First, *regularization-based* methods impose constraints on the update of neural weights important to previous tasks to alleviate catastrophic forgetting (Li and Hoiem, 2017; Kirkpatrick et al., 2017; Zenke et al., 2017; Ritter et al., 2018). Second, *architecture-based* methods dynamically change model architectures to acquire new information while remembering previous knowledge (Chen et al., 2016; Rusu et al., 2016; Fernando et al., 2017; Mallya et al., 2018). Finally, *memory-based* methods maintain a memory to save key samples of previous tasks to prevent forgetting (Rebuffi et al., 2017; Lopez-Paz and Ranzato, 2017; Shin et al., 2017; Chaudhry et al., 2019). These methods mainly focus on learning a single type of tasks. More recently, researchers have considered lifelong language learning (Sun et al., 2020; Qin and Joty, 2022), where the model is expected to continually learn from different types of tasks.

Few-shot Learning (FSL) aims to solve tasks containing only a few labeled samples, which faces the issue of over-fitting. To address this, existing methods have explored three different directions: (*i*) *data-based* methods use prior knowledge to augment data to the few-shot set (Santoro et al., 2016; Benaim and Wolf, 2018; Gao et al., 2020); (*ii*) *model-based* methods reduce the hypothesis space using prior knowledge (Rezende et al., 2016; Triantafillou et al., 2017; Hu et al., 2018); and (*iii*) *algorithm-based* methods try to find a more suitable strategy to search for the best hypothesis in the whole hypothesis space (Hoffman et al., 2013; Ravi and Larochelle, 2017; Finn et al., 2017).

Summary. Existing work in CRL which involves a sequence of tasks containing *sufficient* training data, mainly focuses on alleviating the catastrophic forgetting of previous relational knowledge when the model is trained on new tasks. The work in few-shot learning mostly leverages prior knowledge to address the over-fitting of novel few-shot tasks. In contrast to these lines of work, we aim to solve a more challenging yet more practical problem CFRL where the model needs to learn relational patterns from a sequence of few-shot tasks continually.

3 Methodology

In this section, we first formally define the CFRL problem. Then, we present our method for CFRL.

3.1 Problem Definition

CFRL involves learning from a sequence of tasks $\mathbb{T} = (\mathcal{T}^1, \ldots, \mathcal{T}^n)$, where every task $\mathcal{T}^k$ has its own training set D^k_{train}, validation set D^k_{valid}, and test set D^k_{test}. Each dataset D contains several samples $\{(x_i, y_i)\}_{i=1}^{|D|}$, whose labels y_i belong to the relation set R^k of task $\mathcal{T}^k$. In contrast to the previously addressed continual relation learning (CRL), CFRL assumes that except for the first task which has enough data for training, the subsequent new tasks are all *few-shot*, meaning that they have only few labeled instances (see Fig. 1). For example, consider there are three relation learning tasks $\mathcal{T}^1, \mathcal{T}^2$ and $\mathcal{T}^3$ with their corresponding relation sets R^1, R^2, and R^3, each having 10 relations. In CFRL, we assume the existing task $\mathcal{T}^1$ has enough training data (*e.g.,* 100 samples for every relation in R^1), while the new tasks $\mathcal{T}^2$ and $\mathcal{T}^3$ are few-shot with only few (*e.g.,* 5) samples for every relation in R^2 and R^3. Assuming that the relation number of each few-shot task is N and the sample number of every relation is K, we call this setup **N-way K-shot** continual learning. The problem setup of CFRL is aligned with the real scenario, where we generally have sufficient data for an existing task, but only few labeled data as new tasks emerge.

The model in CFRL is expected to first learn $\mathcal{T}^1$ well, which has sufficient training data to obtain good ability to extract the relation information in the sentence. Then at time step k, the model will be trained on the training set D^k_{train} of few-shot task $\mathcal{T}^k$. After learning $\mathcal{T}^k$, the model is expected to perform well on both $\mathcal{T}^k$ and the previous $k-1$ tasks, as the model will be evaluated on $\hat{D}^k_{\text{test}} = \cup_{i=1}^{k} D^i_{\text{test}}$ consisting of all known relations after learning $\mathcal{T}^k$, *i.e.,* $\hat{R}^k = \cup_{i=1}^{k} R^i$. This requires the model to overcome the *catastrophic forgetting* of previous knowledge and to learn new knowledge well with very few labeled data.

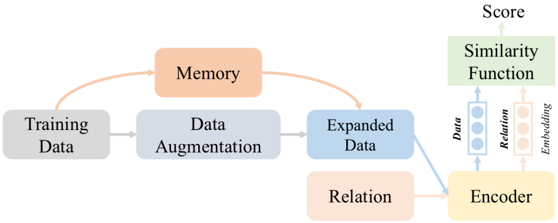

Figure 2: Our framework for CFRL. The Data Augmentation component is used only for few-shot tasks ($k > 1$).

To overcome the catastrophic forgetting problem, a memory $\mathcal{M} = \{\mathcal{M}^1, \mathcal{M}^2, ...\}$, which stores some key samples of previous tasks is maintained during the learning. When the model is learning $\mathcal{T}^k$, it has access to the data saved in memory $\mathcal{M}^1, ..., \mathcal{M}^{k-1}$. As there is no limit on the number of tasks, the size of memory $\mathcal{M}^k$ is constrained to be small. Therefore, the model has to select only key samples from the training set D^k_{train} to save them in $\mathcal{M}^k$. In our CFRL setting, only one sample per relation is allowed to be saved in the memory.

3.2 Overall Framework

Our framework for CFRL is shown in Fig. 2 and Alg. 1 describes the overall training process (see Appendix A.1 for a block diagram). At time step k, given the training data D^k_{train} for the task $\mathcal{T}^k$, depending on whether the task is a few-shot or not, the process has four or three working modules, respectively. The general learning process (§3.3) has three steps that apply to all tasks. If the task is a few-shot task ($k > 1$), we apply an additional step to create an augmented training set $\widetilde{D}^k_{\text{train}}$. For the initial task ($k = 1$), we have $\widetilde{D}^k_{\text{train}} = D^k_{\text{train}}$.

For any task $\mathcal{T}^k$, we use a siamese model to encode every new relation $r_i \in R^k$ into $\mathbf{r}_i \in \mathbb{R}^d$ as well as the sentences, and train the model on $\widetilde{D}^k_{\text{train}}$ to acquire relation information of the new data (§3.3.2). To overcome forgetting, we select the most informative sample for each relation $r_i \in R^k$ from D^k_{train} and update the memory $\hat{\mathcal{M}}^k$ (§3.3.3). Finally, we combine $\widetilde{D}^k_{\text{train}}$ and $\hat{\mathcal{M}}^k$ as the training data for learning new relational patterns and

remembering previous knowledge (§3.3.4). We also simultaneously update the representation of all relations in $\hat{R}^k$, which involves making a forward pass through the current model. The learning and updating are done iteratively for convergence.

For data augmentation in few-shot tasks (§3.4), we select reliable samples with high relational similarity score from an unlabelled Wikipedia corpus using a fine-tuned BERT (Devlin et al., 2019), which serves as the relational similarity model $\mathcal{S}_\pi$. In the interests of coherence, we first present the general learning method followed by the augmentation process for few-shot learning.

3.3 General Learning Process

We first introduce the encoder network as it is the basic component of the whole framework.

3.3.1 The Encoder Network

The siamese encoder (f_θ) aims at extracting generic and relation related features from the input. The input can be a labeled sentence or the name of a relation. We adopt two kinds of encoders:

- **Bi-LSTM** To have a fair comparison with previous work, we use the same architecture as Han et al. (2020). It takes GloVe embeddings (Pennington et al., 2014) of the words in a given input and produces a vector representation through a Bi-LSTM (Hochreiter and Schmidhuber, 1997).

- **BERT** We adopt BERT$_{\text{base}}$ which has 12 layers and 110M parameters. As the new tasks are few-shot, we only fine-tune the 12-th encoding layer and the extra linear layer. We include special tokens around the entities ('#' for the head entity and '@' for the tail entity) in a given labeled sentence to improve the encoder's understanding of relation information. We use the [CLS] token features as the representation of the input sequence.

3.3.2 Learning with New Data

At time step k, to have a good understanding of the new relations, we fine-tune the model on the expanded dataset $\widetilde{D}^k_{\text{train}}$. The model f_θ first encodes the name of each new relation $r_j \in R^k$ into its representation $\mathbf{r}_j \in \mathbb{R}^d$ by making a forward pass. Then, we optimize the parameters (θ) by minimizing a loss $\mathcal{L}_{\text{new}}$ that consists of a cross entropy loss, a multi-margin loss and a pairwise margin loss.

The **cross entropy** loss $\mathcal{L}_{\text{ce}}$ is used for relation classification as follows.

$$\sum_{(x_i,y_i)\in\widetilde{D}^k_{\text{train}}} \sum_{j=1}^{|\hat{R}^k|} \delta_{y_i,r_j} \times \log \frac{\exp(g(f_\theta(x_i),\mathbf{r}_j))}{\sum_{l=1}^{|\hat{R}^k|} \exp(g(f_\theta(x_i),\mathbf{r}_l))} \tag{1}$$

where $\hat{R}^k$ is the set of all known relations at step k, $g(,)$ is a function used to measure similarity between two vectors (*e.g.*, cosine similarity or L2 distance), and $\delta_{a,b}$ is the Kronecker delta function–$\delta_{a,b} = 1$ if a equals b, otherwise $\delta_{a,b} = 0$.

In inference, we choose the relation label that has the highest similarity with the input sentence (Eq. 8). To ensure that an example has the highest similarity with the true relation, we additionally design two **margin-based** losses, which increase the score between an example and the true label while decreasing the scores for the wrong labels. The first one is a **multi-margin** loss defined as:

$$\begin{aligned}\mathcal{L}_{\text{mm}} = \sum_{(x_i,y_i)\in\widetilde{D}^k_{\text{train}}} \sum_{j=1, j\neq t_i}^{|\hat{R}^k|} \max\Big(0,\\ m_1 - g(f_\theta(x_i),\mathbf{r}_{t_i}) + g(f_\theta(x_i),\mathbf{r}_j)\Big)\end{aligned} \tag{2}$$

where t_i is the correct relation index in $\hat{R}^k$ satisfying $r_{t_i} = y_i$ and m_1 is a margin value. The $\mathcal{L}_{\text{mm}}$ loss attempts to ensure intra-class compactness while increasing inter-class distances. The second one is a **pairwise margin** loss $\mathcal{L}_{\text{pm}}$:

$$\sum_{(x_i,y_i)\in\widetilde{D}^k_{\text{train}}} \max(0, m_2 - g(f_\theta(x_i),\mathbf{r}_{t_i}) + g(f_\theta(x_i),\mathbf{r}_{s_i})) \tag{3}$$

where m_2 is the margin for $\mathcal{L}_{\text{pm}}$ and $s_i = \arg\max_s g(f_\theta(x_i), \mathbf{r}_s)$ s.t. $s \neq t_i$, the closest wrong label. The $\mathcal{L}_{\text{pm}}$ loss penalizes the cases where the similarity score of the closest wrong label is higher than the score of the correct label (Yang et al., 2018). Both $\mathcal{L}_{\text{mm}}$ and $\mathcal{L}_{\text{pm}}$ improve the discriminative ability of the model (§4.4).

The **total loss** for learning on $\mathcal{T}^k$ is defined as:

$$\mathcal{L}_{new} = \lambda_{\text{ce}}\mathcal{L}_{\text{ce}} + \lambda_{\text{mm}}\mathcal{L}_{\text{mm}} + \lambda_{\text{pm}}\mathcal{L}_{\text{pm}} \tag{4}$$

where λ_{ce}, λ_{mm} and λ_{pm} are the relative weights of the component losses, respectively.

3.3.3 Selecting Samples for Memory

After training the model f_θ with Eq. (4), we use it to select one sample per new relation. Specifically, for every new relation $r_j \in R^k$, we obtain the centroid feature $\mathbf{c}_j$ by averaging the embeddings of all samples labeled as r_j in D^k_{train} as follows.

$$\mathbf{c}_j = \frac{1}{|D^k_{r_j}|} \sum_{(x_i,y_i)\in D^k_{r_j}} f_\theta(x_i) \tag{5}$$

where $D^k_{r_j} = \{(x_i, y_i) | (x_i, y_i) \in D^k_{\text{train}}, y_i = r_j\}$. Then we select the instance closest to $\mathbf{c}_j$ from $D^k_{r_j}$ as the most informative sample and save it in memory $\mathcal{M}^k$. Note that the selection is done from D^k_{train}, not from the expanded set $\widetilde{D}^k_{\text{train}}$.

3.3.4 Alleviating Forgetting through Memory

As the learning of new relational patterns may cause catastrophic forgetting of previous knowledge (see baselines in §4), our model needs to learn from the memory data to alleviate forgetting. We combine the expanded set $\widetilde{D}^k_{\text{train}}$ and the whole memory data $\hat{\mathcal{M}}^k = \cup^k_{j=1}\mathcal{M}^j$ into $\widetilde{H}^k$ to allow the model to learn new relational knowledge and consolidate previous knowledge. However, the memory data is limited containing only one sample per relation. To learn effectively from such limited data, we design a novel method to generate a *hard negative sample* set P_i for every sample in $\hat{\mathcal{M}}^k$.

The negative samples are generated on the fly. After sampling a mini-batch B_t from $\widetilde{H}^k$, we consider all memory data in B_t as M_{B_t}. For every sample $(\hat{x}_i, \hat{y}_i)$ in M_{B_t}, we replace its head entity e^h_i or tail entity e^t_i with the corresponding entity of a randomly selected sample in the same batch B_t to get the hard negative sample set $P_i = \{(\hat{x}^{P_i}_j, \hat{y}_i)\}^{|P_i|}_{j=1}$. Then $(\hat{x}_i, \hat{y}_i)$ and P_i are used to calculate a margin-based **contrastive loss** $\mathcal{L}_{\text{con}}$ as follows.

$$\mathcal{L}_{\text{con}} = \sum_{(\hat{x}_i,\hat{y}_i)\in M_{B_t}} \max\Big(0, m_3 - g(f_\theta(\hat{x}_i), \mathbf{r}_{\hat{t}_i}) + \sum_{(\hat{x}^{P_i}_j,\hat{y}_i)\in P_i} g(f_\theta(\hat{x}^{P_i}_j), \mathbf{r}_{\hat{t}_i})\Big) \tag{6}$$

where $\hat{t}_i$ is the relation index satisfying $r_{\hat{t}_i} = \hat{y}_i$ and m_3 is the margin value for $\mathcal{L}_{\text{con}}$. This loss forces the model to distinguish the valid relations from the hard negatives so that the model learns more precise and fine-grained relational knowledge. In addition, we also use the three losses $\mathcal{L}_{\text{ce}}$ and $\mathcal{L}_{\text{mm}}$ and $\mathcal{L}_{\text{pm}}$ defined in §3.3.2 to update θ on B_t. The total loss on the memory data is:

$$\mathcal{L}_{\text{mem}} = \lambda_{\text{ce}}\mathcal{L}_{\text{ce}} + \lambda_{\text{mm}}\mathcal{L}_{\text{mm}} + \lambda_{\text{pm}}\mathcal{L}_{\text{pm}} + \lambda_{\text{con}}\mathcal{L}_{\text{con}} \tag{7}$$

where λ_{ce}, λ_{mm}, λ_{pm} and λ_{con} are the relative weights of the corresponding losses.

Updating Relation Embeddings After training the model on $\widetilde{H}^k$ for few steps, we use the memory $\hat{\mathcal{M}}^k$ to update the relation embedding $\mathbf{r}_i$ of all known relations. For a relation $r_i \in \hat{R}^k$, we average the embeddings (obtained by making a forward pass through f_θ) of the relation name and memory data to obtain its updated representation $\mathbf{r}_i$. The training of θ and updating of $\mathbf{r}_i$ is done iteratively to grasp new relational patterns while alleviating the catastrophic forgetting of previous knowledge.

3.3.5 Inference

For a given input x_i in $\hat{D}^k_{\text{test}}$, we calculate the similarity between x_i and all known relations, and pick the one with the highest similarity score:

$$y_i^* = \arg\max_{r\in\hat{R}^k} g(f_\theta(x_i), \mathbf{r}) \tag{8}$$

3.4 Data Augmentation for Few-shot Tasks

For each few-shot task $\mathcal{T}^k$, we aim to get more data by selecting reliable samples from an unlabeled corpus $\mathcal{C}$ with tagged entities before the general learning process (§3.3) begins. We achieve this using a relational similarity model $\mathcal{S}_\pi$ and sentences from Wikipedia as $\mathcal{C}$. The model $\mathcal{S}_\pi$ (described later) takes a sentence as input and produces a normalized vector representation. The cosine similarity between two vectors is used to measure the relational similarity between the two corresponding sentences. A higher similarity means the two sentences are more likely to have the same relation label. We propose two novel selection methods, which are complementary to each other.

(a) Augmentation via Entity Matching For each instance (x_i, y_i) in D^k_{train}, we extract its entity pair (e^h_i, e^t_i) with e^h_i being the head entity and e^t_i being the tail entity. As sentences with the same entity pair are more likely to express the same relation, we first collect a candidate set $\mathcal{Q} = \{\widetilde{x}_j\}^{|\mathcal{Q}|}_{j=1}$ from $\mathcal{C}$, where $\widetilde{x}_j$ shares the same entity pair (e^h_i, e^t_i) with x_i. If $\mathcal{Q}$ is a non-empty set, we pair all $\widetilde{x}_j$ in $\mathcal{Q}$ with x_i, and denote each pair as $\langle \widetilde{x}_j, x_i \rangle$. Then we use $\mathcal{S}_\pi$ to obtain a similarity score s_j for $\langle \widetilde{x}_j, x_i \rangle$. After getting scores for all pairs, we pick the instances $\widetilde{x}_j$ with similarity score s_j higher than a predefined threshold α as new samples and label them with relation y_i. The selected instances are then augmented to D^k_{train} as additional data.

(b) Augmentation via Similarity Search The hard entity matching could be too restrictive at times. For example, even though the sentences "*Harry Potter* is written by *Joanne Rowling*" and "*Charles Dickens* is the author of *A Tale of Two Cities*" share the same relation *author*, hard matching fails to find any relevance. Therefore, in cases when entity matching returns an empty $\mathcal{Q}$, we resort to similarity search using Faiss (Johnson et al., 2017). Given a query vector $\mathbf{q}_i$, it can efficiently search for vectors $\{\mathbf{v}_j\}^K_{j=1}$ with the top-K highest similarity scores in a large vector set $\mathcal{V}$. In our case, $\mathbf{q}_i$ is the representation of x_i and $\mathcal{V}$ contains the representations of the sentences in $\mathcal{C}$. We use $\mathcal{S}_\pi$ to obtain these representations; the difference is that $\mathcal{V}$ is pre-computed while $\mathbf{q}_i$ is obtained during training. We labeled the top-K most similar instances with y_i and augment them to D^k_{train}.

Similarity Model To train $\mathcal{S}_\pi$, inspired by Soares et al. (2019), we adopt a *contrastive learning* method to fine-tune a $\text{BERT}_{\text{base}}$ model on $\mathcal{C}$, whose sentences are already tagged with entities. Based on the observation that sentences with the same entity pair are more likely to encode the same relation, we use sentence pairs containing the same entities in $\mathcal{C}$ as positive samples. For negatives, instead of using all sentence pairs containing different entities, we select pairs sharing only one entity as **hard negatives** (*i.e.*, pair (x_i, x_j) where $e^h_i = e^h_j$ and $e^t_i \neq e^t_j$ or $e^t_i = e^t_j$ and $e^h_i \neq e^h_j$). We randomly sample the same number of negative samples as the positive ones to balance the training.

For an input pair (x_i, x_j), we compute the similarity score based on the following formula.

$$\sigma(x_i, x_j) = \frac{1}{1 + \exp(-\mathcal{S}_\pi(x_i)^T \mathcal{S}_\pi(x_j))} \quad (9)$$

where $\mathcal{S}_\pi(x)$ is the normalized representation of x obtained from the final layer of BERT. Then we optimize the parameters π of $\mathcal{S}_\pi$ by minimizing a binary cross entropy loss $\mathcal{L}_{\text{pretrain}}$ as follows.

$$-\sum_{(x_i,x_j)\in\mathcal{C}_p} \log\sigma(x_i, x_j) - \sum_{(x'_i,x'_j)\in\mathcal{C}_n} \log(1 - \sigma(x'_i, x'_j)) \quad (10)$$

where $\mathcal{C}_p$ is a positive batch and $\mathcal{C}_n$ is a negative batch. This objective tries to ensure that sentence pairs with the same entity pairs have higher cosine similarity than those with different entities.

4 Experiment

We define the benchmark and evaluation metric for CFRL before presenting our experimental results.

4.1 Benchmark and Evaluation Metric

Benchmark As the benchmark for CFRL needs to have sufficient relations as well as data and be suitable for few-shot learning, we create the CFRL benchmark based on **FewRel** (Han et al., 2018b). FewRel is a large-scale dataset for few-shot RE, which contains 80 relations with hundreds of samples per relation. We randomly split the 80 relations into 8 tasks, where each task contains 10 relations (*10-way*). To have enough data for the first task $\mathcal{T}^1$, we sample 100 samples per relation. All the subsequent tasks $\mathcal{T}^2$, ..., $\mathcal{T}^8$ are few-shot; for each relation, we conduct *2-shot*, *5-shot* and *10-shot* experiments to verify the effectiveness of our method.

In addition, to demonstrate the generalizability of our method, we also create a CFRL benchmark based on the **TACRED** dataset (Zhang et al., 2017) which contains only 42 relations. We filter out the special relation "n/a" (not available) and split the remaining 41 relations into 8 tasks. Except for the first task that contains 6 relations, all other tasks have 5 relations (*5-way*). Similar to FewRel, we randomly sample 100 examples per relation in $\mathcal{T}^1$ and conduct *5-shot* and *10-shot* experiments.

Metric At time step k, we evaluate the model performance through relation classification accuracy on the test sets $\hat{D}^k_{\text{test}} = \cup^k_{i=1} D^i_{\text{test}}$ of all seen tasks $\{\mathcal{T}^i\}^k_{i=1}$. This metric reflects whether the model can alleviate catastrophic forgetting while acquiring novel knowledge well with very few data. Since the model performance might be influenced by task sequences and few-shot training samples, we run every experiment 6 times each time with a different random seed to ensure a random task order and model initialization, and report the average

Method	Task index							
	1	2	3	4	5	6	7	8
SeqRun	92.78	52.11	30.08	24.33	19.83	16.90	14.36	12.34
Joint Train	**92.78**	76.29	69.39	64.75	60.45	**57.64**	52.80	50.03
EMR	92.78	69.14	56.24	50.03	46.50	43.21	39.88	37.51
EMAR	85.20	62.02	52.45	48.95	46.77	44.33	40.75	39.04
IDLVQ-C	92.23	69.15	57.42	51.66	49.31	46.24	42.25	40.56
ERDA	92.57	**79.17**	**70.43**	**65.01**	**61.06**	**57.54**	**54.88**	**53.23**

Table 1: Accuracy (%) of different methods at every time step on **FewRel** benchmark for 10-**way** 5-**shot** CFRL. ERDA is significantly better than IDLVQ-C with p-value < 0.001.

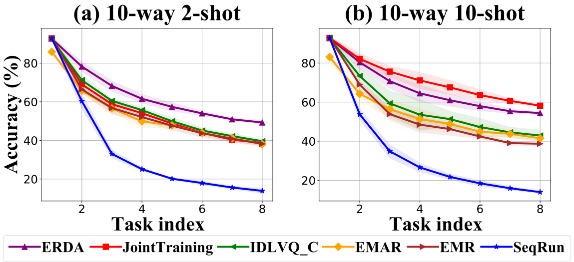

Figure 3: Comparison results at each time step on **FewRel** benchmark for 10-**way** 2-**shot** and 10-**shot** settings. For both settings, ERDA is significantly better than IDLVQ-C with p-value < 0.001. The variance is reported as light color region.

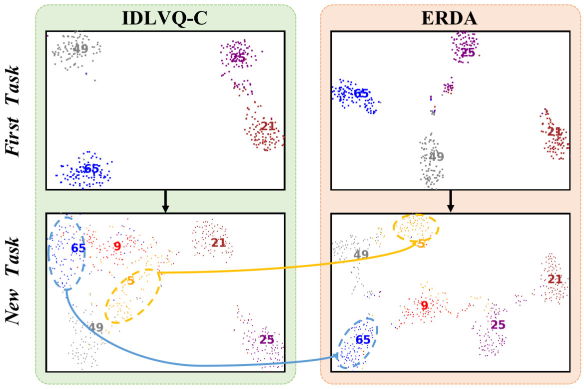

Figure 4: t-SNE visualization of IDLVQ-C and ERDA at two stages. Colors represent different relation classes with numbers being the relation indices. The initial embeddings of four base classes after learning the first task are shown in the upper row. As the data for the first task is sufficient, both methods can obtain separable embedding space. The lower row shows the embeddings of four base classes and two novel classes (Id 5 and 9) after learning a new few-shot task. Compared with IDLVQ-C, ERDA shows better intra-class compactness (circled regions) and larger inter-class distances (see the distances between 5 and 9, and 9 and 65).

accuracy along with variance. We perform paired t-test for statistical significance.

4.2 Model Settings & Baselines

The model settings are shown in Appendix A.2. We compare our approach with the following baselines:

- **SeqRun** fine-tunes the model only on the training data of the new tasks without using any memory data. It may face serious catastrophic forgetting and serves as a **lower bound**.
- **Joint Training** stores all previous samples in the memory and trains the model on all data for each new task. It serves as an **upper bound** in **CRL**.
- **EMR** (Wang et al., 2019) maintains a memory for storing selected samples from previous tasks. When training on a novel task, EMR combines the new training data and memory data.
- **EMAR** (Han et al., 2020) is the state-of-the-art on CRL, which adopts memory activation and reconsolidation to alleviate catastrophic forgetting.
- **IDLVQ-C** (Chen and Lee, 2021) introduces quantized reference vectors to represent previous knowledge and mitigates catastrophic forgetting by imposing constraints on the quantized vectors and embedded space. It was originally proposed for image classification with state-of-the-art results in incremental few-shot learning.

4.3 Main Results

We compare the performance of different methods using the same setting as EMAR (Han et al., 2020), which uses a Bi-LSTM encoder. We also report the results with a BERT encoder.

FewRel Benchmark We report our results on *10-way 5-shot* in Table 1, while Fig. 3 shows the results on the *10-way 2-shot* and *10-way 10-shot* settings.[2] From the results, we can observe that:

● Our proposed ERDA outperforms previous baselines in all CFRL settings, which demonstrates the superiority of our method. Simply fine-tuning the model with new few-shot examples leads to rapid drops in accuracy due to severe over-fitting and catastrophic forgetting. Although EMR and EMAR adopt a memory module to alleviate forgetting, their performance still decreases quickly as they require plenty of training data for learning a new task. Compared with EMR and EMAR, IDLVQ-C is slightly better as it introduces quantized vectors that can better represent the embedding space of few-shot tasks. However, IDLVQ-C does not necessarily push the samples from different relations to be far apart in the embedding space and the up-

---

[2] To avoid visual clutter, we report only mean scores over 6 runs in Table 1 and refer to Table 6 and Table 5 in Appendix for variance and elaborate results for different task order.

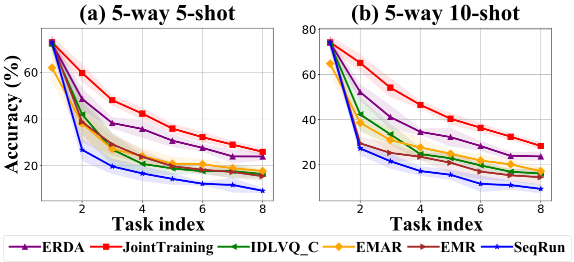

Figure 5: Comparison results at every time step on **TACRED** benchmark for 5-**way** 5-**shot** and 10-**shot** settings. ERDA is significantly better than IDLVQ-C with p-value < 0.001 for both settings. The variance is reported as light color region.

dating method for the reference vectors may not be optimal. ERDA outperforms IDLVQ-C by a large margin through embedding space regularization and self-supervised data augmentation. To verify this, we show the embedding space of IDLVQ-C and ERDA using t-SNE (Van der Maaten and Hinton, 2008). We randomly choose four classes from the first task of FewRel and two classes from the new task, and visualize the test data of these classes in Fig. 4. As can be seen, the embedding space obtained by ERDA shows better intra-class compactness and larger inter-class distances.

- Unlike CRL, joint training does not always serve as an upper bound in CFRL due to the extremely imbalanced data distribution. Benefiting from the ability to learn feature distribution with very few data, both ERDA and IDLVQ-C perform better than joint training in the *2-shot* setting. However, as the number of few-shot samples increases, the performance of IDLVQ-C falls far behind joint training, while ERDA still performs better. In the *5-shot* setting, ERDA could achieve better results than joint training which verifies the effectiveness of self-supervised data augmentation (more on this in §4.4). Although ERDA performs worse than joint training in the *10-shot* setting, its results are still much better than other baselines.
- After learning all few-shot tasks, ERDA outperforms IDLVQ-C by **9.69**%, **12.67**% and **11.49**% in the *2-shot*, *5-shot* and *10-shot* settings, respectively. Moreover, the relative gain of ERDA keeps growing with the increasing number of new few-shot tasks. This demonstrates the ability of our method in handling a longer sequence of CFRL tasks.

TACRED Benchmark Fig. 5 shows the *5-way 5-shot* and *5-way 10-shot* results on TACRED. We can see that here also ERDA outperforms all other methods by a large margin which verifies the strong generalization ability of our proposed method.

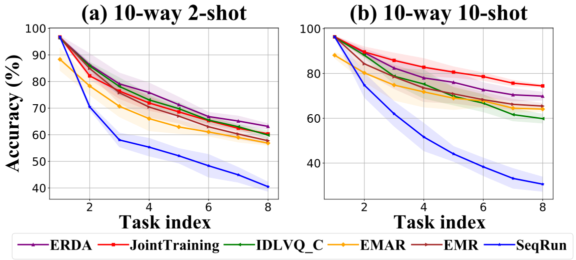

Figure 6: Comparison results of different methods with a BERT encoder on **FewRel** benchmark for 10-**way** 2-**shot** and 10-**shot** settings. ERDA is significantly better than IDLVQ-C with p-value $= 0.005$ for 2-shot setting and is significantly better than EMR with p-value $= 0.002$ for 10-shot setting.

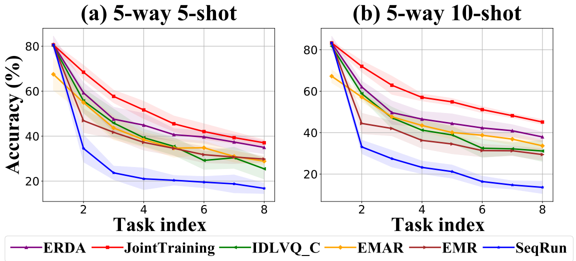

Figure 7: Results of different methods with a BERT encoder on **TACRED** benchmark for 5-**way** 5-**shot** and 10-**shot** settings. ERDA is significantly better than EMR with p-value $= 0.004$ for 5-shot setting and is significantly better than EMAR with p-value $= 0.02$ for 10-shot setting.

Results with BERT We show the results with $\text{BERT}_{\text{base}}$ of different methods on FewRel in Fig. 6 for *10-way 2-shot* and *10-shot* and Table 4 for *10-way 5-shot* (in Appendix). The results of on TACRED benchmark are shown in Fig. 7 for *5-way 5-shot* and *10-shot*. From the results, we can observe that ERDA outperforms previous baselines in all CFRL settings with a BERT encoder.

4.4 Ablation Study

We conduct several ablations to analyze the contribution of different components of ERDA on the FewRel *10-way 5-shot* setting. In particular, we investigate seven other variants of ERDA by removing one component at a time: (*a*) the multi-margin loss $\mathcal{L}_{\text{mm}}$, (*b*) the pairwise margin loss $\mathcal{L}_{\text{pm}}$, (*c*) the margin-based contrastive loss $\mathcal{L}_{\text{con}}$, (*d*) the whole 2-stage data augmentation module, (*e*) the entity matching method of augmentation, (*f*) the similarity search method of augmentation, and (*g*) memory.

From the results in Table 3, we can observe that all components improve the performance of our model. Specifically, $\mathcal{L}_{\text{mm}}$ yields about **1.51**% performance boost as it brings samples of the same

λ_{con}	0	0.01	0.02	0.05	0.1	0.2	0.5	1.0
Accuracy (%)	$51.95_{\pm 1.15}$	$52.66_{\pm 1.23}$	$\mathbf{53.38}_{\pm 0.63}$	$53.10_{\pm 0.69}$	$53.23_{\pm 1.49}$	$52.99_{\pm 0.79}$	$52.13_{\pm 1.50}$	$52.27_{\pm 1.07}$

Table 2: Accuracy (%) after learning all tasks with different λ_{con} on **FewRel** benchmark (10-**way** 5-**shot**).

relation closer to each other while enforcing larger distances among different relation distributions. The $\mathcal{L}_{\text{pm}}$ improves the accuracy by **3.18**%, which demonstrates the effect of contrasting with the nearest wrong label. The adoption of $\mathcal{L}_{\text{con}}$ leads to **1.28**% improvement, which shows that generating hard negative samples for memory data can help to better remember previous relational knowledge. To better investigate the influence of $\mathcal{L}_{con}$, we conduct experiments with different λ_{con} and show the results in Table 2. We can see that the model achieves the best accuracy of 53.38 with $\lambda_{con} = 0.02$ while the accuracy is only 52.13 with $\lambda_{con} = 0.5$. In addition, the performance of the variant without $\mathcal{L}_{con}$ is worse than the performance of all other variants, which demonstrates the effectiveness of $\mathcal{L}_{con}$.

The data augmentation module improves the performance by **1.72**% as it can extract informative samples from unlabeled text which provide more relational knowledge for few-shot tasks. The results of variants without entity matching or similarity search verify that the two data augmentation methods are generally complementary to each other.

One could argue that the data augmentation module increases the complexity of ERDA compared to other models. However, astute readers can find that even without data augmentation, ERDA outperforms IDLVQ-C significantly for all tasks (compare 'ERDA *w.o.* DA' with the baselines in Table 1).

ERDA's Performance under CRL Although ERDA is designed for CFRL, we also evaluate the embedding space regularization ('ERDA *w.o.* DA') in the CRL setting. We sample 100 examples per relation for every task in FewRel and compare our method with the state-of-the-art method EMAR. The results are shown in Fig. 8. We can see that ERDA outperforms EMAR in all tasks by **1.25** - **4.95**% proving that the embedding regularization can be a general method for CRL.

Method	Task index							
	1	2	3	4	5	6	7	8

Table 3: Ablations on **FewRel** benchmark (10-**way** 5-**shot**). The variance over 6 runs is reported in Table 7 in Appendix. We show the analysis of '*w.o.* M' in Appendix A.4.

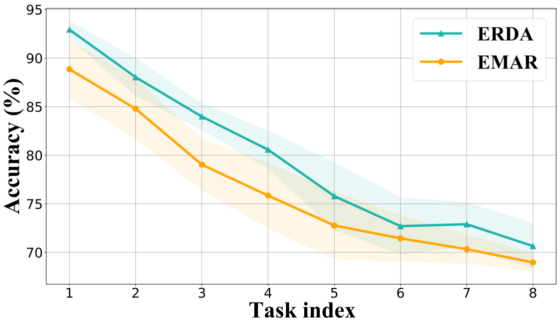

Figure 8: Relation extraction results for ERDA (our) and EMAR (Han et al., 2020) on the FewRel benchmark under the CRL setting. We randomly split the 80 relations into 8 tasks, where each task contains 10 relations. And we sample 100 examples per relation. From this figure, we can observe that ERDA outperforms EMAR in all CRL tasks.

5 Conclusion

We have introduced continual few-shot relation learning (CFRL), a challenging yet practical problem where the model needs to learn new relational knowledge with very few labeled data continually. We have proposed a novel method, named ERDA, to alleviate the over-fitting and catastrophic forgetting problems which are the core issues in CFRL. ERDA imposes relational constraints in the embedding space with innovative losses and adds extra informative data for few-shot tasks in a self-supervised manner to better grasp novel relational patterns and remember previous knowledge. Extensive experimental results and analysis show that ERDA significantly outperforms previous methods in all CFRL settings investigated in this work. In the future, we would like to investigate ways to combine meta-learning with CFRL.

A Appendix

A.1 Block Diagram of ERDA Training

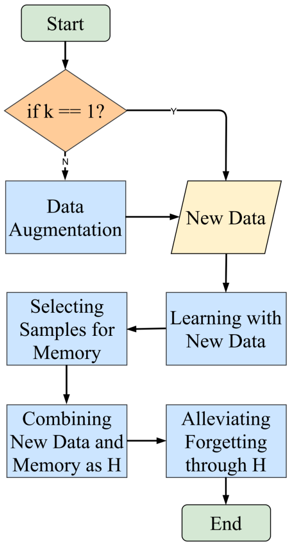

Figure 9: The block diagram of ERDA's training at time step k.

A.2 Hyperparameter Search

We follow the settings in Han et al. (2020) for the Bi-LSTM encoder to have a fair comparison. For data augmentation, we set the threshold $\alpha = 0.65$ and the number of samples selected by Faiss (K) as 1. We adopt $0.2, 0.2$ and 0.01 for the three margin values m_1, m_2 and m_3, respectively. The loss weights $\lambda_{\text{ce}}, \lambda_{\text{mm}}, \lambda_{\text{pm}}$ and λ_{con} are set to 1.0, 1.0, 1.0 and 0.1, respectively. In Alg. 1, we set 1 for $iter_1$ and 2 for $iter_2$. Hyperparameter search is done on the validation sets. We follow EMAR (Han et al., 2020) and use a grid search to select the hyperparameters. Specifically, the search spaces are:

- Search range for α is $[0.3, 0.8]$ with a step size of 0.05.
- Search range for K is $[1, 3]$ with a step size of 1.
- Search range for m_1 and m_2 is $[0.1, 0.3]$ with a step size of 0.1.
- Search range for m_3 is $[0.01, 0.03]$ with a step size of 0.01.
- Search range for $iter_2$ in Alg. 1 is $[1, 3]$ with a step size of 1.

A.3 The Influence of Task Order

To evaluate the influence of the task order, we show the results (ERDA and IDLVQ-C) of six different runs with different task order on the FewRel benchmark for *10-way 5-shot* setting in Table 5. From the results, we can see that the order of tasks will influence the performance. For example, ERDA achieves 55.59 accuracy after learning task8 on the second run while the accuracy after learning task8 on the fifth run is only 51.35. More importantly, ERDA outperforms IDLVQ-C by a large margin in all six different runs.

A.4 The Contribution of Memory

We conduct the ablation without memory ('*w.o.* M') to analyze the contribution of the memory module on the FewRel *10-way 5-shot* setting. From the results in Table 7, we can observe that ERDA shows much better performance than '*w.o.* M', which verifies the importance of the memory module. In addition, comparing the results of '*w.o.* M' and 'SeqRun' in Table 1, we can find that '*w.o.* M' achieves much better accuracy. This demonstrates the effectiveness of improving the representation ability of the model through margin-based losses.

Variational Graph Autoencoding as Cheap Supervision for AMR Coreference Resolution

Abstract

Coreference resolution over semantic graphs like AMRs aims to group the graph nodes that represent the same entity. This is a crucial step for making document-level formal semantic representations. With annotated data on AMR coreference resolution, deep learning approaches have recently shown great potential for this task, yet they are usually data hungry and annotating data is costly. We propose a general pretraining method using variational graph autoencoder (VGAE) for AMR coreference resolution, which can leverage any general AMR corpus and even automatically parsed AMR data. Experiments on benchmarks show that the pretraining approach achieves performance gains of up to 6% absolute F1 points. Moreover, our model significantly improves on the previous state-of-the-art model by up to 11% F1 points.

1 Introduction

Abstract Meaning Representation (AMR) is a way to preserve the semantic meaning of a sentence in a graph (Banarescu et al., 2013). As shown in Figure 1, AMRs are directed and acyclic graphs where the nodes and edges indicate concepts and their semantic relations. As a sentence-level semantic representation, AMRs have been shown to be effective in many NLP tasks, including text summarization (Liu et al., 2015; Dohare et al., 2018), information extraction (Rao et al., 2017; Li et al., 2020b; Zhang and Ji, 2021), and machine translation (Song et al., 2019; Pham et al., 2020).

More recently, the NLP tasks that are beyond the single-sentence level (Nallapati et al., 2016; Rajpurkar et al., 2016; Li et al., 2017; Chen et al., 2021) are attracting rising attention, and thus representing multiple sentences with AMR becomes important. To expand AMRs to represent multiple sentences, the task of AMR coreference resolution (O'Gorman et al., 2018) has been proposed, aiming at recognizing the concepts from multiple AMRs that represent the same entity. Figure 1 illustrates the AMR graphs of two consecutive sentences in a news article. Given them as the input, an AMR coreference resolver needs to group *police* and *they* (colored with blue), as well as *shop* and the implicit mention *shop* (dashed and colored with pink). Unlike text-based coreference resolution, where dense textual information is available, AMR coreference resolution deals with sparsely connected graphs and implicit graph nodes. More importantly, only a handful of annotated data (around 8K AMRs) exists for AMR coreference resolution. Furthermore, annotating such coreference information and sentence AMRs requires linguists, making the annotation *very costly*. Both situations add extra difficulties to this task.

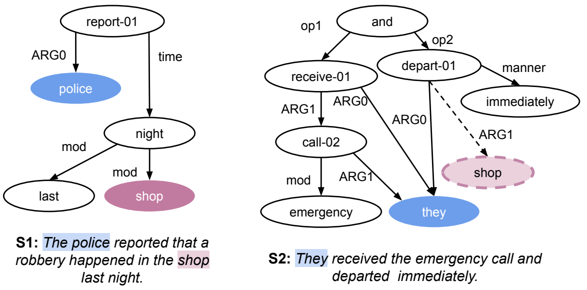

Figure 1: An example of multi-sentence AMR coreference resolution. It contains two coreference clusters, marked by blue and pink respectively: *police* in S1 and *They* in S2; *shop* in S1 and the implicit mention of *shop* (with dashed edge and node) in S2.

Early attempts on AMR coreference resolution adopt rule-based methods. For instance, Liu et al. (2015) only consider the nodes that represent entities (e.g., *police* in Figure 1), and they rely on string match to detect coreference. This method can cause errors, as concepts with the same surface string may not point to the same entity. It also fails

May 22-27, 2022

to recognize any situations that involve a pronoun (e.g., *police* and *they*). Anikina et al. (2020) build a pipeline system that uses a textual coreference resolution model (Lee et al., 2017) and a text-to-AMR aligner (Flanigan et al., 2014). Though this system can theoretically resolve many situations, in fact, it suffers from severe error propagation (Fu et al., 2021). With the availability of recent human-annotated data (O'Gorman et al., 2018) on AMR coreference resolution, later work starts exploring data-driven models. Fu et al. (2021) extend a standard text-based coreference model (Lee et al., 2017) on AMRs by replacing the LSTM encoder with a graph neural network (GNN). They show a significant performance boost over previous rule-based methods, and their generated document-level AMRs can help a downstream neural summarization system, demonstrating the potential of this task. However, the performance is still far from satisfactory, and they find that the main reason is the lack of annotated data. This calls for approaches that can leverage cheap and/or existing supervision signals to make further improvements.

In this paper, we propose a model and a corresponding pretraining method based on Variational Graph Autoencoder (VGAE) (Kipf and Welling, 2016b). Our model extends AMRCoref (Fu et al., 2021), the current state-of-the-art model, by replacing the core GNN encoder with an improved VGAE encoder. Our model can leverage the reconstruction loss and variational restriction from the VGAE module as additional supervision at no extra cost. Since the loss by our VGAE model can work on any AMR graphs, we also study pretraining our model on the full AMR bank[1] with gold or automatically parsed annotations. In this way, the training signal can be further enriched; thus, the data hunger issue can be alleviated. Though there exist some work applying VAEs and VGAEs on concept knowledge graphs (Li et al., 2020a), corpus-level graphs (Xie et al., 2021) and text (Su et al., 2018), we are the first to study VGAE on a graph-based formal semantic representation, to the best of our knowledge.

Experiments on the MS-AMR benchmark (O'Gorman et al., 2018) show that our model outperforms the previous state-of-the-art system by 11 absolute F1-score points. Besides, we find that pretraining with a larger AMR bank is helpful regardless of whether gold or silver AMR annotations are used. This indicates another potential boost on the performance if more automatically annotated data can be used. Code and pretrained models are made public[2].

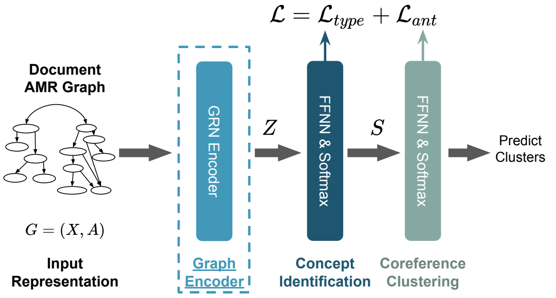

Figure 2: AMRCoref framework (Fu et al., 2021). The dashed rectangle indicates the core graph encoding component, which is also our main focus.

2 Baseline: AMRCoref

We take the end-to-end AMR coreference resolution model (**AMRCoref**, Fu et al. 2021) as our baseline system. Generally, it adapts a text-based end-to-end coreference model (Lee et al., 2017) on AMRs by clustering AMR nodes instead of text spans. Another major difference is that they also consider omitted AMR nodes (e.g., the dashed node *shop* in Figure 1), which are represented by their parent nodes and the corresponding relation (e.g., *depart-01* and *:ARG1*). As illustrated in Figure 2, AMRCoref consists of four essential modules: input representation, graph encoding, node type identification, and antecedent prediction.

2.1 Input Representation

As the first step of AMRCoref, it calculates the embedding $h_i^{(0)}$ for each AMR node x_i from its character-level embedding e_i^c, token-level embedding e_i^t and fixed embedding e_i^{bert} generated by a pretrained BERT model:

$$h_i^{(0)} = W^{concept}([e_i^c; e_i^t; e_i^{bert}]) + b^{concept}, \quad (1)$$

where $W^{concept}$ and $b^{concept}$ are model parameters. The character-level and token-level embeddings can be learned from scratch. One can choose to eliminate BERT embedding e_i^{bert} as a simple base model.

---

[2] `https://github.com/IreneZihuiLi/VG-AMRCoref`

2.2 Graph Encoder

Next, the representations $H^{(0)} = [h_1^{(0)}, \ldots, h_N^{(0)}]$ of all AMR nodes $X = [x_1, \ldots, x_N]$ are sent to a graph encoder together with the AMR edges. Since the input AMRs are disconnected (each AMR alone represents a sentence), Fu et al. (2021) heuristically connect the root nodes of these sentence AMRs to make a connected graph G. Specifically, $G = (X, A)$, where the edge set A consists of both the original AMR edges and the added ones between pairs of roots.

The graph encoder, f_{GRN}, is based on the Graph Recurrent Network (GRN, Song et al. 2018; Beck et al. 2018). It utilizes the gated operations of an LSTM (Hochreiter and Schmidhuber, 1997) step to simultaneously update each node representation h_i by exchanging information from its incoming N_{in}^i and outgoing neighbors N_{out}^i that can be easily obtained from the edge set A:

$$\begin{aligned} m_{in}^{(l-1)} &= \sum_{j \in N_{in}^i} [h_j^{(l-1)}; r_{ij}], \\ m_{out}^{(l-1)} &= \sum_{j \in N_{out}^i} [h_j^{(l-1)}; r_{ij}], \\ h_i^{(l)} &= \mathrm{LSTM}(h_i^{(l-1)}, [m_{in}^{(l-1)}; m_{out}^{(l-1)}]), \end{aligned} \tag{2}$$

where each r_{ij} represents the embedding of the edge from x_i to x_j. After L steps of information exchange, $z_i = [h_i^{(0)}; h_i^{(L)}]$ is used as the representation of node x_i for the next step.

2.3 Concept Identification

The concept identification subtask is to determine the type for each AMR node from 6 predefined candidate types. Taking Figure 1 as an example, these types are: `func` (functional node like *and*), `ent` (entity node like *police*), `ver` (regular verbal node like *report-01*), `verx` ($x \in [0, 1, 2]$) (verbal node with implicit argument like *depart-01*).

Given the node representation z_i from the graph encoder, a feed-forward network (FFNN^{type}) with softmax activation is adopted to calculate the probability distribution for its node type p_i^{type}:

$$p_i^{type} = \mathrm{softmax}(\mathrm{FFNN}^{type}(z_i)). \tag{3}$$

This subtask is introduced for detecting implicit mentions as shown in Figure 1, and it can also provide additional supervision defined by cross-entropy loss:

$$\mathcal{L}_{type} = -\frac{1}{N} \sum_{i=1}^{N} \log p_i^{type}[\hat{t}_i], \tag{4}$$

where $\hat{t}_i$ is the index of the correct node type for node x_i.

2.4 Coreference Clustering

In the last step, coreference clusters are predicted by finding the antecedent for each AMR node. Taking node x_i for example, the score of a precedent node x_j being its antecedent is defined as:

$$\begin{aligned} s(x_j, x_i) &= f^m(x_j) + f^m(x_i) + f^{ant}(x_j, x_i), \\ f^m(x_i) &= \mathrm{FFNN}^m([z_i; p_i^{type}]), \\ f^{an}(x_j, x_i) &= \mathrm{FFNN}^{ant}([z_j, z_i]), \end{aligned} \tag{5}$$

where FFNN^m classifies if the given node involves in a coreference link, and FFNN^{ant} determines if the given node pair form a coreference relation. Next, the scores are normalized into a probability distribution via a softmax layer, and the probability $p_{i,j}$ for x_j being the antecedent of x_i is:

$$p_{x_j, x_i} = \frac{e^{s(x_j, x_i)}}{\sum_{x' \in \mathcal{Y}(x_i)} e^{s(x', x_i)}}, \tag{6}$$

where $\mathcal{Y}(x_i)$ represents all precedents of x_i. The antecedent loss is a marginal log-likelihood on all correct antecedents of all the nodes, given the gold clustering for node i is $\mathrm{GOLD}(x_i)$:

$$\mathcal{L}_{ant} = -\log \prod_{i=1}^{N} \sum_{\hat{x} \in \mathcal{Y}(x_i) \cap \mathrm{GOLD}(x_i)} p_{\hat{x}, x_i}. \tag{7}$$

Finally, the training loss is a combination of antecedent loss and node type prediction loss:

$$\mathcal{L} = \mathcal{L}_{type} + \mathcal{L}_{ant}. \tag{8}$$

3 Proposed Method: VG-AMRCoref

This section describes our proposed model (**VG-AMRCoref**) that adopts Variational Graph Autoencoder (VGAE) to enable the cheap supervision of graph reconstruction. For fair comparison, we replace the original graph encoder of *AMRCoref* (Figure 2) with our optimized VGAE module. By doing so, we make it possible to pretrain our model on other standard AMR data for stronger robustness and generalizability. We illustrate the model framework in Figure 3.

3.1 VGAE-based Graph Encoding

After obtaining node embeddings $H^{(0)}$ and the edge set A from the Concept Representation step

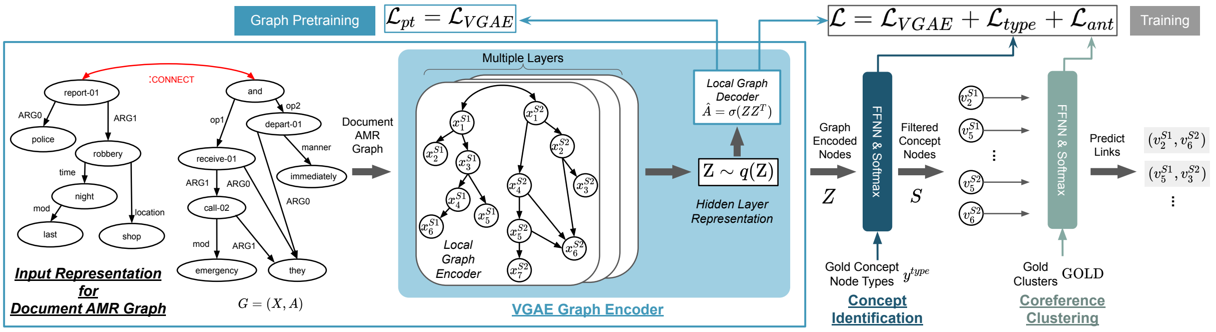

Figure 3: VG-AMRCoref model illustration: The model consists of three main components: Graph Encoder, Concept Identification and Coreference Cluster Prediction.

(Sec.2.1), a VGAE graph encoder is applied to further encode the input graph nodes into the representations with more contextual information. VGAE consists of a local graph encoder and a a local graph decoder.

Local Graph Encoder The local graph encoder functions as a typical graph neural network, where the node features in the lth layer are defines as:

$$H^{(l)} = f(H^{(l-1)}, A). \tag{9}$$

A typical VGAE model usually applies a Graph Convolutional Network (GCN) (Kipf and Welling, 2016a) as its local graph encoder f_{GCN}. Eq. 9 can be further defined as:

$$f_{GCN}\left(H^{(l)}, A\right) = \phi\left(\widetilde{D}^{\frac{1}{2}}\widetilde{A}\widetilde{D}^{-\frac{1}{2}}H^{(l)}W^{(l)}\right), \tag{10}$$

where $\phi(\cdot)$ is the Sigmoid activation function, $\widetilde{A} = A + I$, I is the identity matrix, and $\widetilde{D}$ is the diagonal node degree matrix of $\widetilde{A}$.

We study equipping the vanilla VGAE model with other major graph encoders, such as Graph Attention Network (GAT, Veličković et al. 2017) and Graph Recurrent Network (GRN, Beck et al. 2018; Song et al. 2018), to better capture the contextual information of each node. The GAT encoder f_{GAT} considers attention from the neighbors:

$$\begin{aligned} f_{GAT}\left(H^{(l)}, A\right) &= \phi\left(\sum \boldsymbol{\alpha} W^{(l-1)} H^{(l-1)}\right), \\ \boldsymbol{\alpha} &= \mathrm{Attention}(H^{(l-1)}), \end{aligned} \tag{11}$$

and the definition of the GRN encoder f_{GRN} is given in Eq. 2.

This local graph encoder also takes L layers. Same with the baseline (Sec. 2.2), we choose the hidden layer features after encoding to be $Z = [H^{(0)}; H^{(L)}]$ for the next step. Besides, Z indicates the stochastic latent variable, and it is modeled by a Gaussian prior distribution $\prod_i \mathcal{N}(z_i, 0, I)$. For $z_i \in Z$:

$$q(z_i|X, A) = \mathcal{N}(z_i|\boldsymbol{\mu}_i, diag(\sigma_i^2)), \tag{12}$$

we have $\boldsymbol{\mu} = f_{\boldsymbol{\mu}}(X, A)$ and $\log \boldsymbol{\sigma} = f_{\boldsymbol{\sigma}}(X, A)$.

Local Graph Decoder The hidden layer representation Z is also fed into a local graph decoder of VGAE. This decoder reconstructs the edge set A from Z. Typically, it is calculated by dot-product:

$$\begin{aligned} A' &= \sigma(ZZ^T), \\ p(A' \mid Z) &= \prod_{i=1}^{N}\prod_{j=1}^{N} p\left(A'_{ij} \mid z_i, z_j\right). \end{aligned} \tag{13}$$

The loss from the VGAE module $\mathcal{L}_{VGAE}$ is defined by the reconstruction loss on the edge set $\mathcal{L}_{edge}$ and the variational restriction on the hidden parameters $\mathcal{L}_{var}$:

$$\begin{aligned} \mathcal{L}_{VGAE} &= \mathcal{L}_{edge} + \mathcal{L}_{var} \\ &= E_{q(Z|X,A)}[\log p(A'|Z)] \\ &\quad - KL[q(Z|X, A)||p(Z)], \end{aligned} \tag{14}$$

where $KL[q(\cdot)||p(\cdot)]$ is the Kullback-Leibler divergence between q and p.

3.2 Task Training

Next, the encoded AMR graph node Z from Eq. 12 is sent to the Concept Identification and Coreference Clustering step, which are described in Sec. 2.3 and 2.4. As shown in Figure 3, the overall loss $\mathcal{L}$ comes from three parts: VGAE loss $\mathcal{L}_{VGAE}$, concept type loss $\mathcal{L}_{type}$ and the antecedent loss $\mathcal{L}_{ant}$, referring to Eq. 14, 4 and 7, respectively:

$$\mathcal{L} = \mathcal{L}_{VGAE} + \mathcal{L}_{type} + \mathcal{L}_{ant}. \tag{15}$$

Table 2: Development results on MS-AMR regarding multiple local graph encoders (**Encoder**).

3.3 Graph Encoder Pretraining

Eq. 14 shows that VGAE can be trained in a self-supervised way, which only needs node features X and the edge set A. So we propose to pretrain the VGAE graph encoder using AMR graphs when only AMR graphs are available. In this pretraining stage, the loss function $\mathcal{L}_{pt}$ is defined as:

$$\mathcal{L}_{pt} = \mathcal{L}_{VGAE}. \tag{16}$$

After pretraining, the VGAE graph encoder will be fine-tuned on the coreference resolution downstream task.

4 Experiments

4.1 Experimental Settings

Datasets Following previous work, we choose the **MS-AMR** benchmark (O'Gorman et al., 2018), which has manually annotated coreference information over gold AMRs. It contains 273 documents for training, 9 for development and 9 for testing. In addition to the in-domain test set, we also evaluate on the Little Prince data (**LP**) that is annotated by (Fu et al., 2021) for out-of-domain evaluation. For pretraining, we choose the AMR bank 3.0 (LDC2020T02), the largest AMR corpus with only regular sentence-level AMRs. Please note that these AMRs are manually labeled and do not contain comprehensive document-level coreference annotations, thus they can not be utilized for task training. We consider this dataset as **AMR-gold**. To reduce the reliance on the annotated dataset, we conduct another setting, **AMR-silver**: we take the sentences of the AMR-gold dataset and apply a well-trained neural AMR parser (Van Noord and Bos, 2017) to generate silver AMR graphs. When doing this, a few documents failed because of post-processing issues[3], so one may notice that it has slight differences with AMR-gold, but we consider this to be acceptable. Smatch F1 score (Cai and Knight, 2013) on the silver results is 0.71, indicating an acceptable AMR parsing quality. We show the statistics in Table 1.

Evaluation Metrics To be consistent with previous work (Fu et al., 2021), we apply three evaluation metrics and an average F1 of all: MUC F1 (Vilain et al., 1995), B^3 F1 (Bagga and Baldwin, 1998) and $CEAF_{\phi4}$ F1 (Luo, 2005).

Hyperparameters For all of the experiment, we follow Fu et al. (2021) to set hyperparameters for fair comparison. For instance, the character embedding and concept type dimension are 32; the concept embedding dimension is 256. The pretrained `BERT-base-cased` model is used. We choose the number of local graph encoder layer of VGAE to be 3, an empirical value following Fu et al. (2021), and provide more details in the Ablation Study later. The optimizer is Adam (Kingma and Ba, 2017). We report average results on 5 runs with different random seeds.

Baselines We choose to compare with the following 4 models. **Rule-based** (Liu et al., 2015): it merges entity nodes with the same surface string to build document AMRs. **Pipeline** (Anikina et al., 2020): it combines a pretrained text-based coreference model and an AMR-to-text aligner into a pipeline, where the text-based coreference resolution results are projected onto AMRs via AMR-to-text alignments. **AMRCoref** and **AMRCoref+bert** are the baselines (Section 2) without and with BERT features, respectively.

4.2 Main Results

Since the local graph decoder has multiple choices including GRN, GCN and GAT, as described in Eq. 9, so we compare the performance on the development set to select the best setting in Table 2. Results show that our model can get the best performance when applying GAT, so we choose this setting in the main experiments.

Table 3 shows the main results on the test set. Here we study three variations of our proposed model: **VG-AMRCoref** learns node em-

Table 3: Main results: we compare variations of our proposed model with selected baselines, and report both in-domain and out-domain performances.

beddings from scratch; **VG-AMRCoref+pretrain** first pretrains the VGAE encoder using AMR-gold, and then fine-tune on the task; **VG-AMRCoref+pretrain+bert** is a model that adds pretrained BERT embeddings further. These three models are using GAT as the graph encoder. To compare with Fu et al. (2021) that applies a GRN as the graph encoder, we also conducte the **VG-AMRCoref (GRN)** that applies the same encoder. Both VG-AMRCoref (GRN) and VG-AMRCoref can be fairly compared with AMRCoref, given that they use the same training data and are under the same setting (without BERT). When applying GRN, our model improves about 8.6% and 3.2% Average F1 gains on in- and out-domain. When applying GAT, we could have a significant improvement, specifically, 20.7% and 9.1% Average F1 gains on in- and out-domain. With pretraining, VG-AMRCoref+pretrain performs better than VG-AMRCoref, improving 1.8% and 5.8% on the Average F1 score. This shows that our graph pretraining approach that learns from external data is effective, especially on the out-domain. Finally, we can notice that small gains can be found in the two domains when integrating with BERT knowledge. A possible reason is that only fixed BERT embeddings are applied. Since AMRCoref is undertrained, we see BERT improves the F1 scores by a large margin there. Overall, our best model outperforms the best baseline by around 11.1% and 3.4% on in- and out-domain. Besides, though there is a performance gap between the in- and out- domain test sets, our model shows improvements on both two domains.

One may notice a significant gap between the dev and test results when comparing Table 2 and 3, which is also reported by Fu et al. (2021). After a careful check on the data, we find that the average cluster sizes of the dev and test sets are 3.6 and 5.6, respectively. Since the model predicts as correct if the predicted ancestor is in the same cluster as the current mention, a larger cluster size gives better chances to make correct decisions. We also calculate the average distance between a mention to its closest ancestor, and the values for the dev and test sets are 7.1 and 5.8. This also indicates that the dev set is even more difficult.

Model	MUC	B^3	$\text{CEAF}_{\phi 4}$	**Avg. F1**
GAT Encoder	84.26	71.39	49.70	68.45
+ VGAE $\mathcal{L}_{var}$	86.29	71.84	54.47	70.87
+ VGAE $\mathcal{L}_{edge}$	85.96	74.01	56.29	72.08

Table 4: Ablation study on VGAE loss components: results on MS-AMR Test set.

4.3 Ablation Study

We include ablation study on VGAE loss, number of graph layers, and the affect of pretraining data size.

VGAE Loss We first study how the VGAE loss from Eq. 14 can affect model performance. We start with a basic setting: applying GAT as the graph encoder (GAT Encoder). Then we add variational restriction (+VGAE $\mathcal{L}_{var}$), as well as the reconstruction loss of edge set (+VGAE $\mathcal{L}_{edge}$). We show the results on the MS-AMR test set in Table 4. With variational loss $\mathcal{L}_{var}$, we see an improvement of about 2.4% of Average F1. And with the edge set reconstruction loss $\mathcal{L}_{edge}$, we see the Average F1 increases again by 1.4%. In total, we see an overall improvement of 3.6% with the VGAE loss.

Number of Graph Layers Previous study shows that more graph layers may hurt the per-

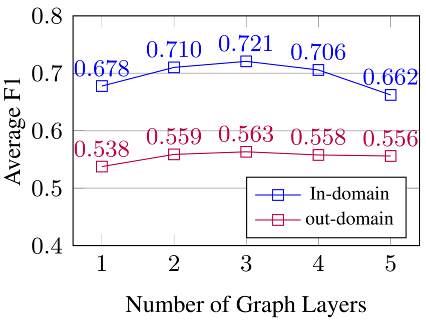

Figure 4: Ablation study on number of graph layers: results on in- and out- domain test sets using VG-AMRCoref model.

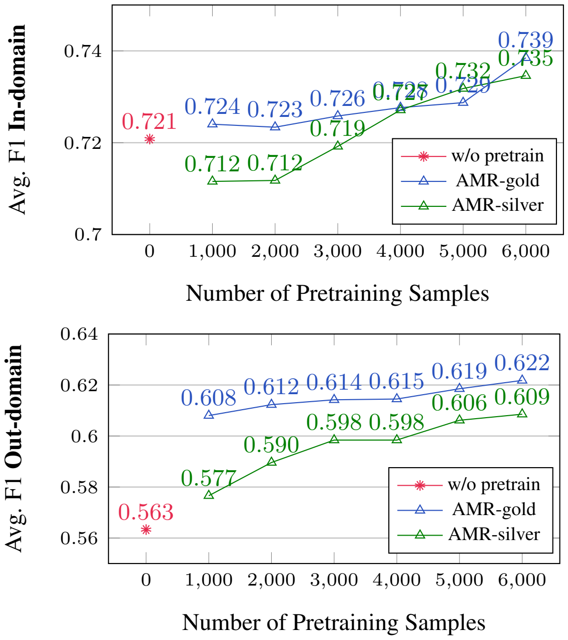

Figure 5: Ablation study on pretraining data size: results on MS-AMR test set.

formance (Zhou et al., 2020; Fu et al., 2021), due to the over-smoothing issue led by message passing over multiple layers on the graph. We compare 1 to 5 graph layers in the VGAE encoder, and show the Average F1 score of two domains (test set) in Figure 4. When the number of layers is 3, the model achieves the best performance on both in- and out-domain. The performance increases from 1 to 3, and decreases from 3 to 5. This observation is consistent with the AMRCoref model.

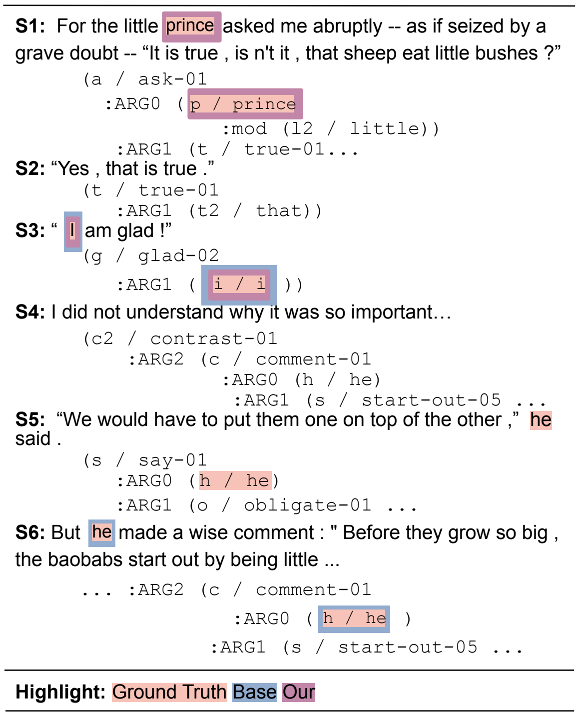
Pretraining Data Size Our main results have shown that pretraining on the AMR-gold dataset makes a significant difference, especially for out-domain. We further investigate if our model can benefit from silver AMR data. We compare the Average F1 score with different pretraining sizes of AMR-gold and AMR-silver in Figure 5. In both domains, the x-axis shows the number of pretraining data size. Gold and silver datasets have the same trend: more pretraining data leads to better performance. Though pretraining using the silver dataset is slightly worse than the gold dataset, our model can still improve. Specifically, while the AMR parser (Van Noord and Bos, 2017) is not the current state-of-the-art, results show that applying silver dataset is positive. In the future, we plan to optimize with better AMR parsers and larger datasets to see if the silver data may achieve even better results than the gold dataset.

5 Case Study

To further understand the predicted results of our model, we compare our best performed model (VG-AMRCoref+pretrain+bert) and the best baseline model (AMRCoref+bert) with two case studies.

Figure 6 shows one example taken from the LP test set. Given that the whole document is too long, we keep a part of the content and highlight the coreference cluster tokens with different colors to indicate ground truth, base model prediction and our model prediction. Note that we illustrate both AMRs and original sentences to show the context better, while the sentences were not directly participated in the training and testing. This content piece shows a dialogue between two characters: `me` and `little prince`. In the ground truth, the coreference cluster is indicating little prince, and this can be easily recognized from the token *prince* in S1 and the token *he* in S5 and S6. However, to find out if the token *I* in S3 belongs to this cluster, one needs to read from S1. Because dialogues are going in turns, it is important to figure out which character said S3. Here, the answer should be `little prince` (token *I* means himself) and should be included in the cluster. This could be challenging due to the deep understanding of the previous content and also the difficulty of long dependency. Our model successfully recognized the coreference tokens in this situation.

We illustrate another example from the MS-AMR test set in Figure 7. As can be observed form the ground truth, the highlighted tokens are indicating the coreference cluster of the main character in this article, `I`. The base model predicts a wrong answer in S1 (*who*), and misses the correct token *I* in that sentence. While both models ignore the token *I* in S2 and S3, compare with the base model,



S1: For the little prince asked me abruptly -- as if seized by a grave doubt -- “It is true , is n't it , that sheep eat little bushes ?”

```
        (a / ask-01
           :ARG0 (p / prince
                     :mod (l2 / little))
            :ARG1 (t / true-01...
```

S2: “Yes , that is true .”

```
        (t / true-01
            :ARG1 (t2 / that))
```

S3: “ I am glad !”

```
        (g / glad-02
            :ARG1 ( i / i ))
```

S4: I did not understand why it was so important…

```
        (c2 / contrast-01
             :ARG2 (c / comment-01
                     :ARG0 (h / he)
                      :ARG1 (s / start-out-05 ...
```

S5: “We would have to put them one on top of the other ,” he said .

```
        (s / say-01
            :ARG0 (h / he)
            :ARG1 (o / obligate-01 ...
```

S6: But he made a wise comment : " Before they grow so big , the baobabs start out by being little ...

```
        ... :ARG2 (c / comment-01
                      :ARG0 ( h / he )
                    :ARG1 (s / start-out-05 ...
```

Highlight: Ground Truth Base Our

Figure 6: An example from LP Test set: for better understanding, we also put the original sentences here with the AMRs. (Best viewed in Color.)

our model is able to identify more correct coreference tokens. Consistent with the previous example case, both models tend to predict only a part of the ground truth that they are more confident with, in order to keep a reasonable good performance.

While automatic evaluation only shows the overall performance, our case studies provide some interesting observations. The base and our model tend to predict fewer coreference nodes than the ground truth, but our model can capture larger and more accurate coreference clusters than the base model.

6 Related Work

Encoding AMRs using Graph Neural Networks Recently, graph neural networks (GNNs) have shown their simplicity and effectiveness in many NLP tasks, especially in encoding graph-structured input, such as knowledge graphs and other task-specific graphs (Li et al., 2020a; Xiong and Gao, 2019; Yin et al., 2019; Song et al., 2020b). Some methods are proposed to encode AMR graphs. For example, Graph Convolutional Networks (GCNs, Kipf and Welling 2016a) and some variations are well-studied for AMRs (Zhang et al., 2020; Cai and Lam, 2020). On the other hand, Song et al. (2019) applied Graph Recurrent Networks (GRNs, Song et al. 2018) on AMRs, achieving reasonable performance for neural machine translation. As a variant of GAT (Veličković et al., 2017), relation-aware self-attention (Shaw et al., 2018) is recently proposed and has been shown more effective (Zhu et al., 2019; Song et al., 2020a) than other GNN variants on presenting AMRs for text generation. We have similar observations where GAT gives better results over GCN and GRN on encoding AMRs for AMR coreference resolution.

Highlight: Ground Truth Base Our

Figure 7: An example from MS-AMR Test set: for a better understanding, we also put the original sentences here with the AMRs. (Best viewed in Color.)

Graph Pretraining Previous work shows that pretraining a model may bring better generalizability and performance gain, such as the pretrained language model, BERT (Devlin et al., 2018). There is limited research that focuses on pretraining graph neural networks. The work by Hu et al. (2019) proposes two methods to pretrain GNNs in both individual node level and the entire graph level. Though there are a few attempts to pretrain GNNs in a similar way with BERT, i.e., Graph Transformer (Dwivedi and Bresson, 2020), and Knowledge Graph Pretraining (Yu et al., 2020), there is still limited study in other NLP tasks. Our work fills this gap by taking advantage of knowledge learned from external data.

Coreference Resolution Coreference resolution has long been an active research topic in NLP. Recently, Clark and Manning (2016) proposed a reinforcement learning approach to optimize a neural mention-ranking model for coreference. The first end-to-end neural coreference resolution method (Lee et al., 2017) targets span embeddings from context-dependent boundary representations using a head-finding attention mechanism. Then, Kantor and Globerson (2019) proposed the Entity Equalization mechanism to capture mentions in clusters using a neural network. Applying these textual coreference methods to AMR graphs requires extra AMR-to-text alignment, which can cause severe error propagation.

To promote multi-sentence AMR coreference resolution, O'Gorman et al. (2018) annotated MS-AMR dataset, which considered coreferences, implicit role coreferences and bridging relations. Very recent work by Fu et al. (2021) is the first end-to-end AMR coreference resolution model for multi-sentence. This model achieves better and robust performance compared with selected baselines.

7 Conclusion

This work proposed a new model (VG-AMRCoref) that is capable of self-supervised training for multi-sentence AMR coreference resolution. It applies VGAEs to encode document-level AMRs, significantly improving performance by up to 11% on the F1 score. We further proposed a simple but effective graph pretraining method using VGAEs, which can simultaneously boost in in-domain and out-domain performances. Analysis shows that potential boost performance may happen if more automatically parsed AMR data is available. One future work will focus on applying larger scale silver AMR datasets for pretraining to improve AMR coreference resolution. Another future direction is to investigate the generated document-level AMRs on more downstream tasks, like question answering and dialogue understanding.

Abstract

Recent works of opinion expression identification (OEI) rely heavily on the quality and scale of the manually-constructed training corpus, which could be extremely difficult to satisfy. Crowdsourcing is one practical solution for this problem, aiming to create a large-scale but quality-unguaranteed corpus. In this work, we investigate Chinese OEI with extremely-noisy crowdsourcing annotations, constructing a dataset at a very low cost. Following Zhang et al. (2021), we train the annotator-adapter model by regarding all annotations as gold-standard in terms of crowd annotators, and test the model by using a synthetic expert, which is a mixture of all annotators. As this annotator-mixture for testing is never modeled explicitly in the training phase, we propose to generate synthetic training samples by a pertinent mixup strategy to make the training and testing highly consistent. The simulation experiments on our constructed dataset show that crowdsourcing is highly promising for OEI, and our proposed annotator-mixup can further enhance the crowdsourcing modeling.

1 Introduction

Opinion mining is a fundamental topic in the natural language processing (NLP) community, which has received great attention for decades (Liu and Zhang, 2012). Opinion expression identification (OEI) is a standard task of opinion mining, which aims to recognize the text spans that express particular opinions (Breck et al., 2007). Figure 1 shows two examples. This task has been generally solved by supervised learning (İrsoy and Cardie, 2014) with the well-established corpus annotated by experts. Almost all previous studies are based on English datasets such as MPQA (Wiebe et al., 2005).

By carefully examining this task, we can find that the corpus annotation of opinion expressions is by no means an easy process. It is highly ambiguous across different persons. As shown in Figure 1, it is very controversial to define the boundaries of opinion expressions (Wiebe et al., 2005). Actually, this problem is extremely serious for languages such as Chinese, which is based on characters even with no explicit and clearly-defined word boundaries. Thus, Chinese-alike languages will inevitably involve more ambiguities.

Figure 1: Two examples of opinion expression identification with crowdsourcing and expert annotations in our constructed dataset. The left and right sentences are of positive and negative polarities, respectively.

In order to obtain a high-quality corpus, we usually need to train the annotators with great efforts, making them acquainted with a specific fine-grained guideline drafted by experts, and then start the data annotation strictly. Finally, it is better with a further expert checking on borderline cases where the annotators disagree most to ensure the quality of the annotated corpus. Apparently, the whole process is quite expensive. Thus, crowdsourcing with no training (just a brief guideline) and no expert checking is more practical in real considerations (Snow et al., 2008). While on the other hand, the difficulty of the Chinese OEI task might lead to very low-quality annotations by crowdsourcing.

In this work, we present the first study of Chinese OEI by using crowdsourcing. We manually construct an OEI dataset by crowdsourcing, which is used for training. Indeed, the dataset is cheap but with a great deal of noises according to our initial observation. We also collect the small-scale devel-

opment and test corpus with expert annotations for evaluation.[1] Our dataset is constructed over a set of Chinese texts closely related to the COVID-19 topic. Following, we start our investigation by using a strong BERT-BiLSTM-CRF model, treating the OEI task as a standard sequence labeling problem following the previous studies (Breck et al., 2007; İrsoy and Cardie, 2014; Katiyar and Cardie, 2016). Our primary goal is to answer whether these extremely-noisy crowdsourcing annotations include potential value for the OEI task.

In order to make the best use of our crowdsourcing corpus, we follow Zhang et al. (2021) to treat all crowd annotations as gold-standard in terms of different annotators. We introduce the annotator-adapter model, which employs the crowdsourcing learning approach of Zhang et al. (2021) in OEI for the first time. It jointly encodes both texts and annotators, then predicts the corresponding crowdsourcing annotations in the BERT-BiLSTM-CRF architecture. Concretely, we train the annotator-adapter model by each individual annotator and the corresponding annotations, then test the model by using a pseudo expert annotator, which is a linear mixture of crowd annotators. Considering that this expert is never modeled during the training, we further exploit a simple mixup (Zhang et al., 2018) strategy to simulate the expert decoding accurately.

Experimental results show that crowdsourcing is highly competitive, giving an overall F1 score of 53.86 even with a large-scale of noises, while the F1 score of expert corpus trained model is 57.08. We believe that this performance gap is totally acceptable for building OEI application systems. In addition, our annotator-mixup strategy can further boost the performance of the annotator-adapter model, giving an F1 increase of $54.59 - 53.86 = 0.73$. We conduct several analyses to understand the OEI with crowdsourcing and our suggested methods comprehensively.

In summary, we make three majoring contributions as a whole in this work:

- We present the initial work of investigating the OEI task with crowdsourcing annotations, showing its capability on Chinese.
- We construct a Chinese OEI dataset with crowdsourcing annotations, which is not only valuable for Chinese OEI but also instructive for crowdsourcing researching.
- We introduce the annotator-adapter for crowdsourcing OEI and propose the annotator-mixup strategy, which can effectively improve the crowdsourcing modeling.

All of our codes and dataset will be available at github.com/izhx/crowd-OEI for research purpose.

2 Dataset

The outbreak of COVID-19 brings strong demand for building robust Chinese opinion mining systems, which are practically built in a supervised manner. A large-scale training corpus is the key to the system construction, while almost all existing related datasets are in English (Wiebe et al., 2005). Hence, we manually construct a Chinese OEI dataset by crowdsourcing. We focus on opinion expressions with **positive** or **negative** polarities only. The construction consists of four steps: (1) text collection, (2) annotator recruitment, (3) crowd annotation, and (4) expert checking and correction.

2.1 Text Collection

We choose the Sina Weibo[2], which is a Chinese social media platform similar to Twitter, as our data source. To collect the texts strongly related to COVID-19, we select around 8k posts that are created from January to April 2020 and related to seven hot topics (Table 1). To make these posts ready for annotating, we use HarvestText[3] to clean them and segment the resulting texts into sentences. Next, we conduct another cleaning step to remove the duplicates and sentences with relatively poor written styles (e.g., high-proportion of non-Chinese symbols, very short /long length, etc.).

After the above procedure, there are still a large proportion of sentences that involve no sentiment.

---

[1] In addition, we provide expert annotations of trainset to train a upper-bound model.

[2] https://weibo.com

[3] https://github.com/blmoistawinde/HarvestText

So we filter out them by a BERT sentiment classifier that trained on an open-access Weibo sentiment classification dataset.[4] Only sentences with high confidence of not expressing any sentiment are dropped,[5] we can therefore keep the most valuable contents while avoiding unnecessary annotations and thus reduce the overall annotating cost.

2.2 Annotator Recruitment

We have five professionals who have engaged in the annotation of sentiment and opinion-related tasks previously and are with rich experience as experts. They annotate 100 sentences together as examples (i.e., label the positive and negative opinion expressions inside the texts), and establish a simple guideline based on their consensus after several discussions. The guideline includes the task definition and a description of annotation principle.[6]

Next, we recruit 75 (crowd) students in our university for annotating. They come from different grades and different majors, such as Chinese, Literature, and Translation. We offer them the above annotation guideline to understand the task. We choose the doccano[7] to build up our annotation platform, and let these annotators be familiar with our task by the expert-annotated examples.

2.3 Crowd Annotation

When all crowd workers are ready, we start the crowd annotation phase. The prepared texts are split into micro-tasks so that each one consists of 500 sentences. Then we assign 3 to 5 workers to each micro-task, and their identities are remained hidden from each other. Each worker will not access a new task unless their current one is finished.

In the annotation of each sentence, workers need to label the positive and negative opinion expressions according to the guideline and their understandings. The number of positive or negative expressions in one sentence has no limit. They can also mark a sentence as "No Opinion" and skip it if they think there are no opinion expressions inside.

2.4 Expert Checking and Correction

Dataset		Number of			Average
Section	Quality	Unique Annotation	Positive Expression	Negative Expression	Span Length
Train	crowd	32582	11640	35263	5.05
	silver	8047	4167	11411	4.71
	gold	8047	3488	10096	4.79
Dev	crowd	3427	2338	3905	5.22
	gold	803	706	1035	5.02
Test	crowd	6265	3573	5290	4.48
	gold	1517	999	1373	4.30

Table 2: Data statistics of our constructed dataset. For gold and silver corpus, each annotation corresponds to one sentence. For the crowd corpus, each sentence has 3 to 5 annotations. So we have a total number of $803 + 1517 + 8047 = 10,367$ unique sentences and $32,582 + 3427 + 6265 = 42,274$ crowd annotations.

After all crowd annotations are accomplished, we randomly select a small proportion of sentences and let experts reannotate them, resulting in the **gold-standard** *development* and *test* corpus.[8] Specifically, for each sentence, we let 2 experienced experts individually reannotate it with references from the corresponding crowdsourcing annotations. They will give the final annotation of each sentence if their answers reach an agreement. And if they have divergences, a third expert will help them to modify answers and reach the agreement.

Then, we let all five experts go through the remaining dataset[9], selecting the best annotations for each sentence, which can be regarded as the **silver-standard** *training* corpus. In the selection, Each sentence is assigned to 1 expert, and the expert is only allowed to choose one (or several identical) best answer(s) from all the candidate crowdsourcing annotations. Finally, only for comparisons, we also annotated the **gold-standard** *training* corpus, which will not be used in our model training.

2.5 Dataset Statistics

In the end, we arrive at $42,274$ crowd annotations by 70 valid annotators,[10] covering $10,367$ sentences. A total number of $803 + 1517 = 2320$ sentences, including expert annotations, would be used for development and test evaluations. Table 2 shows the overall data statistics. The average number of annotators per sentence is 4.05, and each annotator labels an average of 827 sentences in the whole corpus. The overall Cohen's Kappa value of the crowd annotations is 0.35. When ignoring the

[5] Note that there are still a small number of sentences in our final dataset that have no opinion expression inside.

[6] We share the guideline in the Appendix A.

[7] https://github.com/doccano/doccano

[8] The corresponding crowdsourcing annotations consist of the **crowdsourcing** *development* and *test* corpus.

[9] The remaining part is the **crowdsourcing** *training* corpus.

[10] We removed 5 annotators who gave up this work in their first assigned task as a basic quality assurance.

characters which no annotators think that they are in any expression, the Kappa is only 0.17.[11]

The Kappa values are indeed very low, indicating the great and unavoidable ambiguities of the task with natural annotations.[12] However, these values do not make much sense since we do not impose any well-designed comprehensive guidelines during annotation. In fact, a comprehensive guideline for crowd workers is almost impracticable in our task, because they are quite often to disagree with a particular guideline by their own unique and naive understandings. If we impose such a guideline to them forcibly, the annotation cost would be increased drastically (i.e., at least ten times more expensive according to our preliminary investigation) for their reluctance as well as endless expert guidance. In the remaining of this work, we will try to verify the real value of these crowdsourcing annotations empirically: Is the collected training corpus really beneficial for our Chinese OEI task?

3 Methodology

The OEI task aims to extract all polarized text spans that express certain opinions in a sentence. It can be naturally converted into a sequence labeling problem by using the BIO schema, tagging each token by the boundary information of opinion expressions, where "B-X" and "I-X" (i.e., "X" can be either "POS" or "NEG" denoting the polarity) indicate the start and other positions of a certain expression, and "O" denotes a token do not belong to any expression. In this work we adopt the CRF-based system (Breck et al., 2007) to the neural setting and enhance it with BiLSTM encoder as well as pre-trained BERT representation.

3.1 BERT-BiLSTM-CRF Baseline

Given a sentence $\boldsymbol{x} = x_1 \cdots x_n$ (where n denotes the sentence length), we first convert it into contextual representations $\boldsymbol{r}_1 \cdots \boldsymbol{r}_n$ by the pre-trained BERT with adapter tuning (Houlsby et al., 2019):

$$\boldsymbol{r}_1 \cdots \boldsymbol{r}_n = \text{ADBERT}(x_1 \cdots x_n). \qquad (1)$$

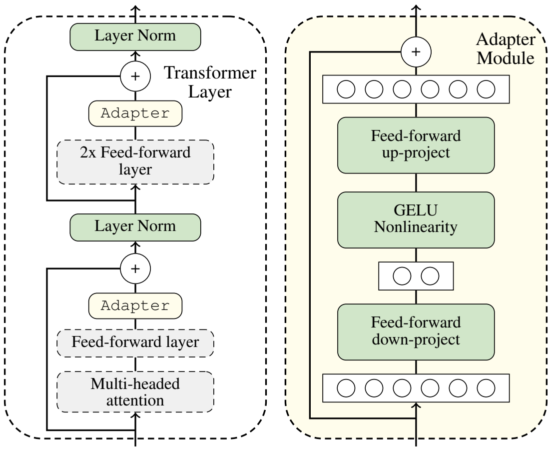

Figure 2: The Adapter (right) and Transformer integrated with Adapter inside (left). During the adapter tuning, green layers are trainable, including the adapters, the LayerNorm, and other task-specific modules.

Unlike the standard BERT exploration, ADBERT introduces two extra adapter modules inside each transformer layer, as shown in Figure 2 for the details. With this modification, we do not need finetuning all BERT parameters, and instead, learning the parameters of adapters is enough for obtaining a strong performance. Thus ADBERT is more parameter efficient. The standard adapter layer can be formalized as:

$$\begin{aligned} \text{down-proj:} \quad & \boldsymbol{h}_{\text{mid}} = \text{GELU}(\boldsymbol{W}_{\text{down}} \boldsymbol{h}_{\text{in}} + \boldsymbol{b}_{\text{down}}), \\ \text{up-proj:} \quad & \boldsymbol{h}_{\text{out}} = \boldsymbol{W}_{\text{up}} \boldsymbol{h}_{\text{mid}} + \boldsymbol{b}_{\text{up}} + \boldsymbol{h}_{\text{in}}, \end{aligned} \qquad (2)$$

where $\boldsymbol{W}_{\text{down}}$, $\boldsymbol{W}_{\text{up}}$, $\boldsymbol{b}_{\text{down}}$ and $\boldsymbol{b}_{\text{up}}$ are model parameters, which are much smaller than the parameters of transformer in scale, and the dimension size of $\boldsymbol{h}_{\text{mid}}$ is also smaller than that of the corresponding transformer dimension.[13]

The rest part of the baseline is a standard BiLSTM-CRF model, which is a stack of BiLSTM, MLP and CRF layers, and then we can obtain sequence-level scores for each candidate output $\boldsymbol{y}$:

$$\begin{aligned} \text{score}(\boldsymbol{y}) &= \text{BiLSTM-CRF}([\boldsymbol{r}_1 \cdots \boldsymbol{r}_n]), \\ p(\boldsymbol{y}) &= \frac{\exp\big(\text{score}(\boldsymbol{y})\big)}{\sum_{\tilde{Y}} \exp\big(\text{score}(\tilde{\boldsymbol{y}})\big)}, \end{aligned} \qquad (3)$$

where $p(\boldsymbol{y})$ is the probability of the given ground-truth, and $\tilde{Y}$ is all possible outputs for score normalization. The model parameters are updated by the sentence-level cross-entropy loss $\mathcal{L} = -\log p(\boldsymbol{y}^*)$ when $\boldsymbol{y}^*$ is regarded as gold-standard.

---

[11] To compute the Kappa value of sequential annotations, we treat each token (not sentence) as an instance, and then aggregate the results of one sentence by averaging.

[12] The average value of F1 scores that each annotator against the expert is 41.77%, which is significantly lower than $60\%+$ of crowdsourcing NER dataset (Rodrigues et al., 2014b).

[13] The dimension sizes of $\boldsymbol{h}_{\text{in}}$ and $\boldsymbol{h}_{\text{out}}$ are consistent with the corresponding transformer hidden states.

Crowdsourcing training. In the crowdsourcing setting, we only have annotations from multiple non-expert annotators, thus no gold-standard label is available for our training. To handle the situation, we introduce two straightforward and widely-used methods. First, we treat all annotations uniformly as training instances, despite that they may offer noises for our training objective, which is denoted by `All` for short. Second, we exploit majority voting[14] to obtain an aggregated answer of each sentence for model training, denoted as `MV`.

3.2 Annotator Adapter

In most previous crowdsourcing studies, there is a common agreement that crowd annotations are noisy, which should be rectified during training (Rodrigues et al., 2014a; Nguyen et al., 2017; Simpson and Gurevych, 2019). Zhang et al. (2021) propose to regard all crowdsourcing annotations as gold-standard, and introduce a representation learning model to jointly encode the sentence and the annotator and extract annotator-aware features, which models the unique understandings of annotators (this setting is indeed very consistent with our corpus). Since our constructed dataset has no gold-standard training labels[15], we adopt their unsupervised representation learning approach, which is named `annotator-adapter`. It applies the Parameter Generator Network (PGN) (Platanios et al., 2018; Jia et al., 2019; Üstün et al., 2020) to generate annotator-specific adapter parameters for the ADBERT, as shown in Figure 3.

Given an input sentence-annotator pair ($\boldsymbol{x} = x_1, \ldots, x_n, a$), we exploit an embedding layer to convert the annotator ID a into its vectorial form $\boldsymbol{e}^a$, and then PGN is used to generate the model parameters of several high-level adapter layers inside BERT conditioned by $\boldsymbol{e}^a$. Concretely, we apply PGN to the last p layers of BERT, where p is one hyper-parameter of our model. We refer to PGN-ADBERT for the updated input representation.

Formally, for an adapter defined by Equation 2, all its parameters are dynamically generated by:

$$\begin{aligned} \boldsymbol{W}_{\text{down}} &= \boldsymbol{T}_{\boldsymbol{W}_{\text{down}}} \times \boldsymbol{e}^a, \quad \boldsymbol{b}_{\text{down}} = \boldsymbol{T}_{\boldsymbol{b}_{\text{down}}} \times \boldsymbol{e}^a, \\ \boldsymbol{W}_{\text{up}} &= \boldsymbol{T}_{\boldsymbol{W}_{\text{up}}} \times \boldsymbol{e}^a, \quad \boldsymbol{b}_{\text{up}} = \boldsymbol{T}_{\boldsymbol{b}_{\text{up}}} \times \boldsymbol{e}^a, \end{aligned} \tag{4}$$

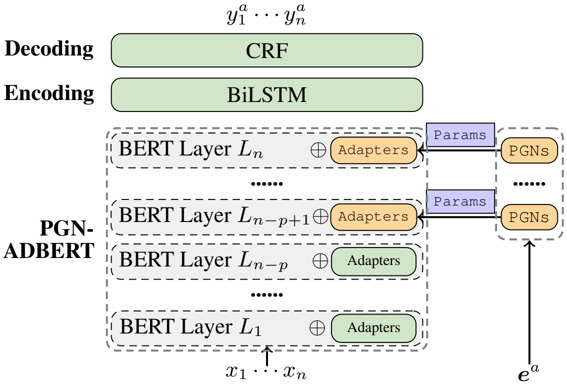

Figure 3: The annotator-adapter model. Given a joint input of the text $x_1 \cdots x_n$ and the annotator ID a, we first convert a to its embedding $\boldsymbol{e}^a$. Then, PGN use $\boldsymbol{e}^a$ generate annotator-specific parameters for the adapters in top p BERT layers (i.e., from L_n to L_{n-p+1}) to compute annotator-aware input representations. Finally, the BiLSTM encode the representations to high-level features and the CRF decoder predict the labels $y_1^a \cdots y_n^a$ that a gives to $x_1 \cdots x_n$.

where $\boldsymbol{T}_{\boldsymbol{W}_{\text{down}}}$, $\boldsymbol{T}_{\boldsymbol{b}_{\text{down}}}$, $\boldsymbol{T}_{\boldsymbol{W}_{\text{up}}}$ and $\boldsymbol{T}_{\boldsymbol{b}_{\text{up}}}$ are learnable model parameters for the PGN-ADBERT. For any matrix-format model parameter $\boldsymbol{W} \in \mathbb{R}^{M \times N}$, we have $\boldsymbol{T}_{\boldsymbol{W}} \in \mathbb{R}^{M \times N \times d}$, where d is the dim of the annotator embedding. Similarly, for the vectorial parameter $\boldsymbol{b} \in \mathbb{R}^N$, we have $\boldsymbol{T}_{\boldsymbol{b}} \in \mathbb{R}^{N \times d}$.

Thus, the overall input representation of the annotator-adapter can be rewritten as:

$$\boldsymbol{r}_1 \cdots \boldsymbol{r}_n = \text{PGN-ADBERT}(x_1 \cdots x_n, \boldsymbol{e}^a), \tag{5}$$

which jointly encodes the text and the annotator.

At the training stage, it uses the embedding of crowd annotators to generate crowd model parameters to learn crowd annotations. At the inference stage, it uses the centroid point of all annotator embeddings to estimate the expert, predicting the high-quality opinion expressions for raw texts. This expert embedding can be computed directly by:

$$\boldsymbol{e}^{\text{expert}} = \frac{1}{|A|} \sum_{a \in A} \boldsymbol{e}^a, \tag{6}$$

where A represents all annotators.

3.3 Annotator Mixup

By scrutinizing the annotator-adapter model, we can find that there is a minor mismatch during the model training and testing. During the training, the input annotators are all encoded individually. While during the testing, the input expert is a mixture of the crowd annotators, which is never modeled. To tackle this divergence, we introduce the

---

[14] The voting is conducted at the token-level and then merge continuous tokens if they belong to a same-type expression.

[15] We have added the gold-standard annotations in the revision of this work, but we keep this data setting.

mixup (Zhang et al., 2018) strategy over the individual annotators to generate a number of synthetic samples with linear mixtures of annotators, making the training and testing highly similar.

The mixup strategy is essentially an effective data augmentation method that has received increasing attention recently in the NLP community (Zhang et al., 2020; Sun et al., 2020). The method is applied between two individual training instances originally, by using linear interpolation over a hidden input layer and the output. In this work, we confine the mixup onto the two training instances with the same input sentence for annotator mixup.

Formally, given two training instances $(\boldsymbol{x}_1 \circ a_1, \boldsymbol{y}_1)$ and $(\boldsymbol{x}_2 \circ a_2, \boldsymbol{y}_2)$, the mixup is executed only when $\boldsymbol{x}_1 = \boldsymbol{x}_2$, thus the interpolation is actually performed between $(a_1, \boldsymbol{y}_1)$ and $(a_2, \boldsymbol{y}_2)$. Concretely, the input interpolation is conducted at the embedding layer, and the output interpolation is directly mixed at the sentence-level:

$$\begin{aligned} \boldsymbol{e}^{\text{mix}} &= \lambda \boldsymbol{e}^{a_1} + (1-\lambda)\boldsymbol{e}^{a_2}, \\ \boldsymbol{y}_{\text{mix}} &= \lambda \boldsymbol{y}_1 + (1-\lambda)\boldsymbol{y}_2, \end{aligned} \tag{7}$$

where $\lambda \in [0, 1]$ is a hyper-parameter which is usually sampled from the $\text{Beta}(\alpha, \alpha)$ distribution, and $\boldsymbol{y}_*$ is the one-hot vectorial form, where $* \in [1, 2, \text{mix}]$.[16] Finally, the loss objective of the new instance is calculated by:

$$\mathcal{L}_{\text{mix}} = -\log \frac{\exp\left(\text{score}(\boldsymbol{y}_{\text{mix}})\right)}{\sum_{\widetilde{Y}} \exp\left(\text{score}(\tilde{\boldsymbol{y}})\right)}, \tag{8}$$

where all scores are computed based on $\boldsymbol{x}_1/\boldsymbol{x}_2$ and $\boldsymbol{e}^{\text{mix}}$, and $\widetilde{Y}$ is all possible outputs for $\boldsymbol{x}_1/\boldsymbol{x}_2$.

Finally, we can produce a number of augmented instances by the annotator mixup. These instances, together with the original training instances, are used to optimize our model parameters. The enhanced model is able to perform inference more robustly by using the mixture (i.e, average) of annotators, which is the estimation of the expert.

4 Experiment

4.1 Setting

Evaluation. We use the span-level precision (P), recall (R) and their F1 for evaluation, since OEI is essentially a span recognition task. Following Breck et al. (2007); İrsoy and Cardie (2014), we exploit three types of metrics, namely *exact* matching, *proportional* matching and *binary* matching, respectively. The *exact* metric is straightforward and has been widely applied for span-level entity recognition tasks, which regards a predicted opinion expression as correct only when its start-end boundaries and polarity are all correct. Here we exploit the *exact* metric as the major method. The two other metrics are exploited because the exact boundaries are very difficult to be unified even for experts. The *binary* method treats an expression as correct when it contains an overlap with the ground-truth expression, and the *proportional* method uses a balanced score by the proportion of the overlapped area referring to the ground-truth.

We use the best-performing model on the development corpus to evaluate the performance of the test corpus. All experiments are conducted on a single RTX 2080 Ti card at an 8-GPU server with a 14 core CPU and 128GB memory. We run each setting by 5 times with different random seeds, and the median evaluation scores are reported.

Hyper-parameters. We exploit the bert-base-chinese for input representations.[17] The adapter bottleneck size and the BiLSTM hidden size are set to 128 and 400, respectively. For the annotator-adapter, we set the annotator embedding size $d = 8$ and generate the adapter parameters for the last $p = 6$ BERT layers. For the annotator mixup, we set α of the $\text{Beta}(\alpha, \alpha)$ distribution to 0.5.

We apply the sequential dropout to the input representations, which randomly sets the hidden vectors in the sequence to zeros with a probability of 0.2, to avoid overfitting. We use the Adam algorithm to optimize the parameters with a constant learning rate 1×10^{-3} and a batch size 64, and apply the gradient clipping mechanism by a maximum value of 5.0 to avoid gradient explosion.

Baselines. Two annotator-agnostic baselines (i.e., `ALL` and `MV`) and the silver-corpus trained model `Silver` are all implemented in the same baseline structure and hyper-parameters. We also implement two annotator-aware methods presented in Nguyen et al. (2017), where the annotator-dependent noises have been modeled explicitly. The `LSTM-Crowd` model encodes the output label bias (i.e., noises) for each individual annotator (biased-distributions) towards the expert (zeroed-distribution), and the `LSTM-Crowd-cat` model

---

[16] Note that $\boldsymbol{y}_*$ is at the sentence-level, where the dimension size is the number of all possible outputs of the given input. We mix the loss of $\boldsymbol{y}_1$ and $\boldsymbol{y}_2$ instead of themself in practice.

Table 3: The test results, where all methods are backended by BERT-BiLSTM-CRF for a fair comparison. The `Gold` and `Silver` denotes models trained with expert annotations and sentence-level expert aggregation (silver-standard in §2.4), respectively. The † indicates statistical significance compared to baselines with $p < 0.01$ by paired t-test.

applies a similar idea but implementing at the BiLSTM hidden layer. During the testing, zero-vectors are exploited to simulate the expert accordingly. Their main idea is to reach a robust training on the noisy dataset, which is totally different from our approach. In addition, we aggregate crowd labels of the training corpus by a Bayesian inference method (Simpson and Gurevych, 2019), namely `BSC-seq`, based on their code[18] and then evaluate its results with the same BERT-BiLSTM-CRF architecture.

4.2 Main Results

Table 3 shows the test results on our dataset. In general, the *exact* matching scores are all at a relatively low level, demonstrating that precise opinion boundaries are indeed difficult to identify. With the gradual relaxation of metrics (from *exact* to *binary*), scores are increased accordingly, showing that these models can roughly locate the opinion expressions to a certain degree.

Dataset comparison. Similar to the tasks like NER (Zhou et al., 2021), POS tagging, dependency parsing (Straka, 2018) and so on, in which English models have performed better than the Chinese, we see the same pattern in our OEI task. The exact matching F1 57.08 of the `Gold` corpus trained model still has a performance gap compared with that of the English MPQA dataset (i.e., 63.71 by a similar BERT-based model of Xia et al. (2021)). This may due to (1) the opinion boundaries in the word-based English MPQA are easier to locate than our character-based Chinese dataset; (2) the social media domain of our dataset, is more difficult than the news domain of MPQA.

Method comparison. First, we compare two annotator-agnostic methods (i.e., `All` and `MV`) with annotator-aware ones (i.e., the rest of models). As shown in Table 3, we can see that annotator-aware modeling is effective as a whole, bringing better performance on *exact* matching. In particular, our basic annotator-adapter model is able to give the best F1 among these selected baselines, demonstrating its advantage in crowdsourcing modeling. When the annotator-mixup is applied, the test scores are further boosted, showing the effectiveness of our annotator mixup. The overall tendencies of the two other metrics are similar by comparing our models with the others.

Our final performance is not only comparable to the `silver` corpus trained model, which we can take it as a weak upper-bound. but also close to the upper-bound model with expert annotations (i.e., `Gold`). Thus, our result for Chinese OEI is completely acceptable, demonstrating that crowdsourcing annotations are indeed with great value for model training. The observation indicates that crowdsourcing could be a highly-promising alternative to build a Chinese OEI system at a low cost.

4.3 Analysis

Here we conduct fine-grained analyses to better understand the task and these methods in-depth, where the evaluation by *exact* matching is used in this subsection. There are several additional analyses which are shown in the Appendix.

Performance by the opinion expression length. Intuitively, the identification of opinion expressions can be greatly affected by the length of the expressions, and longer expressions might be more challenging to be identified precisely. Figure 4 shows

---

[18] https://github.com/UKPLab/arxiv2018-bayesian-ensembles

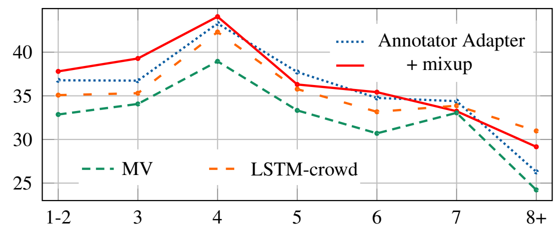

Figure 4: F1 scores of *exact* matching in terms of the opinion expression length. We bucket the opinion expressions into seven categories, where each category includes more than 100 opinion expressions.

the F1 scores in terms of expression lengths by the four models we focused. We can see that the F1 score decreases dramatically when the expression length becomes larger than 4, which is consistent with our intuition. In addition, the annotator-adapter model is better than previous methods, and the mixup model can reach the best performance on almost all the categories, indicating the robustness of our annotator mixup.

Influence of the opinion number per sentence. One sentence may have more than one opinion expressions, where these opinions might be mutually helpful or bring increased ambiguities. It is interesting to study the model behaviors in terms of opinion numbers. Here we conduct experimental comparisons by dividing the test corpus into three categories: (1) only one opinion expression exists in a sentence; (2) at least two opinions exist, and they are of the same sentiment polarity; (3) both positive and negative opinion expressions exist. As shown in Figure 5, the sentences with multiple opinions of a consistent polarity can obtain the highest F1 score. The potential reason might be that the expressed opinions of these sentences are usually highly affirmative with strong sentiments, and the consistent expressions can be mutually helpful according to our assumption. For the other two categories, it seems that they are equally difficult according to the final scores. For all three categories, two annotator-adapter models demonstrate better performance than the others.

Self-evaluation of crowd annotators. The annotator adapter uses a pseudo expert embedding to predict opinion expressions and evaluate performance on the gold-standard annotations of experts. It is interesting to examine the self-evaluation performance on the crowd annotations of the test corpus as well. During the inference, we use the crowd annotators as inputs, and calculate the model performance on the corresponding crowd annotations.

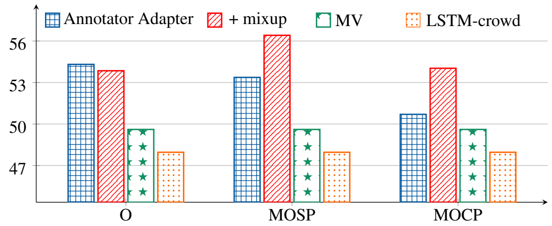

Figure 5: F1 scores of *exact* matching by following three category sentences: (1) one-opinion (**O**), (2) multiple-opinion single-polarity (**MOSP**), and (3) multiple-opinion contradict-polarity (**MOCP**).

Model	Exact		
	P	R	F1
ALL	52.24	34.17	41.32
MV	43.79	38.70	41.09
LSTM-Crowd	46.57	38.19	41.97
LSTM-Crowd-cat	52.10	32.79	40.25
Annotator-Adapter	**55.81**	42.80	**48.45**
Annotator-Adapter + mixup	52.76	**43.68**	47.79

Table 4: The evaluation results on the crowd test set, i.e., we compute F1 scores between model predictions and crowd annotations. The ALL and MV have no modifications. The other annotator-aware models have replaced the expert vector with the specific annotator vector corresponding to the annotations when testing.

Table 4 shows the results. First, two annotator-agnostic models (i.e., `ALL` and `MV`) have similar poor performance since they are trying to estimate the expert annotation function rather than learn crowd annotations. Second, the performance of two annotator-noise-modeling methods, `LSTM-Crowd` and `LSTM-Crowd-cat`, respectively, is close to the annotator-agnostic ones, showing that they are also incapable to model individual annotators. Then, our two annotator-adapter models achieve leading performance compared with all baseline methods, giving a significant gap (at least $47.79 - 41.97 = 5.82$ in F1). They are more capable of predicting crowd annotations, demonstrating the ability to model the annotators effectively. To our surprise, the mixup annotator-adapter model does not exceed the basic one, indicating that the mixed annotator embeddings in training could slightly hurt the modeling of individual annotators.

5 Related Work

OEI is one important task in opinion mining (Liu, 2012), and has received great interests (Breck et al., 2007; İrsoy and Cardie, 2014; Xia et al., 2021). The early studies can be dated back to Wilson et al. (2005) and Breck et al. (2007), which exploit CRF-based methods for the task with manually-crafted features. SemiCRF is exploited next in order to exploit span-based features (Yang and Cardie, 2012). Recently, neural network models have attracted the most attention. İrsoy and Cardie (2014) present a deep bi-directional recurrent neural network (RNN) to identify opinion expressions. BiLSTM is also used in Katiyar and Cardie (2016) and Zhang et al. (2019), showing improved performance on OEI. Fan et al. (2019) design an Inward-LSTM to incorporate the opinion target information for identifying opinion expressions given their target, which can be seen as a special case of our task. Xia et al. (2021) employ pre-trained BERT representations (Devlin et al., 2019) to increase the identification performance of joint extraction of the opinion expression, holder and target by a span-based model.

All the above studies are in English and based on the MPQA (Wiebe et al., 2005), or customer reviews (Wang et al., 2016, 2017; Fan et al., 2019) since there are very few datasets available for other languages. Hence, we construct a large-scale Chinese corpus for this task by crowdsourcing, and borrow a novel representation learning model (Zhang et al., 2021) to handle the crowdsourcing annotations. In this work, we take the general BERT-BiLSTM-CRF architecture as the baseline, which is a competitive model for OEI task.

Crowdsourcing as a cheap way to collect a large-scale training corpus for supervised models has been gradually popular in practice (Snow et al., 2008; Callison-Burch and Dredze, 2010; Trautmann et al., 2020). A number of models are developed to aggregate a higher-quality corpus from the crowdsourcing corpus (Raykar et al., 2010; Rodrigues et al., 2014a,b; Moreno et al., 2015), aiming to reduce the gap over the expert-annotated corpus. Recently, modeling the bias between the crowd annotators and the oracle experts has been demonstrated effectively (Nguyen et al., 2017; Simpson and Gurevych, 2019; Li et al., 2020), focusing on the label bias between the crowdsourcing annotations and gold-standard answers, regarding crowdsourcing annotations as annotator-sensitive noises. Zhang et al. (2021) do not hold crowdsourcing annotations as noisy labels, while regard them as ground-truths by the understanding of individual crowd annotators. In this work, we follow the idea of Zhang et al. (2021) to explorate our crowdsourcing corpus, and further propose the annotator mixup to enhance the learning of the expert representation for the test stage.

6 Conclusion

We presented the first work of Chinese OEI by crowdsourcing, which is also the first crowdsourcing work of OEI. First, we constructed an extremely-noisy crowdsourcing corpus at a very low cost, and also built gold-standard dataset by experts for experimental evaluations. To verify the value of our low-cost and extremely-noisy corpus, we exploited the annotator-adapter model presented by Zhang et al. (2021) to fully explore the crowdsourcing annotations, and further proposed an annotator-mixup strategy to enhance the model. Experimental results show that the annotator-adapter can make the best use of our crowdsourcing corpus compared with several representative baselines, and the annotator-mixup strategy is also effective. Our final performance can reach an F-score of 54.59% by exact matching. This number is actually highly competitive by referring to the model trained on expert annotations (57.08%), which indicates that crowdsourcing can be highly recommendable to set up a Chinese OEI system fast and cheap, although the collected corpus is extremely noisy.

Ethical/Broader Impact

We construct a large-scale Chinese opinion expression identification dataset with crowd annotations. We access the original posts by manually traversing the relevant Weibo topics or searching the corresponding keywords, and then copy and anonymize the text contents. All posts we collected are open-access. In addition, we also anonymize all annotators and experts (only keep the ID for the research purpose). All annotators were properly paid by their actual efforts. This dataset can be used for both the Chinese opinion expression identification task as well as crowdsourcing sequence labeling.

Acknowledgments

We thank all reviewers for their hard work. This research is supported by grants from the National Key Research and Development Program of China (No. 2018YFC0832101) and the National Natural Science Foundation of China (No. 62176180).

A Annotation Guideline

In this annotation task, we will give a number of sentences that have a high probability of expressing positive or negative sentiment, and your goal is to label the words that expresses these sentiments in each sentence. An intuitive criteria for determining whether words are expressing sentiment is that if these words are replaced, the sentiment expressed by the sentence will also change. Sentimental words will not usually be names of people, places, time or pronouns, etc. It is important to note that (1) you need to carefully understand the emotion expressed by the sentence, not judge it according to your own values, and (2) the labeled words usually do not include the target of the sentiment, such as pronouns, names of people, etc., which are generally not affected by the replacement of these words.

B Hyper-parameter Tuning

We also implement the baseline models in the fine-tuning style, results (in Table 5) show that the adapter-based models are comparable and parameter-efficient.

PGN Adapter Layers First, we examine the influence of PGN adapter layers mentioned in §3.2 by p, which is a hyper-parameter in our annotator-adapter. As shown in Table 5, we can see that the performance is stable between $p \in [6, 8, 10]$. After considering both the parameter scale and the capability of our model, we set $p = 6$ for a trade-off.

Annotator Mixup The mixup includes a hyperparameter α to control the interpolation by the distribution $\mathrm{Beta}(\alpha, \alpha)$. Here we show the influence of α by setting it with 0.2, 0.5, 0.8, and 1.0. We find that the model performance has no significant differences between these values, as shown in Table 5. To train our mixup model, we also have a reasonable small trick: training the mixup model in two stages. First, the model is trained only with the original corpus. When the model achieves the best performance on the devset, we begin the second-stage training by using the original corpus as well as the augmented corpus. Their performance difference is shown in Table 5, which indicates that the two-stage training is important for our mixup model.

C Expert-Evaluation of Crowd Annotators

We evaluate the performance of each learned annotator of three annotator-aware models towards the expert's view. The goal is achieved by using the individual annotator embeddings as input to obtain the output predicted by this specific annotator, and then measure the output performance based on the gold-standard test corpus. Table 7 shows the results. There is a huge discrepancy between the scores of different learned annotators of `LSTM-Crowd` or `annotator-adapter`, demonstrating annotators have different abilities in predicting gold labels. This is mainly because the annotators have different abilities meanwhile the annotations they gave have different qualities. All annotators in the annotator-adapter model are unable to outperform the expert (centroid point), verifying that the estimated expert is strong and reasonable. In addition, the learned annotators of our mixup model have closer performances since the annotator-mixup change the learning objective from modeling annotators to modeling the expert, which can further boost the performance of the estimated expert.

D Case Study

For a more intuitive understanding of our task and various models, we offer a paradigmatic example from the test set to analyze their outputs. Table 6 shows the gold annotation and model predictions. As shown, the `ALL` method can correctly recognize all three opinions, but fails to predict the correct boundaries. The `MV` method splits one opinion into two, and is able to recall one full opinion expression exactly. The `LSTM-Crowd` is similar to `ALL` yet slightly better. Both the annotator-adapter and our mixup models can obtain better results for this example. Note that all three opinions are difficult to be fully recognized even by crowd annotators.

Table 7: The F1 scores by using different crowd annotators as input on the gold testset. Exact matching scores are reported. The LSTM-Crowd just learns an estimation of expert assisted by modeling the label bias of annotators, while the annotator-adapter model learns the different understandings of each annotator but not the expert annotations. Our final mixup model is much more stable across different annotators. The observation indicates that, with the application of annotator-mixup, all annotators can learn from each other and improve towards the expert level together, which can enhance the expert-modeling.

Sequence-to-Sequence Knowledge Graph Completion and Question Answering

Abstract

Knowledge graph embedding (KGE) models represent each entity and relation of a knowledge graph (KG) with low-dimensional embedding vectors. These methods have recently been applied to KG link prediction and question answering over incomplete KGs (KGQA). KGEs typically create an embedding for each entity in the graph, which results in large model sizes on real-world graphs with millions of entities. For downstream tasks these atomic entity representations often need to be integrated into a multi stage pipeline, limiting their utility. We show that an off-the-shelf encoder-decoder Transformer model can serve as a scalable and versatile KGE model obtaining state-of-the-art results for KG link prediction and incomplete KG question answering. We achieve this by posing KG link prediction as a sequence-to-sequence task and exchange the triple scoring approach taken by prior KGE methods with autoregressive decoding. Such a simple but powerful method reduces the model size up to 98% compared to conventional KGE models while keeping inference time tractable. After finetuning this model on the task of KGQA over incomplete KGs, our approach outperforms baselines on multiple large-scale datasets without extensive hyperparameter tuning.[1]

1 Introduction

A knowledge graph (KG) is a multi-relational graph where the nodes are entities from the real world (e.g. *Barack Obama, United States*) and the named edges represent the relationships between them (e.g. *Barack Obama - born in - United States*). KGs can be either domain-specific such as WikiMovies (Miller et al., 2016) or public, cross-domain KGs encoding common knowledge such as Wikidata and DBpedia (Heist et al., 2020). These graph-structured databases play an important role in knowledge-intensive applications including web search, question answering and recommendation systems (Ji et al., 2020).

Most real-world knowledge graphs are incomplete. However, some missing facts can be inferred using existing facts in the KG (Bordes et al., 2013). This task termed knowledge graph completion (KGC)[2] has become a popular area of research in recent years (Wang et al., 2017) and is often approached using knowledge graph embedding (KGE) models. KGE models represent each entity and relation of the KG by a dense vector embedding. Using these embeddings the model is trained to distinguish correct from incorrect facts. One of the main downstream applications of KGEs is question answering over incomplete KGs (KGQA) (Choudhary et al., 2021).

Taking into account the large size of real world KGs (Wikidata contains ≈90M entities) and the applicability to downstream tasks, KGE models should fulfill the following desiderata: (i) *scalability* – i.e. have model size and inference time independent of the number of entities (ii) *quality* – reach good empirical performance (iii) *versatility* – be applicable for multiple tasks such as KGC and QA, and (iv) *simplicity* – consist of a single module with a standard architecture and training pipeline. Traditional KGE models fulfill quality and simplicity. They build upon a simple architecture and reach a high quality in terms of KGC. However, as they create a unique embedding per entity/relation, they scale linearly with the number of entities in the graph, both in model size and inference time, and offer limited versatility. Methods such as DKRL (Xie et al., 2016a) and KEPLER (Wang et al., 2021) attempt to tackle the scalability issue using compositional embeddings. However, they fail to achieve quality comparable to conventional KGEs. KG-BERT (Yao et al., 2019) utilizes pretrained BERT for link prediction and holds po-

Volume 1: Long Papers, pages 2814 - 2828
May 22-27, 2022

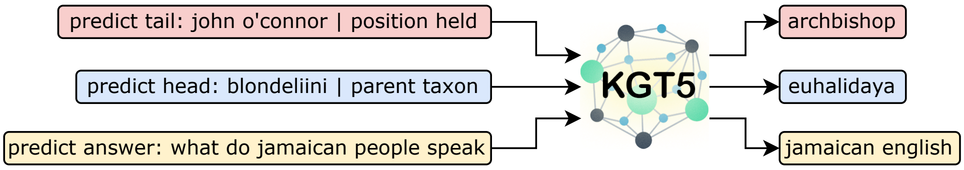

Figure 1: Overview of our method KGT5. KGT5 is first trained on the link prediction task (predicting head/tail entities, given tail/head and relation). For question answering, the same model is further finetuned using QA pairs.

tential in terms of versatility as it is applicable to downstream NLP tasks. However, it is not scalable due to its underlying cross-encoder.[3] QA methods which leverage KGEs outperform traditional KGQA approaches on incomplete KGs, but combining KGEs with the QA pipeline is a non-trivial task; models that attempt to do this often work on only limited query types (Huang et al. 2019; Sun et al. 2021; Saxena et al. 2020) or require multi-stage training and inference pipelines (Ren et al., 2021). Here, in order to achieve quality, these models have sacrificed versatility and simplicity. A comparison of approaches in terms of desiderata is summarized in Tab. 9 in the appendix.

Our paper shows that all of these desiderata can be fulfilled by a simple sequence-to-sequence (seq2seq) model. To this end, we pose KG link prediction as a seq2seq task and train an encoder-decoder Transformer model (Vaswani et al., 2017) on this task. We then use this model pretrained for link prediction and further finetune it for question answering; while finetuning for QA, we regularize with the link prediction objective. This simple but powerful approach, which we call KGT5, is visualised in Fig. 1. With such a unified seq2seq approach we achieve (i) scalability – by using compositional entity representations and autoregressive decoding (rather than scoring all entities) for inference (ii) quality – we obtain state-of-the-art performance on two tasks (iii) versatility – the same model can be used for both KGC and KGQA on multiple datasets, and (iv) simplicity – we obtain all results using an off-the-shelf model with no task or dataset-specific hyperparameter tuning.

In summary, we make the following contributions:

- We show that KG link prediction and question answering can be treated as sequence-to-sequence tasks and tackled successfully with a single encoder-decoder Transformer (with the same architecture as T5-small (Raffel et al., 2020)).
- With this simple but powerful approach called KGT5, we reduce model size for KG link prediction up to 98% while outperforming conventional KGEs on a dataset with 90M entities.
- We show the versatility of this approach through the task of KGQA over incomplete graphs. By pretraining on KG link prediction and finetuning on QA, KGT5 performs similar to or better than much more complex methods on multiple large-scale KGQA benchmarks.

2 Background & Related Work

Given a set of entities $\mathcal{E}$ and a set of relations $\mathcal{R}$, a knowledge graph $\mathcal{K} \subseteq \mathcal{E} \times \mathcal{R} \times \mathcal{E}$ is a collection of subject-predicate-object (s, p, o) triples. Link prediction is the task of predicting missing triples in $\mathcal{K}$ by answering queries of the form of $(s, p, ?)$ and $(?, p, o)$. This is typically accomplished using knowledge graph embedding (KGE) models.

Conventional KGEs assign an embedding vector to each entity and relation in the KG. They model the plausibility of (s, p, o) triples via model specific scoring functions $f(e_s, e_p, e_o)$ using the subject (e_s), predicate (e_p) and object (e_o) specific embeddings. Once trained, these embeddings are used for downstream tasks such as question answering.

Knowledge graph question answering (KGQA) is the task of answering a natural language question using a KG as source of knowledge. The questions can be either simple factual questions that require single fact retrieval (e.g. *Which languages are spoken in India?*), or they can be complex questions that require reasoning over multiple facts in the KG (e.g. *What are the genres of movies, in which Leonardo DiCaprio was leading actor?*). KGEs can be utilized to perform KGQA when the background KGs are incomplete.

In the next few sections we will go into more detail about existing work on KGEs and KGQA.

2.1 Knowledge Graph Embeddings

Atomic KGE models. Multiple KGE models have been proposed in the literature, mainly differing in

---

[3] Shen et al. (2020) estimate it would take KG-BERT 3 days for an evaluation run on a KG with just 40k entities.

the form of their scoring function $f(e_s, e_p, e_o)$. A comprehensive survey of these models, their scoring functions, training regime and link prediction performance can be found in Wang et al. (2017) and Ruffinelli et al. (2020). It is important to note that although these models obtain superior performance in the link prediction task, they suffer from a linear scaling in model size with the number of entities in the KG, and applying them to question answering necessitates separate KGE and QA modules.

Compositional KGE models. To combat the linear scaling of the model size with the number of entities in a KG, entity embeddings can be composed of token embeddings. DKRL (Xie et al., 2016b) embeds entities by combining word embeddings of entity descriptions with a CNN encoder, followed by the TransE scoring function. KEPLER (Wang et al., 2021) uses a Transformer-based encoder and combines the typical KGE training objective with a masked language modeling objective. Both of these approaches encode entities and relations separately which limits the transferability of these models to downstream tasks such as question answering. MLMLM (Clouatre et al., 2021) encodes the whole query with a RoBERTa-based model and uses `[MASK]` tokens to generate predictions. However, it performs significantly worse than atomic KGE models on link prediction on large KGs, and is yet to be applied to downstream text-based tasks.

2.2 Knowledge Graph Question Answering

Knowledge Graph Question Answering (KGQA) has been traditionally solved using semantic parsing (Berant et al. 2013; Bast and Haussmann 2015; Das et al. 2021a) where a natural language (NL) question is converted to a symbolic query over the KG. This is problematic for incomplete KGs, where a single missing link can cause the query to fail. Recent work has focused on KGQA over incomplete KGs, which is also the focus of our work. These methods attempt to overcome KG incompleteness using KG embeddings (Huang et al. 2019; Saxena et al. 2020; Sun et al. 2021; Ren et al. 2021). In order to use KGEs for KGQA, these methods first train a KGE model on the background KG, and then integrate the learned entity and relation embeddings into the QA pipeline. This fragmented approach brings several disadvantages; for example Huang et al. (2019)'s method only works for single fact question answering, while EmQL (Sun et al., 2021) requires prior knowledge of the NL question's query structure. EmbedKGQA (Saxena et al., 2020) is capable of multi-hop question answering but is unable to deal with questions involving more than one entity. Hence, these methods are lacking in versatility. LEGO (Ren et al., 2021) can theoretically answer all first order logic based questions but requires multiple dataset dependent components including entity linking, relation pruning and branch pruning modules; here, to obtain versatility, LEGO has sacrificed simplicity.

3 The KGT5 Model

We pose both knowledge graph link prediction and question answering as sequence-to-sequence (seq2seq) tasks. We then train a simple encoder-decoder Transformer – that has the same architecture as T5-small (Raffel et al., 2020) but without the pretrained weights – on these tasks. While training for question answering, we regularize with the link prediction objective. This method, which we call KGT5, results in a scalable KG link prediction model with vastly fewer parameters than conventional KGE models for large KGs. This approach also confers simplicity and versatility to the model, whereby it can be easily adapted to KGQA on any dataset regardless of question complexity.

Posing KG link prediction as a seq2seq task requires textual representations of entities and relations, and a verbalization scheme to convert link prediction queries to textual queries; these are detailed in §3.1. The link prediction training procedure is explained in §3.2 and inference in §3.3. The KGQA finetuning and inference pipeline is explained in §3.4.

3.1 Textual Representations & Verbalization

Text mapping. For link prediction we require a one-to-one mapping between an entity/relation and its textual representation. For Wikidata-based KGs, we use canonical mentions of entities and relations as their textual representation, followed by a disambiguation scheme that appends descriptions and unique ids to the name.[4] For datasets used for QA only we do not enforce a one-to-one mapping as, in this case, unnecessary disambiguation can even harm model performance.[5]

---

[4] Please see appendix A for details on textual representations.

[5] This is because QA systems consider surface forms during evaluation, not entity IDs. For example, it will be better to have the same mention for both the single and album version of a song rather than append a unique number to their mentions.

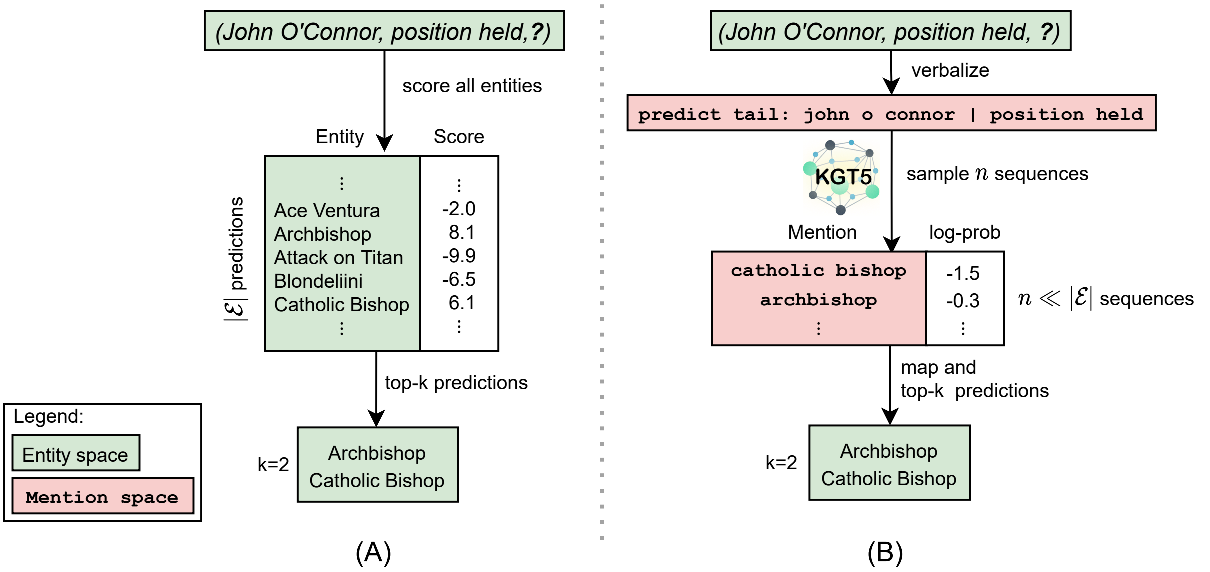

Figure 2: Inference pipeline of (A) conventional KGE models versus (B) KGT5 on the link prediction task. Given a query $(s, p, ?)$, we first verbalize it to a textual representation and then input it to the model. A fixed number of sequences are sampled from the model decoder and then mapped back to their entity IDs. This is in contrast to conventional KGEs, where each entity in the KG must be scored. Please see §3.3 for more details.

Verbalization. We convert $(s, p, ?)$ query answering to a sequence-to-sequence task by *verbalizing* the query $(s, p, ?)$ to a textual representation. This is similar to the verbalization performed by Petroni et al. (2019), except there is no relation-specific template. For example, given a query *(barack obama, born in, ?)*, we first obtain the textual mentions of the entity and relation and then verbalize it as `'predict tail: barack obama | born in'`. This sequence is input to the model, and output sequence is expected to be the answer to this query, `'united states'`, which is the unique mention of entity *United States*.

3.2 Training KGT5 for Link Prediction

To train KGT5, we need a set of (input, output) sequences. For each triple (s, p, o) in the training graph, we verbalize the queries $(s, p, ?)$ and $(?, p, o)$ according to §3.1 to obtain two input sequences. The corresponding output sequences are the text mentions of o and s respectively. KGT5 is trained with teacher forcing (Williams and Zipser, 1989) and cross entropy loss.[6]

One thing to note is that unlike standard KGE models, we train *without explicit negative sampling*. At each step of decoding, the model produces a probability distribution over possible next tokens. While training, this distribution is penalised for being different from the 'true' distribution (i.e. a probability of 1 for the true next token, 0 for all other tokens) using cross entropy loss. Hence, this training procedure is most similar to the 1vsAll + CE loss in Ruffinelli et al. (2020), except instead of scoring the true entity against all other entities, we are scoring the true token against all other tokens at each step, and the process is repeated as many times as the length of the tokenized true entity. This avoids the need for many negatives, and is independent of the number of entities.

Dataset	Entities	Rels	Edges	Token. vocab
WikiKG90Mv2	91M	1,387	601M	32k
Wikidata5M	4.8M	828	21M	30k
MetaQA	43k	9	70k	10k
WQSP†	158k	816	376k	32k
CWQ†	3.9M	326	6.9M	32k

Table 1: Statistics of the KGs used. †We use subsets of FreeBase (Google, 2015) for WebQuestionsSP (WQSP) and ComplexWebQuestions (CWQ).

3.3 Link Prediction Inference

In conventional KGE models, we answer a query $(s, p, ?)$ by finding the score $f(s, p, o)$ $\forall o \in \mathcal{E}$, where f is the model-specific scoring function. The entities o are then ranked according to the scores.

In our approach, given query $(s, p, ?)$, we first

---

[6] More details about training are available in Appendix B

verbalize it (§3.1) before feeding it to KGT5. We then *sample* a fixed number of sequences from the decoder,[7] which are then mapped to their entity ids.[8] By using such a generative model, we are able to approximate (with high confidence) top-m model predictions without having to score all entities in the KG, as is done by conventional KGE models. For each decoded entity we assign a score equal to the (log) probability of decoding its sequence. This gives us a set of (entity, score) pairs. To calculate the final ranking metrics comparable to traditional KGE models, we assign a score of $-\infty$ for all entities not encountered during the sampling procedure. A comparison of inference strategy of conventional KGE models and KGT5 is shown in Figure 2.

3.4 KGQA Training and Inference

For KGQA, we pretrain the model on the background KG using the link prediction task (§3.2). This pretraining strategy is analogous to 'KGE module training' used in other KGQA works (Sun et al. 2021; Ren et al. 2021). The same model is then finetuned for question answering. Hereby, we employ the same strategy as Roberts et al. (2020): we concatenate a new task prefix (`predict answer:`) with the input question and define the mention string of the answer entity as output. This unified approach allows us to apply KGT5 to any KGQA dataset regardless of question complexity, and without the need for sub-modules such as entity linking.

To combat overfitting during QA finetuning (especially on tasks with small KGs) we devise a regularisation scheme: we add link prediction sequences sampled randomly from the background KG to each batch such that a batch consists of an equal number of QA and link prediction sequences. For inference, we use beam search followed by neighbourhood-based reranking (§4.3) to obtain the model's prediction which is a single answer.

4 Experimental Study

We investigate whether KGT5–i.e. a simple seq2seq Transformer model–can be jointly trained to perform both knowledge graph link prediction as well as question answering. Hereby, we first describe the used datasets (§4.1), the baselines we compared to (§4.2) and the experimental setup (§4.3). The results of our experiments are analysed in §4.4-§4.8. Before going into detail, we summarize our key findings:

1. For link prediction on large KGs, the text-based approach of KGT5 reduces model size to comparable KGE models by up to 98% and reaches or outperforms current state-of-the-art.
2. On the task of KGQA over incomplete KGs, our simple seq2seq approach obtains better results than the current state-of-the-art across multiple datasets.
3. KG link prediction training might be more beneficial than language modeling pretraining on knowledge intensive tasks such as KGQA.
4. Although KGT5 is good at generalizing to unseen facts, it is rather poor at memorizing facts. This problem can be alleviated, if needed, by using an ensemble of KGT5 and conventional link prediction or KGQA systems.

4.1 Datasets

We evaluate the link prediction capability of KGT5 on Wikidata5M (Wang et al., 2021) and WikiKG90Mv2 (Hu et al., 2021), two of the largest publicly available benchmark KGs. Although KGT5 is designed for large problems, we evaluate on the smaller benchmark KGs FB15k-237 (Toutanova and Chen, 2015), WN18RR (Dettmers et al., 2018) and YAGO3-10 (Dettmers et al., 2018) for comparability.

We evaluate the QA capabilities of KGT5 on three large-scale KGQA benchmark datasets: MetaQA (Zhang et al., 2018), WebQuestionsSP (WQSP) (Yih et al., 2016) and ComplexWebQuestions (CWQ) (Talmor and Berant, 2018). Questions in MetaQA span from 1-hop to 3-hop questions requiring path-based reasoning on a KG based on WikiMovies (Miller et al., 2016). WQSP contains both 1-hop and 2-hop path based questions while CWQ contains questions requiring steps such as compositional, conjunctive, comparative and superlative reasoning. Both WQSP and CWQ can be answered using Freebase (Google, 2015) as the background KG. We create subsets of Freebase using the scheme proposed by Ren et al. (2021) which results in KGs that are much smaller than Freebase but can still be used to answer all ques-

---

[7] See Appendix C for additional details on sampling and our choice of decoding strategy.

[8] The decoded sequence may or may not be an entity mention. We experimented with constrained decoding (Cao et al., 2021) to force the decoder to output only entity mentions; however, we found this unnecessary since the model almost always outputs an entity mention, and increasing the number of samples was enough to solve the issue.

tions in CWQ and WQSP.

Following prior work (Sun et al., 2019a) we randomly drop 50% of edges from all KGs to simulate KG incompleteness. This stochasticity causes different works to have different KGs, making it hard to compare results without re-implementing methods. Ren et al. (2021) implemented all comparison methods using their own KG splits which they have not yet published.[9] Our KG split is available along with our implementation[1] and we encourage further studies to use it. We do not re-implement comparison methods but instead report the numbers for our methods and baselines separately. We also report the accuracy obtained by executing the ground truth SPARQL queries (GT query) for test questions. GT query serves as an estimate of the hardness of a KG split and helps us compare model performance across KG splits. Note that for training all models, we only use (NL question, answer entity) pairs - *no ground truth query information is used for training*. Statistics of the KGs used in our experiments are shown in Tab. 1. Statistics of the QA datasets are shown in Tab. 11.

4.2 Comparison Models

For KG completion on Wikidata5M, we compared with several standard KGE models that have been shown to achieve good performance across multiple datasets (Ruffinelli et al., 2020) but with a large number of parameters. Among low-parameter models, we compared to the text based approaches KEPLER (Wang et al., 2021), DKRL (Xie et al., 2016a) and MLMLM (Clouatre et al., 2021). We also consider low-dimensional versions of the state-of-the-art method ComplEx. For the small benchmark KGs we compared with the currently best performing model NBFNet (Zhu et al., 2021).

For KGQA, we compared against several methods that have been shown to achieve SOTA on QA over incomplete KGs. These include PullNet (Sun et al., 2019a), EmQL (Sun et al., 2021), EmbedKGQA (Saxena et al., 2020) and LEGO (Ren et al., 2021). Additionally, for the MetaQA datasets, we compared with a relation-path finding baseline, which we call PathPred. This simple

Table 4: Hits@1 (gain vs GT query) on ComplexWebQuestions (CWQ) and WebQuestionsSP (WQSP) datasets in the 50% KG setting. Baseline results are from Ren et al. (2021). We use the same KG as used by the baselines for WQSP and a slightly *harder* KG for CWQ. Please see §4.5 for more details.

method maps a NL question to a relation path using distantly supervised data obtained from QA pairs in the training set.[10]

4.3 Experimental Setup

In all our main experiments we used a model with the same architecture as T5-small (~60M parameters) but without the pretrained weights. For tokenizing sequences, we trained a BPE tokenizer using the SentencePiece (Kudo and Richardson, 2018) library on the verbalised KGs (see Tab. 1 for tokenizer statistics).

We used AdaFactor (Shazeer and Stern, 2018) with a learning rate warmup schedule for link prediction training, batch size 320 and 10% dropout. We adopted the same procedure as Roberts et al. (2020) for QA finetuning - we halved the batch size and fixed the learning rate to 0.001. All experiments were performed using 4 Nvidia 1080Ti GPUs and models were implemented using the HuggingFace library (Wolf et al., 2019). *We performed no dataset-specific hyperparameter tuning* for KGT5 and used the same architecture, batch size, dropout and learning rate schedule throughout all experiments.[11] All models were trained until validation accuracy did not significantly increase for 10k steps.[12]

For inference, we used sampling size = 500 for link prediction and beam size = 4 for KGQA. We further performed a neighbourhood-based reranking for KGQA: given question q, topic entity from question e, predicted answer entity a and (log) probability of predicted entity p_a, we compute score for a being answer as

$$\begin{aligned} score(a) &= p_a + \alpha \quad \text{if } a \in \mathcal{N}(e) \\ &= p_a \qquad\quad \text{otherwise} \end{aligned} \tag{1}$$

where α is a constant hyperparameter and $\mathcal{N}(e)$ is the n-hop neighbourhood of the topic entity (n = 1, 2 or 3). Re-ranking was only done on datasets where topic entity annotation is available as part of test questions.

Model	1-hop	2-hop	3-hop
GT query	63.3	45.8	45.3
PullNet	65.1 (+1.8)	52.1 (+6.3)	59.7 (+14.4)
EmbedKGQA	**70.6 (+7.3)**	54.3 (+8.5)	53.5 (+8.2)
EmQL	63.8 (+0.5)	47.6 (+1.8)	48.1 (+2.8)
LEGO	69.3 (+6.0)	**57.8 (+12.0)**	63.8 (+18.5)
GT query	67.7	48.7	44.4
PathPred	67.7 (+0.0)	48.7 (+0.0)	44.4 (+0.0)
KGT5	**75.0 (+7.3)**	36.2 (-8.2)	**64.4 (+20.0)**
KGT5-PP-Ens.	**76.0 (+8.3)**	**65.4 (+16.7)**	**76.6 (+32.2)**

Table 5: Hits@1 (gain vs GT query) on MetaQA in the 50% KG setting. Baseline results are from Ren et al. (2021). There are two ground truth query (GT query) rows since the KG used by baseline models is different from ours. KGT5-PP-Ens. is the KGT5-PathPred ensemble model. Please see §4.5 for more details.

4.4 Link Prediction with KGT5

Tab. 3 shows link prediction performance on WikiKG90Mv2, one of the largest benchmark KGs available. Here we compare against TransE, ComplEx and their variants. *-MPNet and *-concat methods use text embeddings as part of entity representations, and operate on the same textual data as KGT5. KGT5 achieves the highest MRR on validation set while having 98% fewer parameters than the next best performing model on the leaderboard.[13]

Tab. 2 shows link prediction performance on Wikidata5M, a smaller but better studied KG. We see that KGT5 outperformed all low-parameter count models on all metrics. When compared to the large ComplEx model, there is a drop of 0.008 points in MRR and a gain of 0.012 points in hits@1.

We performed a more fine-grained analysis of

---

[10] Please see Appendix D for details of PathPred.

[11] The vocabulary size for MetaQA is 10k, compared to ~30k for other datasets. This was necessary in order to train a BPE tokenizer on such a small KG.

[12] ~5M steps for large KGs (WD5M, W90M), ~500k steps for smaller KGs and ~30k steps for QA finetuning

[13] The authors of OGB-LSC did not provide us with scores on the hidden test set because we used the entity mentions that were provided with the dataset. These entity mentions have now been removed; we provide them for reproducibility on our resource website.

model predictions according to the type of query for Wikidata5M (Tab. 13 in the appendix). We found that KGT5 excelled at answering queries which have none or only a few correct answers in the train set; performance dropped when several entities can be correct for a query. This could be due to the nature of sampling: low probability sequences are harder to sample and also harder to rank correctly. Additionally, the limited sampling (§3.3) may not even provide the correct answer if there exist more known positives than sampled answers.

Based on these observations we created an ensemble of ComplEx and KGT5 which answers queries as follows: if the query does not have answers in the train KG, use KGT5; otherwise use ComplEx (614M). As shown in Tab. 2, the ensemble created by this simple rule outperformed all other single models and achieved the state-of-the-art on Wikidata5M.[14,15] Such an ensemble neither achieves the goal of scalability nor versatility but instead serves as an ablation to point out weak spots of KGT5.

Tab. 10 in the appendix shows link prediction performance on KGs with $\leq$ 150k entities. Here KGT5 sometimes falls behind the baselines; Transformer models are known to struggle when data is scarce, and this could be the reason for poor performance on these small datasets.

4.5 QA over Incomplete KGs with KGT5

Due to the lack of public KG splits, we compared KGQA methods using *gain over ground truth query model*, which is available for both the comparison methods (from Ren et al. 2021) as well as our methods.[16] Tab. 4 shows hits@1 performance on Freebase-based datasets ComplexWebQuestions and WebQuestionsSP. On both datasets, KGT5 outperformed all baselines. The gains were the largest on ComplexWebQuestions which is the hardest dataset in terms of complexity and KG size.

Tab. 5 shows hits@1 performance on the MetaQA datasets. On MetaQA 1- and 3-hop, KGT5 was either equal or better than all baselines (in terms of gain). On MetaQA 2-hop however, the performance was significantly worse compared to the baselines, and even worse than ground truth querying. We did a more fine-grained analysis of the performance of KGT5 on different question types (Tab. 15-16 in the appendix). We found that KGT5 performance suffered most on questions where the head and answer entity were of the same type (for e.g. *actor* → *movie* → *actor* questions). These question types are absent in the 1-hop and 3-hop datasets. When head and answer entities had different types (for e.g. *director* → *movie* → *language* questions), KGT5 was able to answer them better than GT query.

Model	**MetaQA**			**WQSP**
	1-hop	**2-hop**	**3-hop**	
KGT5	75.0	36.2	64.4	50.5
– reranking	73.1	35.8	63.3	47.2

Table 6: Effect of neighbourhood reranking on KGQA with 50% KG. The numbers reported are hits@1.

To remedy this issue and create a model more faithful towards the knowledge present in the incomplete KG, we devised an ensemble of KGT5 with the PathPred baseline. The ensemble works as follows: Given a question q, try to answer it using PathPred. If this returns an empty set, use KGT5. This ensemble outperformed all single models on all MetaQA datasets, often by large margins (Tab. 5).

Additionally, we performed an ablation to study the effect of neighbourhood reranking on KGQA performance (Tab. 6). We found that reranking gave small but consistent gains on all datasets.

4.6 Relation to Knowledge Probing

Knowledge probing works such as LAMA (Petroni et al., 2019) aim to answer the following question: can models (e.g. BERT) which are pretrained on *generic text corpora* with a *language modeling objective* be used as knowledge bases? In our case, the model has been explicitly trained with the *link prediction objective*, and a knowledge probing experiment would be akin to checking train set performance of link prediction (which is discussed in §4.8). Furthermore, we do not claim that KGT5 is as general purpose as large LMs, or that it contains generic world knowledge. Hence we do not perform knowledge probing experiments on datasets such as T-Rex or Google-RE (Petroni et al., 2019).

---

[14] In this ensemble KGT5 was used to answer 42% of the queries; the rest were answered by ComplEx

[15] To the best of our knowledge current state-of-the-art on Wikidata5M is ComplEx published with Kochsiek and Gemulla (2021) presented in Tab. 2.

[16] Details about KGs used by us compared to baselines can be seen in Tab. 14.

Method	**WQSP**	**CWQ**
T5-small + QA finetuning	31.3	27.1
KGT5 (50% KG pretraining)	50.5	34.5
KGT5 (full KG pretraining)	56.1	36.5
EmbedKGQA	66.6	-
CBR-KGQA (Das et al., 2021b)	**73.1**	**70.4**

Table 7: Hits@1 in the full-KG KGQA setting. For details please see §4.8.

Model	**Test MRR**	**Train MRR**	**Params**
ComplEx	0.308	0.721	614M
KGT5	0.300	0.304	60M

Table 8: Train vs. test performance on link prediction on Wikidata5M. Please see §4.8 for details.

4.7 KG vs LM pretraining

We analyzed how generic corpora pretraining performed compared to KG link prediction training for the task of KGQA. We compared with T5-small (Raffel et al., 2020), which has the same architecture as KGT5 but pretrained on a mixture of tasks, most notably language modeling on web text. From Tab. 7 we see that KGT5 vastly outperformed T5-small. This is not surprising: the data for KGT5 pretraining was tailored towards the task performed–KGQA–which was not the case for T5-small. However, this shows that it is the link prediction pretraining that is responsible for the excellent KGQA performance of KGT5.

4.8 Limitations

Full-KG Question Answering. Tab. 7 shows hits@1 performance in the full KG setting. KGT5 performance only marginally improves when pretrained on full KG compared to 50% KG, and lags far behind both EmbedKGQA (a ComplEx-based method) as well as CBR-KGQA (a semantic parsing method that uses (NL-query, SPARQL-query) parallel data). This indicates that although KGT5 excels at generalizing to unseen facts, it may not be good at memorizing facts. This is further supported by the *train set* link prediction performance of KGT5 (Tab. 8); although both ComplEx and KGT5 have comparable test MRR, train MRR of ComplEx is significantly better. One possible explanation could be that the reduced model capacity of KGT5 – which has only 60M parameters – does not allow it to memorize facts seen during pretraining, leading to poor train MRR and full-KG KGQA performance. Hence we recommend against using KGT5 as a standalone KGQA method, and it should be used only when query-parsing does not yield good results.

Use of textual mentions. Since KGT5 requires textual representations for every entity, it cannot be directly applied to all KGs, and is especially unsuitable for KGs that contain CVT nodes as entities (e.g. full Freebase). Also, care must be taken when comparing models that make use of entity names/descriptions with those that do not. In our experiments, we noticed a significant proportion of validation triples in WikiKG90Mv2 required just text processing (eg. `<Giovanni Bensi, family name, Bensi>`) and we found a few cases of potential data leakage when definitions are used in WN18RR (eg. `<hylidae - the amphibian family of tree frogs, hypernym, amphibian family>`). However, from a practical perspective, models which can leverage text data could be more advantageous, and one must assess the pros and cons of a technique before applying it.

5 Conclusion and Future Work

We have shown that KG link prediction and question answering can be treated as seq2seq tasks and tackled successfully with a single encoder-decoder Transformer model. We did this by training a Transformer model with the same architecture as T5-small on the link prediction task, and then finetuning it on the QA task. This simple but powerful approach, which we call KGT5, performed competitively with the state-of-the-art methods for KG completion on large KGs while using upto 98% fewer parameters. On the task of KGQA on incomplete KGs, we found that our unified approach outperformed baselines on multiple large-scale benchmark datasets. Additionally, we compared language modeling pretraining with KG link prediction training and found that for knowledge-intensive tasks such as KGQA, link prediction training could be more beneficial.

One promising direction for future exploration would be to see whether KG link prediction training could be considered as an additional pretraining objective when training large seq2seq models. Furthermore, the impact of model size, and whether larger Transformer models can indeed store more relational information should be investigated.

Table 9: Comparison of related work in terms of the desiderata described in §1.

A Textual representations of entities and relations

For Wikidata based datasets we obtain canonical mentions of entities and relations from the corresponding Wikidata page titles (canonical names). However, multiple entities can have identical canonical mentions; we disambiguate such entities by appending the name with their 1-line description if available. In all other cases of identical canonical mentions we extend each mention with a unique id. This results in a one-to-one mapping between entities and their textual representations. For WikiKG90Mv2 we used the entity names and descriptions provided as part of OGB v1.3.2 data dump. For Wikidata5M, these were extracted from a 2019 WikiData dump.

For the Freebase based question answering datasets, such as WQSP and CWQ, we use the *identifier triples* (Chah, 2017) to retrieve mention strings. In particular, we use the canonical name (in English) connected by the relation type `/type/object/name`. Furthermore, we disambiguate similar to the Wikidata based datasets with an alias retrieved via the relation `/common/topic/alias` or append part of the description `/common/topic/description` if available.

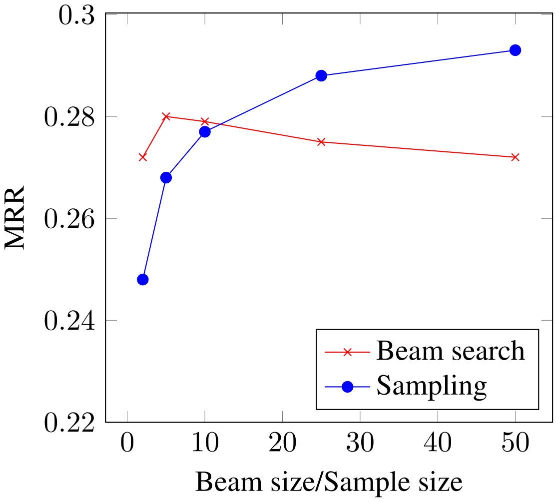

Figure 3: Link prediction performance on Wikidata5M. Increasing the sample size steadily increases MRR for the sampling strategy; the opposite effect is seen with beam size ≥ 5 and beam search.

B Teacher forcing

At each step of decoding, the model produces a probability distribution over possible next tokens. While training, this distribution is penalised for being different from the 'true' distribution (i.e. a probability of 1 for the true next token, 0 for all other tokens) using cross entropy loss. In teacher forcing (Williams and Zipser, 1989) the target token is used as the next token during decoding.

An entity usually consists of multiple tokens. Consider an input sequence $input$, target entity mention tokenized as $[w_1, w_2, .., w_T]$ and vocabulary $[v_1, v_2, ..., v_M]$. Then

$$
\begin{aligned}
y_{t,c} &= \mathbb{1}_{c=w_t} \\
p_{t,c} &= \mathbb{P}(v_c | input, w_1, w_2, ..., w_{t-1}) \\
J_t &= -\sum_{c=1}^{M} y_{t,c} \log p_{t,c} \\
Loss &= \frac{1}{T} \sum_{t=1}^{T} J_t
\end{aligned}
$$

where $\mathbb{P}$ is the model's output distribution.

C Sampling strategy for link prediction

At each step of decoding we get a probability distribution over tokens. We sample a token from this distribution and then autoregressively decode until the 'stop' token. By repeating this sampling procedure multiple times we can get multiple predictions for the same input sequence. The score for a sequence is the sum of log probabilities for

Model	WN18RR			FB15k-237			YAGO3-10		
	MRR	H@1	H@10	MRR	H@1	H@10	MRR	H@1	H@10

NBFNet (Zhu et al., 2021)	**0.551**	**0.497**	**0.666**	**0.415**	**0.321**	**0.599**	-	-	-
KGT5 (Our method)	0.508	0.487	0.544	0.276	0.210	0.414	0.426	0.368	0.528
KGT5-ComplEx Ensemble	0.542	**0.507**	0.607	0.343	0.252	0.377	**0.552**	**0.481**	0.680

Table 10: Link prediction results on small KGs ($\leq$ 150k entities). KGT5 is generally worse than both NBFNet and ComplEx on FB15k-237 and YAGO3-10 datasets. Performance on WN18RR is somewhat better; however a part of this could be due to the use entity definitions (see §4.8). Please see §4.4 for more details.

Dataset	**Train**	**Validation**	**Test**
MetaQA 1-hop	96,106	9,992	9,947
MetaQA 2-hop	118,980	14,872	14,872
MetaQA 3-hop	114,196	14,274	14,274
WQSP	2,998	100	1,639
CWQ	27,639	3,519	3,531

Table 11: Numbers of questions in the KGQA datasets used in our experiments.

its tokens. For an input sequence $input$, and an entity mention tokenized as $[w_1, w_2, ..., w_T]$, the score for the entity would be

$$\sum_{t=1}^{T} \log(\mathbb{P}(w_t|input, w_1, w_2, ..., w_{t-1}))$$

where $\mathbb{P}$ is the model's output distribution.

Another way to obtain large number predictions could have been beam search (Graves, 2012). This would also have the advantage of being deterministic and guaranteed to produce as many predictions as we want. Although in theory wider beam sizes should give improved performance, it has been observed that for beam sizes larger than 5, performance of generative models suffers drastically (Yang et al., 2018) and sampling generally produces better results. We observe the same phenomenon in our work where beam size 50 produces far worse results than sampling 50 times (fig. 3). Modifying the stopping criteron (Murray and Chiang, 2018) or training method (Welleck et al., 2019) might be helpful solutions that we hope to explore in future work.

D Path Predictor on MetaQA

Being an artificially generated template-based dataset, MetaQA has far more questions than any other dataset that we compare with (Tab. 11). It also has very little variety in the forms of questions (Tab. 12). Hence we try to answer the following question: Can we create a simple model that maps a NL question to a relation path, and then does KG traversal with this path to answer questions? We achieve this by using distant supervision to get the question → path mapping data, which is then processed to get the final model. We call this model PathPred. *We do not use ground truth queries to create this data.*

Dataset	Train Questions	Distinct Qtypes	Distinct NL questions	Train QA pairs
1-hop	96,106	11	161	184,884
2-hop	118,980	21	210	739,782
3-hop	114,196	15	150	1,521,495

Table 12: Statistics for MetaQA QA datasets. Since it is a template-based dataset, there is very little linguistic variation - for each linguistic variation, there are more than 1,000 QA pairs on average in the 1-hop dataset. This is further amplified for 2-hop and 3-hop datasets since there are more correct answers on average per question.

A question in MetaQA consists of the question text q_{text}, a topic entity h and a set of answers $\{a_1, a_2, ...\}$ (answers only in train set). Since the topic entity annotation is present for all questions (including test set), we can replace the entity in the question to get a base template q_{base}.[17]

Given a training tuple of (q_{base}, h, a), we find all the k-hop relation paths $[r_1, .., r_k]$ between h and a (k=1,2 or 3 depending on the dataset). We then aggregate these paths for each distinct q_{base}, and take the most frequent path as the mapping from q_{base} to relation path. This mapping from question template q_{base} to a relation path $[r_1, .., r_k]$ constitutes the PathPred model.

For a test question (q_{text}, h), we first get q_{base} from q_{text}. We then use the aforementioned map-

---

[17] As an example given a q_{text} '*who are the co-actors of Brad Pitt*' and topic entity annotation '*Brad Pitt*', we can get a base template q_{base} as '*who are the co-actors of NE*' where *NE* (named entity) is the substitution string.

Model	MRR				Hits@1			
	No. of entities to filter			All queries	No. of entities to filter			All queries
	0	1 to 10	>10		0	1 to 10	>10	
ComplEx	0.534	**0.351**	**0.045**	0.296	0.464	**0.233**	**0.027**	0.241
KGT5	**0.624**	0.215	0.015	0.300	**0.567**	0.164	0.011	0.267

Table 13: For a test query $(s, r, ?)$, there can be multiple entities o such that (s, r, o) is in train set. These entities need to be 'filtered' before evaluation. This table shows model performance on queries requiring different amounts of filtering. Dataset is Wikidata5M. The ComplEx checkpoint used in this analysis is slightly worse than the SOTA.

Model(s)	MetaQA			WQSP	CWQ
	1-hop	2-hop	3-hop		
Baselines (LEGO, EmbedKGQA, EMQL, PullNet)	63.3	45.8	45.3	56.9	25.2
Ours (KGT5, KGT5 Ensemble)	67.7	48.7	44.4	56.9	24.5

Table 14: Percentage of questions answerable using ground truth query. For the baselines that we compare with, we do not have access to the exact same 50% KG split used by them. This table lists the percentage of questions answerable using GT query, for the KGs used by the comparison models (LEGO, EmbedKGQA, EMQL, PullNet) as well as by our models (KGT5, KGT5 + PathPred Ensemble). The GT query numbers for baselines were made available by Ren et al. 2021.

ping to get a relation path using q_{base}. This relation path is then used to traverse the KG starting from h to arrive at the answer(s).

In the KGT5 + PathPred ensemble (§4.5, Tab. 5), we first apply the PathPred technique; if the resulting answer set is empty – which can happen due to KG incompleteness – we apply KGT5 to get the answer.

Learning to Mediate Disparities Towards Pragmatic Communication

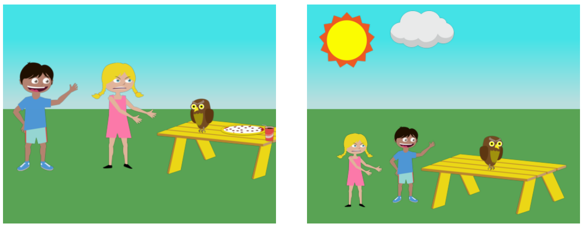
Abstract

Human communication is a collaborative process. Speakers, on top of conveying their own intent, adjust the content and language expressions by taking the listeners into account, including their knowledge background, personalities, and physical capabilities. Towards building AI agents with similar abilities in language communication, we propose Pragmatic Rational Speaker (PRS), a framework extending Rational Speech Act (RSA). The PRS attempts to learn the speaker-listener disparity and adjust the speech accordingly, by adding a light-weighted disparity adjustment layer into *working memory* on top of speaker's *long-term* memory system. By fixing the long-term memory, the PRS only needs to update its working memory to learn and adapt to different types of listeners. To validate our framework, we create a dataset that simulates different types of speaker-listener disparities in the context of referential games. Our empirical results demonstrate that the PRS is able to shift its output towards the language that listeners are able to understand, significantly improve the collaborative task outcome.

1 Introduction

In human communication, speakers often adjust their language production by taking into consideration listeners' personality, background knowledge, perceptual or physical capabilities etc (Clark, 1996). Recent years have seen an increasing amount of work that explores pragmatic reasoning based on Rational Speech Act (RSA) (Andreas and Klein, 2016; Fried et al., 2018a,b; White et al., 2020; Cohn-Gordon et al., 2018), multi-agent emergent communication framework (Lazaridou et al., 2020; Lazaridou and Baroni, 2020), and Theory of Mind in communication (Bara et al., 2021; Zhu et al., 2021). However, except for (Zhu et al., 2021), most previous works assume that the listeners and the speakers have the same background knowledge and capabilities, including vocabulary size, visual access, and relative locations. This assumption is a great simplification of real-world communication where speakers and listeners often have various types of disparities.



(a) Target (b) Distractor

Literal Speaker: There is an owl on the table.
Rational Speaker: There is a pizza on the table.
Listener's Disparity: understands hypernym of food only.
Pragmatic Rational Speaker: There is food on the table.

Figure 1: **TASK:** Given two images, the speaker generates a description for the target image and asks the listener to pick out the image described. Both players win if the listener picks the correct one. In this example, a Literal Speaker could generate multiple captions that suit the target, such as the one above, whereas a Rational Speaker limits the description to the unique features of the target (e.g. pizza). If the listener only understands the hypernym of food (disparity), a Pragmatic Rational Speaker would learn the disparity and use *food* instead of *pizza* to help the listener understand.

To address this limitation, this paper extends the Rational Speech Act (RSA) (Frank and Goodman, 2012) model towards rational agents learning to adapt behaviors based on their experience with the listener. The design choice of our model is inspired by the human cognitive system (Cowan, 2008; Wardlow, 2013) where a limited capacity ***working memory*** is built on top of the ***long-term memory*** to adjust the output to be task and environment specific. Each communication is a modification on the long-term memory (Reed, 2012) with situation-specific factors. In our framework, we fix the long-term memory which captures lan-

guage structure for communication, and introduce a light-weighted working memory (Miyake and Shah, 1999) for the Pragmatic Rational Speaker to modify and accommodate two goals: 1) a **task goal** which retrieves relevant information from the long-term memory and accomplish the task, and 2) a **disparity goal** which learns and adjusts the conversation to accommodate the listener's disparity through reinforcement learning. We separate each component as they are independent of each other in utility, and can be easily switched and adapted for new tasks and new environment.

Different from previous works which only demonstrate how learned models affect task performance (e.g. (Shridhar et al., 2020; Zhu et al., 2021; Corona et al., 2019)), one of our goals is to also provide transparency on what models have indeed learned towards the end goal. It's well established that end-to-end neural models can often take advantage of spurious data bias to gain end performance. Models that only report end measure without showing their internal works would not be sufficient to tell the whole story about model's abilities.

To serve this goal, we situated our investigation in the context of a referential game[1] as shown in Figure 1. We carefully curated a dataset to simulate two types of disparity: *knowledge disparity* and *perceptual disparity*. Our empirical results demonstrate that our model is able to significantly improve the collaborative game performance by shifting communication towards the language that the listeners with disparities are able to understand. In addition, our results show that separating working memory from long-term memory leads to faster learning and better performance than the previous model which conducted joint end-to-end learning.

Our contributions are the following. 1) Following human cognition, we demonstrate the benefits of separating working memory from the long-term memory, compared to end-to-end joint training. 2) We propose a new dataset to simulate multiple distinct types of disparities, and demonstrate the pragmatic adaptability of our model. 3) Instead of focusing on mere end task performance, we show model's strong language shift ability to accommodate listener's disparities. The dataset and code are available through `https://github.com/sled-group/Pragmatic-Rational-Speaker` to facilitate future work on pragmatics and theory of mind in language interpretation and generation.

2 Related Work

It has been studied (Leung et al., 2021; Stephens et al., 2010; Wardlow, 2013) in psychology that human speakers adjust the way how we speak for successful communication after learning the listener's disparity. Some recent work (Zarrieß and Schlangen, 2019; Zhu et al., 2021; Corona et al., 2019; Hawkins et al., 2021) attempt to address similar questions. We build our model upon the following two concepts.

Rational Speech Act (RSA)

The Rational Speech Act (RSA) model (Frank and Goodman, 2012) is a probabilistic model for the speakers and listeners to pragmatically reason about each other's intention. In the context of a referential game (Monroe and Potts, 2015), for example (Figure 1), given an image m, it starts with a literal speaker S_0 to generate caption c: $P_{S_0}(c|m)$. A rational listener L_1 reasons about the literal speaker's (S_0) strategy and picks the best image that matches the description. A rational speaker S_1 then takes the rational listener's (L_1) strategy into account and produces a caption c that maximizes the collaborative game goal.

$$P_{L_1}(m|c) \propto P_{S_0}(c|m) \cdot P(m)$$

$$P_{S_1}(c|m) \propto P_{L_1}(m|c) \cdot P(c)$$

In previous work (Andreas and Klein, 2016) and (Lazaridou et al., 2020; Lazaridou and Baroni, 2020), the same referential game setup was used to propose a rational speaker that learns to reason the collaborative game and to produce natural sounding image captions based on RSA. However, they were mainly addressing the *task goal*, assuming the speaker and listener have the exact same capabilities and knowledge background, which is unrealistic. In our work, we created listeners with disparity d and extend this model for the speaker to accommodate both the *task* and *disparities* goals.

Working Memory

Working memory (also short-term memory) is used in neuropsychology and cognitive science (Cowan,

---

[1] Different from traditional referential ground work as (Liu et al., 2013; Gorniak and Roy, 2004; Siebert and Schlangen, 2008; DeVault et al., 2005; Liu et al., 2012), we adopted this term from a recent line of work (Lazaridou et al., 2020; Andreas and Klein, 2016) to refer to the task described in Figure 1.

	Role	Long Term	Work Mem - Task	Work Mem - Disparity
S_0	Literal Speaker	Image Caption		
S_1	Rational Speaker	Image Caption	Simulated Listener	
S_1^d	Pragmatic Rational Speaker	Image Caption	Simulated Listener	Disparity Adjustment
L_1	Rational Listener	Caption Grounding		
L_1^d	Rational Listener w/ Disparity	Caption Grounding with disparity		

Table 1: Types of Speaker and Listener

2008; Miyake and Shah, 1999) to refer to the memory that controls attention, plans and carries out behavior. It is a combination of multiple components, including the contribution of long-term memory (Reed, 2012; Sawangjit et al., 2018) and situation-specific task processing (Funahashi, 2017).

The classical artificial intelligence work such as ACT (Heise and Westermann, 1989) and SOAR (Laird et al., 1987) also incorporated the concept of working memory to model human short-term memory. The similar concept has been used in recent work such as (Hermann et al., 2017; Hill et al., 2017). Our work is a novel application of the working memory to pragmatically adjust communication for speaker-listener disparities (*disparity* goal), and take advantage of the internal simulation architecture to achieve the *task* goal.

Similar to (Kottur et al., 2017; Lazaridou et al., 2020), our model learns to converge language to adapt to listener's disparities through interactions, instead of ground truth supervision on language generation. The speakers have zero prior knowledge on the listener's background nor an oracle access to probe the listener's brain.

Different from previous works, our model is able to generalize to distinct types of disparities. In addition, while previous models were trained in an end-to-end joint fashion, our work separates training and demonstrates the efficiency of working memory. Most importantly, few of the previous work were able to showcase model's language capabilities and only evaluate them by the end performance (e.g. accuracy), whereas our work emphasizes on evaluating how well the models learn to shift the language towards better understanding.

3 Dataset

There are many levels of disparities during verbal communication (Stephens et al., 2010), including phonetic, lexical, grammatical, semantic representations, etc. In our work, we assembled two datasets, and challenge the speaker model to handle two types of disparities: 1) knowledge disparity, and 2) perceptual disparity.

The *knowledge disparity* is simulated through the *hypernym* dataset, where the listener only understands the hypernym for all the objects (e.g. "food" instead of "pizza"), whereas the speaker understands both. This dataset challenges the speaker model at the *lexical* level to learn what listener's vocab limitation, and shift towards the words that they understand.

The *perceptual disparity* is simulated through the *limited visual* dataset, where the listener has impaired vision or some objects were physically blocked from the eyesight. This dataset challenges the speaker to shift attention and pick the visible objects for the listener to describe. For control and demonstration purposes, we remove all the animal-related objects and words from listener's training.

These datasets are used to simulate listener's disparities and train the listener's model as described in Section 4.2. The speaker's long term memory was trained with the original data which has full knowledge of the vocab and objects, but no idea what the listeners are or aren't capable of. Detailed dataset components can be found in the Appendix.

We modified the Abstract Scenes (Gilberto Mateos Ortiz et al., 2015) dataset for our experiments. There are 10020 images, each including 3 ground truth captions, and a median of 6 to 7 objects. We assembled $\sim$35k pairs of images that differ by ≤ 4 objects as the *Hard* set, $\sim$25k pairs that differ by > 4 objects as the *Easy* set, and together as the *Combined* set. The image pairs were split into training, validation and testing by a ratio of 8:1:1.

4 Method

Given a pair of images m_0, m_1, the target image indicator $t \in \{0, 1\}$, and the listener's disparity d, the speaker generates a caption c for the target image m_t, and the listener needs to pick out the correct target t given c. Both receive a reward of $+1$ upon correct choice, and -1 otherwise.

Following the RSA model, as shown Figure 2,

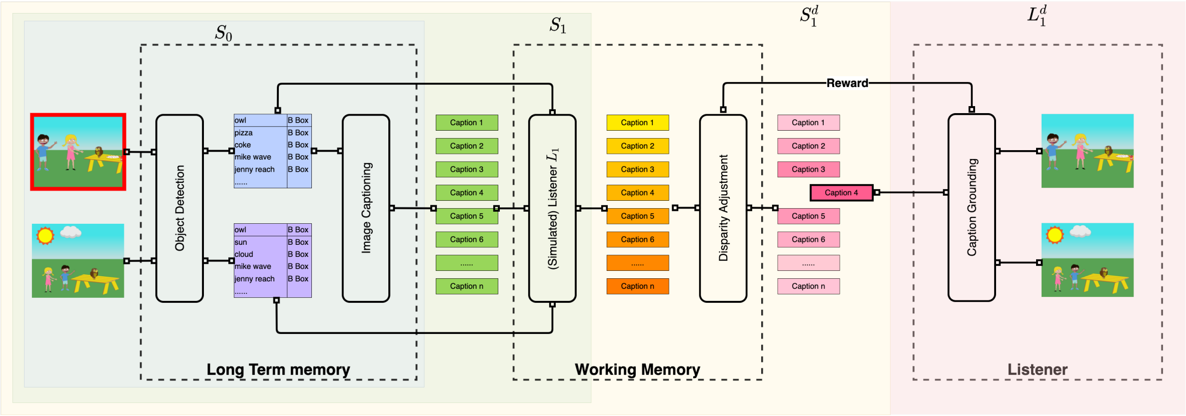

Figure 2: Speaker and Listener Models: Literal Speaker S_0 uses and object detector and image captioning module to generate a list of candidate captions in the fixed long term memory. The Rational Speaker S_1 simulates an internal listener to rank (illustrated by color gradient) the candidate captions by their uniqueness in describing the target image. The Pragmatic Rational Speaker S_1^d interacts with the actual listener to rerank the captions and pick out the best one to accommodate the disparity and the task goal. Both simulated listener and disparity adjustment components are inside the working memory for task specific and disparity specific adjustments.

we start by building the Literal Speaker $\mathbf{S_0}$, gradually increase model structure and functionality with the vanilla Rational Speaker $\mathbf{S_1}$ and the Pragmatic Rational Speaker $\mathbf{S_1^d}$. Upon retrieving a list of candidate captions C from the long-term memory, the final goal for $\mathbf{S_1^d}$ is to output the best caption c in the working memory, that accommodates both 1) **task goal:** describes the unique features of the target image, and 2) **disparity goal:** learns and accommodates the listener's disparity.

Table 1 is a brief summary of each model. The Literal Speaker $\mathbf{S_0}$ generates candidate captions c for a given image m (Eq 1), which serves as the long-term memory. The Rational Listener $\mathbf{L_1}$ picks out an image as the target given speaker's description (Eq 2). The vanilla Rational Speaker $\mathbf{S_1}$ achieves the *task goal* by simulating the listener's mind internally in its working memory (Eq 3). $\mathbf{L_1^d}$ incorporates disparity to the Rational Listener. The Pragmatic Rational Speaker $\mathbf{S_1^d}$ adds a light-weight disparity adjustment layer (Eq 5) to learn and accommodate listener's disparity through interactions, and achieves both goals. Each component can be easily switched and adapted to new tasks or environment.

$$\mathbf{S_0} : P(c|m_t) \tag{1}$$

$$\mathbf{L_1} : P(t|m_0, m_1, c) \propto P_{S_0}(c|m_t) \cdot P(m_t) \tag{2}$$

$$\begin{aligned}\mathbf{S_1} :&P(c|m_0, m_1, t) \propto \\ &P_{L_1}(t|m_0, m_1, c) \cdot P(c|m_0, m_1)\end{aligned} \tag{3}$$

$$\begin{aligned}\mathbf{L_1^d} :&P(t|m_0, m_1, c, d) \propto \\ &P_{S_1}(c|m_0, m_1, t, d) \cdot P(t|m_0, m_1, d)\end{aligned} \tag{4}$$

$$\begin{aligned}\mathbf{S_1^d} :&P(c|m_0, m_1, t, d) \propto \\ &P_{L_1^d}(t|m_0, m_1, c, d) \cdot P(c|m_0, m_1, d)\end{aligned} \tag{5}$$

4.1 Literal Speaker S_0

The Literal Speaker S_0 (Figure 2) is an object detection based image captioning module that generates caption candidates for the target image.

$$\begin{aligned}o_1, \ldots, o_k, b_1, \ldots, b_k &= \mathtt{ObjDet}(m_t) \\ e_1, \ldots, e_k &= \mathtt{WordEmb}(o_1, \ldots, o_k) \\ c_1, \ldots, c_n &= \mathtt{Transformer}(e_1, \ldots, b_1, \ldots)\end{aligned} \tag{6}$$

For a given target image m_t, since it's important to ground words to the scenes in order to control the disparities in vocabularies, we applied the object detector YOLO3 (Redmon and Farhadi, 2018) to extract a list of k detected objects $O = \{o_1, o_2, \ldots, o_k\}$, and their corresponding bounding boxes $B = \{b_1, b_2, \ldots, b_k\}$. Each image chooses at most $max\_obj = 9$ detected objects, and the names of each were embedded with a pre-trained BERT (Devlin et al., 2019) word embedding $E = \{e_1, e_2, \ldots, e_k\}$. These embeddings are then concatenated with their bounding box locations, and sent to the Transformer Decoder to generate $beam\_size = 30$ candidate captions $C = \{c_1, c_2, \ldots, c_n\}$ for each target image.

4.2 Rational Listener (L_1)

Without disparity concerns, the Rational Listener picks out the image that they believe is the target.

$$\begin{aligned} g_0 &= \texttt{FT\_Transformer}(m_0, c) \\ g_1 &= \texttt{FT\_Transformer}(m_1, c) \\ t &= \text{argmax}_{i \in \{0,1\}} \texttt{CosSim}(g_i, c) \end{aligned} \quad (7)$$

Recall that S_0 used a `Transformer` decoder to connect the image and its corresponding captions. We reuse the same Fixed pre-trained Training-mode Transformer module (named `FT_Transformer`) to decide which image does the caption ground better in. Adopting the idea of teacher-forcing language training, the output (g_i) of `FT_Transformer` with an input pair (m_i, c) should closely resemble the original input c if the input image m_i is indeed the one used to generate the caption c. By calculating the cosine similarity of each (g_i, c) pair, the image that grounds better (higher `CosSim`) in the description would be chosen as the target.

This module allows the agents to quickly and accurately make the decisions without further training. In theory, if the speaker and the listener were to have the exact same brain (same model and weights), the performance of this task should approach 100%. The results of "No Disparity" speaker in Figure 3 confirmed the design choice.

4.3 Rational Speaker (S_1)

Without disparity concerns, the Rational Speaker (S_1) fulfills the **task goal** by simulating (Figure 2) the Rational Listener (L_1)'s behavior, and rank the candidate captions generated by the Literal Speaker (S_0) according to how well they can describe the target image apart from the distractors. This design is under the fair assumption that both speakers and listeners are aware of the collaborative game goal, but can be switched for other task purposes.

$$\begin{aligned} &\text{For } i \in \{0, \cdots, n\}, \text{where } n = |C| : \\ &t_i, p_i = \texttt{Simulate\_L}_1(m_0, m_1, c_i) \\ &c = c_{\text{argmax}_i [[t_i == t^*]] \cdot p_i} \end{aligned} \quad (8)$$

Given an image pair (m_0, m_1), and a list of candidate captions $C = \{c_1, \cdots, c_n\}$ generated by S_0, the Rational Speaker goes through each caption c_i and simulates how well the listener ($\texttt{Simulate\_L}_1$) would pick out the correct target image. If a candidate caption c_i helps the simulator pick out the correct target image (i.e. $t_i == t^*$) with high confidence (p_i), then it will be chosen as the final caption sent over to the actual listener. The simulated listener shares the same architecture as L_1 and initializes the weights pre-trained from S_0. By doing so, the Rational Speaker takes the listener's intention into account and achieves the task goal.

4.4 Listener with Disparities (L_1^d)

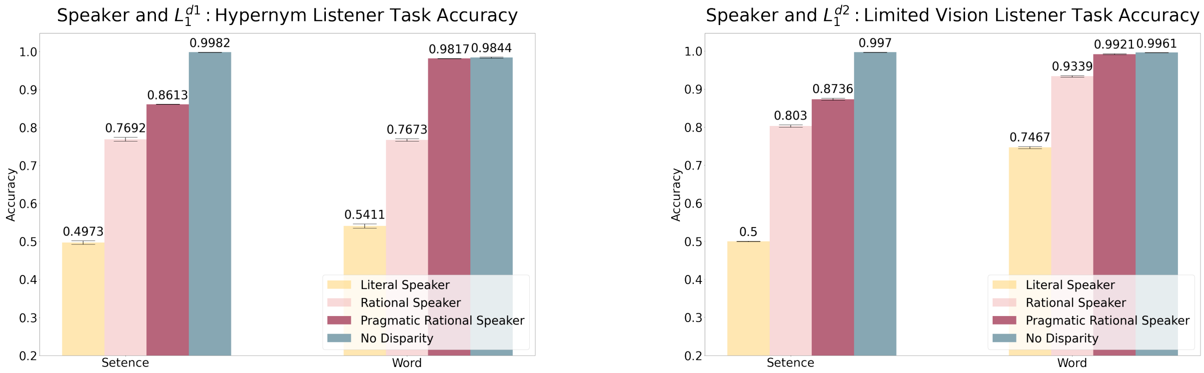
In the real world, however, it is hardly the case that different agents have the exact same knowledge background, experiences, physical capabilities, etc. The listener's decision making process is influenced by various kinds of disparities d.

To study speaker's ability of situated language adjustment, we created two representative types of listeners with different knowledge background and visual capabilities by training different caption grounding modules (`FT_Transformer`) with the datasets assembled in Section 3. These disparities would challenge the speaker model to adjust the language at different levels.

1. L_1^{d1} : Hypernym. With limited vocabulary and knowledge in a certain domain, people tend to refer to objects in their hypernym form (e.g. "animal" instead of "cat"). In this experiment, we create listeners that would refer to all the detected objects by their hypernyms. This disparity would require the speaker to switch individual words that share similar meanings.

2. L_1^{d2} : Limited Visual. Due to the physical orientation or impaired vision capability, it is likely that some objects are blocked or hardly visible to one party but not the other. In this experiment, we remove all the animal objects from listener's visual detected object list (O), and replace the relevant descriptions with the special token '[UNK]'. This disparity would require the speaker to shift attention, and choose alternative objects to describe.

We investigate in listeners with a subset of speaker's capabilities under the argument that in the opposite case, the listener could use only a subset of the knowledge to achieve best performance without having the speakers to adjust the speech. Other disparities can be inferred through transfer learning or are left for further investigation with broader information access and datasets.



(a) L_1^{d1}: Hypernym (b) L_1^{d2}: Limited Vision

Figure 3: Referential game Accuracy: The Pragmatic Rational Speakers are able to significantly outperform Literal Speakers and vanilla Rational Speakers across different types of disparities. Word level models achieve higher performance and is much closer to the No Disparity upper bound than the sentence level communication.

4.5 Pragmatic Rational Speaker (S_1^d)

On top of the Rational Speaker (S_1), the Pragmatic Rational Speaker incorporates a disparity adjustment layer to learn and accommodate the listener's disparity through emergent communication.

$$\begin{aligned} &\text{For } i \in \{0, \cdots, n\}, \text{where } n = |C| : \\ &q_i = \texttt{MLP}(\texttt{SentenceEmb}(\texttt{c}_\texttt{i})) \\ &a_i = [[t_i == t^*]] \cdot p_i \cdot q_i \\ &c = c_{\text{argmax}_i a_i} \end{aligned} \tag{9}$$

We use a pretrained BERT model to embed each candidate caption c_i, add a single MLP layer, and approximate the REINFORCE policy through Equation 9. The reward (r_{c^*}) for each chosen caption c^* is $+1$ or -1. The loss is calculated for all the chosen captions across each batch (Eq 10).

$$L = -\sum_{c^*} \log(a_{c^*}) \cdot r_{c^*} \tag{10}$$

4.6 Communication with Words

We conducted the same sets of experiments using individual words (object names) instead of sentences to demonstrate the effects of working memory on disparity accommodation and internal task simulation, reducing the noise that came from the imperfection of the image description generator. The simplified pipeline uses the detected object name embedding for disparity adjustment, and the listener picks the target images by conducting simple word matching.

5 Results and Analysis

We evaluate our models (S_0, S_1, S_1^d) on the referential game (Figure 1) along four dimensions: **End-task Performance, Efficiency, Transparency, and Balance of Goals.** Recall that each speaker model has different capabilities (Table 1) and only S_1^d is able to fulfill both *task* and *disparity* goals. Implementation details and more experiment results can be found in Appendix.

1. **[Task Performance]** that measures overall accuracy of the collaborative game. Task performance is often the sole evaluation metrics in previous work.

2. **[Efficiency]** that measures time used for model training across tasks.

3. **[Transparency]** that uncovers the underlying distribution shift of vocabulary use learned to accommodate different types of disparities.

4. **[Balance of Goals]** that the working memory needs to consider between the task and disparity goals to achieve maximum performance

5.1 Task Performance Comparison

To assess the performance of the speakers in the collaborative game, Figure 3 presents the task accuracies with Literal Speaker (S_0), Rational Speaker (S_1), Pragmatic Rational Speaker (S_1^d), and No Disparity (S_1^{nd}). S_1^{nd} has the same structure as S_1 and was trained on the same disparity dataset as the corresponding listener. It serves as the upper bound of performance. The same experiments also were conducted at the word level.

For each type of listener disparity, the performance is $S_0 << S_1 < S_1^d < S_1^{nd}$. The vanilla Rational Speaker (S_1) improved the overall performance from Literal Speaker by over 25% because it is achieving the task goal to describe the target image apart from the distractor. The Pragmatic Rational Speaker (S_1^d) is able to learn and adjust for the listener's disparity, and further improve the game performance by $\sim$10%. There is still, however a gap between S_1^d and the upper bound S_1^{nd}, where the speaker and the listener have the exact knowledge and capability limitation, potentially due to the imperfection in caption generations.

Breaking down between the *hard*, *easy* datasets in Figure 4 (recall that image pairs that differ by ≤ 4 objects are in the *Hard* set, otherwise the *Easy* set), S_1^d on the *easy* dataset is able to gain a lot more improvement upon its Rational Speaker compared to the pair trained on the *hard* dataset. The gap between S_1^d and No Disparity is also a lot smaller for the model trained on the *easy* dataset. This is likely because when a pair of images differ more objects (easier), the model has more options to adjust upon, hence the larger improvement.

Compared to the sentence level model, the word level pragmatic speaker for L_1^{d1} achieves even higher improvement against the corresponding Rational Speaker. They both achieve almost perfect accuracy with close to zero gap to the upper bound. This suggests the high potential of the disparity adjustment design, especially after reducing the caption generation and interpretation noise.

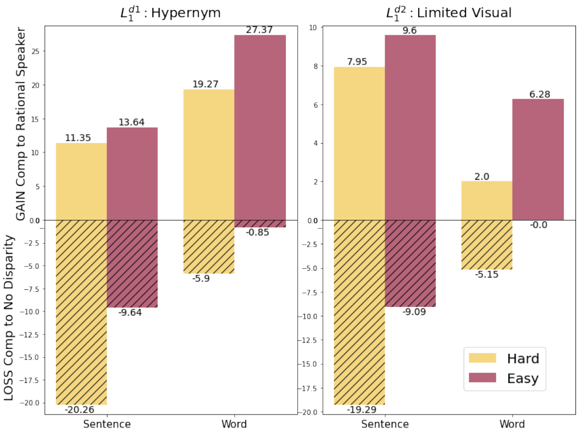


Figure 4: Pragmatic Rational Speaker Performance Gain/Loss compared to Rational Speaker and No Disparity (upper bound).

5.2 Learning Efficiency

To study the training efficiency of the working memory, we compared our model to the joint training "Multi-Task leaning" model in (Lazaridou et al., 2020)'s work, retrained and evaluated in our dataset. The image captioning model and the REINFORCE learning are joint trained through a combined loss:

$$L = \lambda_f L^{functional} + \lambda_s L^{structural}$$

Functional in our task refers to the REINFORCE learning to achieve both task and disparity goals (evaluated by Accuracy), and *structural* refers to the caption generation loss for natural-sounding language (evaluated by BLEU4). We used $\lambda_f = \lambda_s = 1$ as in previous work for our experiments.

	Train(min)	Accuracy%	BLEU4
Joint	19.04	60.14	27.79
Separate	21.02	**77.34**	**29.3**
• LM	11.59		29.3
• WM	**9.43**	77.34	

(a) L_1^{d1}: Hypernym

	Train(min)	Accuracy%	BLEU4
Joint	29.52	63.69	27.29
Separate	29.95	**81.09**	**29.3**
• LM	11.59		29.3
• WM	**18.36**	81.09	

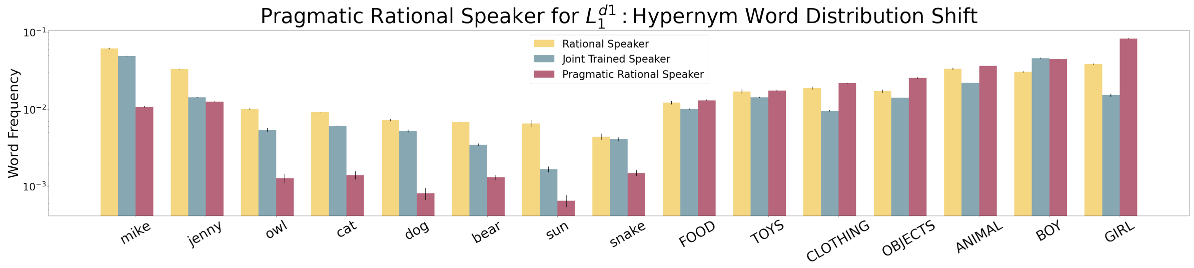
(b) L_1^{d2}: Limited Vision

Table 2: Compared to joint training, separate training only needs to train the long-term memory once, and can achieve higher performance. **LM**: Long-term Memory, **WM**: Working Memory.

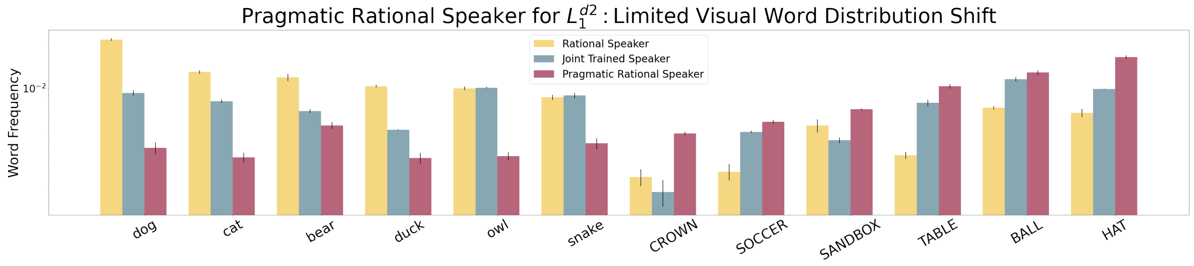
Detailed training and comparison strategies can be found in the Appendix. Table 2 shows that for each type of disparity, our model separating working memory from long-term memory is able to achieve higher accuracy and higher BLEU4 score than the joint training. Moreover, the Joint Trained model needs to retrain all the weights for each type of disparity from scratch, whereas our model only needs to train the long-term memory once, and retrain the light weighted working memory for each type of disparity, which is much more efficient.

5.3 Transparency: Vocabulary Adjustment

To gain insights in whether the Pragmatic Rational Speaker (PRS) is actually adjusting the descriptions for listeners' disparities or taking the advantage of statistical bias to achieve higher task performance, we plotted the word distribution shift across different types of disparities. Qualitative examples can be found in Figure 6. For each experiment, the word frequencies of all the chosen captions were calculated for the Rational Speakers, the Pragmatic Rational Speakers, and Joint Training. We collected the top choice of each speaker per image

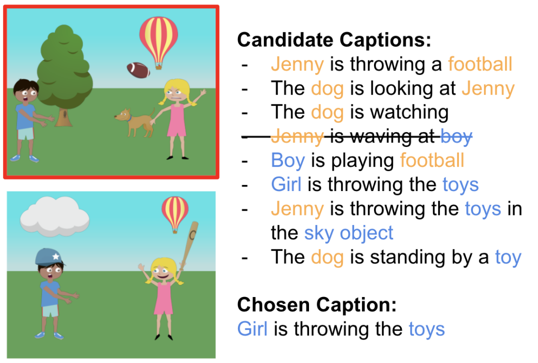


(a) L_1^{d1}: Hypernym



(b) L_1^{d2}: Limited Vision

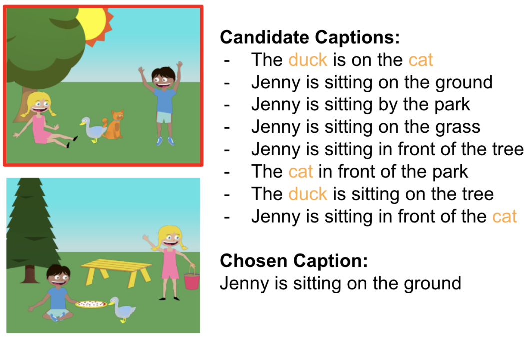
Figure 5: Word Distribution Shift: The Pragmatic Rational Speaker for L_1^{d1} avoids specific object names and prioritizes some hypernyms. The Pragmatic Rational Speaker for L_1^{d2} avoids animal related words in communication.



Candidate Captions:
- Jenny is throwing a football
- The dog is looking at Jenny
- The dog is watching
- ~~Jenny is waving at boy~~
- Boy is playing football
- Girl is throwing the toys
- Jenny is throwing the toys in the sky object
- The dog is standing by a toy

Chosen Caption:
Girl is throwing the toys

(a) L_1^{d1}: Hypernym



Candidate Captions:
- The duck is on the cat
- Jenny is sitting on the ground
- Jenny is sitting by the park
- Jenny is sitting on the grass
- Jenny is sitting in front of the tree
- The cat in front of the park
- The duck is sitting on the tree
- Jenny is sitting in front of the cat

Chosen Caption:
Jenny is sitting on the ground

(b) L_1^{d2}: Limited Vision

Figure 6: Qualitative examples for each disparity adjustment. The orange words are the vocabulary that the Pragmatic Rational Speaker is avoiding, and the blue words are the preferred alternative for the listeners. The ~~strikethrough~~ sentences are discarded because they can be used to describe both images.

pair, repeated the experiments 3 times, and reported the mean and standard deviation in Figure 5.

In the Hypernym disparity (Figure 5a) experiment, where the listener only understands the hypernym of detected objects, the lower-case words on the left are the top detected object names, and the upper-case words on the right are hypernyms. On the left side, the word frequencies of PRS significantly dropped from the Rational Speaker. On the right side, the model is maintaining similar level, or using some of the hypernyms more frequently (y-axis in log scale). Note that the Rational Speaker can generate both hypernym and hyponym regardless of disparities, and multiple valid captions available for all speakers to choose from. For the Joint Trained Speaker, we also observed a hyponym usage drop (left), but it's unclear how it accommodates the disparity without using hypernyms. This result shows that PRS learned to avoid using hyponyms, and replaced them with their hypernym to accommodate the disparity.

For the Limited Visual disparity (Figure 5b), since all the animal objects are missing for the listener, there is a sharp decline in S_1^{d2}'s use of animal related words during the communication. Instead, it is choosing other objects such as "hat", and "ball" to describe the target image. The PRS is accommodating listener L_1^{d2}'s disparity by shifting the attention and choosing alternative objects other than animals to communicate. The behavior of the Joint Trained Speaker is harder to interpret.

5.4 Balancing Between Goals

Recall that the working memory of the Pragmatic Rational Speaker (S_1^d) has two two goals: 1) **Task Goal**: an internal simulation of a listener to rank the candidate captions by their uniqueness in describing the target image, and 2) **Disparity Goal**: a disparity adjustment layer to learn and accommodate the listener's disparity through interactions. Each goal component can be formalized in the above two terms (Equation 11). We parameterized each term with λ_l and λ_d to study how different $\lambda_l : \lambda_d$ weight ratio could affect rational speaker's ability to achieve both goals.

$$a_i = ([[t_i == t^*]] \cdot p_i)^{\lambda_l} \cdot (q_i)^{\lambda_d} \qquad (11)$$

Figure 7 shows that when the Pragmatic Rational Speaker puts a high emphasis on adjusting the listener's disparity λ_d, it would "forget" to describe the unique characters of the target image and lower the overall performance. On the other hand when the PRS emphasize too much on the task goal, it would "forget" to accommodate listener's disparities, and lower the overall performance as well. In the end, we chose $\lambda_l : \lambda_d = 1 : 1$ for all experiments demonstrated above.

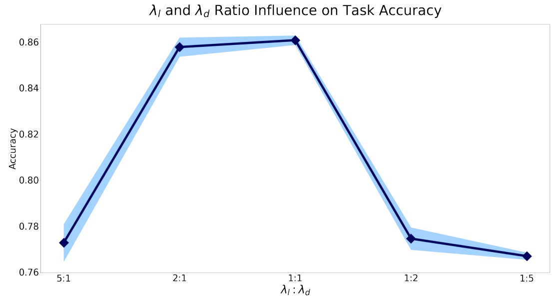


Figure 7: Balancing between the task goal and the disparity adjustment goal: the Pragmatic Rational Speaker needs a balanced emphasise on both λ_l and λ_d in order to achieve both goals simultaneously.

6 Conclusion and Future Work

In this work, we present a novel framework based on the Rational Speech Act framework for pragmatic communication that can adjust the conversation content according to listener's disparities by adding a light-weighted working memory on top of speaker's long-term memory. The Pragmatic Rational Speaker significantly improved the collaborative game performance by shifting the conversation towards the language that the listeners are able to understand. The flexibility and training efficiency also makes it easy to be applied broadly.

There are, however, several limitations that requires further investigation. First of all, despite recent progress, algorithms that connect language and the visual world are still limited. For example, caption generation, even in this simple setup, often does not faithfully capture what's been conveyed in the images. As our framework heavily relies on the quality of various models that bridge language and vision, e.g., as part of our long term memory, it's important to improve functionality and performance of these base models.

We conducted our experiments in a relative simple and artificial environment with the purpose of easy control and demonstration. We emphasize on evaluating model's actual language ability of adjusting for the disparities on top of task performance. The next step would be to apply the framework to more realistic images and interactive environment.

Other than listener's knowledge background and perceptual capabilities, there are a lot of other reasons for language communication to be adjusted, such as the physical environment, relative positions, speaker's personalities, etc. Studying how a rational agent can accommodate these disparities would require additional multimodal datasets and information processing methods.

At the moment, the Pragmatic Rational Speaker trains a new layer in working memory from scratch for each type of disparity. This could have backward influence on the long-term memory. In lifelong learning (Parisi et al., 2019) like humans, the working memory can shape their long-term memory. At the very least, the model could store each learned disparity adjustments for future encounter. This modification is left for future work.

Last but not least, instead of training for every single type of disparity to name, human learners have the ability of meta-learning and zero-shot transferring existing knowledge to a new category. Future work on pragmatic reasoning should be easily adaptable to different disparities and situations.

A Speaker and Listener Model Architecture Breakdown

(a) **Literal Speaker** S_0: for each input image, we run YOLO3 object detector to get a list of detected object names. Each name is embedded with pre-trained BERT embedding, and concatenated with their bounding box location. The embedded images goes through a Transformer Decoder to generate a list of candidate captions.

(b) **Rational Listener** L_1: for each pair of images and an input caption, the Rational Listener reuses a pre-trained Transformer Decoder as in S_0 to figure out which image does the caption ground better in. Inspired the teacher-forcing caption training procedure, given an image and the input caption, if it generates a sentence that's closer to the input caption than the other image, then this image is chosen as the target.

(c) **Rational Speaker** S_1: for a pair of images, and a list of candidate captions generated by S_0, the Rational Speaker goes through each candidate caption via the internal simulated listener (same model as L_1 with no disparity), to figure out whether the caption can help the listener pick the correct target image, and if so, how confident. It ranks all the captions by the correctness and confidence score.

(d) **Pragmatic Rational Speaker** S_1^d: given a list of ranked (by S_1) candidate captions, the Pragmatic Rational Speaker picks the most confident one and send it to the actual listener with disparities (L_1^d), and receives a reward feedback. This feedback helps S_1^d to learn the disparity, and rerank all the captions to accommodate the difference and optimize for the task goal.

B Implementation Details

We pretrained the image captioning models using 2 layers of Transformer Decoder with 4 attention heads each, and 512 in internal dimension for 100 epochs each. The dropout rate was 0.5, learning rate started at $1e^{-4}$, on a scheduled decline rate of 0.8 for each 20 unimproved epochs.

We also pretrained the literal listeners and the literal speaker with different disparity datasets. All the weights are fixed before being integrated into the interactive learning phase. During disparity learning, each pair of speaker and listener were trained for 150 epochs, with batch size of 128, learning rate starting at $1e^{-3}$, and on decline at the rate of 0.8 per 20 unimproved epoches. Each experiment is repeated 3 times. The mean and standard deviation were reported in figures. Similarly in the word level training, the model was trained for 200 epochs, and with learning rate starting at 2, and on a scheduled decline rate of 0.8 for each 50 unimproved epochs.

For the efficiency comparison experiment, we used the *combined* test dataset for this experiment, trained each component until 50 unimproved epochs, and selected the top performances within the first 30 minutes of each. All models have reached stable performance by then. All experiments done on a single NVIDIA(R) GeForce(R) RTX 2070 SUPER(TM) 8GB GDDR6 and 10th Gen Intel(R) Core(TM) i9-10900K processor.

Unsupervised Corpus Aware Language Model Pre-training for Dense Passage Retrieval

Luyu Gao and Jamie Callan
Language Technologies Institute
Carnegie Mellon University
{luyug, callan}@cs.cmu.edu

Abstract

Recent research demonstrates the effectiveness of using fine-tuned language models (LM) for dense retrieval. However, dense retrievers are hard to train, typically requiring heavily engineered fine-tuning pipelines to realize their full potential. In this paper, we identify and address two underlying problems of dense retrievers: i) fragility to training data noise and ii) requiring large batches to robustly learn the embedding space. We use the recently proposed Condenser pre-training architecture, which learns to condense information into the dense vector through LM pre-training. On top of it, we propose coCondenser, which adds an unsupervised corpus-level contrastive loss to warm up the passage embedding space. Experiments on MS-MARCO, Natural Question, and Trivia QA datasets show that coCondenser removes the need for heavy data engineering such as augmentation, synthesis, or filtering, and the need for large batch training. It shows comparable performance to RocketQA, a state-of-the-art, heavily engineered system, using simple small batch fine-tuning.[1]

1 Introduction

Building upon the advancements of pre-trained language models (LM; Devlin et al. (2019); Liu et al. (2019)), dense retrieval has become an effective paradigm for text retrieval (Lee et al., 2019; Chang et al., 2020; Karpukhin et al., 2020; Qu et al., 2021; Gao et al., 2021a; Zhan et al., 2022). Recent research has however found that fine-tuning dense retrievers to realize their capacity requires carefully designed fine-tuning techniques. Early works include iterative negative mining (Xiong et al., 2021) and multi-vector representations (Luan et al., 2020). The recent RocketQA system (Qu et al., 2021) significantly improves the performance of a dense retriever by designing an optimized fine-tuning pipeline that includes i) denoising hard negatives, which corrects mislabeling, and ii) large batch training. While this is very effective, the entire pipeline is very heavy in computation and not feasible for people who do not have tremendous hardware resources, like those in academia. In this paper, we ask, instead of directly using the pipeline, can we take the insights of RocketQA to perform language model pre-training such that the pre-trained model can be easily fine-tuned on any target query set.

Concretely, we ask what the optimized training in RocketQA solves. We hypothesize that typical LMs are sensitive to mislabeling, which can cause detrimental updates to the model weights. Denoising can effectively remove the bad samples and their updates. On the other hand, for most LMs, the CLS vectors are either trained with a simple task (Devlin et al., 2019) or not explicitly trained at all (Liu et al., 2019). These vectors are far from being able to form an embedding space of passages (Lee et al., 2019). The large training batches in RocketQA help the LM to stably learn to form the full embedding space. To this end, we want to pre-train an LM such that it is locally noise-resistant and has a well-structured global embedding space. For noise resistance, we borrow the Condenser pre-training architecture (Gao and Callan, 2021), which performs language model pre-training actively conditioning on the CLS vector. It produces an information-rich CLS representation that can robustly condense an input sequence. We then introduce a simple corpus level contrastive learning objective: given a target corpus of documents to retrieve from, at each training step sample text span pairs from a batch of documents and train the model such that the CLS embeddings of two spans from the same document are close and spans from different documents are far apart. Combining the two, we propose coCondenser pre-training, which unsupervisedly learns a corpus-aware pre-trained model for dense retrieval.

---

[1] Our code is available at https://github.com/luyug/Condenser.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2843 - 2853

In this paper, we test coCondenser pre-training on two popular corpora, Wikipedia and MS-MARCO. Both have served as information sources for a wide range of tasks. This popularity justifies pre-training models specifically for each of them. We directly fine-tune the pre-trained coCondenser using small training batches without data engineering. On Natural Question, TriviaQA, and MS-MARCO passage ranking tasks, we found that the resulting models perform on-par or better than RocketQA and other contemporary methods.

2 Related Work

Dense Retrieval Transformer LM has advanced the state-of-the-art of many NLP tasks (Devlin et al., 2019; Liu et al., 2019; Yang et al., 2019; Lan et al., 2020) including dense retrieval. Lee et al. (2019) are among the first to demonstrate the effectiveness of Transformer dense retrievers. They proposed a simple Inverse Cloze Task (ICT) method to further pre-train BERT (Devlin et al., 2019). Follow-up works explored other pre-training tasks (Chang et al., 2020) as well end-to-end co-training of reader and retriever (Guu et al., 2020). Karpukhin et al. (2020) is the first to discover that careful fine-tuning can learn effective dense retriever directly from BERT. Later works then started to investigate ways to further improve fine-tuning (Xiong et al., 2021; Qu et al., 2021). Among them, Qu et al. (2021) proposed the RocketQA fine-tuning pipeline which hugely advanced the performance of dense retrievers.

Until very recently, pre-training for dense retrieval has been left unexplored. A concurrent work, DPR-PAQ (Oğuz et al., 2021), revisits pre-training and proposes domain matched pre-training, using a 65-million-size synthetic QA pair dataset generated with pre-trained Natural Question and Trivia QA pipelines to pre-train dense retrievers.

This paper uses a recently proposed dense retrieval pre-training architecture, Condenser (Gao and Callan, 2021). Unlike previous works that design pre-training tasks, Condenser explored the idea of designing a special pre-training architecture to improve representation effectiveness.

One reason why dense retrieval is of immediate great value is that there is a rich literature that studies efficient dense retrieval for first stage retrieval (Johnson et al., 2017; Guo et al., 2020). There are also mature dense retrieval libraries, such as FAISS (Johnson et al., 2017). By pre-encoding the corpus into a MIPS index, retrieval can run online with millisecond-level latency (Johnson et al., 2017; Guo et al., 2020).

Contrastive Learning Contrastive learning has become a very popular topic in computer vision (Chen et al., 2020; He et al., 2020). Recent works have brought the idea to natural language processing to learn high-quality sentence representation (Giorgi et al., 2020; Wu et al., 2020). In this work, we use contrastive learning to do pre-training for dense retrieval. Different from earlier work, instead of individual representations (Giorgi et al., 2020), we are interested in the full learned embedding space, which we will use to warm start the retriever.

The large batch requirement had been a limiting factor in contrastive learning (Chen et al., 2020) under resource-limited setups where GPU (accelerator) memory is not sufficiently large. In general, this extends to any training procedure that uses contrastive loss, including dense retrieval pre-training (Guu et al., 2020; Chang et al., 2020). Gao et al. (2021b) recently devised a gradient cache technique that upper-bounds peak memory usage of contrastive learning to almost constant. In subsection 3.3, we show how to adapt it for coCondenser pre-training.

3 Method

In this section, we first give a brief review of Condenser. Then we discuss how to extend it to coCondenser and how to perform memory-efficient coCondenser pre-training.

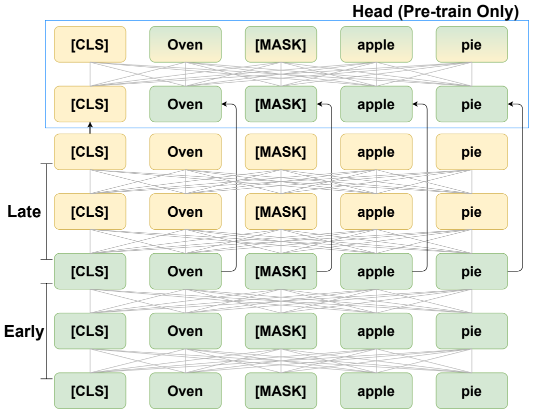

Figure 1: Condenser: Shown are 2 early and 2 late backbone layers. In our experiments each have 6 layers. Condenser Head is dropped during fine-tuning. This illustration is taken from the Condenser paper (Gao and Callan, 2021).

3.1 Condenser

In this paper, we adopt a special pre-training architecture, Condenser (Gao and Callan, 2021). Condenser is a stack of Transformer blocks. As shown in Figure 1, these Transformer blocks are divided into three groups, early backbone encoder layers, late backbone encoder layers, and head layers. An input $x = [x_1, x_2, ..]$ is first prepended a CLS, embedding, and run through the backbone layers.

$$[h^0_{cls}; h^0] = \text{Embed}([\text{CLS}; x]) \tag{1}$$

$$[h^{early}_{cls}; h^{early}] = \text{Encoder}_{\text{early}}([h^0_{cls}; h^0]) \tag{2}$$

$$[h^{late}_{cls}; h^{late}] = \text{Encoder}_{\text{late}}([h^{early}_{cls}; h^{early}]) \tag{3}$$

The head takes the CLS representation from the late layers but using a short circuit, the token representations from the early layers. This late-early pair then runs through the head's Transformer blocks.

$$[h^{cd}_{cls}; h^{cd}] = \text{Head}([h^{late}_{cls}; h^{early}]) \tag{4}$$

The head's outputs are then used to do masked language model (MLM; Devlin et al. (2019)) training.

$$\mathcal{L}^{\text{mlm}} = \sum_{i \in \text{masked}} \text{CrossEntropy}(W h^{cd}_i, x_i) \tag{5}$$

To utilize the capacity of the late layers, Condenser is forced to learn to aggregate information into the CLS token, which will then participate in the LM prediction. Leveraging the rich and effective training signal produced by MLM, Condenser learns to utilize the powerful Transformer architecture to generate dense CLS representations. We hypothesize that with this LM objective typically used to train token representations now put on the dense CLS representation, the learned LM gains improved robustness against noise.

3.2 coCondenser

While Condenser can be trained on a diverse collection of corpora to produce a universal model, it is not able to solve the embedding space issue: while information embedded in the CLS can be non-linearly interpreted by the head, inner products between these vectors still lack semantics. Consequently, they do not form an effective embedding space. To this end, we augment the Condenser MLM loss with a contrastive loss. Unlike previous work that pre-trains on artificial query passage pairs, in this paper, we propose to simply pre-train the passage embedding space in a query-agnostic fashion, using a contrastive loss defined over the target search corpus. Concretely, given a random list of n documents $[d_1, d_2, ..., d_n]$, we extract randomly from each a pair of spans, $[s_{11}, s_{12}, ..., s_{n1}, s_{n2}]$. These spans then form a training batch of coCondenser. Given a span s_{ij}'s corresponding *late* CLS representation h_{ij}, its corpus-aware contrastive loss is defined over the batch as shown below.

$$\mathcal{L}^{co}_{ij} = -\log \frac{\exp(\langle h_{i1}, h_{i2} \rangle)}{\sum_{k=1}^{n} \sum_{l=1}^{2} \mathbb{I}_{ij \neq kl} \exp(\langle h_{ij}, h_{kl} \rangle)} \tag{6}$$

Familiar readers may recognize this as the contrastive loss from SimCLR (Chen et al., 2020), for which we use random span sampling as augmentation. Others may see a connection to noise contrastive estimation (NCE). Here we provide an NCE narrative. Following the spirit of the distributional hypothesis, passages close together should have similar representations while those in different documents should have different representations. Here we use random spans as surrogates of passages and enforce the distributional hypothesis through NCE, as word embedding learning in Word2Vec (Mikolov et al., 2013). We can also recognize this as a span-level language model objective, or "skip-span". Denote span s_{ij}'s Condenser MLM loss $\mathcal{L}^{\text{mlm}}_{ij}$. The batch's loss is defined as an average sum of MLM and contrastive loss, or from an alternative perspective, word and span LM loss.

$$\mathcal{L} = \frac{1}{2n} \sum_{i=1}^{n} \sum_{j=1}^{2} [\mathcal{L}^{\text{mlm}}_{ij} + \mathcal{L}^{co}_{ij}] \tag{7}$$

3.3 Memory Efficient Pre-training

The RocketQA pipeline uses supervision and large-batch training to learn the embedding space. We would also like to run large-batch unsupervised pre-training to construct effective stochastic gradient estimators for the contrastive loss in Equation 6. To remind our readers, this large-batch pre-training happens only once for the target search corpus. We will show that this allows effective small batch fine-tuning on task query sets.

However, due to the batch-wise dependency of the contrastive loss, it requires fitting the large batch into GPU (accelerator) memory. While this can be done naively with interconnected GPU nodes or TPU pods, which can have thousands of gigabytes of memory, academia, and smaller organizations are often restricted to machines with four commercial GPUs. To break the memory constraint and perform effective contrastive learning, we adjust the gradient caching technique (Gao et al., 2021b) for our setup. We describe the procedure here for people who want to perform coCondenser pre-training but have limited resources. Denote $\mathcal{L}^{co} = \sum_i \sum_j \mathcal{L}_{ij}^{co}$, we can write Equation 7 as,

$$\mathcal{L} = \frac{1}{2n}[\mathcal{L}^{co} + \sum_i \sum_j \mathcal{L}_{ij}^{\text{mlm}}] \tag{8}$$

The spirit of gradient caching is to decouple representation gradient and encoder gradient computation. Before computing the model weight update, we first run an extra backbone forward for the entire batch. This provides numerical values of $[h_{11}, h_{12}, ..., h_{n1}, h_{n2}]$, from which we compute:

$$v_{ij} = \frac{\partial}{\partial h_{ij}} \sum_i \sum_j \mathcal{L}_{ij}^{co} = \frac{\partial \mathcal{L}^{co}}{\partial h_{ij}} \tag{9}$$

i.e. the contrastive loss gradient with respect to the CLS vector. We store all these vectors in a gradient cache, $C = [v_{11}, v_{12}, .., v_{n1}, v_{n2}]$. Using v_{ij}, denote the model parameter Θ, we can write the derivative of the contrastive loss as shown below.

$$\frac{\partial \mathcal{L}^{co}}{\partial \Theta} = \sum_i \sum_j \frac{\partial \mathcal{L}^{co}}{\partial h_{ij}} \frac{\partial h_{ij}}{\partial \Theta} \tag{10}$$

$$= \sum_i \sum_j v_{ij}^\top \frac{\partial h_{ij}}{\partial \Theta} \tag{11}$$

We can then write the gradient of Equation 8.

$$\frac{\partial \mathcal{L}}{\partial \Theta} = \frac{1}{2n} \sum_i \sum_j [v_{ij}^\top \frac{\partial h_{ij}}{\partial \Theta} + \frac{\partial \mathcal{L}_{ij}^{\text{mlm}}}{\partial \Theta}] \tag{12}$$

Since v_{ij} is already in the cache C, each summation term now only concerns span s_{ij} and its activation, meaning that we can compute the full batch's gradient in an accumulation fashion over small sub-batches. In other words, the full batch no longer needs to concurrently reside on the GPUs.

3.4 Fine-tuning

At the end of pre-training, we discard the Condenser head, keeping only the backbone layers. Consequently, the model reduces to its backbone, or effectively a Transformer Encoder. We use the backbone weights to initialize query encoder f_q and passage encoder f_p. Each outputs the last layer CLS. Recall that they have already been warmed up in pre-training. A (query q, passage p) pair similarity is defined as an inner product.

$$s(q, p) = \langle f_q(q), f_p(p) \rangle \tag{13}$$

Query and passage encoders are supervisedly fine-tuned on the target task's training set. We train with a supervised contrastive loss and compute for query q, negative log likelihood of a positive document d^+ against a set of negatives $\{d_1^-, d_2^-, ..d_l^- ..\}$.

$$\mathcal{L} = -\log \frac{\exp(s(q, d^+))}{\exp(s(q, d^+)) + \sum_l \exp(s(q, d_l^-))} \tag{14}$$

We run a two-stage training as described in the DPR (Karpukhin et al., 2020) toolkit. As shown in Figure 2b, in the first stage, the retrievers are trained with BM25 negatives. The first-stage retriever is then used to mine hard negatives to complement the negative pool. The second stage retriever trains with the negative pool generated in the first round. This is in contrast to the multi-stage pipeline of RocketQA shown in Figure 2a.

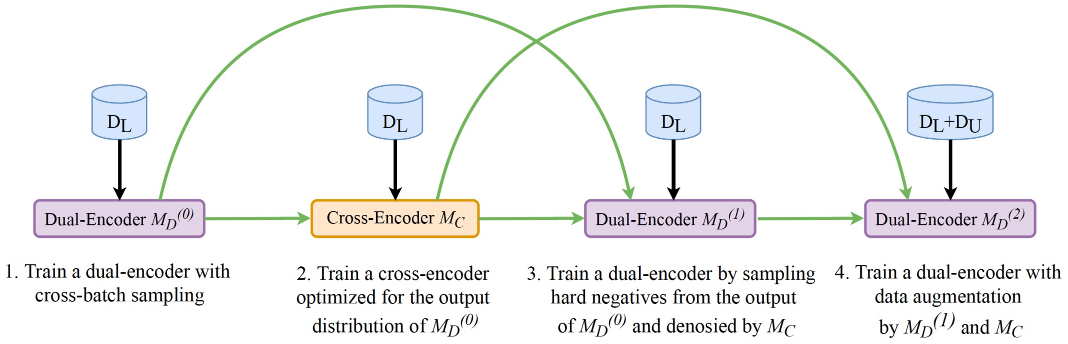
4 Experiments

In this section, we first describe the implementation details of coCondenser pre-training. We then conduct dense retrieval experiments to test the effectiveness of fine-tuned coCondenser retrievers.

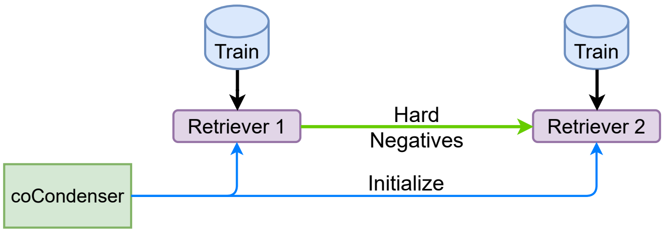
4.1 Pre-training

The coCondenser pre-training starts with vanilla BERT and goes in two stages, universal Condenser pre-training and corpus aware coCondenser pre-training. In the first stage, we pre-train a Condenser and warm start the backbone layers with pre-trained 12-layer $\text{BERT}_{\text{base}}$ weights (Devlin et al., 2019). The backbone uses an equal split, 6 early layers, and 6 late layers. The Condenser pre-training uses the same data as BERT: English Wikipedia and the BookCorpus. The first stage Condenser pre-training takes roughly a week on 4 RTX 2080 Ti GPUs or 2 days on a v3-8 cloud TPU.

The Condenser model from stage one, including both backbone and head, is taken to warm start stage two coCondenser pre-training on the target corpus (Wikipedia or MS-MARCO web collection). We keep the Condenser architecture unchanged in the second step. We use AdamW optimizer with a learning rate 1e-4, weight decay of 0.01, and linear learning rate decay. Each model weight update uses 2K documents. We train using gradient



(a) RocketQA retriever training pipeline (taken from Qu et al. (2021)).



(b) coCondenser retriever training pipeline.

Figure 2: RocketQA training pipelines and two-round retriever training pipeline in coCondenser.

cache update, as described in subsection 3.3. We used the released Condenser model for the first stage. The second stage takes roughly 2 days on 4 RTX 2080 Ti GPUs or 19 hours on a v3-8 cloud TPU. Our GPU implementations are based on Pytorch (Paszke et al., 2019) and TPU implementations on JAX (Bradbury et al., 2018).

After the second stage finishes, we discard the Condenser head, resulting in a model of the *exact* same architecture as $\text{BERT}_{\text{base}}$.

4.2 Dense Passage Retrieval

Next, we fine-tune the learned coCondenser to test retrieval performance. Following RocketQA, we test on Natural Question and MS-MARCO passage ranking. We also report performance on Trivia QA, whose pre-processed version is released in DPR.

4.2.1 Setup

Dataset We use MS-MARCO passage ranking (Bajaj et al., 2018), Natural Question(NQ; Kwiatkowski et al. (2019)) and Trivia QA(TQA; Joshi et al. (2017)). MS-MARCO is constructed from Bing's search query logs and web documents retrieved by Bing. Natural Question contains questions from Google search. Trivia QA contains a set of trivia questions. We report official metrics MRR@10, Recall@1000 for MS-MARCO, and Recall at 5, 20, and 100 for NQ and TQA.

Data Preparation We use Natural Question, Trivia QA, and Wikipedia cleaned and released with DPR toolkit (Karpukhin et al., 2020). NQ and TQA each have about 60K training data post-processing. Similarly, we use the MS-MARCO corpus released with RocketQA open-source code (Qu et al., 2021). For reproducibility, we use the official relevance file instead of RocketQA's extended one, which has about 0.5M training queries. The BM25 negatives for MS-MARCO are taken from the official training triples.

Training MS-MARCO models are trained with Tevatron toolkit (Gao et al., 2022) using AdamW with a 5e-6 learning rate, linear learning rate schedule, and batch size 64 for 3 epochs. NQ and TQA models are trained with the DPR toolkit following published hyperparameters by Karpukhin et al. (2020). All models are trained on one RTX 2080 Ti. We added gradient caching to DPR to deal with memory constraints. The models are trained only on each task's corresponding training set. We note that RocketQA is trained on a concatenation of several datasets (Qu et al., 2021).

Model Validation Since for dense retrieval, validating a checkpoint requires encoding the full corpus, evaluating a checkpoint becomes very costly. Due to our computation resource limitation, we follow the suggestion in the DPR toolkit and take

Method	MS-MARCO Dev		Natural Question Test			Trivia QA Test

the last model training checkpoint. We do the same for MS-MARCO.

Comparison Systems We take RocketQA (Qu et al., 2021), the state-of-the-art fine-tuning technique, as our main baseline.

We borrowed several other baselines from the RocketQA paper, including lexical systems BM25, DeepCT (Dai and Callan, 2019), DocT5Query (Nogueira and Lin, 2019) and GAR (Mao et al., 2020); and dense systems DPR (Karpukhin et al., 2020), ANCE (Xiong et al., 2021), and ME-BERT (Luan et al., 2020).

We also included the concurrent work DPR-PAQ (Oğuz et al., 2021), which pre-trains using a 65-million-size synthetic QA pair dataset. The pre-training data is created by using retriever-reader pairs trained on Natural Question and Trivia QA. Designing the synthesis procedure also requires domain knowledge, thus under the context of this paper, we refer to this as a *semi-supervised* pre-training method. We include 4 DPR-PAQ variants based on base/large architectures of BERT/RoBERTa models.

Finally, we fine-tune a Condenser model which is produced in the first stage of pre-training.

4.2.2 Results

Table 1 shows development (dev) set performance for MS-MARCO passage ranking and test set performance for Natural Question and Trivia QA. Across three query sets, dense systems show superior performance compared to sparse systems. We also see a big performance margin between systems involving either careful fine-tuning or pre-training (RocketQA, DPR-PAQ, Condenser, coCondenser) over earlier dense systems. This result confirms recent findings that low dimension embeddings possess a strong capacity for dense retrieval, a capacity however hard to exploit naively.

coCondenser shows small improvements over RocketQA. Importantly, this is achieved with *greatly* reduced computation and data engineering effort in fine-tuning. Notably on MS-MARCO, coCondenser reduced the RocketQA's 4096 batch size to 64 (Table 5). A comparison of the two training pipelines of RocketQA and coCondenser can be found in Figure 2.

Comparison with DPR-PAQ shows several interesting findings. Combining large semi-supervised pre-training with the better and larger LM RoBERTa$_{\text{large}}$, DPR-PAQ achieves the best results on Natural Question. On the other hand, when starting from BERT (base/large), DPR-PAQ shows similar performance to coCondenser, which is based on BERT$_{\text{base}}$. This suggests that large-scale semi-supervised pre-training is still the way to go to get the very best performance. However, when computational resources are limited and a large pre-training set is missing, the unsupervised coCondenser is a strong alternative. On the other hand, as it moves to MS-MARCO where DPR-PAQ's pre-training supervision becomes distant,

MS-MARCO Passage Ranking Leaderboard		
Rank	Method	**MRR@10**

2	coCondenser*	42.8
MS-MARCO Document Ranking Leaderboard		
Rank	Method	**MRR@100**
1	UniRetriever	44.0
2	coCondenser + MORES+*	43.6

Table 2: Performance on the MS-MARCO leaderboards with reranking. *Our submissions.

we observe that DPR-PAQ becomes less effective than RocketQA and coCondenser.

The comparison between Condenser and coCondenser demonstrates the importance of the contrastive loss in coCondener: coCondenser can be robustly fine-tuned thanks to its pre-structured embedding space, allowing it to have better Recall (fewer false negatives) across all datasets.

4.3 Reranking on MS-MARCO Eval

Due to the leaderboard nature of MS-MARCO Eval set, we cannot do ablation studies on it but have only made two submissions. We follow other top-performing systems and add some form of reranker. For the passage ranking leaderboard, we rerank the top 1000 retrieved passages with an ensemble of ERNIE (Sun et al., 2020) and RoBERTa. We also fine-tuned a coCondenser on the MS-MARCO document ranking dataset. As passage retrieval is the focus of this paper, we retrieve based on the first passage of 512 tokens. The top100 are reranked by a fast modular reranker (Gao et al., 2020). Performance of best systems and ours are recorded in Table 2. At the time of this paper's submission, both of our systems are the 2nd best on the two leaderboards. For passages ranking, we are excited to see that other people are able to further improve coCondenser with additional fine-tuning techniques. For document, we leave the study of retrieval beyond first passage to future work and refer readers to other leaderboard systems.

5 Analysis

Recall the two desired properties of coCondernser are local noise resistance to mislabeling and a well-structured, pre-trained embedding space. In this section, to investigate the former, we introduce and compare with a knowledge distillation (Hinton et al., 2015) setup where we substitute noisy hard labels with soft labels from a cross-encoder. For the latter, we measure the quality of 1st stage retriever mined negatives to see if coCondenser embedding can help find related but not relevant hard negatives. We also provide ablation studies of loss components and, pre-training and fine-tuning stages.

5.1 Learning with Soft Labels

To analyze the local robustness of coCondenser, we introduce a knowledge distillation upper-bound model: instead of training using the noisy labels, we first train a cross encoder and then fine-tune a coCondenser model using soft labels generated from the cross-encoder. Unlike Qu et al. (2021) that uses cross encoder for filtering, here we directly expose the logits as soft labels. Concretely, given cross encoder g, a batch of M queries $\{q_1, q_2, .., q_M\}$, each paired with N passages (positive and hard negatives) $\{p_{11}, .., p_{1N}, .., p_{MN}\}$, for a query q_l we define its soft target distribution T,

$$T_{ij} = \text{softmax}_j(g(q_l, d_{ij})) \text{ if } i = l \text{ else } 0 \quad (15)$$

i.e., the soft labels are normalized logits from g for the local passages and 0 for the rest. Let $S_{ij} = \text{softmax}_{ij}(s(q, p_{ij}))$, the normalized bi-encoder similarities. Loss is defined as Kullback-Leibler divergence between S and T,

$$\mathcal{L}_{kd} = D_{\text{KL}}(S||T) \quad (16)$$

This setup a) focuses on improving labels for *local* hard negatives and positives while b) avoids evaluating cross encoder g for in-batch negatives. In Table 3, we compare coCondenser trained with the original hard labels and the cross-encoder generated soft labels. Using soft labels indeed produces some improvement. On the other hand, without help from the cross-encoder, coCondenser still yields performance within small margins, showing coCondenser's superior local noise resistance.

		MS-MARCO Dev		
Model	Label	MRR@10	R@100	R@1K
BERT	Hard	33.4	85.1	95.4
coCondenser	Hard	38.2	91.3	98.4
coCondenser	Soft	**39.1**	**91.9**	**98.6**

Table 3: Fine-tuning with hard v.s. soft labels.

5.2 Quality of Mined Negatives

Intuitively, a globally better-structured embedding space will be less likely to collapse, producing a more accurate set of mined negatives for the second stage retriever to learn over. In other words, the

2nd stage retriever will produce less unexpected top (hard) negatives. To quantitatively measure this, we propose a new metric, top n neighborhood recall at depth k (nb-recall^n@k): for a query, the coverage over the 2nd stage retriever's top n candidates by the 1st stage retrievers top k candidates,

$$\text{nb-recall}^n@k = \frac{\{\text{stage1 top k}\} \cap \{\text{stage2 top n}\}}{n} \tag{17}$$

Essentially, this measures how the mined hard negatives agree with the actual negatives, or simply, how well the 1st stage retriever locating hard negatives. We measure neighborhood recall of BERT, Condenser and coCondenser retrievers, averaged over all MS-MARCO Dev queries, for $n = 50, 100$ and various k values, in Figure 3, We see consistent higher nb-recall of Condenser over BERT and coCondenser over Condenser. The former comes from stronger CLS representation while the latter is due to the globally better-structured embedding space.

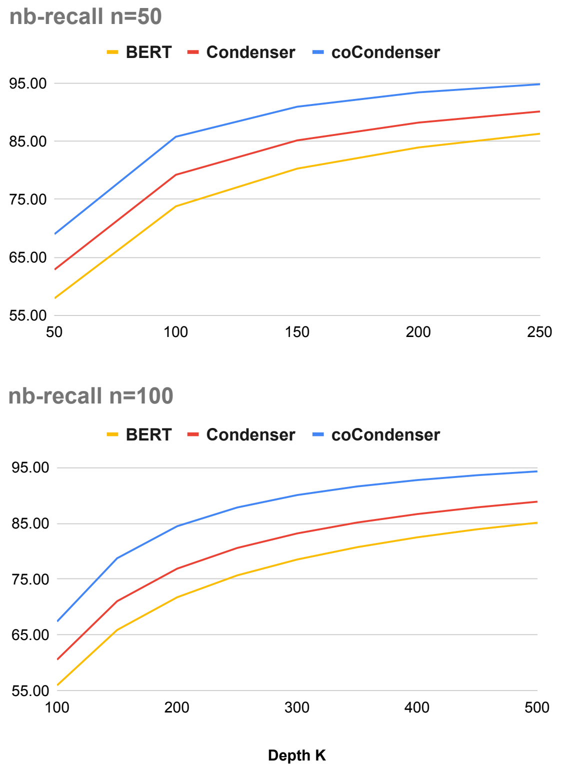

Figure 3: MS-MARCO Dev Neighborhood Recall

5.3 Pre-training Loss Ablation

In this section, we conduct an ablation study to understand the second stage pre-training loss components' influence on the final quality. In particular, we consider a Condenser model further pre-trained with only the contrastive loss.

Model	MS-MARCO Dev MRR@10	 R@100	 R@1K
Condenser	36.6	89.4	97.4
+ Contrative loss	36.7	90.3	98.0
+ MLM loss†	**38.2**	**91.3**	**98.4**

Table 4: Effect of loss components. †: This is the coCondenser model.

In Table 4, we see that further pre-training Condenser with only contrastive loss leads to better recall but similar MRR. The contrastive loss learns a better embedding space but by itself cannot keep the CLS locally discriminative. The original Condenser is able to rank better locally, producing similar MRR with fewer recalled passages. When both contrastive and Condenser MLM loss are used, we see improvements on all metrics. This again stresses the importance of the Condenser MLM loss during the second contrastive learning stage.

5.4 Training Stages

We seek to understand the contribution of each pre-training and fine-tuning stage of coCondenser retriever. We consider pre-trained Condenser from the first stage and coCondenser from the second stage. For each, we consider retrievers trained with and without hard negatives (HN). For reference, we compare also with various RocketQA training stages. Results are shown in Table 5. We see that each stage of RocketQA is critical. As each is added, performance improves steadily. On the other hand, this also suggests the full pipeline has to be executed to get the best performance. In comparison, we see Condenser with hard negatives has

Method	**Batch Size**	**MS-MARCO Dev** MRR@10	 R@1000
RocketQA			
Cross-batch negatives	8192	33.3	-
+ Hard negatives	4096	26.0	-
+ Denoising	4096	36.4	-
+ Data augmentation	4096	37.0	97.9
coCondenser			
Condenser w/o HN	64	33.8	96.1
+ Hard negatives	64	36.6	97.4
coCondenser w/o HN	64	35.7	97.8
+ Hard negatives	64	**38.2**	**98.4**

Table 5: MS-MARCO Dev performance for various training stages RocketQA and coCondenser.

performance very close to the full RocketQA system. Condenser with hard negatives also has better MRR than coCondenser without hard negatives, meaning that Condenser from the first pre-training stage is already very strong locally but the embedding space trained from a relatively cold start is still not optimal, causing global misses. Adding the corpus aware loss, coCondenser without hard negatives has Recall very close to the full RocketQA system, using only a size 64 batch. This again confirms our hypothesis that fine-tuning can benefit from a pre-trained passage embedding space. Further adding hard negatives, we get the strongest coCondenser system that is both locally and globally effective. Note that all Condenser systems achieve their performance *without* denoising, showing the superior noise resistance capability learned using the Condenser architecture. Practically, our systems also do not require data augmentation, which removes engineering effort in designing augmentation techniques and defining augmentation data.

6 Conclusion

This paper introduces *coCondenser*, an unsupervised corpus-aware language model pre-training method. We demonstrate proper pre-training can establish not only language understanding ability but also corpus-level representation power. Leveraging the Condenser architecture and a corpus aware contrastive loss, coCondenser acquires two important properties for dense retrieval, noise resistance, and structured embedding space. This corpus-aware pre-training needs to be done once for a search corpus and is query agnostic. The learned model can be shared among various types of end task queries.

Experiments show that coCondenser can drastically reduce the costs of fine-tuning a strong dense retriever. We also find coCondenser yields performance close or similar to semi-supervised pre-trained models that are several times larger.

Importantly, coCondenser provides a *hands-off* way to pre-train a very effective LM for dense retrieval. In particular, it effectively removes the effort for designing and testing pre-training as well as fine-tuning techniques. With our models, practitioners can use limited resources to train dense retrieval systems with state-of-the-art level performance. Future works may also investigate integrating additional pre-training and/or fine-tuning methods to further improve performance.

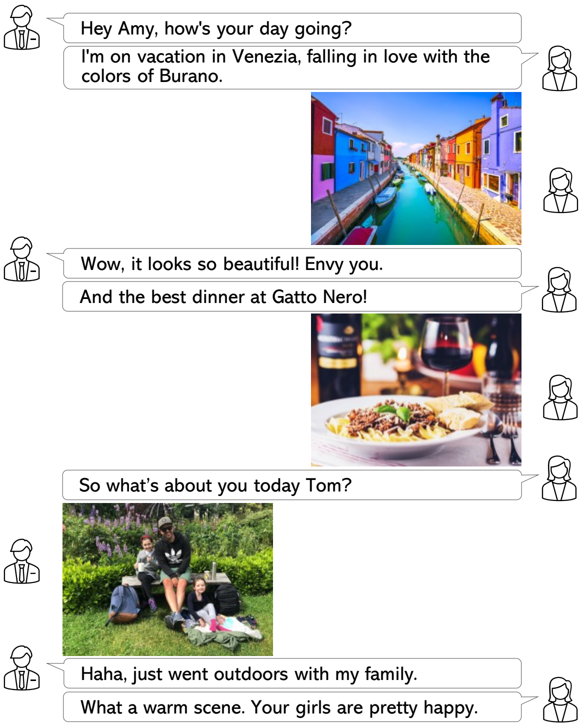
Abstract

Responsing with image has been recognized as an important capability for an intelligent conversational agent. Yet existing works only focus on exploring the multimodal dialogue models which depend on retrieval-based methods, but neglecting generation methods. To fill in the gaps, we first present a new task: multimodal dialogue response generation (MDRG) - given the dialogue context, one model needs to generate a text or an image as response. Learning such a MDRG model often requires multimodal dialogues containing both texts and images which are difficult to obtain. Motivated by the challenge in practice, we consider MDRG under a natural assumption that only limited training examples are available. Under such a low-resource setting, we devise a novel conversational agent, Divter, in order to isolate parameters that depend on multimodal dialogues from the entire generation model. By this means, the major part of the model can be learned from a large number of text-only dialogues and text-image pairs respectively, then the whole parameters can be well fitted using just a few training examples. Extensive experiments demonstrate our method achieves state-of-the-art results in both automatic and human evaluation, and can generate informative text and high-resolution image responses.

1 Introduction

With the development of instant messaging technology in the recent decades, the intermediary of online conversation has also changed from pure text to a variety of visual modalities (e.g., image, gif animation, short video). Similar to communicating by the messenger tools (e.g., Facebook, WhatsApp, WeChat) in reality, an excellent intelligent conversational agent should not only be able to converse freely with plain text, but also have the ability to perceive and share the real visual physical world.



Hey Amy, how's your day going?

I'm on vacation in Venezia, falling in love with the colors of Burano.

Wow, it looks so beautiful! Envy you.

And the best dinner at Gatto Nero!

So what's about you today Tom?

Haha, just went outdoors with my family.

What a warm scene. Your girls are pretty happy.

Figure 1: An example of human conversations. They are talking about vacation and outdoors with both text and various images.

Although recently some large-scale pre-trained text-only dialogue generation models, such as DialoGPT (Zhang et al., 2020), Blender (Roller et al., 2021), Meena (Adiwardana et al., 2020), have shown excellent performance, they still cannot rely exclusively on plain text to completely simulate the rich experience of visual perception. Recently, various vision-language tasks have been introduced and attracted widespread attention, such as visual question answering (Ren et al., 2015; Lu et al., 2016; Anderson et al., 2018; Li et al., 2019a; Huang et al., 2020), image captioning (Xu et al., 2015; Anderson et al., 2016; Ghanimifard and Dobnik, 2019; Cornia et al., 2020), image-grounded dialogue (Das et al., 2017; Yang et al., 2021; Agarwal et al., 2020; Qi et al., 2020; Chen et al., 2021; Liang et al., 2021).

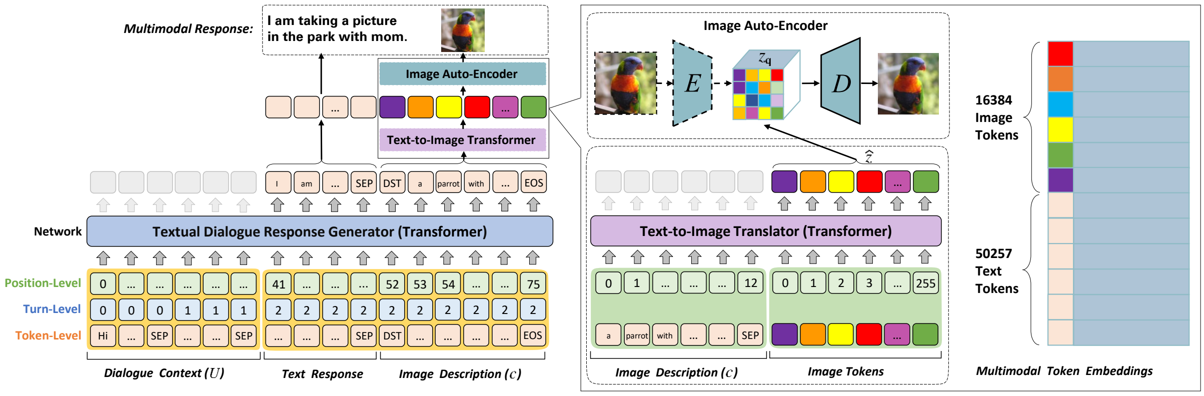

Figure 2: The overview of our multimodal dialogue response generation model. The Textual Dialogue Response Generator takes the text dialogue context U as input and generates a sequence contains text response and a image description (e.g., "a parrot with red belly and green back is standing on the railing."). With the description as a condition, the Text-to-Image Translator generates image representation $\hat{z}$. The Image Decoder $\mathcal{V}_D$ reconstructs $\hat{z}$ to a realistic and consistent high resolution image.

Specifically, in human conversations, the images can easily show rich visual perception, which is hard to be expressed by plain text. As the example shown in Figure 1, images are required in at least three circumstances: (i) the other speaker has little knowledge (e.g., colorful Burano, in the 1st image) of the objects only you had seen; (ii) to share more details (e.g., red wine and pasta, in the 2nd image) of the objects even you have common knowledge of them; (iii) to express your emotions (e.g., happy, in the 3rd image) about a specific event. An existing related task is photo sharing (Zang et al., 2021), which aims to select and share the image based on the textual context, is a challenging task that requires models to understand the background story which complemented by human imaginations, rather than to locate related visual objects or explicitly mention main visible content in the image as the previous works do. Zang et al. (2021) propose a retrieval-based method to resolve the above challenge. However, the performance of the retrieval-based method is limited in specific domains by the size of the pre-constructed conversational history repository, especially for long-tail contexts that are not covered in the history, where the set of image responses of a retrieval system is also fixed. On the other hand, a better way is to generate a new one accordingly.

In this paper, we formulate a new problem: **M**ultimodal **D**ialogue **R**esponse **G**eneration (**MDRG**), that is, given the dialogue context, the model should not only generate a pure text response but also have the capacity to generate a multimodal response (e.g., containing both image and text). We argue that there are still some hindrances to application, since (1) the sophisticated neural end-to-end architecture will overfit to very few well-annotated training data (e.g., a few existing 10k multimodal dialogues). Evidence is that when discussing the topics outside the training data domain, its performance drops dramatically; and (2) as human effort is expensive, it is not easy to collect enough training data for a new domain. Based on the above facts, we take a step further to extend the assumption of MDRG to a low-resource setting where only a few multimodal dialogues are available.

To tackle the above challenges, our key idea is to make parameters that rely on multimodal dialogues small and independent by disentangling textual response generation and image response generation, and thus we can learn the major part of the generation model from text-only dialogues and <image description, image> pairs that are much easier to be obtained. Specifically, we present **Divter**, a novel conversational agent powered by large-scale visual world experiences. As shown in Figure 2, our Divter is made up of two Transformer-based (Vaswani et al., 2017a) components: a multimodal dialogue response generator, and a text-to-image translator. Divter takes the dialogue context as input, then generates a textual sequence which may contains a text response or a textual image description or both of them. The text-to-image translator takes above image description as condition, then generates a realistic and consistent high resolution image. Both components are independent with the opposite knowledge, and thus can be pre-trained using a large number of text-only dialogues and the <image description, image> pairs respectively. The end-to-end Divter depends on the multimodal dialogues constructed as the tuple: (*dialogue context, text response / <image description, image>*) , but the joint learning and estimation of the two components just require a few training examples depending on specific domains.

Contributions of this work are three-fold:

- To the best of our knowledge, it is the first work on the multimodal dialogue response generation. We explore the task under a low-resource setting where only a few multimodal dialogues are assumed available.
- We present Divter, a novel conversational agent which can effectively understand dialogue context and generate informative text and high-resolution image responses.
- Extensive experiments on PhotoChat Corpus (Zang et al., 2021) indicate the effectiveness of Divter, it achieves a significant improvement with pure text dialogue generation model and retrieval-based image sharing method.

2 Related Work

2.1 Textual Dialogue Response Generation

End-to-end response generation for textual open-domain dialogues is inspired by the successful application of neural sequence-to-sequence models on machine translation (Sutskever et al., 2014). On top of the basic architecture (Shang et al., 2015; Vinyals and Le, 2015), the vanilla encoder-decoder method is widely extended to address the critical challenges in open-domain dialogue systems, including improving the diversity of responses (Li et al., 2016a; Zhao et al., 2017; Tao et al., 2018), modeling conversation contexts (Serban et al., 2016; Xing et al., 2017; Zhang et al., 2019; Zhao et al., 2020), controlling attributes of responses (See et al., 2019; Zhou et al., 2018; Xu et al., 2019), biasing responses to some specific personas (Li et al., 2016b; Zhang et al., 2018), incorporating extra knowledge into generation (Dinan et al., 2019; Ghazvininejad et al., 2018; Kim et al., 2020; Li et al., 2020), and building general pre-trained agents (Adiwardana et al., 2020; Zhang et al., 2020; Roller et al., 2021; Qi et al., 2021). Different from the previous works on open-domain dialogue response generation that converse freely with plain text, our work lies in the research of multimodal response generation.

2.2 Text-to-Image Generation

In the research of text-to-image generation, various works have been extensively studied. Mansimov et al. (2016) shown the Draw generative model (Gregor et al., 2015) could generate images from natural language descriptions. Reed et al. (2016) proposed a generative adversarial network to improve the image fidelity. Then some improvement methods continue to optimize the generation architecture, such as stacked generators (Zhang et al., 2017), attentional network (Xu et al., 2018), and extra knowledge (Li et al., 2019b). Nguyen et al. (2017) provided a unified probabilistic interpretation of related activation maximization methods to produce high-quality images at higher resolutions. Separately, Cho et al. (2020) used uniform masking with a large range of masking ratios and align the suitable pre-training datasets to the proper objectives. More recently, Ramesh et al. (2021) and (Ding et al., 2021) adopt transformer-based methods which autoregressively model the text and image tokens as a single stream of data. For this multimodal response generation scenario, we use the textual image description to bridge above textual dialogue generation and text-to-image generation models, where the image description is the output of the former and input of the latter in a low-resource setting.

3 Problem Formalization

Suppose that we have dataset $\mathcal{D}_S = \{(U_i, R_i)\}_{i=1}^{n}$, where $\forall i \in \{1, \ldots, n\}$, $U_i = \{u_{i,1}, \ldots, u_{i,n_i}\}$ is the dialogue context with $u_{i,j}$ the j-th utterance, and R_i is the response regarding to U_i. $u_{i,j}$ and R_i could contain two modalities: text, and image. The goal is to learn a **generation** model $P(R|U;\theta)$ (θ denotes the parameters of the model) with $\mathcal{D}_S$. Thus, given a new dialogue context U, one can generate a multimodal response R following $P(R|U;\theta)$.

4 Approach

This section first formulates the unified tokenization method for multimodal dialogues. We then introduce the two important components in our proposed multimodal dialogue response generation model (**Divter**) under low-resource scenario, including (i) textual dialogue response generator; (ii) text-to-image translator. Figure 2 shows the overall of our **Divter**.

4.1 Multimodal Tokenization

To learn a multimodal generation model, we should first model the unified representations of both text and image. Inspired by the success of DALLE (Esser et al., 2020) and VQGAN (Ramesh et al., 2021), to utilize the highly expressive transformer architecture for text-to-image generation, we need to express an image in the form of a sequence, similar to what we usually do for pure text tokenization.

4.1.1 Text Tokenization

The tokenization for text is already well-studied, e.g., BPE (Gage, 1994). This work uses 50257 BPE-encoded tokens and distributed embedding of Transformer architecture (Vaswani et al., 2017b) to model the texts in a dialogue.

4.1.2 Image Tokenization

The tokenizer for image is a discrete Auto-Encoder (VQGAN[1]) $\mathcal{V}$ as shown in Figure 2. $\mathcal{V}$ uses an encoder $\mathcal{V}_E$ to compress each image r^v of shape $H \times W \times 3$ into $\hat{z}$ of shape $h \times w \times d_z$, then each vector of dimension d_z would be quantized to its closest embedding z_k in a learned, discrete codebook $\mathcal{Z} = \{z_k\}_{k=1}^{K} \in \mathbb{R}^{d_z}$ under the action of element-wise quantization $\mathbf{q}(\cdot)$

$$z_{\mathbf{q}} = \mathbf{q}(\hat{z}) := \left(\underset{z_k \in \mathcal{Z}}{\arg\min} \|\hat{z}_{ij} - z_k\|\right) \in \mathbb{R}^{h \times w \times d_z} \tag{1}$$

Thus r^v can be represented by a spatial collection of codebook entries $z_{\mathbf{q}} \in \mathbb{R}^{h \times w \times d_z}$. The decoder $\mathcal{V}_D$ maps the $z_{\mathbf{q}}$ back to a image $\hat{r^v}$ to reconstruct the input. In this work, $H = W = 256$, $h = w = 16$, $K = 16384$, $d_z = 256$. The learning details of $\mathcal{V}$ and $\mathcal{Z}$ could be found in Ramesh et al. (2021).

4.2 Low-resource Learning Model

Learning an effective multimodal generation model with a single sequence-to-sequence model often requires a large number of training instances. However, only very few multimodal dialogues are available due to the privacy restrictions on social media and the expensive human effort. On the other hand, as shown in Figure 3, there existed a large number of open source text-only dialogues (e.g. Reddit comments[2], formulated as $\mathcal{D}_C = \{(U_i, r_i^e)\}_{i=1}^{N}$ with (U_i, r_i^e) a <text dialogue context, text response> pair) , and a large number of <image description, image> pairs (e.g. YFCC100M (Thomee et al., 2016), formulated as $\mathcal{D}_P = \{(c_j, r_j^v)\}_{j=1}^{M}$ with (c_j, r_j^v) a <textual image-description, image> pair). Based on the above facts and the low-resource challenges on MDRG task, we adapt to incorporate generative text-to-image translation into text-only open domain dialogue response generation. More specifically: (i) if the multimodal dialogue context contains an image, we replace the image with its description to form a text-only context, and take this context as the input of the text-only dialogue generation model $\mathcal{G}$ (pre-trained with $\mathcal{D}_C$); (ii) if we need to generate an image as a part of response, we could first generation a textual description with $\mathcal{G}$, then adopt a text-to-image translator module $\mathcal{F}$ (pre-trained with $\mathcal{D}_P$) to translate the description to a synonymous image. To bridge $\mathcal{G}$ and $\mathcal{F}$, we further extend the formalization of $\mathcal{D}_S$ to a new $\widetilde{\mathcal{D}}_S$ in which each image r^v is paired with its textual description c. Both the (i) and (ii) actions can be independently learned, which becomes the key to aiding the small $\widetilde{\mathcal{D}}_S$ with the large $\mathcal{D}_C$ and $\mathcal{D}_P$.

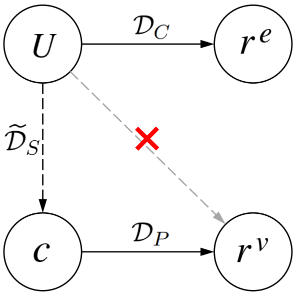

Figure 3: Abstract Logic of the proposed approach. Solid lines mean that there exists large-scale training set to pre-train the generation model, while dotted lines mean that only very few training instances are available, "×" means bad generation quality.

By this means, the current goal is to learn a generation model $P(R|U;\theta)$ with $\mathcal{D} = \{\widetilde{\mathcal{D}}_S, \mathcal{D}_C, \mathcal{D}_P\}$. With the pre-trained $\mathcal{G}$ and $\mathcal{F}$ available, we finally use $\widetilde{\mathcal{D}}_S$ to jointly finetune $\mathcal{G}$ and $\mathcal{F}$ to obtain the capacity of generating multimodal responses.

Figure 2 illustrates the architecture of our model. The model is made up of two components: a textual dialogue response generator $\mathcal{G}$ and a text-to-image translator $\mathcal{F}$. In the rest of this section, we will elaborate these two modules in detail.

4.2.1 Textual Dialogue Response Generator

The textual dialogue response generator $\mathcal{G}$ is a sequence-to-sequence model based on the Trans-

---

[1] https://github.com/CompVis/taming-transformers

[2] https://files.pushshift.io/reddit/

former architecture (Vaswani et al., 2017b), it consists of a 24-layers Transformer with a hidden size of 1024 and 16 heads. Specifically, given a text dialogue context $U = \{u_1, \ldots, u_l\}$ from $\widetilde{D}_S$ as source, and the target is a text $\widetilde{R} = \{w_1, \cdots, [\text{SEP}], [\text{DST}], \cdots, [\text{SEP}], \cdots, w_T\}$ with w_t the t-th word, the [DST] token means the following subsequence is a textual image description c. The generation loss is defined by

$$\mathcal{L}_{\mathcal{G}} = \mathbb{E}_{(U,\widetilde{R}) \sim \widetilde{D}_S}[-\log p(\widetilde{R})] \tag{2}$$

$$p(\widetilde{R}) = \prod_t p(w_t | U, w_{1:t-1}) \tag{3}$$

Inference Given a new text dialogue context U, when a generated image description c occurs, it will be fed into the following text-to-image translator, then constructed to the codebook embeddings of its synonymous image.

4.2.2 Text-to-Image Translator

The text-to-image translator $\mathcal{F}$ is also a sequence-to-sequence generation model based on the Transformer architecture, it consists of 24-layers Transformer with a hidden size of 1024 and 16 attention heads. Given an image $r^v \in \mathbb{R}^{H \times W \times 3}$ and its textual description $c = \{w_1, \cdots, w_T\}$ from $\widetilde{D}_S$, with the $\mathcal{V}_E$ and $\mathcal{Z}$ available, we can represent r^v in terms of the codebook indices of its encodings. More precisely, the quantized encoding of image r^v is given by $z_{\mathbf{q}} = \mathbf{q}(\mathcal{V}_E(r^v)) \in \mathbb{R}^{h \times w \times d_z}$, and could be transferred to a sequence $s \in \{0, \cdots, |\mathcal{Z}| - 1\}^{h \times w}$ of indices from the codebook $\mathcal{Z}$, which is obtained by replacing each code with its index in the codebook $\mathcal{Z}$

$$s_{i,j} = k \ \text{ such that } \ (z_{\mathbf{q}})_{i,j} = z_k \tag{4}$$

Then we concatenate tokenized c and s to a single stream of tokens

$$x = \{w_1, \cdots, w_T, [\text{SEP}], s_1, \cdots, s_{h \times w}\} \tag{5}$$

and train an autoregressive transformer to model the joint distribution over the text and image tokens, the generation loss is defined by

$$\mathcal{L}_{\mathcal{F}} = \mathbb{E}_{(c, r^v) \sim \widetilde{D}_S}[-\log p(x)] \tag{6}$$

$$p(x) = \prod_t p(w_t | w_{1:t-1}) \prod_i p(s_i | c, s_{1:i-1}) \tag{7}$$

Inference Given a description c, we leverage the text-to-image translator to generate the representations $\hat{z} = \mathcal{F}(c) \in \mathbb{R}^{h \times w \times d_z}$ of its synonymous image.

4.2.3 Learning Details

Let us denote $\{\theta_g, \theta_\pi, \theta_\phi\}$ as the parameters of textual dialogue response generator $\mathcal{G}$, image tokenizer $\mathcal{V}$ and text-to-image translator $\mathcal{F}$. In the pre-training stage, we use textual dialogues $\mathcal{D}_C$ to estimate θ_g, use the ImageNet (Deng et al., 2009) to estimate θ_π, use <image description, image> pairs $\mathcal{D}_P$ to estimate θ_ϕ. Then we fix θ_π, and jointly fine-tune θ_g and θ_ϕ with $\widetilde{D}_S$, thus the final objective is to minimize the integrated loss

$$\mathcal{L} = \mathcal{L}_{\mathcal{G}} + \lambda \mathcal{L}_{\mathcal{F}} \tag{8}$$

where λ is a hyper parameter.

Remarks. In this work, we mainly focus on integrating text and image responses generation, but our proposed approach actually provides a recipe for a general solution to low-resource MDRG in which the target modality could be gifs, videos, or speech sounds, etc. To do that, one only needs to modify the text-to-image translator to make it compatible with the specific modality type, then pre-train a new text-to-<target modality> translator.

5 Experiments

5.1 Dataset

To evaluate the performance of Divter, we conduct comprehensive experiments on the PhotoChat dataset released by Zang et al. (2021), which is a multimodal conversational dataset consisting of 10917 images and 12286 dialogues, each of which is paired with a user image that is shared during the conversation, and each image is paired with its text description. The dataset has been split into 10286 train, 1000 dev, and 1000 test instances. More details are described in Appendix A.1.

5.2 Evaluation Metrics

We conduct evaluation with both automatic metrics and human judgements. For automatic evaluation, we focus on four aspects: (1) Image Intent Prediction, the goal of this task is to predict whether a image should be produced in the next turn for given context; (2) Text Description Generation; (3) Image Generation Quality ; (4) Text Response Generation. For (1), we follow Zang et al. (2021), which formulates the problem as a binary classification task, and use **F1** as metric; for (2) and (4), we use **PPL**, **BLEU** (Papineni et al., 2002), **Rouge** (Lin, 2004) and **F1**; for (3) we follow Ramesh et al. (2021) and use Frechet Inception Distance (**FID**) and Inception Score (**IS**).

Models	Intent	Image Description Generation				Image Generation		Text Response Generation

Divter (*w/o* joint learning)	55.6	5.20	15.00	11.36	15.73	**29.04**	15.4 ± 0.6	**59.21**	6.47	1.58	5.63

Table 1: Automatic evaluation results of Divter and baselines on the test set. (*w/o* joint learning) means fine-tuning $\mathcal{G}$ and $\mathcal{F}_\phi$ respectively rather than using Eq. 8. Numbers in bold mean that the improvement to the best baseline is statistically significant (t-test with p-value < 0.01). * reported by Zang et al. (2021).

Models	Context Coherence	Text Fluency	Image Quality	Background Consistency	Kappa
SCAN	–	–	**1.95**	0.96	0.65
S2S-TF	0.42	0.58	0.25	0.20	0.67
Divter	**1.59**	**1.95**	1.83	**1.61**	0.63

Table 2: Human evaluation results.

Models	Overall Improvement			Kappa
	W(%)	L(%)	T(%)	
Divter (pure text) vs. DialoGPT	34.4	35.7	29.9	0.64
Divter vs. DialoGPT	53.5	27.4	19.1	0.68

Table 3: Human evaluation results. (W, L, T) means (Win, Lose, Tie).

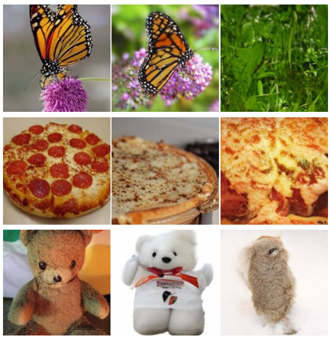

Figure 4: Qualitative assessment of various variants for image generation with same context as input in PhotoChat test set. 1st column: Divter. 2nd column: Divter *w/o* $\mathcal{G}$ pre-train. 3rd column: Divter *w/o* $\mathcal{F}$ pre-train.

For human evaluation, we randomly sample 200 dialogue contexts and generate responses from PhotoChat for Divter and baselines. Three human annotators are asked to score the response quality on a scale of {0, 1, 2} from four aspects: (1) **Context Coherence**: Whether the text response is coherent with the context; (2) **Text Fluency**: Whether the text response is natural and fluent; (3) **Image Quality**: The quality (including definition and integrity) of the image response; (4) **Background Consistency of Image**: For each dialogue, We select the top-8 generated/retrieved images group and ask the annotators to decide whether the group is consistent with the dialogue background, a qualitative assessment is also shown in Figure 5. We report the average scores over three annotators, and the higher score means the better.

We also compare both pure text Divter and multimodal Divter with DialoGPT, respectively. The "pure text Divter" means we block the [DST] token in the vocabulary in the decoding stage, so that the responses would only contain texts. We also randomly sample 200 dialogues. To each annotator, two responses from different models are presented, which are randomly shuffled to hide their sources. The annotators then judge which response is more effective in improving the dialogue experience and attractiveness. The agreement among the annotators is measured by Fleiss' Kappa (Fleiss, 1971).

5.3 Implementation Details

For the textual dialogue response generator $\mathcal{G}$, we use DialoGPT (Zhang et al., 2020) as pre-trained model initialization, trained on 147M conversation-like exchanges extracted from Reddit comment chains over a period spanning from 2005 through 2017. In the fine-tuning stage, we concatenate the context turns with the token [SEP] as a single sequence, we adopt Adam optimizer as an initial learning rate of 1e-5, and the batch size is 256, the training of PhotoChat is conducted on 16 Nvidia Tesla V100 32G GPU cards. We use beam search(size=5) to decode the text sequence.

For the image tokenizer $\mathcal{V}$, we inherit the model released by Ramesh et al. (2021).

For the text-to-image translator $\mathcal{F}$, we randomly select 5M <categorical image description, image> pairs from ImageNet, and <image description, image> pairs from YFCC100M (Thomee et al., 2016) as training data. We set the maximum image description length as 32, then pre-train $\mathcal{F}$ for 3.5 million steps with a batch size of 256 accumulated on 16 Nvidia Tesla V100 32G GPUs. In the fine-tuning stage, we train PhotoChat for 50000 steps.

		Generated / Retrieved Images
1	Generation (Generated Description: objects in the photo: animal, dog, carnivore, grassland)		Retrieval (Should contain "dog".)	
2	Generation (Generated Description: objects in the photo: coffee cup, drink, bottle, mug, tea.)		Retrieval (Should contain "coffee cup".)	
3	Generation (Generated Description: objects in the photo: curtain.)		Retrieval (Should contain "curtain".)	

Figure 5: Examples of the images generated by Divter and the images retrieved by SCAN. The dialogue contexts are presented in Appendix A.2.

In the inference stage, we use CLIP (Radford et al., 2021) to rerank the generated 256 samples.

In the joint learning, we first train $\mathcal{F}$ for 48000 steps, then jointly train $\mathcal{G}$ and $\mathcal{F}$ for 2000 steps. The λ in Eq.8 is 0.2. Early stopping on validation is adopted as a regularization strategy. All the hyper parameters are determined by grid search. More details are described in Appendix A.3.

We implement the image Auto-Encoder using the code `https://github.com/CompVis/taming-transformers`, implement the Textual Dialogue Response Generator using the code `https://github.com/microsoft/DialoGPT`, and implement the Text-to-Image Translator using the code `https://github.com/lucidrains/DALLE-pytorch`.

5.4 Baselines

Two pre-trained models **BERT-base** (Devlin et al., 2019) and **T5-3B** (Raffel et al., 2020) are selected as baselines to measure the "Image Intent Prediction" task in Section 5.2. They takes the text dialogue context as input, and predict "whether a image will be shared in the next turn".

SCAN is proposed by Lee et al. (2018), the model captures interplay between image regions and text tokens to infer image-text similarity, SCAN achieves state-of-the-art performance of the "Image Retrieval" task on PhotoChat.

S2S-TF is a single sequence-to-sequence model with 24-layers Transformer, we only use PhotoChat to train this multimodal generation model.

5.5 Evaluation Results

As shown in Table 1, our Divter achieves not only comparable performance with the state-of-the-art retrieval-based image response intent prediction model but also achieves remarkable performance in all the generation metrics. This indicates that Divter can accurately judge the timing of generating image response with the given dialogue context, and produce text responses that are coherent to the context, and generate high-quality image responses. The significant performance gap between Divter and the baseline models (e.g. S2S-TF, Divter variants) without pre-training indicates the superiority of our proposed learning strategy. Table 2 reports the results of human evaluation, our Divter also significantly outperforms the baselines on most of the aspects. The comparison results shown in Table 3 indicates (1): out Divter can achieve comparable performance on pure text response generation with DialoGPT; (2): the multimodal responses generated by Divter achieve a significant improvement on the dialogue experience and attractiveness in contrast to pure text dialogue model (DialoGPT).

5.6 Ablation Study

We conduct extensive ablation experiments over different variants to better understand their relative importance to the MDRG task. As shown in Table 1, all the variants lead to worse performance

Example 1	**Example 2**
A: OMG...the new ice cream shop is amazing. ...... **A:** I had the twist chocolate and vanilla but it was so fresh tasiting. like you just made it. like you just made it. **B:** I call it the malado gilato. **A:** Sam wouldn't let me have another lick bc he thought I'd eat it all. **D:** That sounds interesting. **D:** Yes, could you please share it with me? **D:** Objects in the photo: Chocolate Ice cream, Dairy, Drink. **D:**   **D:** Wow! The ice cream looks so delicious. **D:** Sure, it tastes pretty good.	**A:** Have you been out in nature lately? **B:** Yes. ...... **A:** I'm sitting at home now looking through some old photographs. **B:** I see. than. **A:** Would you like to see one of my favorites It's a cool shot of a honey bee near a beautiful flower. **D:** Objects in the photo: Honey bee, Insect, Animal, Flower. **D:**   **D:** It is a nice picture. Thank you for sharing. **D:** Haha, just enjoy the beautiful scenery. **D:** Yeah, definitely.

Table 4: Examples of PhotoChat test set. In each example, the turns with the prefix of "A"/"B" are the given context; the blue text is the text description generated by Divter; the **left** image and the red response are generated by Divter, the **right** image is the ground-truth image.

in most of the metrics. For a more intuitive comparison, the qualitative assessment results are also shown in Figure 4. In particular, both quantitative and qualitative results on the ablation study validate that: (1) pre-training is crucial to low-resource multimodal dialogue response generation, since removing any component from pre-training causes performance drop when training data is small; (2) in terms of impact to performance of image generation, $\mathcal{F} > \mathcal{G}$, in terms of impact to performance of text generation, $\mathcal{G} > \mathcal{F}$; (3) The joint learning also has contributions to Divter, indicating that leveraging the integrated learning of textual context and visual image benefits more in contrast to any single one of them.

5.7 Case Study

To further investigate the quality of multimodal responses generated by Divter, we show two examples on the PhotoChat test data in Table 4. The given context of the first one is about "ice cream", and the second one is about "honey bee". As we can see, Divter can not only generate a realistic high-resolution image which is coherent to the background, but also generate the informative text responses grounded on the image. Separately, The high-quality generated images are comparable to those real-world ground truths, which demonstrates the practicability of Divter.

5.8 Discussions

Benefits over retrieval-based methods To further investigate and compare the generalization capability between Divter and the retrieval-based method, we also get top-10 generated images from Divter and equivalent retrieved images from SCAN model given the same context. As shown in Figure 5, on the one hand, the diversity and richness of the generated images are desirable, on the other hand, those retrieved results often suffer from wrong consistency with dialogue background. For example in the second case, the dialogue is talking about "coffee", but the retrieved images contain some uncorrelated objects like "milk", "cake", "dog' and "snack". And in the third example, all the retrieval results are mistaken since there is little "curtain" in the training and retrieval space. This demonstrates the fact that the performance of retrieval-based method is extremely limited in specific domains by the size of the pre-constructed conversational history repository, especially in the low-resource scenario. Furthermore, our proposed generation based method shows better generalization capability to tackle the low-resource challenge.

6 Conclusion

In this paper, we explore multimodal dialogue response generation under a low-resource setting. To overcome the challenges from the new task and insufficient training data, we propose Divter, a neural conversational agent which incorporates text-to-image generation into text-only dialogue response generation, in which most parameters do not rely on the training data any more and can be estimated from large scale textual open domain dialogues and <image description, image> pairs. Extensive experiments demonstrate Divter achieves state-of-the-art results in automatic and human evaluation. In the future, we will explore more efficient methods to inject more modalities into response generation.

A Appendix

A.1 Dataset

Table 5 reports the statistics of the PhotoChat dataset.

Split	images	dialogues	turns	tokens
Train	8,917	10,286	130,546	827,154
Dev	1,000	1,000	12,701	80,214
Test	1,000	1,000	12,852	80,847
Total	10,917	12,286	156,099	988,215

Table 5: PhotoChat statistics.

A.2 Dialogue Contexts in Figure 5

Table 6 presents the textual dialogue contexts of the examples shown in the Figure 5.

	Textual Dialogue Context
1	A: hows your day going? A: beautiful sky today A: Have you been near a mountain lately B: yes A: beatiful right, just took a hike today with my dog. B: my college placed in mountain area B: super enjoy the lot A: Oh great, do you have an aquarium at your college? B: how is your dog A: He is great. I'll share a pic. B: i want to see your dog
2	B: hi B: hello friend A: hi A: how are you A: i am doing well B: how are yow B: great A: i am having some coffee B: ok A: you should come over for a cup! A: do you like coffee?
3	A: what are you doing? A: great moment B: Just finishing up with some work so I can start fresh tomorrow!! B: Great moment? What's that mean? A: you chat dude B: ??? A: Curtain you have like B: I don't understand. A: why dude?

Table 6: Dialogue contexts of the examples shown in the Figure 5.

A.3 More Implementation Details

The CLIP model assigns a score based on how well the image matches the description, we use CLIP to rerank the generated 256 samples, and select the best image as the final response. To obtain high-quality training set, we discard the instances with the prefix of "The photo has your * #" in descriptions, "*" includes "mom", "dad", "daughter", "sister", "uncle", etc. "#" is name of a person. To build the training set for text-to-image translator $\mathcal{F}$ from ImageNet, we combine the text "Objects in the photo:" and textual categorical name of each image to build the <categorical image description, image> pair. To train the baseline S2S-TF model, we also use the image tokenizer $\mathcal{V}$ to tokenize each image, and combine the image tokens with text tokens to form a single stream as the generation source/target.

CAKE: A Scalable Commonsense-Aware Framework For Multi-View Knowledge Graph Completion

Abstract

Knowledge graphs store a large number of factual triples while they are still incomplete, inevitably. The previous knowledge graph completion (KGC) models predict missing links between entities merely relying on fact-view data, ignoring the valuable commonsense knowledge. The previous knowledge graph embedding (KGE) techniques suffer from invalid negative sampling and the uncertainty of fact-view link prediction, limiting KGC's performance. To address the above challenges, we propose a novel and scalable **<u>C</u>ommonsense-<u>A</u>ware <u>K</u>nowledge <u>E</u>mbedding** (**CAKE**) framework to automatically extract commonsense from factual triples with entity concepts. The generated commonsense augments effective self-supervision to facilitate both high-quality negative sampling (NS) and joint commonsense and fact-view link prediction. Experimental results[1] on the KGC task demonstrate that assembling our framework could enhance the performance of the original KGE models, and the proposed commonsense-aware NS module is superior to other NS techniques. Besides, our proposed framework could be easily adaptive to various KGE models and explain the predicted results.

1 Introduction

In recent years, knowledge graphs (KGs) such as Freebase (Bollacker et al., 2008), DBpedia (Lehmann et al., 2015) and NELL (Mitchell et al., 2018) have been widely used in many knowledge-intensive applications, including question answering (Sun et al., 2020; Saxena et al., 2020), dialogue systems (Yang et al., 2020; Zhou et al., 2018) and recommender systems (Wang et al., 2021, 2019a). However, the KGs constructed manually or automatically are inevitably incomplete, requiring KGC to infer new facts.

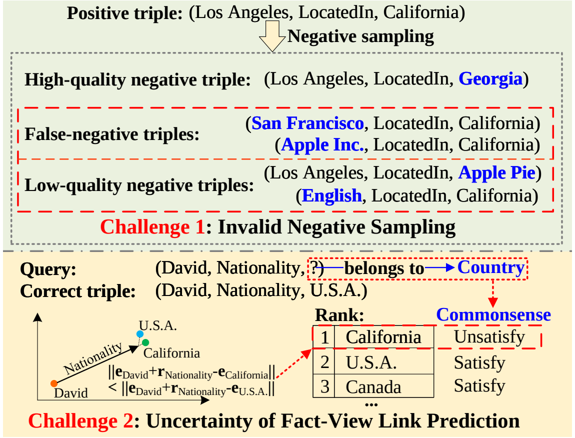

Figure 1: Two examples exhibit the challenges that needed to be addressed. **Challenge 1**: Given a positive triple, some generated negative triples are false-negative or low-quality. **Challenge 2**: For link prediction, the entity $California$ ranks higher than the correct entity $U.S.A.$ due to the uncertainty of KG embeddings. However, the correct answer entity should belong to the concept $Country$ in the view of commonsense.

The previous KGC models can be classified into three main streams: (1) Rule learning-based models mine logic rules for induction reasoning, such as AMIE+ (Galárraga et al., 2015), DRUM (Sadeghian et al., 2019) and AnyBurl (Meilicke et al., 2019). (2) Path-based models (Liu et al., 2020; Xiong et al., 2017; Lin et al., 2018) search paths for multi-hop reasoning. (3) KGE models such as TransE (Bordes et al., 2013) and its variants (Sun et al., 2019; Zhang et al., 2019a, 2020) learn the embeddings of entities and relations to score the plausibility of triples for link prediction.

Among all the existing KGC models, KGE approaches achieve higher efficiency and better performance. Specifically, the KGE-based KGC pipeline can be divided into two stages: learning knowledge graph (KG) embeddings at the training and link prediction at the inference. Learning KG embeddings relies on a basic procedure of negative sampling (Li et al., 2021). Link prediction aims to

infer the missing entity or relation in a triple via ranking the candidate triples' scores in virtue of the learned KG embeddings.

However, the two separate stages both have drawbacks: (1) **Invalid negative sampling**: all the previous NS (Wang et al., 2014; Cai and Wang, 2018; Sun et al., 2019; Zhang et al., 2019b; Denis et al., 2015) cannot avoid sampling the false-negative triples and low-quality negative triples, simultaneously. For instance, given the positive triple $(Los\ Angeles, LocatedIn, California)$ as shown in Figure 1, the existing NS strategies might sample the corrupted triples such as $(San\ Francisco, LocatedIn, California)$, which is actually a missing correct triple namely false-negative triple. On the other hand, the quality of some generated negative triples such as $(San\ Francisco, LocatedIn, Apple\ Pie)$ is too poor to make little sense for training the KGE models. (2) **Uncertainty of fact-view link prediction**: performing link prediction solely based on facts in a data-driven fashion suffers from uncertainty due to the deviation of KG embeddings compared to the symbolic representations, limiting the accuracy of KGC. Take the tail entity prediction $(David, Nationality, ?)$ in Figure 1 as an instance. The correct tail entity should belong to the concept $Country$ in the view of commonsense. Whereas the entity $California$ that is inconsistent with commonsense even ranks highest via scoring the candidate triples with KG embeddings.

Last but not least, although some KGE approaches exploit external information, including entity types (Xie et al., 2016b), textual descriptions (Xie et al., 2016a) and images of entities (Xie et al., 2017). Such auxiliary information is hard to access and enhances the single representation of entities rather than providing the semantics of commonsense. However, the valuable commonsense is always acquired by the expensive hand annotation (Rajani et al., 2019), so its high cost leads to relatively low coverage. Besides, the existing large-scale commonsense KGs such as ConceptNet (Speer et al., 2017) only contain the concepts without the links to the corresponding entities, causing them unavailable to the KGC task.

To address the above challenges, we propose a novel and scalable Commonsense-Aware Knowledge Embedding (**CAKE**) framework to improve the NS in the training of KGE and boost the performance of KGC **benefited from the self-supervision of commonsense**. In specific, we attempt to automatically construct explicit commonsense via an instance abstraction technique from KGs. Then, contrary to random sampling, we **purposefully** generate the high-quality negative triples by taking advantage of the commonsense together with the characteristics of complex relations. Furthermore, a multi-view link prediction is conducted to determine the entity candidates that belong to the correct concepts in the commonsense view and predict the answer entities with the learned KG embeddings from the perspective of fact. In summary, the contributions of our work are three-fold:

- We propose a **scalable** KGC framework with an **automatic commonsense generation** mechanism to extract valuable commonsense from factual triples and entity concepts.
- We develop a **commonsense-aware negative sampling** strategy for generating valid and high-quality negative triples. Meanwhile, a **multi-view link prediction** mechanism is proposed to improve the accuracy of KGC.
- Extensive experiments on four benchmark datasets illustrate **the effectiveness and the scalability** of our whole framework and each module. We promise to release all the codes and datasets when this paper is published.

2 Related Work

2.1 KGC Models

The existing KGC models can be classified into three main categories: (1) Rule learning-based algorithms such as AMIE+ (Galárraga et al., 2015), DRUM (Sadeghian et al., 2019) and AnyBurl (Meilicke et al., 2019) automatically mine logic rules from KGs and apply these rules for inductive link prediction. However, these models are inefficient due to the time-consuming rule searching and evaluation. (2) Path-based models search paths linking head and tail entities, including path ranking approaches (Lao et al., 2011; Liu et al., 2020) and reinforcement learning-based models (Xiong et al., 2017; Lin et al., 2018). Whereas, multi-hop path-based models also spend much time in path searching. (3) KG embedding (KGE) models such as TransE (Bordes et al., 2013), RESCAL (Nickel et al., 2011), ComplEx (Trouillon et al., 2016), RotatE (Sun et al., 2019) and HAKE (Zhang et al.,

2020) learn the embeddings of entities and relations to score the plausibility of triples for predicting the missing triples efficiently. KGE approaches achieve higher efficiency and better performance on KGC compared with the others. However, the natural uncertainty of embeddings limits the precision of KGC relying solely on facts. More specifically, the KGE models generally need a primary negative sampling (NS) procedure to randomly or purposely sample some triples that are not observed in the KG as negative triples for training (Li et al., 2021).

2.2 Negative Sampling of KGE

Following the local closed-world assumption (Dong et al., 2014), the existing NS techniques for KGE can be classified into five categories: (1) Randomly and uniformly sampling: the majority of the KGE models generate negative triples via randomly replacing an entity or relation in a positive triple from a uniform distribution (Wang et al., 2014). (2) Adversarial-based sampling: KBGAN (Cai and Wang, 2018) integrates the KGE model with softmax probabilities to select the high-quality negative triples in an adversarial training framework. Self-adversarial sampling (Sun et al., 2019) performs similar to KBGAN, but it utilizes a self-scoring function without a generator. (3) Domain-based sampling: domain-based NS (Wang et al., 2019b) and type-constrained NS (Denis et al., 2015) both leverage domain or type constraints on sampling the corrupted entities that belong to the correct domain. (4) Efficient sampling: NSCaching (Zhang et al., 2019b) employs cache containing candidates of negative triples to improve the efficiency of sampling. (5) None-sampling: NS-KGE (Li et al., 2021) eliminates the NS procedure by converting loss functions of KGE into a unified square loss.

However, all the previous NS algorithms cannot address the issue of false-negative triples since these NS techniques, except for none sampling, would attempt to sample the corrupted triples with higher probability while they might be correct and just missing in the KG. Domain-based NS relies heavily on the constraint of the single type rather than the commonsense, limiting the diversity of negative triples. KBGAN introduces generative adversarial networks (GAN) in the NS framework, making the original model more complex and hard to train. None sampling has to convert each original KGE model into square loss, which weakens the performance of KGE models. These drawbacks of the NS strategies degrade the training of KGE and further limit the performance of KGC.

2.3 Commonsense Knowledge Graph

Different from the factual triples, commonsense could inject rich abstract knowledge into KGs. However, the valuable commonsense is hard to access due to the costly hand annotation. In recent years, many researches attempt to construct general commonsense graphs such as ConceptNet (Speer et al., 2017), Microsoft Concept Graph (Ji et al., 2019) and ATOMIC (Sap et al., 2019). However, these commonsense graphs only contain the concepts without the links to the corresponding entities, causing them inapplicable to the KGC task. On the other hand, although some KGE models such as JOIE (Hao et al., 2019) employ the ontology built-in most of the KGs, i.e., NELL (Mitchell et al., 2018) and DBpedia (Lehmann et al., 2015), the relations in ontology such as isA, $partOf$ and $relatedTo$ mainly represent the type hierarchy but not the explicit commonsense. Such relations are useless for KGC because there are few overlaps between the ontological and the factual relations.

3 Methodology

In this section, we introduce our novel and scalable CAKE framework. As shown in Figure 2, the entire pipeline consists of three developed modules: the automatic commonsense generation (ACG) module, the commonsense-aware negative sampling (CANS) module and the multi-view link prediction (MVLP) module. Firstly, the ACG module extracts the commonsense from the factual triples with the entity concepts via an instance abstraction mechanism (§ 3.2). Then, the CANS module employs the generated commonsense to produce the high-quality negative triples, which takes the characteristics of complex relations into account (§ 3.3). Afterwards, our approach feeds the positive and the weighted negative triples into the KGE model for learning entity and relation embeddings (§ 3.4). Finally, the MVLP module conducts link prediction in a coarse-to-fine fashion by filtering the candidates in the view of commonsense and predicting the answer entities with KG embeddings from the candidates in the view of fact (§ 3.5).

3.1 Notations and Problem Formalization

Commonsense. Commonsense has gained widespread attraction from its successful use in

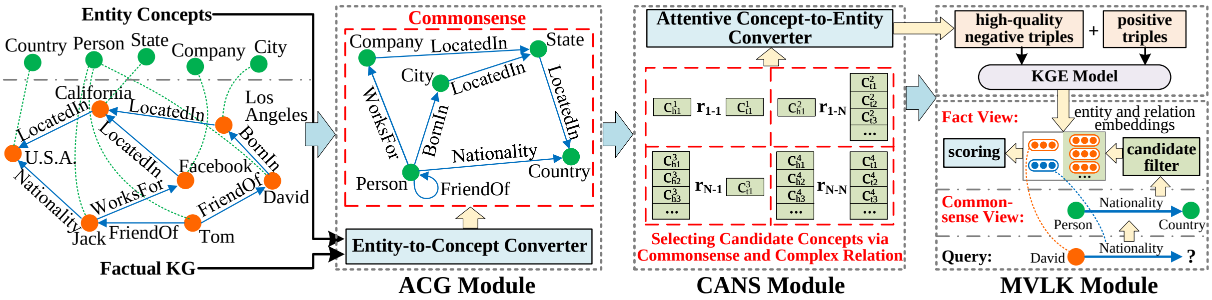

Figure 2: An overview of the CAKE framework. The orange dotes indicate the entities. The green dotes represent the entity concepts. In the CANS module, r_{1-1}, r_{1-N}, r_{N-1} and r_{N-N} denote the diverse complex relations of 1-1, 1-N, N-1 and N-N, respectively. c^j_{hi} and c^j_{ti} indicate the i-th head concept and tail concept that are selected by the commonsense and the characteristics of complex relations specific to the j-th relation.

understanding high-level semantics, which is generally represented as the concepts with their ontological relations in some well-known commonsense graphs such as ConceptNet (Speer et al., 2017) and Microsoft Concept Graph (Ji et al., 2019). Notably, we extend the commonsense in two forms: the individual form $\mathcal{C}_1$ and the set form $\mathcal{C}_2$. Both $\mathcal{C}_1$ and $\mathcal{C}_2$ are the sets of triples while each triple in $\mathcal{C}_1$ is constituted of a head entity's concept c_h and a tail entity's concept c_t associated with their instance-level relation r, which can be written as follows:

$$\mathcal{C}_1 = \{(c_h, r, c_t)\} \tag{1}$$

On the contrary, each triple in $\mathcal{C}_2$ consists of a relation r linking the corresponding head concept set C_h and tail concept set C_t, which is shown as:

$$\mathcal{C}_2 = \{(C_h, r, C_t)\} \tag{2}$$

The detailed description of commonsense generation is introduced in section 3.2.

KGE Score Function. We could leverage any KGE model to learn the entity and relation embeddings owing to our scalable framework independent of the KGE model. Thus, we define a uniform symbol $E(h, r, t)$ to represent the score function of any KEG model for evaluating the plausibility of a triple (h, r, t). More specifically, the three most typical score function patterns are given as follows:

(1) The **translation**-based score function, such as TransE (Bordes et al., 2013):

$$E(h, r, t) = \|\mathbf{h} + \mathbf{r} - \mathbf{t}\| \tag{3}$$

where $\mathbf{h}$, $\mathbf{r}$ and $\mathbf{t}$ denote the embeddings of head entity h, relation r and tail entity t, respectively.

(2) The **rotation**-based score function, such as RotatE (Sun et al., 2019):

$$E(h, r, t) = \|\mathbf{h} \circ \mathbf{r} - \mathbf{t}\| \tag{4}$$

where $\circ$ indicates the hardmard product.

(3) The **tensor decomposition**-based score function, such as DistMult (Yang et al., 2015):

$$E(h, r, t) = \mathbf{h}^\top diag(\mathbf{M}_r)\mathbf{t} \tag{5}$$

where $diag(\mathbf{M}_r)$ represents the diagonal matrix of the relation r.

Link Prediction. Following most of the previous KGC models, we regard link prediction as an entity prediction task. Given a triple query with an entity missing $(h, r, ?)$ or $(?, r, t)$, link prediction takes every entity as a candidate. It calculates the score of each candidate triple by employing the learned KG embeddings and the score function. Then, we rank the candidate entities in light of their scores and output the top n entities as results.

3.2 Automatic Commonsense Generation

In terms of the representation of commonsense defined in section 3.1, our approach could theoretically generate commonsense from any KG automatically as long as there exist some concepts linked to the entities in the KG. Specifically, we develop an entity-to-concept converter to replace the entities in each factual triple with corresponding concepts. Meanwhile, the relations in commonsense entail the instance-level relations in factual KGs. Take an instance in Figure 2, the factual triple $(David, Nationality, U.S.A.)$ can be transformed to a concept-level triple $(Person, Nationality, Country)$. Particularly, the commonsense in the individual form $\mathcal{C}_1$ is achieved by wiping out the reduplicated concept-level triples. Afterwards, we merge the concept-level triples that contain the same relation into a set to construct the commonsense in the set form $\mathcal{C}_2$.

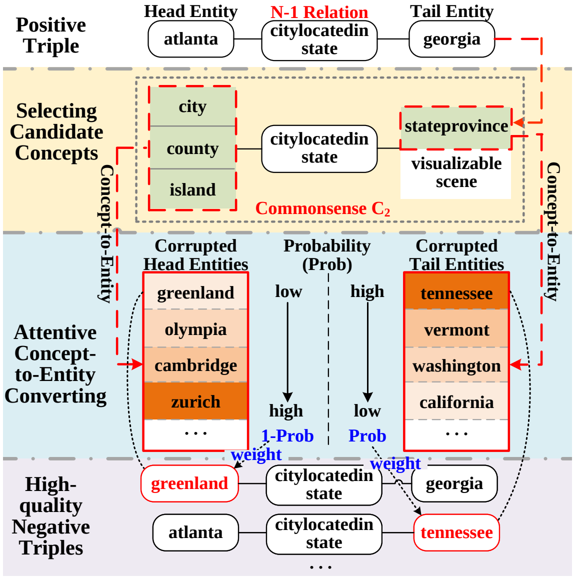

Figure 3: An example of generating the high-quality negative triples containing an N-1 relation by our designed CANS module on NELL-995.

3.3 Commonsense-Aware Negative Sampling

Intuitively, the negative triples satisfying commonsense are more challenging to distinguish from positive triples, contributing to more effective training signals. Therefore, we try to sample the negative triples that conform to the commonsense.

To reduce the false-negative triples, we exploit the characteristics of complex relations, namely 1-1, 1-N, N-1, and N-N defined in TransH (Wang et al., 2014) for negative sampling, where **1** implies that the entity is unique when given the relation and another entity, on the contrary, **N** denotes that there might be multiple entities in this case (non-unique entity). Based on this observation, two specific sampling strategies are proposed: (1) **uniqueness sampling**: in terms of corrupting a unique entity such as the tail entity of the N-1 relation, the corrupted triples except for the original positive one are definitely actual negative triples. Furthermore, the corrupted entities that share at least one concept with the correct entity are regarded as high-quality negative triples, contributing to a more consistent training signal. (2) **None-unique sampling**: for corrupting a non-unique entity such as a head entity linked by the N-1 relation, the entities belonging to the same concept(s) with the correct entity are more likely to be false-negative due to the non-uniqueness of the head entity. Thus, the weights of these negative triples being false-negative should be as low as possible in training. Meanwhile, we try to sample the triples conforming to the commonsense $\mathcal{C}_2$ for high quality.

For a better understanding, an example of generating high-quality negative triples with an N-1 relation is shown in Figure 3. The whole NS procedure can be divided into two steps. **Step 1**: selecting the candidate concepts with commonsense $\mathcal{C}_2$. The candidate head concepts *city*, *county* and *island* are determined according to commonsense $\mathcal{C}_2$ and non-unique sampling. Besides, based on the uniqueness sampling strategy, the candidate tail concept is selected as the same concept *stateprovince* as that of *Georgia*. **Step 2**: attentive concept-to-entity converting. To reduce false-negative while ensuring the high quality of the negative triples, the corrupted entities belonging to the candidate concepts are sampled from the following distribution:

$$\begin{aligned} w(h'_j, r, t) &= 1 - p((h'_j, r, t)|\{(h_i, r_i, t_i)\}) \\ &= 1 - \frac{\exp \alpha E(h'_j, r, t)}{\sum_i \exp \alpha E(h'_i, r, t)} \end{aligned} \tag{6}$$

$$\begin{aligned} w(h, r, t'_j) &= p((h, r, t'_j)|\{(h_i, r_i, t_i)\}) \\ &= \frac{\exp \alpha E(h, r, t'_j)}{\sum_i \exp \alpha E(h, r, t'_i)} \end{aligned} \tag{7}$$

where h'_i and t'_i are the corrupted head and tail entities obtained by non-unique sampling and uniqueness sampling. w and p denote the weight and the probability of the negative triple, respectively. α is the temperature of sampling motivated by the self-adversarial sampling (Sun et al., 2019). Remarkably, considering that a triple with a higher probability is more likely to be a positive one, the weight of a negative triple containing the corrupted head entity such is defined as Eq. 6 to prevent the issue of false-negative. Besides, the negative triples containing the corrupted tail entities with higher probability are endowed with higher-quality weight since there is no false-negative issue. Thus, both the corrupted head entity *greenland* and the corrupted tail entity *tennessee* with the high weights are selected to generate high-quality negative triples. Similarly, we can generate the high-quality negative triples with an 1-N relation via uniqueness sampling for head entity and none-uniqueness sampling for tail entity. Besides, the negative triples with a 1-1 relation can be obtained by only conducting the uniqueness sampling for both head and tail entities. On the contrary, only none-uniqueness sampling is required for generating negative triples with an N-N relation.

3.4 Traning the KGE Model

Based on the negative triples obtained by CANS, we train the KGE model to learn the entity and relation embeddings for enlarging the gap between the scores of the positive and high-quality negative triples. In this work, we employ the following loss function as our optimization objective:

$$
\begin{aligned}
L = &-\log\sigma(\gamma - E(h,r,t)) \\
&-\sum_{i=1}^{n} 0.5 \cdot [w(h_i',r,t)\log\sigma(E(h_i',r,t)-\gamma) \\
&\qquad + w(h,r,t_i')\log\sigma(E(h,r,t_i')-\gamma)]
\end{aligned}
\tag{8}
$$

in which γ is the margin. σ is the sigmoid function.

3.5 Multi-View Link Prediction

Benefiting from the same relations among commonsense and facts, commonsense could directly provide a definite range for link prediction results. Hence we develop a novel multi-view link prediction (MVLK) mechanism in a coarse-to-fine paradigm to facilitate more likely predicted results. Firstly, at the coarse prediction stage, we pick out the candidate entities in the view of commonsense. Specifically, take a query $(h,r,?)$ for an example, commonsense $\mathcal{C}_1$ is employed for filtering the reasonable concepts of the tail entity. The candidate concept set of tail entity is defined as

$$\mathbf{C}_{1t} = \{c_{ti} | (c_{hi}, r, c_{ti}) \in \mathcal{C}_1\} \tag{9}$$

where c_{hi} is the i-th concept of h, and c_{ti} denotes the tail concept in the commonsense (c_{hi}, r, c_{ti}). Then, the entities belonging to the concept set $\mathbf{C}_{1t}$ can be determined as the candidate entities since they satisfy commonsense and are more likely to be the correct tail entities from the perspective of commonsense compared with other entities.

Then, at the fine prediction stage, we score each candidate entity e_i derived from the coarse prediction stage in the view of fact as following

$$score(e_i) = E(h,r,e_i) \tag{10}$$

where $E(h,r,e_i)$ denotes the score function employed for training the KGE model. Subsequently, the prediction results will rank the scores of candidate entities in ascending order and output the entities with higher ranks.

4 Experiments and Results

In this section, we perform extensive experiments of KGC on four widely-used KG datasets containing concepts. We firstly describe datasets, baseline models, implementation details and evaluation protocol. Then, the effectiveness of our proposed framework CAKE and each module is demonstrated by compared with several baselines. Furthermore, we conduct extensive experiments, including the ablation study and the case study.

Dataset	#Rel	#Ent	#Con	#Train	#Valid	#Test
FB15K	1,345	14,951	89	483,142	50,000	59,071
FB15K237	237	14,505	89	272,115	17,535	20,466
NELL-995	200	75,492	270	123,370	15,000	15,838
DBpedia-242	298	99,744	242	592,654	35,851	30,000

Table 1: Statistics of the experimental datasets. #Rel, #Ent, #Con represent the number of relations, entities and concepts of each dataset, respectively.

4.1 Experiment Settings

Datasets. Four real-world datasets containing ontological concepts are utilized for experiments, including FB15K (Bordes et al., 2013), FB15K237 (Toutanova and Chen, 2015), NELL-995 (Xiong et al., 2017) and DBpedia-242. Particularly, DBpedia-242 is extracted from DBpedia (Lehmann et al., 2015) which contains totally 242 concepts. The statistics of the datasets are summarized in Table 1. Notably, the entities in FB15K and FB15K237 always belong to more than one concept while each entity in NELL-995 and DBpedia-242 has only one concept.

Baselines. We compare our CAKE model with three state-of-the-art KGE models, including TransE (Bordes et al., 2013), RotatE (Sun et al., 2019) and HAKE (Zhang et al., 2020). Meanwhile, these baselines are also the basic models integrated with our framework. It is unnecessary to use many baselines since the focus of this work is to observe the impact of applying our CAKE framework to original KGE models instead of defeating all the SOTA models. We provide the results of baselines by running their source codes[2] with the suggested parameters. Note that all the existing type-based and ontology-based models are not chosen as baselines since they are specific to a few KGs and cannot work on most of the datasets in our experiment.

Implementation Details. Each complex relation is labelled in the same way as in TransH (Wang et al., 2014). We use Adam optimizer for the training and tune the hyper-parameters of our model by grid search on the validation sets. Specifically, the

Table 2: Link prediction results on four datasets. **Bold** numbers are the best results for each type of model.

embedding size and the batch size are the same as those of each basic model for a fair comparison. The negative sampling size is set as 16 for all the models considering the memory limitation and efficiency. The learning rate is chosen from 0.0001 to 0.01. The margin is tuned in {9, 12, 18, 24, 30}. The sampling temperature is adjusted in {0.5, 1.0}. The entity and relation embeddings are initialized randomly. All the experiments are conducted in Pytorch and on GeForce GTX 2080Ti GPUs.

Evaluation Protocol. Following the procedure of MVLP in Section 3.5, we can obtain the rank of the correct entity for each test example. Then, the performance of link prediction is evaluated by three commonly-used metrics: mean rank (MR), mean reciprocal rank (MRR), and proportion of the correct entities ranked in the top n (Hits@N). All the metrics are in the filtered setting by wiping out the candidate triples already exist in the datasets.

4.2 Experimental Results

Table 2 exhibits the evaluation results of link prediction on the four datasets. We can observe that both CANS and MVLP modules effectively improve the performance of each basic model on each dataset. Moreover, the entire CAKE framework further facilitates more performance gains than each separate module and outperforms all the baselines consistently and significantly. Compared with the performance average of the three baseline models, our CAKE model improves MRR by **7.2**%, **11.5**%, **16.2**% and **16.7**% on FB15K, FB15K237, DBpedia-242 and NELL-995. These results demonstrate the superiority and effectiveness of integrating commonsense with the original KGE models.

self-adversarial sampling (Sun et al., 2019). The comparison results are obtained by combining these NS techniques[3] with the most classical KGE model TransE(Bordes et al., 2013). From the results shown in Table 3, our CANS module significantly outperforms all the other NS techniques on all the datasets. Specifically, domain-based NS, self-adversarial sampling and our CANS module consistently outperform the others due to the consideration of the quality of negative triples. Furthermore, our CANS module performs better than domain-based NS and self-adversarial sampling since CANS could reduce false-negative. These results illustrate the superior ability of our CANS module to generate more high-quality negative triples for enhancing the performance of any KGE model.

4.3 Ablation Study

We verify the effectiveness of each contribution via integrating the whole framework CAKE and the following ablated models into the basic model HAKE: (1) neglecting the characteristics of complex relations in CANS (-CRNS), (2) removing the commonsense in CANS while retaining the characteristics of complex relations (-CSNS), and (3) omitting the commonsense-view prediction from MVLP (-MVLP). The results in Table 4 demonstrate that our whole model CAKE performs better than all the ablated models on each dataset. It illustrates that introducing commonsense and the characteristics of complex relations both make sense in the NS process for generating more effective negative triples. Besides, MVLP facilitates link prediction performance benefited from determining the reasonable candidate entities by prior commonsense. In general, each contribution plays a pivotal role in our approach.

4.4 Case Study

We provide the case study of explainable link prediction with commonsense as shown in Figure 4. Given a query with the tail entity missing $(rockets, teamplaysinleague, ?)$ on NELL-995, our model could output the answer entities and provide the corresponding entity concepts together with the commonsense specific to the query. We can observe that all the top-

[3] The codes of these NS techniques are obtained from: uniform sampling: https://github.com/thunlp/KB2E, none sampling: https://github.com/rutgerswiselab/NS-KGE, NSCaching: https://github.com/yzhangee/NSCaching, self-adversarial sampling: https://github.com/DeepGraphLearning/KnowledgeGraphEmbedding.

5 entities including the correct entity nba belong to the concept $sportsleague$ which satisfies the commonsense $(rockets, teamplaysinleague, sportsleague)$. More interestingly, the commonsense and the entity concepts could explain the rationality of the predicted answer entities to enhance the users' credibility of the answers.

5 Conclusion

In this paper, we propose a novel and scalable commonsense-aware knowledge embedding framework, which could automatically generate commonsense from KGs with entity concepts for the KGC task. We exploit the generated commonsense to produce effective and high-quality negative triples. On the other hand, we design a multi-view link prediction technique in a coarse-to-fine paradigm to filter the candidate entities in the view of commonsense and output the predicted results from the perspective of fact. The experiments on four datasets demonstrate the effectiveness and the scalability of our proposed framework and each module compared with the state-of-the-art baselines. Furthermore, our framework could explain link prediction results and potentially assemble new KGE models to improve their performance.

Abstract

Most dominant neural machine translation (NMT) models are restricted to make predictions only according to the local context of preceding words in a left-to-right manner. Although many previous studies try to incorporate global information into NMT models, there still exist limitations on how to effectively exploit bidirectional global context. In this paper, we propose a **C**onfidence **B**ased **B**idirectional **G**lobal **C**ontext **A**ware (CB-BGCA) training framework for NMT, where the NMT model is jointly trained with an auxiliary conditional masked language model (CMLM). The training consists of two stages: (1) multi-task joint training; (2) confidence based knowledge distillation. At the first stage, by sharing encoder parameters, the NMT model is additionally supervised by the signal from the CMLM decoder that contains bidirectional global contexts. Moreover, at the second stage, using the CMLM as teacher, we further pertinently incorporate bidirectional global context to the NMT model on its unconfidently-predicted target words via knowledge distillation. Experimental results show that our proposed CB-BGCA training framework significantly improves the NMT model by +1.02, +1.30 and +0.57 BLEU scores on three large-scale translation datasets, namely WMT'14 English-to-German, WMT'19 Chinese-to-English and WMT'14 English-to-French, respectively.

1 Introduction

In recent years, Neural Machine Translation (NMT) has achieved great progress and attracted more attention. Most dominant NMT models mainly adopt an encoder-decoder framework (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017; Meng and Zhang, 2019; Song et al., 2019; Miao et al., 2021) with the teacher-forcing strategy (Goodfellow et al., 2016) for training. Despite its success, the unidirectional property of teacher-forcing strategy restricts NMT models to only focus on the local context, i.e., the preceding words of the to-be-predicted target word at each decoder step. Apparently, this strategy tends to be limited because word dependencies are always bidirectional involving both preceding and succeeding words on the target side.

To address this issue, many previous researches attempt to exploit global information on the target side (Liu et al., 2016; Zhang et al., 2016; Serdyuk et al., 2018; Zhang et al., 2018; Su et al., 2018; Zhang et al., 2019a,b; Su et al., 2019; Zhou et al., 2019; Zhang et al., 2020). Typically, they introduce the modelling of target-side global context in the reverse direction by pairing the conventional left-to-right (L2R) NMT model with a right-to-left (R2L) auxiliary model. However, in these methods, the modelling of reverse global context is separate from the local context of preceding words. Thus, they cannot sufficiently encourage the NMT model to exploit bidirectional global context (Devlin et al., 2019). Meanwhile, some of them adopt bidirectional decoding, which often relies on multi-pass decoding or specially customized decoding algorithms (Liu et al., 2016; Zhang et al., 2018; Zhou et al., 2019; Zhang et al., 2020).

Another series of studies (Conneau and Lample, 2019; Edunov et al., 2019; Weng et al., 2020; Baziotis et al., 2020; Yang et al., 2020; Chen et al., 2020) resort to leveraging target-side bidirectional global context contained in large-scale pre-trained language models (PLM), such as ELMo (Peters et al., 2018) and BERT (Devlin et al., 2019). These PLMs are normally not bilingual-aware for translation and trained independently of the NMT model. As a special case, Chen et al. (2020) design a conditional masked language modelling objective to make BERT aware of source input during the fine-

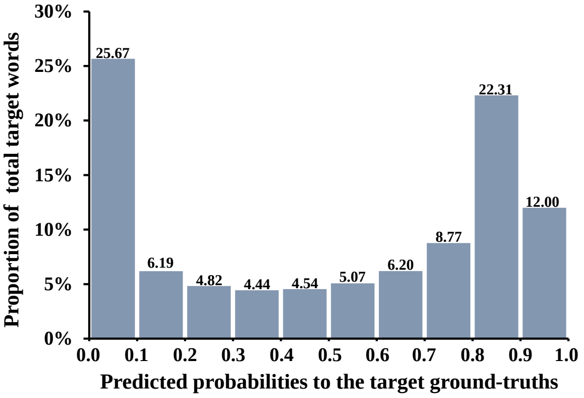

Figure 1: The distribution of the NMT-predicted probabilities to the corresponding ground-truth words on the training set of WMT'14 English-to-German translation task, which is output by a fully-trained Transformer model using teacher-forcing strategy. For instance, the model predicts 25.67% target ground-truth words with probabilities between $0.0 \sim 0.1$ given totally correct preceding words at each time step.

tuning stage. Nevertheless, in these approaches, the pre-trainings of PLMs are independent of NMT models, limiting the potential of model performance.

As for how to effectively incorporate global information into NMT models, another notable deficiency of previous work is that they do not pertinently enhance the NMT model according to its word-level prediction confidence. Ideally, under the teacher-forcing strategy, a well-trained NMT model should assign high probabilities to the target ground-truth words based on correct previous words, which, however, is not the case. Figure 1 depicts the predicted word-level probabilistic distribution of a fully-trained Transformer model. We find that, even based on totally correct preceding words, there is a considerable portion of target ground-truth words that the model predicts with relatively low probabilities. The reasonable cause of this phenomenon is that the NMT model cannot confidently predict these target words according to only the local context of preceding words (Watanabe and Sumita, 2002; Hoang et al., 2017). Hence, we should especially refine the NMT model on these unconfidently-predicted target words.

In this paper, we propose a **C**onfidence **B**ased **B**idirectional **G**lobal **C**ontext **A**ware (CBBGCA) training framework for NMT. Under our framework, the NMT model is jointly trained with a conditional masked language model (CMLM) which is essentially bilingual-aware and contains bidirectional global context on the target side. Specifically, the CBBGCA training consists of two stages. At the first stage, we jointly train the NMT model and CMLM in a multi-task learning manner by sharing the encoders of the two models. This preliminarily enhances the NMT model because the encoder is additionally supervised by the signal from the CMLM decoder that contains bidirectional global context. At the second stage, we employ the CMLM to pertinently refine the training of the NMT model on those unconfidently-predicted target words via confidence based knowledge distillation. By doing so, our model can be further encouraged to effectively leverage the bilingual-aware bidirectional global context contained in the CMLM.

To sum up, the major contributions of our paper are as follows:

- We introduce multi-task learning to benefit the NMT model by sharing its encoder with an auxiliary CMLM, which preliminarily enhances the NMT model to capture bidirectional global context.
- We further propose confidence based knowledge distillation using the CMLM as teacher to especially refine the NMT model on unconfidently-predicted target words, more effectively exploiting the bidirectional global contextual information.
- Extensive experiments on large-scale WMT'14 English-to-German, WMT'19 Chinese-to-English and WMT'14 English-to-French translation tasks show that our CBBGCA training framework respectively improves the state-of-the-art Transformer model by +1.02, +1.30 and +0.57 BLEU points, which demonstrate the effectiveness and generalizability of our approach.

2 CBBGCA Training Framework

In this section, we will introduce our proposed CBBGCA training framework that employs a CMLM to enhance the NMT model according to its prediction confidence. In the following subsections, we first describe the basic architectures of our NMT model and CMLM. Then, we introduce the training procedures of our CBBGCA framework, involving two stages.

2.1 The NMT model and CMLM

Both the NMT model and CMLM are based on Transformer (Vaswani et al., 2017), which is essentially an attentional encoder-decoder framework.[1]

2.1.1 Encoder

The encoders of the NMT model and the CMLM are identical, which are mainly used to learn the semantic representations of the source sentence.

Generally, the encoder consists of L_e identical layers, each of which contains two sub-layers: a self-attention (SelfAtt) sub-layer and a position-wise feed-forward network (FFN) sub-layer. The SelfAtt sub-layer takes the hidden states of the previous layer as inputs and conducts multi-head scaled dot-product attention. Let $\mathbf{h}^{(l)}$ denote the hidden states of the l-th encoder layer, the SelfAtt sub-layer can be formulated as

$$\mathbf{c}^{(l)} = \mathrm{AN}(\mathrm{SelfAtt}(\mathbf{h}^{(l-1)}, \mathbf{h}^{(l-1)}, \mathbf{h}^{(l-1)})), \quad (1)$$

where AN$(\cdot)$ denotes the *AddNorm*, i.e., layer normalization with residual connection. Afterwards, the FFN sub-layer is applied,

$$\mathbf{h}^{(l)} = \mathrm{AN}(\mathrm{FFN}(\mathbf{c}^{(l)})). \quad (2)$$

Note that $\mathbf{h}^{(0)}$ is initialized as the embedding sequence of the source sentence and the hidden states of the L_e-th layer $\mathbf{h}^{(L_e)}$ are used as the final word-level representations of the source sentence.

2.1.2 Decoders

The decoders of the NMT model and the CMLM are similar except their self-attention mechanisms and prediction manners.

The NMT Decoder. It is comprised of L_d identical layers with each having three sub-layers: a masked self-attention (MaskSelfAtt) sub-layer, a cross-attention (CrossAtt) sub-layer and an FFN sub-layer. Particularly, to preserve the autoregressive property at each time step, the MaskSelfAtt sub-layer performs self-attention with an attention mask that prevents the decoder from seeing succeeding words. To generate the hidden states $\mathbf{s}^{(l)}$ of the l-th decoder layer, the MaskSelfAtt sub-layer can be formulated as

$$\mathbf{a}^{(l)} = \mathrm{AN}(\mathrm{MaskSelfAtt}(\mathbf{s}^{(l-1)}, \mathbf{s}^{(l-1)}, \mathbf{s}^{(l-1)})). \quad (3)$$

Then, the CrossAtt sub-layer conducts cross-attention using $\mathbf{a}^{(l)}$ and the source representations $\mathbf{h}^{(L_e)}$,

$$\mathbf{z}^{(l)} = \mathrm{AN}(\mathrm{CrossAtt}(\mathbf{a}^{(l)}, \mathbf{h}^{(L_e)}, \mathbf{h}^{(L_e)})). \quad (4)$$

Next, the FFN sub-layer maps $\mathbf{z}^{(l)}$ into $\mathbf{s}^{(l)}$:

$$\mathbf{s}^{(l)} = \mathrm{AN}(\mathrm{FFN}(\mathbf{z}^{(l)})). \quad (5)$$

Finally, with the source sentence $\mathbf{x}$, the target translation $\mathbf{y}_{<t}$ and the learned top-layer hidden states $\mathbf{s}$, the decoder models the probability distribution over the target vocabulary at the t-th time step as follows:

$$p(y_t|\mathbf{y}_{<t}, \mathbf{x}) = \mathrm{softmax}(\mathbf{W}\mathbf{s}_t), \quad (6)$$

where $\mathbf{W}$ represents the learnable parameter matrix for the linear transformation.

The CMLM Decoder. Typically, it predicts a set of masked target words $\mathbf{y}_m$ given the source sentence $\mathbf{x}$ and the set of observable target words $\mathbf{y}_o$. The CMLM decoder also contains L_d identical layers, each of which also includes a SelfAtt sub-layer, a CrossAtt sub-layer, and an FFN sublayer. Unlike the MaskSelfAtt sub-layer of the NMT decoder, the attention mask is removed in the SelfAtt sub-layer of the CMLM decoder.

Finally, with the learned top-layer hidden states s' of the CMLM decoder, the predicted probability distribution for every masked target word $y_t \in \mathbf{y}_m$ can be formalized as

$$p(y_t|\mathbf{y}_o, \mathbf{x}) = \mathrm{softmax}(\mathbf{W}'\mathbf{s}'_t), \quad (7)$$

where $\mathbf{W}'$ is the learnable parameter matrix of the linear transformation. Note that since the CMLM decoder takes $\mathbf{y}_o$ rather than $\mathbf{y}_{<t}$ as input, which includes both preceding and succeeding words with respect to every masked target word, it should contain bidirectional global contextual information.

2.2 Two-stage Training

The training of CBBGCA framework involves two stages. At the first stage, we jointly train the NMT model and CMLM by multi-task learning. At the second stage, according to the word-level prediction confidence, we employ the CMLM to refine the training of the NMT model through knowledge distillation.

2.2.1 Stage 1: Multi-task Joint Training

In the first training stage, given a batch of training instances, we jointly train the NMT model and CMLM by simultaneously optimizing their respective objectives:

$$L_1(\theta_e, \theta_{nd}, \theta_{cd}) = \lambda L_{\mathrm{nmt}} + (1-\lambda) L_{\mathrm{cmlm}}, \quad (8)$$

---

[1] Please note that our framework can also be adapted to other NMT models.

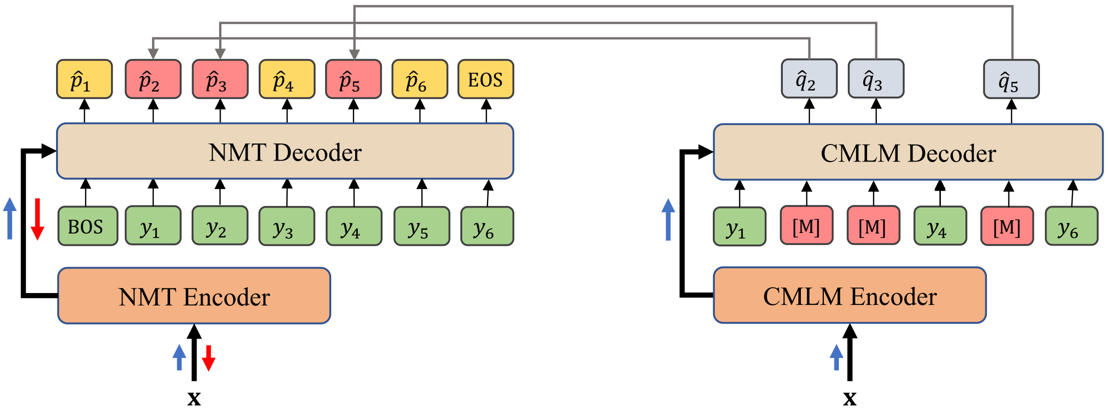

Figure 2: The second training stage. Supposing the NMT-predicted $\hat{p}_2^*$, $\hat{p}_3^*$ and $\hat{p}_5^*$ are lower than ϵ, the set $\mathbf{y}_m$ of masked target words becomes $\{y_2, y_3, y_5\}$. Accordingly, the input $\mathbf{y}_o$ to the CMLM decoder is $y_1, \text{[M]}, \text{[M]}, y_4, \text{[M]}, y_6$. The blue and red arrow also represent the forward an backward propagation pass, respectively. Note that we separate the previously-shared encoder and fix the parameters of the CMLM at this stage.

where λ is a balancing hyper-parameter and θ_e, θ_{nd} and θ_{cd} denote the parameters of the shared encoder, the NMT decoder and the CMLM decoder, respectively. Very importantly, during this procedure of joint training, we share the same encoder for the NMT model and CMLM. In this manner, the NMT model benefits from the multi-task learning because the encoder is additionally supervised by the signal from the CMLM decoder which contains bidirectional global context.

Specifically, using the teacher-forcing strategy, the NMT model is optimized through the following objective:

$$L_{\text{nmt}}(\theta_e, \theta_{nd}) = -\sum_{t=1}^{|\mathbf{y}|} \log p(y_t|\mathbf{y}_{<t}, \mathbf{x}). \quad (9)$$

Besides, we adopt the strategy used in (Ghazvininejad et al., 2019) to optimize the CMLM. Concretely, we randomly select n words, where $n \sim uniform(1, |\mathbf{y}|)$, and replace each word with a special token [M], splitting $\mathbf{y}$ into $\mathbf{y}_o$ and $\mathbf{y}_m$. Formally, we optimize the CMLM by minimizing the following objective for every word in $\mathbf{y}_m$:

$$L_{\text{cmlm}}(\theta_e, \theta_{cd}) = -\sum_{y_t \in \mathbf{y}_m} \log p(y_t|\mathbf{y}_o, \mathbf{x}). \quad (10)$$

2.2.2 Stage 2: Confidence Based Knowledge Distillation (CBKD)

At the second stage, once we obtain the two fully-trained models, we use the CMLM to further refine the training of the NMT model through knowledge distillation (KD). The reason why we introduce such a KD-based model training is that the conventional NMT model predicts a considerable portion of target ground-truth words with relatively low probabilities, as shown in Figure 1. This phenomenon indicates that the NMT model cannot confidently predict these target words based on only local context of preceding words. Therefore, we aim to pertinently distill the knowledge of CMLM into the NMT model on these unconfidently-predicted target words because the CMLM contains bilingual-aware bidirectional global context.

Figure 2 depicts the training procedure of this stage with an illustrative example. Given the source sentence $\mathbf{x}$ and the preceding ground-truth words $\mathbf{y}_{<t}$ at each time step t, we first let the NMT model make predictions for every target word using Equation 6, producing word-level probability distributions $\hat{p}_1, \hat{p}_2, ..., \hat{p}_{|\mathbf{y}|}$. Then, we determine the word set $\mathbf{y}_m$ where the predicted probabilities $\hat{p}_t^*$ to the corresponding ground-truth words are lower than a threshold value ϵ,

$$\mathbf{y}_m = \{y_t | \hat{p}_t^* \leq \epsilon, 1 \leq t \leq |\mathbf{y}|\}. \quad (11)$$

Next, we obtain the set $\mathbf{y}_o$ of partially observable target words by replacing those selected ground-truth words with a special token [M]. Subsequently, we feed $\mathbf{y}_o$ to the CMLM and obtain its predicted probability distribution $\hat{q}_t$ for every word in $\mathbf{y}_m$ using Equation 7.

To pertinently refine the NMT model on the set $\mathbf{y}_m$ of its unconfidently-predicted target words, we use the CMLM with fixed parameters as teacher and transfer its knowledge to the NMT model. Along with the supervision from the corresponding ground-truth words, we optimize the NMT model with a balancing factor α through the following objective:

$$L_{\mathrm{kd}}(\theta_{ne},\theta_{nd}) = \sum_{y_t \in \mathbf{y}_m} \{\alpha \mathrm{KL}(\hat{q}_t || \hat{p}_t) - (1-\alpha)\log \hat{p}_t^*\}, \tag{12}$$

where θ_{ne}, θ_{nd} and $\mathrm{KL}(\cdot)$ represent the NMT encoder parameters, the NMT decoder parameters and the Kullback–Leibler divergence (Sohn et al., 2015), respectively. Here, we follow (Clark et al., 2019) to linearly decrease the factor α from 1 to 0 throughout training. This guides the NMT model to absorb more knowledge from the CMLM at the early period of the stage 2 and gradually re-focus on the ground-truth words to learn better. Finally, the total training objective of this stage is as follows:

$$L_2(\theta_{ne}, \theta_{nd}) = L_{\mathrm{kd}}(\theta_{ne},\theta_{nd}) - \sum_{y_t \in \mathbf{y}_o \backslash [\mathrm{M}]} \log \hat{p}_t^*, \tag{13}$$

where $\mathbf{y}_o \backslash [\mathrm{M}]$ represents $\mathbf{y}_o$ excluding all special tokens [M]. By doing so, we can fully strengthen the ability of the NMT model to leverage the bilingual-aware bidirectional global context contained in the CMLM. Note that the CMLM is not involved at the inference time.

3 Experiments

3.1 Datasets

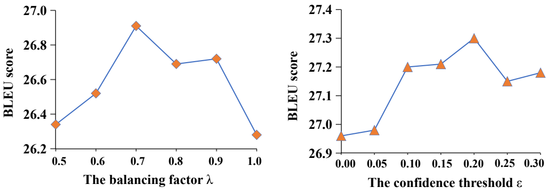
We carry out experiments on three large-scale translation tasks, WMT'14 English-to-German (En→De), WMT'19 Chinese-to-English (Zh→En) and WMT'14 English-to-French (En→Fr). The data are preprocessed using Byte-Pair-Encoding[2] (Sennrich et al., 2016) (BPE). More dataset statistics and the detailed preprocessing procedures are described in Appendix A.

3.2 Implementation Details

We follow the settings used in (Vaswani et al., 2017) to build the NMT model under *Transformer-base* configuration. Concretely, the *Transformer-base* architecture is comprised of 6 encoder and decoder layers, each with 512 as hidden size, the FFN sublayers of 2,048 dimension and 8 heads in multi-head attentions. For more details about the training and inference, please refer to Appendix B.

3.3 Hyper-parameters

Apart from all the hyper-parameters we empirically set based on previous experience, the balancing factor λ in Equation 8 and the confidence threshold ϵ for determining $\mathbf{y}_m$ in Equation 13 are the hyper-parameters we need to manually tune on the validation set.



(a) (b)

Figure 3: The performance of the NMT model on the WMT'14 En→De validation set with different hyper-parameters. (a) The BLEU scores after the first stage with different λ, the balancing factor in Equation 8. (b) The BLEU scores after the second stage with different ϵ, the confidence threshold in Equation 12.

To balance the training of the NMT model and CMLM, we select the minimum λ that can bring steady improvements to the NMT model within 200,000 steps. As shown in Figure 3(a), we gradually vary λ from 0.5 to 1.0 with an increment of 0.1 and evaluate the performance on the validation set. We find that the NMT model achieves its peak when $\lambda = 0.7$. Hence, λ is set to 0.7 for the joint training of the two models at the first stage.

Given the selected λ, at the second training stage, we also investigate the impact of ϵ on the validation set. We adjust its value from 0.0 to 0.3 with an interval of 0.05. As shown in Figure 3(b), the NMT model performs the best when the ϵ is 0.2. Therefore, we set $\epsilon = 0.2$ as the confidence threshold for the second training stage.

3.4 Main Results

In our experiments, **CBBGCA** is the system under our proposed training framework, as described in Section 2.2. **Multi-300k** denotes the baseline system that jointly optimizes the NMT model and CMLM by sharing their encoders throughout the whole 300k training steps, which is used to make comparison with conducting CBKD at the second training stage. For evaluation, in addition to the widely used BLEU (Papineni et al., 2002), we also adopt the Comet (Rei et al., 2020) which is recently a more welcomed metric.

Results on WMT'14 En→De. Table 1 lists several existing competitive NMT systems and ours. First, we can see that "Multi-300k" surpasses "Transformer" by +0.58 BLEU and +0.0101 Comet scores. Moreover, the BLEU and Comet scores

of "CBBGCA" are respectively +1.02 and +0.0226 higher than "Transformer", verifying that CBKD at the second training stage brings further improvement.

Next, our proposed framework outperforms most recent competitive models. Specifically, "CBBGCA" yields a better result than "ABD-NMT" (Zhang et al., 2018) and "FKD-NMT" (Zhang et al., 2019a) that only provide the NMT model with unidirectional future contexts. This proves the power of incorporating target-side bidirectional global context into the NMT model. Note that "ABD-NMT" needs two-pass decoding, which first obtains reverse state sequence by a backward decoder and then uses the forward decoder to generate final translations. The only exception is "SB-NMT" (Zhou et al., 2019) that designs elaborately cumstomized bidirectional decoding algorithms, which is actually not fairly comparable to ours because of its decoding manners and the involvement of synthetic training data.[3] These results demonstrate the effectiveness of our proposed training framework.

Results on WMT'19 Zh→En and WMT'14 En→Fr. From Table 2, the "Multi-300k" preliminarily gains +0.35 and +0.29 BLEU scores over "Transformer" on Zh→En and En→Fr, respectively. Moreover, our "CBBGCA" further strongly outperforms "Multi-300k" and achieves a total of +1.30 and +0.57 BLEU score improvements over "Transformer" on the two datasets, respectively. In term of Comet, comparing different models, we can see similar results. Note that the sizes of WMT'19 Zh→En (20M) and WMT'14 En→Fr (36M) datasets are much larger than that of WMT'14 En→De (4.5M) dataset, demonstrating the effectiveness of our proposed framework on various language pairs.

4 Analysis

4.1 Ablation Study

To fully investigate each part of our proposed training framework, we conduct ablation studies on WMT'14 En→De translation task. Table 3 reports the ablation results on the test set.

We first validate the necessity of our two-stage strategy by only training the model using the multi-task joint training. "*w/.* Dynamic" means the weights in Equation 8 are dynamically adjusted. Specifically, we linearly increase λ from 0.5 to 1.0 throughout the whole training process. We can see that its performance is just slightly higher than the fixed-weight "Multi-300k" and still significantly inferior to the two-stage "CBBGCA".

For the feasible options in two-stage strategy, "*w/o.* ShareEnc" represents not sharing encoders at the first training stage and its performance decreases by 0.56 BLEU score. This shows that the NMT encoder is enhanced by the joint training

---

[3] The result of "SB-NMT" is the reported performance with checkpoint averaging technique from (Zhou et al., 2019).

with the CMLM. As for "*w/o.* CBKD"[4], which means not performing KD on any target words at the second training stage (i.e., α=0), its performance also decreases by 0.40 BLEU score. This demonstrates the effect of pertinently incorporating bidirectional global context into the NMT model on its unconfidently-predicted target words.

4.2 Effects of Different KD Strategies

In our training framework, for each sentence pair, we adopt KD to transfer the knowledge of the CMLM into the NMT model only on the word set $\mathbf{y}_m$. The set is determined by masking k target words whose NMT-predicted probabilities to the corresponding ground-truths are lower than a threshold ϵ. Obviously, there are alternative strategies for the above process. Therefore, we further investigate the following variants:

- **Random**: Regardless of confidence, we randomly select k words of a target sentence to be masked for the CMLM.
- **NMT-High**: As a contrast, we mask the target words whose NMT-predicted probabilities to the ground-truths are higher than $1 - \epsilon$.
- **NMT-Wrong**: We mask the target words where the predictions of the NMT model do not coincide with the corresponding ground-truths.
- **All-at-Once**: In this variant, to validate the necessity of selectively distilling knowledge on a portion rather than all of target words, we generate CMLM-predicted probability distributions for all target words. As an extreme case, we mask all target words at once with only source sentences as input to the CMLM.
- **Part-to-All**: Instead of masking all target words at once, we generate the CMLM-predicted probability distributions in a part-to-all way. Concretely, we first generate the NMT-predicted probability distributions for all words. Then, all target words are divided into several non-overlapping subsets, each corresponding to a certain probability interval. For each time, we mask a subset of target words whose probabilities to the ground-truths are located within the corresponding interval. Particularly, because the hyper-parameter ϵ is 0.2 in "CBBGCA", we have a total of 5 iterations and the intervals are set to $[0.0, 0.2]$, $[0.2, 0.4]$, $[0.4, 0.6]$, $[0.6, 0.8]$, $[0.8, 1.0]$.

System	BLEU	Comet
Transformer	27.30	0.2602
Multi-300k	27.88	0.2703
CBBGCA	**28.32**	**0.2828**
KD Strategy		
Random	28.09	0.2774
NMT-High	27.85	0.2711
NMT-Wrong	27.98	0.2734
All-at-Once	27.64	0.2687
Part-to-All	28.06	0.2769

Table 4: BLEU (%) and Comet scores on the test set of WMT'14 En→De with different KD strategies.

Table 4 lists the results with different KD strategies. We can observe that all these variants are inferior to our "CBBGCA" method. Particularly, the results of "Random" and "NMT-High" indicate that conducting knowledge distillation on either randomly selected or confidently-predicted target words is less effective than on those unconfidently-predicted ones. Next, the result of "NMT-Wrong" is lower than "CBBGCA". It may be due to the fact that the NMT model assigns low probabilities to some correctly-predicted target words. Thus, the NMT model fails to absorb the beneficial knowledge from CMLM on these words. Lastly, "All-at-Once" and "Part-to-All" represent two approaches to generate CMLM-predicted probability distributions for all target words. It is reasonable for "All-at-Once" to obtain a a worse performance since the CMLM cannot predict well without any observable word on the target side. For "Part-to-All", we can see it improves the NMT model over "Multi-300k" but is still worse and takes more computational cost than "CBBGCA". This also echoes the finding in "NMT-High" that applying KD on confidently-predicted target words is not optimal. All these results demonstrate that it is crucial for the NMT model to pertinently exploit bidirectional global contexts on its unconfidently-predicted target words.

4.3 Change of Model Confidence

We also investigate the change of model confidence with respect to target ground-truth words on the

---

[4] It differs from "Multi-300k" in that the CMLM is not optimized at the second stage (200k∼300k steps) in "*w/o.* CBKD". In "Multi-300k", between 200k∼300k steps, the CMLM and NMT model continue to be jointly optimized by sharing their encoders.

	[0,0.1)	[0.1,0.2)	[0.2,0.3)	[0.3,0.4)	[0.4,0.5)	[0.5,1]
Transformer	25.67	6.19	4.82	4.44	4.54	54.34
CBBGCA	25.36	5.81	4.49	4.18	4.40	55.76
Δ	-0.31	-0.38	-0.33	-0.26	-0.14	+1.42

Table 5: The percentage of tokens within each probability interval on the WMT'14 En→De training set.

training set. Table 5 lists the percentage of tokens within each interval, in terms of NMT-predicted probability. Because the probability higher than 0.5 must be the maximum across the vocabulary, we group $0.5 \sim 1.0$ as a whole high-confidence interval while the others are low-confidence intervals. From the table, we can observe that the number of tokens in low-confidence intervals drops. For instance, the number of tokens locating in $[0.0, 0.2]$ becomes 0.69% fewer, which is a notable change considering that the WMT'14 En→De training set contains roughly 4.5 million sentences with a total of approximately 140 million tokens. This indicates that the NMT model becomes more confident about the target ground-truth words.

4.4 Integration with Large-scale PLM

There are also some researches (Edunov et al., 2019; Conneau and Lample, 2019; Yang et al., 2020; Weng et al., 2020; Chen et al., 2020) that focus on incorporating large-scale PLMs into the NMT model. Different from these approaches that require pre-training on massive external data, in this work, the integration of CMLM into the training procedure is to directly provide the NMT model with target-side bidirectional global context without external data. To show that our proposed training framework is compatible and orthogonal to existing approaches involving large-scale PLMs, we conduct experiments with an external Roberta model (Liu et al., 2019) in Appendix C.

4.5 Comparison over Stronger Systems

To further validate our proposed training framework, we conduct experiments over stronger systems. Particularly, we first compare our proposed training framework with (Baziotis et al., 2020) that used a bidirectional LM as prior to regularize the NMT model, which is similar to our method to some extent. Following their setting, we train a target-side language model using a 6-layer Transformer decoder. Then, it is used as the teacher model to impose soft constraints on the output of the NMT model. The upper rows of Table 6 give the comparison results. We can see that our "CBBGCA" still outperforms "Transformer + LM prior".

System	**BLEU**	**Δ**
Transformer	25.54	ref.
Transformer + LM prior	25.85	+0.31
CBBGCA	**26.84**	**+1.30**
Transformer *w/.* BT data	25.85	ref.
Multi-300k *w/.* BT data	26.30	+0.45
CBBGCA *w/.* BT data	**27.12**	**+1.27**

Table 6: BLEU (%) scores on the test set of WMT'19 Zh→En. The upper rows list the results of models trained using only the original training set of WMT'19 Zh→En. The lower rows represents the performances of models trained with additional back-translated data.

In addition, back-translated data are often used to boost NMT models. We also involve additional back-translated data during training. Specifically, we use an in-house English-to-Chinese *Transformer-base* model to translate the English sentences in the WMT'19 Zh→En training set. Then, we add these back-translated data to the WMT'19 Zh→En training set. The lower rows of Table 6 lists the performance of our models under this setting. Similar to previous results, it shows that both of "Multi-300k" and "CBBGCA" consistently improve the NMT model on the BT-augmented WMT'19 Zh→En, demonstrating the the effectiveness of our proposed training framework.

4.6 Case Study

In Appendix D, we give an illustrative example on the WMT'19 Zh→En test set to show the improvements of our model.

5 Related Work

5.1 Exploiting Global Context

This line of research aims at modelling target-side global context in the reverse direction with an auxiliary model. Liu et al. (2016) first adopt L2R and R2L NMT models to independently generate translations through beam search, then re-rank the candidate list via their agreement. Zhang et al. (2018) employ a backward decoder to capture reverse target-side context, which is then exploited by the forward decoder. Serdyuk et al. (2018) propose twin networks, where the forward network is encouraged to generate hidden states similar to those of the backward network. Zhang et al. (2019a) present a future-aware knowledge distillation framework enabling the unidirectional decoder to explore the future context for word predictions. Zhou et al. (2019) propose a synchronous bidirectional NMT model with revised beam search algorithm that involves interactive L2R and R2L decodings. Zhang et al. (2019b) also combine the L2R and R2L NMT models by considering their agreement, helping the model to generate sentences with better prefixes and suffixes. Although these methods indeed gain some improvements, the modelling of reverse global context is independent of the local context of preceding words. Meanwhile, they usually rely on elaborately designed mechanisms for burdensome multi-pass decoding.

5.2 KD from Pre-trained Language Model

Another line of research is to exploit global contextual information contained in large-scale pre-trained language models (PLM) via knowledge distillation (KD). For example, Edunov et al. (2019) and Conneau and Lample (2019) feed the top-layer representations of ELMo or BERT to NMT encoders. Yang et al. (2020) explore three techniques to apply BERT on NMT models, namely asymptotic distillation, dynamic switch for knowledge fusion, and rate-scheduled updating. Weng et al. (2020) propose a training framework consisting of a dynamic fusion mechanism and a continuous KD paradigm to leverage the knowledge of various PLMs. Baziotis et al. (2020) incorporate a language model prior for low-resource NMT. Chen et al. (2020) fine-tune the BERT on the parallel corpus to make it aware of source input, and then utilize it to improve the NMT model via KD over all target words. Compared to this, CBBGCA jointly optimizes the NMT model and auxiliary model, leading to better performance. Moreover, our method just selectively conducts KD on a portion of target words, giving higher distillation efficiency, which is similar to (Wang et al., 2021). Even though these PLM-based approaches have gained remarkable improvements, they unavoidably have some inherent limitations: (1) the monolingual PLMs lacks crucial bilingual information for translation; (2) the independence between PLM pre-trainings and NMT model training. In contrast, our proposed model is able to overcome these limitations.

6 Conclusion

In this paper, we propose a CBBGCA training framework for the NMT model to effectively exploit target-side bidirectional global context with an auxiliary CMLM. The training consists of two stages. At the first stage, we introduce multi-task learning to benefit the NMT model by sharing its encoder with an auxiliary CMLM. Then, at the second stage, through confidence based knowledge distillation, we use the CMLM as teacher to especially refine the NMT model on unconfidently-predicted target words. Experimental results show that our framework can significantly improve the NMT model. Compared with previous work, neither external nor synthetic data are needed and only the NMT model is involved during inference.

Appendix

A Datasets

WMT'14 En→De. For English-to-German translation, the training set from the WMT 2014 contains about 4.5 million parallel sentence pairs. We use the *newstest2013* and *newstest2014* as the validation and test sets, respectively. We apply BPE to preprocess the data, obtaining a shared vocabulary of approximately 32,000 tokens. For evaluation, we adopt the case-sensitive BLEU scores by using the multi-bleu.perl script[5] and the Comet scores as our metrics.

WMT'19 Zh→En. For Chinese-to-English translation, we use the training data from the WMT 2019, which consists of about 20 million sentence pairs. The *newstest2018* and *newstest2019* are used as the validation and test sets, respectively. We also apply BPE to preprocess the data with 30,000 merge operations for both source and target languages. Then, we construct their corresponding vocabularies having roughly 47,000 Chinese tokens and 32,000 English tokens. To evaluate the models, we use cased BLEU scores calculated with the Moses mteval-v13a.pl script[6] as well as the Comet scores.

WMT'14 En→Fr. For English-to-French translation, the training set contains about 36 million parallel sentence pairs. We use the *newstest2013* and *newstest2014* as the validation and test sets, respectively. The preprocessing and evaluation are the same as those for WMT' 14 En→De.

B Implementation Details

During training, we set dropout to 0.1 and use label-smoothing technique of value 0.1. For parameter updating, we employ the Adam optimizer (Kingma and Ba, 2015) with $\beta1 = 0.9$, $\beta2 = 0.998$ and ϵ=10^{-9}. As for learning rate scheduling, we adopt the same strategy as (Vaswani et al., 2017) and set warm-up steps to 4,000. For all the three translation tasks, we train our models on Tesla V-100 GPU where we batch sentence pairs of similar lengths together containing roughly 32000 tokens. At the first stage, we train all models by sharing their encoders for 200,000 steps. At the second stage, we separate their encoders and fix the CMLM parameters. Then, the NMT model is solely optimized with the fixed CMLM by additional 100,000 steps, resulting in a total of 300,000 training steps.

At the inference time, we use beam search with the beam size 5. The results are reported with the statistical significance test (Koehn, 2004) for both translation tasks.

System	**BLEU**	Δ
w/o Roberta		
Transformer	27.30	ref.
Multi-300k	27.88	+0.58
CBBGCA	**28.32**	**+1.02**
w/ Roberta		
Transformer	27.64	+0.34
Multi-300k	28.13	+0.83
CBBGCA	**28.68**	**+1.38**

Table 7: BLEU scores (%) on the test set of WMT'14 En→De. The upper rows (w/o Roberta) represent the performance without using Roberta while the lower rows (w/ Roberta) are the results with the incorporation of the Roberta model using dynamic switch mechanism.

C Integration with Large-scale PLM

In this experiment, we adopt the dynamic switching mechanism used in (Yang et al., 2020) to incorporate externally pre-trained information into the NMT model. Specifically, we use Roberta (Liu et al., 2019) as the large-scale PLM that provides our NMT model with external knowledge. Formally, a context gate is employed to control the amount of information flowing from the pre-trained model and our NMT model, which is computed as

$$g = \sigma(\mathbf{U}\mathrm{r} + \mathbf{V}\mathrm{h}), \tag{14}$$

where $\sigma(\cdot)$ is the sigmoid function, r and h respectively represent the hidden states of each token obtained from the Roberta and the NMT encoder, $\mathbf{U}$ and $\mathbf{V}$ are the trainable parameter matrix. Then, the hidden states of the Roberta model and the NMT encoder are combined as

$$\mathrm{h}' = g \odot \mathrm{r} + (1 - g) \odot \mathrm{h}, \tag{15}$$

where $\odot$ is the operation of element-wise multiplication.

Table 7 lists the performance of our model with the integration of Roberta using dynamic switch

mechanism. We can see that the incorporation of external Roberta brings some improvements to the NMT model under different settings (w/ Roberta vs. w/o Roberta). Besides, it is notable that "CBBGCA" still achieves consistent improvements over "Transformer" and "Multi-300k" regardless of whether using Roberta or not, which demonstrates the compatibility and orthogonality of our proposed training framework to those approaches (Edunov et al., 2019; Conneau and Lample, 2019; Yang et al., 2020; Weng et al., 2020; Chen et al., 2020) of integrating external large-scale PLMs.

D Case Study

We conduct case study to illustrate the improvements of our model. Figure 4 gives an example on the WMT'19 Zh→En test set with the outputs of different models.

We can see that "Transformer" inappropriately translates the Chinese words "*dà huì*" and "*kē jì*" into "*Congress*" and "*technology*", respectively. For "Multi-300k", it correctly translates "*kē jì*" into "*scientific and technological*". Although it is somewhat acceptable for "*kē jì*" to be translated as "*technology*", "*scientific and technological*" is a stricter translation and and more proper modifier considering that the succeeding word"*chéng guǒ*" ("*achievements*" is a noun. The reason is that the multi-task joint training makes the NMT model aware of bidirectional global context rather than only the local context of preceding words.

Moreover, "CBBGCA" successfully translates both "*dà huì*" and "*kē jì*". This indicates that the CBKD at the second training stage further gives our model more confidence to predict the ground truth "*Conference*" rather than its near-synonym "*Congress*". The above analyses show that our proposed training framework actually enhances the NMT model to capture bidirectional global context and significantly improves translation quality.

BRIO: Bringing Order to Abstractive Summarization

Abstract

Abstractive summarization models are commonly trained using maximum likelihood estimation, which assumes a *deterministic* (one-point) target distribution in which an ideal model will assign all the probability mass to the reference summary. This assumption may lead to performance degradation during inference, where the model needs to compare several system-generated (candidate) summaries that have deviated from the reference summary. To address this problem, we propose a novel training paradigm which assumes a *non-deterministic* distribution so that different candidate summaries are assigned probability mass according to their quality. Our method achieves a new state-of-the-art result on the CNN/DailyMail (47.78 ROUGE-1) and XSum (49.07 ROUGE-1) datasets. Further analysis also shows that our model can estimate probabilities of candidate summaries that are more correlated with their level of quality.[1]

1 Introduction

Neural methods for abstractive summarization (Rush et al., 2015; Nallapati et al., 2016; Chopra et al., 2016; Lewis et al., 2020; Zhang et al., 2020) formulate summarization as a sequence-to-sequence (Seq2Seq) problem (Sutskever et al., 2014), learning to generate the summary in an autoregressive manner. Such models are commonly trained with maximum likelihood estimation (MLE), maximizing predictive probability of the reference output given the gold sub-sequence before it. However, during inference the model must also generate the output based on possibly erroneous previous steps. This can hurt model performance, a phenomenon often called *exposure bias* (Bengio et al., 2015; Ranzato et al., 2016). To maintain reasonable performance even in the case of a sub-sequence with errors, we argue that the model must accurately estimate relative quality of different generated outputs, since effective inference requires comparison among these candidates.

System	R-1	R-2	R-L	Acc.(%)
High	53.99	29.85	51.12	100.00
Low	33.48	10.85	30.45	0.00
BART	44.88	21.68	41.92	54.80
Ours	**50.10**	**26.29**	**47.19**	**79.63**

Table 1: Accuracy of different abstractive summarization systems w.r.t ranking the quality of candidate summaries on `CNNDM` dataset. **Acc.** stands for the frequency of the model assigning higher probabilities to better candidate summaries. The candidate summaries are generated by a pre-trained model (BART), and we select the best and the worst candidates (w.r.t. ROUGE scores) for each of the samples. **High** and **Low** represent the average performance of the best and worst candidates respectively. R-1/2/L are the ROUGE-1/2/L scores. The original BART only achieves 54.80% accuracy.

To understand whether existing models can accurately perform such relative comparisons, we conducted a preliminary study on pre-trained BART (Lewis et al., 2020), first generating two candidate summaries from the model and observing whether a higher probability is assigned to the candidate with a higher ROUGE (Lin, 2004) score. As Tab. 1 shows, the accuracy is far from ideal. This is likely due to the fact that MLE training only encourages the model to assign high probability to the reference summary, and is agnostic about any relative comparison between non-reference summaries. However, we argue that it is also important for the order of model scores to be **coordinated** with the actual quality metrics by which the summaries will be evaluated – higher model scores should indicate better quality summaries. In the following we will refer to models that have such scores as "coordinated" for conciseness.

We introduce a training paradigm which requires the abstractive model to be able to be **accurate** with respect to predicting the tokens in the *reference* summaries and **coordinated** with respect to

---

[1] We have made our code, results, and trained models publicly available at https://github.com/yixinL7/BRIO.

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2890 - 2903

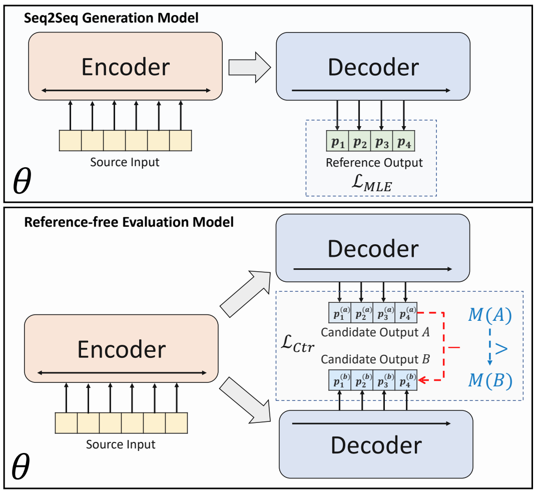

Figure 1: Comparison of MLE loss ($\mathcal{L}_{MLE}$) and the contrastive loss ($\mathcal{L}_{Ctr}$) in our method. MLE assumes a **deterministic** (one-point) distribution, in which the reference summary receives all the probability mass. Our method assumes a **non-deterministic** distribution in which system-generated summaries also receive probability mass according to their quality. The contrastive loss encourages the order of model-predicted probabilities of candidate summaries to be coordinated with the actual quality metric M by which the summaries will be evaluated. We assign the abstractive model a *dual* role – a single model could be used both as a **generation** model and a reference-free **evaluation** model.

the *candidate* summaries. In other words, we give the abstractive model a *dual* role: as a *generation* model, it generates the output summaries in an autoregressive way; as an *evaluation* model, it can be used to score the quality of candidate summaries by estimating a probability distribution over candidate outputs. The generation model is trained using the standard MLE loss, but to train the evaluation model we introduce a *contrastive* loss (Hadsell et al., 2006) defined over different candidate summaries generated by pre-trained abstractive models (Fig. 1), following previous work on ranking-based or contrastive learning (Hopkins and May, 2011; Zhong et al., 2020; Liu et al., 2021b).

Our main contribution is to change the target distribution of abstractive models from a *one-point deterministic* distribution assumed by MLE training to a *non-deterministic* distribution in which candidate summaries are also assigned probability mass according to their quality. The new SOTA performance on CNN/DailyMail (Hermann et al., 2015) and XSum (Narayan et al., 2018) datasets demonstrated the effectiveness of our method. Our in-depth analysis also found that the abstractive models trained using our method can estimate the candidate summary quality more accurately, in concert with the the objective of our training paradigm.

2 Neural Abstractive Summarization

The goal of abstractive summarization is to create a function g that takes a source document D and generates an appropriate summary S

$$S \leftarrow g(D) \tag{1}$$

Training Objective Neural abstractive summarization models aim to learn a neural model g that results in good summaries. Maximum likelihood estimation (MLE) is the standard training algorithm. It aims to maximize the likelihood of the reference summary S^*, i.e.,

$$\theta^* = \operatorname*{argmax}_{\theta} \sum_i \log p_{g_\theta}(S^{*(i)}|D^{(i)};\theta) \tag{2}$$

where θ denotes the parameters of g and p_{g_θ} denotes the probability distribution entailed by these parameters. The summation is over the training set and $\{D^{(i)}, S^{*(i)}\}$ is the i-th training sample.

For a specific sample $\{D^{(i)}, S^{*(i)}\}$, Eq. 2 is equivalent to minimizing the sum of negative log-likelihoods of the tokens $\{s_1^*, \cdots, s_j^*, \cdots, s_l^*\}$ in the reference summary S^* whose length is l, which is the cross-entropy loss:

$$\begin{aligned} \mathcal{L}_{xent} &= \\ -\sum_{j=1}^{l}\sum_{s} & p_{\text{true}}(s|D, S_{<j}^*) \log p_{g_\theta}(s|D, S_{<j}^*;\theta) \end{aligned} \tag{3}$$

where $S_{<j}^*$ denotes the partial reference sequence $\{s_0^*, \cdots, s_{j-1}^*\}$ and s_0^* is a pre-defined start token. p_{true} is a one-hot distribution under the standard MLE framework:

$$p_{\text{true}}(s|D, S_{<j}^*) = \begin{cases} 1 & s = s_j^* \\ 0 & s \neq s_j^* \end{cases} \tag{4}$$

In practice, label smoothing (Szegedy et al., 2016) is a widely used and effective technique that modifies the target distribution in Eq. 4 to a "soft" label by assigning probability mass β to other tokens:

$$p_{\text{true}}(s|D, S_{<j}^*) = \begin{cases} 1-\beta & s = s_j^* \\ \frac{\beta}{N-1} & s \neq s_j^* \end{cases} \tag{5}$$

where N is the size of the dictionary.

Inference and Exposure Bias During inference, the abstractive model g is used to generate the candidate summary in an autoregressive manner. It is intractable to enumerate all the possible candidate outputs, so in practice methods such as *beam search* are used to reduce the search space.

One important step in search is estimating the probability of the next word s_t given the previous predicted sequence $S_{<t}$:

$$p_{g_\theta}(s_t|D, S_{<t}; \theta) \tag{6}$$

Comparing Eq. 6 with Eq. 3, the major difference is that during inference the model makes new predictions based on its **own** previous predictions $S_{<t}$ instead of the *reference* $S^*_{<t}$. As a result, even if the generation model g achieves very high accuracy w.r.t. Eq. 3, once $S_{<t}$ starts to deviate from S^*, there is the risk that the performance of g will significantly degrade. This problem has been identified as the *exposure bias* (Bengio et al., 2015).

3 Coordinating Abstractive Models

Eq. 6 implies that the abstractive model g should be able to assign higher estimated probability to the better candidate summary during inference. However, this intuition is not directly captured in the standard MLE objective used in training – a model obtaining zero MLE loss would assign zero probability to any candidate summary different from the reference. This is obviously improper for any task where multiple reasonable generations may exist (Khayrallah et al., 2020), and also does not say anything about the ordering of two imperfect references. We therefore advocate for making the alternative assumption that the probability of one candidate should be well-correlated with its quality as evaluated by an automatic metric M. Since it is intractable to enumerate all the possible candidate outputs, we only require our model to be able to accurately predict the ranking order of a set of the most probable candidate summaries $\hat{\mathcal{S}}$, which are its own beam search results. In order to achieve this objective, we slightly modify the conditions of Eq. 5, maintaining the general functional form, but instead specifying the *marginal* probability of the non-reference candidates $\mathcal{S}$ to be β, and encouraging *coordination* of probabilities and qualities among non-reference candidates as follows:

$$\begin{cases} p_{\text{true}^\dagger}(S|D) = 1 - \beta & S = S^* \\ \sum_{S \in \mathcal{S}} p_{\text{true}^\dagger}(S|D) = \beta & S \neq S^* \\ p_{\text{true}^\dagger}(S_i|D) > p_{\text{true}^\dagger}(S_j|D) & \begin{array}{l} \forall S_i, S_j \in \hat{\mathcal{S}}, \\ M(S_i) > M(S_j) \end{array} \end{cases} \tag{7}$$

We next describe precisely how we encourage coordination through *contrastive learning*.

Contrastive Learning for Coordination The candidate quality measure M can be defined in many ways. In this work we define it as the ROUGE (Lin, 2004) score of a candidate summary S_i given the reference summary S^*. To coordinate a pre-trained abstractive model, we 1) use it to generate different candidate summaries with various levels of quality,[2] then 2) encourage the model to assign higher estimated probabilities to better candidates by fine-tuning the model with a **contrastive** loss, following the previous work (Hopkins and May, 2011; Zhong et al., 2020):

$$\mathcal{L}_{ctr} = \sum_i \sum_{j>i} \max(0, f(S_j) - f(S_i) + \lambda_{ij}) \tag{8}$$

where S_i and S_j are two different candidate summaries and $\text{ROUGE}(S_i, S^*) > \text{ROUGE}(S_j, S^*)$, $\forall i, j, i < j$. λ_{ij} is the margin multiplied by the difference in rank between the candidates, i.e., $\lambda_{ij} = (j - i) * \lambda$. $f(S_i)$ is the length-normalized estimated log-probability[3]

$$f(S) = \frac{\sum_{t=1}^{l} \log p_{g_\theta}(s_t|D, S_{<t}; \theta)}{|S|^\alpha} \tag{9}$$

where α is the length penalty hyperparameter.

This loss gives the abstractive model a dual purpose, first as a reference-free *evaluation* model, which can be used in a **two-stage** summarization pipeline, where it is used to score the candidates generated by a pre-trained *generation* model and select the final output from them. However, since the autoregressive generation depends on both the **token-level prediction accuracy** and **sequence-level coordination**, the model fine-tuned with the contrastive loss alone can no longer be used as a *generation* model.

Multi-task Fine-tuning Following Edunov et al. (2018), we combine the contrastive (Eq. 8) and cross-entropy (Eq. 3) losses to preserve the **generation** ability of the pre-trained abstractive model:

$$\mathcal{L}_{mul} = \mathcal{L}_{xent} + \gamma \mathcal{L}_{ctr} \tag{10}$$

where γ is the weight of the contrastive loss. We note that the contrastive and the cross-entropy loss can effectively complement each other – since the contrastive loss is defined on the sequence level, the token-level cross-entropy loss serves as a normalization to ensure that the model could assign balanced probability mass across the whole sequence.

---

[2] This is achieved by using diverse beam search (Vijayakumar et al., 2018).

[3] We length-normalize as it is standard in comparing hypotheses in neural sequence generation (Cho et al., 2014).

4 Related Work

Training Methods of Seq2Seq Models In order to align the training objective and evaluation metric, structured losses have been used for the Seq2Seq model training. Among them, margin-based losses (Herbrich et al., 1999; Taskar et al., 2004; Gimpel and Smith, 2010), which require the model to assign higher probability to the better output, are a major category. Many margin-based losses used in modern seq2seq models (Wiseman and Rush, 2016; Edunov et al., 2018) assume a deterministic (one-point) distribution: a model can achieve zero loss if it can assign a much higher probability to the (pseudo)-reference, regardless of relative comparisons of other candidate summaries. By contrast, our method has a non-deterministic assumption (Eq. 7), which focuses on the pair-wise ranking of a set of candidate summaries.

One main challenge of directly optimizing a Seq2Seq model with quality scores of the output is that the discrete sampling process makes the loss non-differentiable. To circumvent this problem, reinforcement learning has been used to reformulate the conditional text generation tasks (Ranzato et al., 2016; Bahdanau et al., 2016; Li et al., 2016; Paulus et al., 2018; Li et al., 2019). Compared to this school of methods, our method is based on supervised learning, and it is more stable and less sensitive to the design choices (e.g. reward shaping), which are well-known challenges of reinforcement learning methods. Minimum risk training (Shen et al., 2016; Wieting et al., 2019) and other online sampling based methods (Bengio et al., 2015; Norouzi et al., 2016; Zhang et al., 2019) belong to another school of methods used to circumvent the problem of non-differentiability. However, they also exhibit similar problems of stability as reinforcement learning.

Contrastive Learning Recently, contrastive learning (Hadsell et al., 2006) has been introduced into several conditional text generation tasks, such as machine translation (Yang et al., 2019; Pan et al., 2021), text summarization (Cao and Wang, 2021; Xu et al., 2021; Sun and Li, 2021), and other tasks (Uehara et al., 2020; Cho et al., 2021; Lee et al., 2021b). Among these application scenarios, most work deployed contrastive learning in the *latent representation space*, following the framework proposed in Chen et al. (2020). However, in this work we adopt contrastive learning over the *discrete* space of the generated texts. Besides, instead of constructing the contrastive learning examples by rule-based methods (e.g. perturbing the reference output), we use the generation models to construct the examples, which makes the contrastive learning task closer to the generation task. Sun and Li (2021) also adopted contrastive learning on the generated texts. However, their formulation belongs to the margin-based losses. We have discussed the difference between our method and the margin-based losses in the previous paragraphs.

Discriminative Reranking Discriminative reranking has been widely studied for conditional generation tasks (Shen et al., 2004; Och et al., 2004; Wan et al., 2015; Mizumoto and Matsumoto, 2016). Some recent works (Liu and Liu, 2021; Lee et al., 2021a) have also explored discriminative reranking of candidates from neural natural language generation models, which adopt large pre-trained language models (e.g. BERT (Devlin et al., 2019)) as the reranker. In this work, we factorize the Seq2Seq model (e.g., BART) trained on the same dataset as the reranking model, which maximizes the parameter sharing across two stages. Besides, our approach contributes an instance of leveraging large pre-trained Seq2Seq models as a quality estimation model (Yuan et al., 2021).

5 Experiments

5.1 Experimental Settings

Datasets We mainly use three datasets in our experiments (statistics in Appendix A).

`CNNDM`[4] (Hermann et al., 2015) is a large scale news dataset. Following Nallapati et al. (2016), we treat the news articles as the source documents and the associated highlights as the summaries.

`XSum`[5] (Narayan et al., 2018) is a highly abstractive dataset of articles from the British Broadcasting Corporation (BBC).

`NYT`[6] (Sandhaus, 2008) contains articles from the New York Times and the associated summaries. We follow Kedzie et al. (2018) for data preprocessing and splitting, and use the associated archival abstracts as the summaries.

Baselines We choose a variety of related models with strong performance as baselines. **BART** (Lewis et al., 2020) and **PEGASUS** (Zhang et al., 2020) are both large pre-trained Seq2Seq LMs standard in the literature. **GSum** (Dou et al.,

---

[4] https://cs.nyu.edu/~kcho/DMQA/

[5] https://github.com/EdinburghNLP/XSum

[6] https://catalog.ldc.upenn.edu/LDC2008T19

2021) is built on BART, and improves performance by using additional guidance from an extractive summarizer. **SimCLS** (Liu and Liu, 2021) introduces a two-stage framework where the pre-trained BART model is used to generate candidates and a pre-trained RoBERTa (Liu et al., 2019) model is fine-tuned as an evaluation model to score the candidate summaries and select from them. It achieves state-of-the-art performance on both `CNNDM` and `XSum`. **GOLD** (Pang and He, 2021) uses offline reinforcement learning to train the BART model by treating the reference summaries as the demonstrations, a different formulation that can also improve the performance of the original BART. **SeqCo** (Xu et al., 2021) and **ConSum** (Sun and Li, 2021) are two recent methods that aim to leverage contrastive learning to improve the performance of the abstractive summarization model (BART).

Implementation Details In the following experiments, we use either BART or PEGASUS as a backbone. We label our proposed methods **BRIO**, with two variants: (1) **BRIO-Ctr** is fine-tuned with the contrastive loss (Eq. 8) only; (2) **BRIO-Mul** is fine-tuned with the multi-task loss (Eq. 10). We use **BRIO-Ctr** as an evaluation model that scores different candidate summaries generated by a Seq2Seq abstractive model and selects the final output from them, and **BRIO-Mul** as a standard Seq2Seq model that takes the source documents as input and generates the output in an autoregressive manner. Further details are in Appendix B.

5.2 Results

The results are shown in Tab 2. For `CNNDM` and `NYT` we use BART as the backbone model while for `XSum` we use the pre-trained PEGASUS model as our base model since it achieves better performance than BART. We have the following observations:

(1) BRIO-Ctr outperforms *SimCLS*, its counterpart as an evaluation model in a two-stage summarization framework. Specifically, both BRIO-Ctr and SimCLS are used to score the candidate summaries generated by a Seq2Seq abstractive model (BART). The final outputs are selected based on those scores. We attribute BRIO-Ctr's superior performance to its use of the same model architecture (BART) for both candidate generation and scoring, while SimCLS uses RoBERTa as the evaluation model. As a result, BRIO-Ctr maximizes the parameter sharing between the two stages, and preserves the power of the Seq2Seq model pre-trained on the same dataset.

System	**R-1**	**R-2**	**R-L**
	CNNDM		
BART*	44.16	21.28	40.90
PEGASUS*	44.17	21.47	41.11
GSum*	45.94	22.32	42.48
ConSum*	44.53	21.54	41.57
SeqCo*	45.02	21.80	41.75
GOLD-*p**	45.40	22.01	42.25
GOLD-*s**	44.82	22.09	41.81
SimCLS*	46.67	22.15	43.54
BART‡	44.29	21.17	41.09
BRIO-Ctr	47.28†	22.93†	44.15†
BRIO-Mul	**47.78**†	**23.55**†	**44.57**†
	XSum		
BART*	45.14	22.27	37.25
PEGASUS*	47.21	24.56	39.25
GSum*	45.40	21.89	36.67
ConSum*	47.34	24.67	39.40
SeqCo*	45.65	22.41	37.04
GOLD-*p**	45.75	22.26	37.30
GOLD-*s**	45.85	22.58	37.65
SimCLS*	47.61	24.57	39.44
PEGASUS‡	47.46	24.69	39.53

BRIO-Ctr	55.98	36.54	52.51
BRIO-Mul	**57.75**†	**38.64**†	**54.54**†

Table 2: Results on `CNNDM`, `XSum` and `NYT`. On `NYT` we only reported our own results due to different data pre-processing. †: significantly better than the baseline model ($p < 0.01$). *: results reported in the original papers. ‡: results from our own evaluation script. R-1/2/L are the ROUGE-1/2/L F_1 scores.

(2) BRIO-Mul is able to establish the new stare-of-the-art performance on `CNNDM`. Notably, the previous state-of-the-art model, *GSum*, takes additional guidance as input and needs a separate encoder to encode the guidance information, while BRIO-Mul uses the same parameterization of BART. Compared to other methods (ConSum, SeqCo, GOLD) that aim to improve upon BART, BRIO-Mul performs much better, showing the effectiveness of our training method.

(3) Since on `XSum` we use PEGASUS instead of BART as the base model, the result shows that our method is not restricted to the specific choice of the base model.

5.3 Analysis

We further perform some in-depth analyses from diverse perspectives on the `CNNDM` dataset to gain more insights into our proposed method.

Coefficient (γ)	R-1	R-2	R-L
0 (BART)	44.29	21.17	41.09
0.1	45.08	21.63	41.71
1	46.01	22.22	42.68
2	46.36	22.79	43.07
5	46.91	23.03	43.63
10	47.22	23.31	43.94
100	**47.78**	**23.55**	**44.57**
1000	46.83	22.17	43.68
$+\infty$ (BRIO-Ctr)	47.28	22.93	44.15

Table 3: Model performance with different γ coefficients weighting the contrastive loss (Eq. 10) on `CNNDM`. BRIO-Ctr is trained with the contrastive loss only, which no longer preserves its generation ability. We report its performance when it is used as an evaluation model to select from candidate summaries. R-1/2/L are the ROUGE-1/2/L F_1 scores.

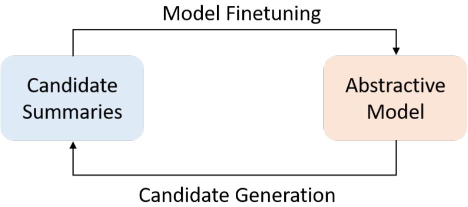

Figure 2: Loop of candidate generation and model finetuning.

System	R-1	R-2	R-L
BART	44.29	21.17	41.09
BRIO-Mul	47.78	23.55	44.57
BRIO-Loop	**48.01**†	**23.80**†	**44.67**†

Table 4: Results on `CNNDM` when the pre-trained model are fine-tuned twice. **BRIO-Loop** is trained on the candidates generated by **BRIO-Mul**. †: significantly better than the baseline (BART) ($p < 0.01$). R-1/2/L are ROUGE-1/2/L F_1 scores.

Coefficients of the Multi-Task Loss The multi-task loss (Eq. 10) used to train our model contains two parts: the cross-entropy loss and the contastive loss. As shown in Tab. 3, as the weight of the contrastive loss (γ) increases, the model's performance improves. However, the cross-entropy loss is still necessary to preserve the model's ability as a generation model. We argue that this is because the token level accuracy is still important during the auto-regressive generation process, where the individual tokens are predicted sequentially. In addition, we also found that the model tends to achieve the best performance (w.r.t the ROUGE scores on the development set) faster with a higher γ. Specifically, it requires less than one entire epoch to achieve the best performance on `CNNDM`, making our approach an efficient fine-tuning method.

Generation-Finetuning as a Loop Since the fine-tuned model (BRIO-Mul) is still able to generate, we can use it to generate a new set of candidates in the same way as we used the pre-trained BART model, and continue fine-tuning it on this newly created set of candidates (Och, 2003). Fig. 2 illustrates this iterative process. The results shown in Tab. 4 illustrate that this new model (BRIO-Loop) outperforms BRIO-Mul. Besides, the model reached the best performance very quickly, showing the potential of adopting our method in an online framework where the new candidates are dynamically generated from the current model. We leave this direction for future work.

Beams	BART		BRIO-Mul	
	R-1	R-2	R-1	R-2
4	**44.29**	**21.17**	47.78	23.55
10	43.83	20.76	47.98	23.81
20	43.53	20.49	48.07	23.92
50	43.06	20.05	48.18	24.01
100	42.79	19.76	**48.23**	**24.09**

Table 5: Results on `CNNDM` with different beam widths (the number of beams) used in beam search. The default beam width is 4. R-1/2 are the ROUGE-1/2 F_1 scores.

Increasing the Beam Width While theoretically a larger beam width (i.e. the number of candidates maintained during beam search) would allow more candidates to be considered and therefore increase the upper bound of the performance, in practice model performance may be lower if the beam width is too large. The reason for this phenomenon is closely related to the low sequence-level coordination of the generator. Specifically, increasing the beam width may introduce candidates with lower quality (Stahlberg and Byrne, 2019), and the generator may not be able to differentiate them from high-quality candidates.

In Tab. 5, we compare the performance of the pre-trained BART and our model (BRIO-Mul) with different beam widths used during inference. We observe that the performance of BART goes down as the beam width increases. On the other hand, our model is able to achieve better performance with a larger number of beams, demonstrating that our training method can improve the coordination of the model by encouraging the model to assign estimated probabilities to candidate summaries well-correlated with their quality.

Training with Different Evaluation Metrics In the previous experiments, we used ROUGE as the evaluation metric to define the target ordering of the candidate summaries (Eq.7). To evaluate our method's performance beyond ROUGE,

System	R-1	R-2	R-L	BS
BART	44.29	21.17	41.09	27.38
BRIO-Mul (R)	**47.78**	**23.55**	**44.57**	32.11
BRIO-Mul (B)	47.53	23.22	44.37	**32.59**

Table 6: Results on `CNNDM` using different evaluation metrics as M in Eq.7. BRIO-Mul (R) is trained with candidate summaries ordered by ROUGE scores, while BRIO-Mul (B) is trained with candidate summaries ordered by BERTScore. R-1/2/L are ROUGE-1/2/L F_1 scores. BS denotes BERTScore.

System	Unigram	Bigram
Reference	.1110	.4865
BART	.0101	.0924
BRIO-Mul	.0262	.2381

Table 7: Ratio of novel n-grams of different models on `CNNDM`. Novel n-grams are those that appear in the summaries but not in the source documents.

we use a model-based semantic similarity metric, BERTScore (Zhang* et al., 2020),[7] as the evaluation metric M in Eq.7 to compare the performance of different candidate summaries. Then, we trained another version of BRIO-Mul based on the order of candidate summaries calculated by BERTScore.

The results in Tab. 6 show that (1) Our model can significantly improve the model performance when either ROUGE or BERTScore is used as the target evaluation metric for ordering candidate summaries. This suggests that it is possible to use our method to optimize any specific target metric, making our method an alternative to reinforcement learning or minimum risk training. (2) Our model that is trained on one evaluation metric (e.g. BERTScore) also achieves improvement on another metric (e.g. ROUGE) compared with the baseline model, which indicates that the improvement made by our model is not from exploiting the potential weaknesses of individual metrics. Besides, this result also demonstrates a non-trivial degree of agreement between ROUGE and BERTScore.

Novel n-grams We compare the ratio of novel n-grams in reference, BRIO-Mul's, and BART's summaries. As Tab. 7 shows, our model is more "abstractive" compared to BART, although reference summaries still contain more novel n-grams. This is likely due to the fact that our model is optimized at the sequence-level, allowing more freedom for paraphrasing and compression.

We further investigate the relation of the "abstractiveness" and model performance by comparing our model (BRIO-Mul) with the baseline model (BART) on different buckets of test examples grouped by the "novelty" of the reference summaries,[8] i.e.,

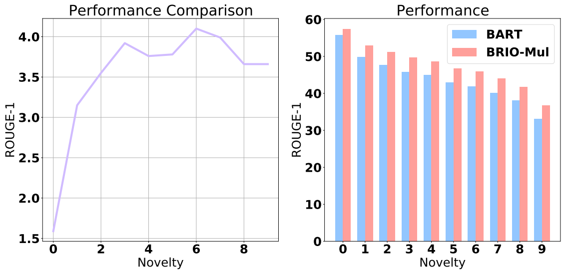

Figure 3: Performance comparison (BART v.s. BRIO-Mul) w.r.t. reference summary novelty. The x-axis represents different buckets of test examples grouped by reference summary novelty (Eq. 11). Larger x-coordinates correspond to examples of which the reference summaries have higher novelty. The left figure shows the performance improvement of our model compared with the baseline model, while the right one shows model performance.

	Own	PEGASUS
BART	.0470	.1205
BRIO-Mul	**.1839**†	**.2768**†

Table 8: Rank Correlation between the model's estimated probabilities of the candidate summaries and the quality scores (ROUGE) of the candidate summaries on `CNNDM`. **Own** stands for the candidates generated by the models themselves, while **PEGASUS** stands for the candidates generated by the pre-trained PEGASUS model. †: significantly better than the baseline model (BART) ($p < 0.01$).

$$\mathrm{Novelty}(D, S^*) = \frac{\sum_{g \in G_{S^*}} \mathbb{1}(g \notin G_D)}{|G_{S^*}|} \tag{11}$$

where D and S^* are the source document and reference summary respectively, G_D and G_{S^*} are the sets of bigrams in D and S^*, $\mathbb{1}$ is the indicator function. The results in Fig. 3 show that when novelty is higher, (1) all models' performance decreases; (2) our model achieves larger improvement over the baseline model.

Rank Correlation We computed the rank correlation between the **estimated probabilities** of the candidate summaries calculated by the generators and the **quality scores** of the candidate summaries. We use Eq. 9 to calculate the estimated probabilities[9] and we use ROUGE-1 as the quality score metric of the candidate summaries. We calculate

	BRIO-Mul	**.2719**	.4271	.6652
XSum	PEGASUS	.2369	.4688	.6990
	BRIO-Mul	**.1423**	.4744	.5881

Table 9: Expected Calibration Error (ECE), accuracy (Acc) and confidence (Conf) on the test set of `CNNDM` and `XSum`.

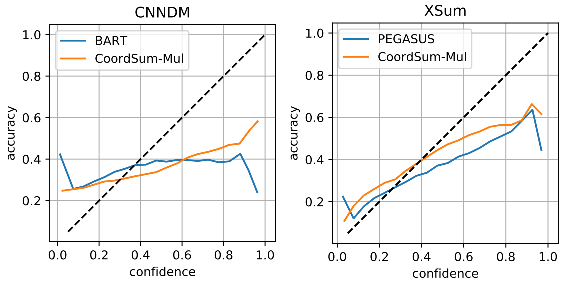

Figure 4: Reliability graphs on the `CNNDM` and `XSum` datasets. The accuracy of model's predictions is plotted against the model's confidence on these predictions.

Spearman's rank correlation for each sample, and use the average score as the overall correlation,

We investigated two specific settings: 1) ranking candidate summaries generated by a different model (PEGASUS); 2) ranking candidate summaries generated by themselves (BART & BRIO-Mul). We use 16 candidates in total for calculation. As Tab. 8 shows, our model achieves better rank correlation on the candidate summaries generated by both itself and the independent model. This suggests that our model can better estimate the quality of candidate summaries.

5.4 Token-level Calibration

Calibration requires that a model's confidence on its predictions is equal to the accuracy of these predictions (Guo et al., 2017). Previous work (Müller et al., 2019; Kumar and Sarawagi, 2019; Wang et al., 2020) has found that a more *calibrated* text generation model tends to have better performance, and techniques like *label smoothing* can improve both the **token-level** calibration and **sequence-level** accuracy (i.e. the ability of generating better results). One intuitive explanation of this phenomenon is to interpret the model's estimated probability of a generated summary as the product of the model's confidences on a series of token-level predictions. Then, since a more calibrated model's *confidence* estimates better the *accuracy* of its predictions, the model's estimated **probability** of one sequence should be more indicative of the **quality** of this sequence, which is essential for the beam search during inference. However, the relation of token-level calibration and sequence-level performance remains inconclusive (Müller et al., 2019).[10] For example, a generator that always predicts a uniform distribution over all tokens would be perfectly calibrated, however, such a model would not generate high-quality outputs.

We investigate this relation from the opposite direction by evaluating whether our model (BRIO-Mul), which is trained to have better **sequence-level** performance, would also be more calibrated at the **token-level** compared with the baseline models that are trained using MLE and label smoothing. We follow previous work by using the *Expected Calibration Error* (Naeini et al., 2015) (ECE) as the evaluation metric of calibration:

$$\mathrm{ECE} = \sum_{m=1}^{M} \frac{|B_m|}{n} |\mathrm{acc}(B_m) - \mathrm{conf}(B_m)| \quad (12)$$

where the samples are grouped into M equal-width buckets by confidence (conf), B_m denotes the m-th bucket, and n is the total number of samples. Following Wang et al. (2020), we evaluate model calibration on the **system-generated** summaries during inference and use the tercom toolkit[11] to assign labels (correct/incorrect) to the system-generated summaries based on the reference summaries.

The results in Tab. 9 show that BRIO-Mul is better calibrated compared to BART, suggesting that our method helps to improve the token-level calibration by explicitly encouraging the model to have more accurate sequence-level probability estimations. The reliability graph is shown in Fig. 4. We found that (1) abstractive models are generally over-confident on their own predictions, (2) models are generally more calibrated on `XSum` than `CNNDM`. This is likely due to the fact that `XSum` has shorter summaries therefore it is less likely to be affected by the exposure bias.

5.5 Few-shot Fine-tuning

The training paradigm proposed in this paper may be extended to any Seq2Seq model. However, it can be a non-trivial overhead to generate the candidate summaries using large neural models on the entire training set. On the other hand, recent work (Raffel et al., 2020; Zhang et al., 2020; Schick and Schütze,

---

[10] In general, better token-level calibration doesn't guarantee better sequence-level performance.

Table 10: Case Study on `CNNDM`. BRIO-Mul learns to ignore the noise pattern ("click here") while BART cannot.

Dataset	System	R-1	R-2	R-L
CNNDM	BART	44.29	21.17	41.09
	BRIO-Few	**45.81**	**21.91**	**42.61**
XSum	PEGASUS	47.46	24.69	39.53
	BRIO-Few	**47.95**	**24.89**	**39.71**

Table 11: Few-shot Fine-tuning. **BRIO-Few** is trained on only 100/1000 training examples on `CNNDM` and `XSum` respectively. R-1/2/L are ROUGE-1/2/L F_1 scores.

2021; Fabbri et al., 2021) has shown that few-shot learning can be an effective fine-tuning method of pre-trained models for text generation tasks.

Therefore, we investigate our model's performance in a few-shot setting. Specifically, we randomly sample 100/1000 examples from the training set of `CNNDM`/`XSum`, and fine-tune the models that are pre-trained using MLE loss on those examples. More training details can be found in Appendix C. The results are shown in Tab. 11. All experiments are repeated three times, and the reported results are the average performance. The results indicate that our model can achieve improvement over the baseline model under the few-shot learning setting with a small computational overhead.

5.6 Case Study on CNNDM

Tab. 10 presents an interesting pattern we observed when comparing the results of BRIO-Mul and BART, which demonstrates that our method helps the abstractive model to filter out noise patterns in the original data. Specifically, some of the reference summaries (331/11490) in `CNNDM` contains the phrase "click here", pointing to a hyperlink, and 103 source documents also contain this phrase. BART picked up this pattern, and generates this phrase in 96 output summaries. On the contrary, our model learns to ignore this noise pattern and never generated it across the whole test set, likely because it identified that generated candidates with this pattern rarely achieve a high ROUGE score, and downweighted the probability accordingly.

6 Conclusion and Future Work

In this work, we presented a new training paradigm that assigns candidate outputs probability mass according to their quality using contrastive learning. While our method has achieved significant improvement on abstractive summarization, we note several directions for the future work to explore. First, since our method makes no assumptions specifically about the summarization task, it can be extended to other conditional text generation tasks such as machine translation. Second, it is possible to apply our method in a reinforcement learning setting, where the candidate summaries are dynamically generated. Finally, in experiments we only used diverse beam search to generate the candidate summaries, but it is likely that other candidate generation methods could yield further improvements.

A Datasets Statistics

Datasets	# Examples			Avg. Words	
	Train	Valid	Test	Doc.	Sum.
CNNDM	287K	13K	11K	791.6	55.6
XSum	203K	11K	11K	429.2	23.3
NYT	44K	5.5K	6.4K	1320.2	123.4

Table 12: Datasets Statistics.

B Implementation Details

We use diverse beam search (Vijayakumar et al., 2018) to generate 16 candidates for each data sample. On `CNNDM` and `XSum`, we use the pre-trained BART[12] and PEGASUS[13] models from the *Transformers* (Wolf et al., 2020) library as the base abstractive models for candidate summary generation and model finetuning respectively. On `NYT`, we first fine-tuned a BART model[14] with MLE training as the base abstractive model, since our data pre-processing is sightly different from the previous work and there are no available pre-trained checkpoints. We use 4 NVIDIA RTX 3090 GPUs for the model training, and the average running time for one epoch is around 20 hours. We use the Adam optimizer (Kingma and Ba, 2015) with learning rate scheduling for the model training:

$$lr = 2 \times 10^{-3} \min(\text{step}^{-0.5}, \text{step} \cdot \text{warmup}^{-1.5})$$

where warmup denotes the warmup steps, which is set to 10000, step is the number of updating steps, lr is the learning rate.

We set the length penalty factor α in the scoring function (Eq. 9) to the same value as used in the original beam search. We search the value of the margin λ in the contrastive loss (Eq. 8) within the range $[1 \times 10^{-5}, 1]$, and decide the value based on the model performance on the validation set. We also performed extensive search for the coefficient γ in Eq. 10. The specific hyper-parameter setting is reported in Tab. 13.

We use the standard ROUGE (Lin, 2004) Perl package[15] for evaluation. The command line parameters are '-c 95 -r 1000 -n 2 -m'. Before the ROUGE evaluation, the reference summaries and system outputs are lower-cased and tokenized.[16]

Datasets	λ (Eq. 8)	α (Eq. 9)	γ (Eq. 10)
CNNDM	0.001	2.0	100
XSum	0.1	0.6	100
NYT	0.001	2.0	100

Table 13: Hyper-parameter Setting.

C Details of Few-shot Fine-tuning

On `CNNDM`, we randomly select 100 examples from the training set for fine-tuning. On `XSum`, we found that at least 1000 examples are needed for the model to achieve better performance compared to the baseline model. All experiments are repeated three times. We randomly select 1000 examples from the original validation set for hyper-parameter selection. We use the Adam optimizer with the learning rate set to 1×10^{-6}. The model is trained for 15 epochs on `CNNDM` and 10 epochs on `XSum`.

Leveraging Relaxed Equilibrium by Lazy Transition for Sequence Modeling

Abstract

In sequence modeling, certain tokens are usually less ambiguous than others, and representations of these tokens require fewer refinements for disambiguation. However, given the nature of attention-based models like Transformer and UT (universal transformer), all tokens are equally processed towards depth. Inspired by the equilibrium phenomenon, we present a lazy transition, a mechanism to adjust the significance of iterative refinements for each token representation. Our lazy transition is deployed on top of UT to build LT (lazy transformer), where all tokens are processed unequally towards depth. Eventually, LT is encouraged to oscillate around a *relaxed* equilibrium. Our experiments show that LT outperforms baseline models on several tasks of machine translation, pre-training, Learning to Execute, and LAMBADA.

1 Introduction

Attention-based models like Transformer (Vaswani et al., 2017) underly two core concepts: *layer* and *refinement*. With layer-stacked structure, the model entirely relies on attention mechanisms (Parikh et al., 2016; Lin et al., 2017) to refine token representations (e.g.,vectors) layer-by-layer from context-informed representations by using residual connections (He et al., 2016; Ebski et al., 2018). However, $layer$ is not necessary. UT (universal transformer) (Dehghani et al., 2019) and its variants (Bai et al., 2019; Lan et al., 2020) iteratively run single-layer but wide Transformer for sequence modeling that token representations are refined at each step by attending to the sequence representation of the previous step, showing higher performance than layer-stacked Transformer does on NMT (Dehghani et al., 2019), pre-training (Lan et al., 2020), language modeling (Bai et al., 2019), and other tasks of varying complexity (Dehghani et al., 2019) with the same number of parameters. The computational bound of recurrence is not the number of tokens in the sequence (like RNN) or the number of stacked layers in the model but is the maximum number of refinements made to token representations, e.g., a pre-defined maximum number of iteration steps.

We follow this line but further ponder *refinement*. Concretely, the model refines token representations iteratively that tokens are equally processed towards depth for disambiguation. Essentially, different token representations are refined at a step equally and concurrently. Thus, regardless of the ambiguous state, a step shows the same importance for all the tokens. However, certain tokens are less ambiguous than others in sequence modeling, especially in NMT. It raises two questions: *1)* do deep representations have to be learned for less-ambiguous tokens; *2)* do tokens must consider the contributions or importance of a step equally?

Meanwhile, our work derives its motivation from the combination of UT and ACT (adaptive computation time) (Graves, 2016) that can dynamically estimate the importance of iteration steps for understanding different sentences in the bAbI task (Weston et al., 2016). However, we consider the importance of every iteration step for all the tokens in the same sequence, sharing a similar motivation with depth-adaptive Transformer (Elbayad et al., 2020). On the other hand, these methods learn a halting probability for each step without considering the correspondence and interdependence throughout the iteration and the model's convergence. We attempt a mechanism like the reset gate in GRU (Chung et al., 2014) that the model is allowed to dynamically forget some information based on the correspondence and interdependence, where in our case, this information is the further refinement at the current step for the corresponding token representation. In this way, we weaken the importance of an iteration step for less-ambiguous token representations to prevent over-refining but retain the significance for more-ambiguous token

Proceedings of the 60th Annual Meeting of the Association for Computational Linguistics
Volume 1: Long Papers, pages 2904 - 2924
May 22-27, 2022

representations to avoid under-refining, refining token representations at the same step unequally.

To this end, we present a lazy transition that performs between two consecutive steps when running UT iteratively. It forms iterative refinements (Ebski et al., 2018) for token representations with a residual structure:

$$h_i^{t_i} = h_i^{t_i-1} + (1 - \sigma_i^{t_i})UT(h_i^{t_i-1}) \quad (1)$$

where $h_i^{t_i}$ is the representation for the i-th token in the sequence at step t_i (token-wise), UT yields the deep refinement $UT(h_i^{t_i-1})$ for $h_i^{t_i}$ by consuming $h_i^{t_i-1}$, and $(1 - \sigma_i^{t_i})$ is a refining rate for adjusting the contribution of $UT(h_i^{t_i-1})$. In this way, we model an equilibrium (Bai et al., 2019; Lan et al., 2020) between two representations of the same token from consecutive steps. Significantly, when off $(1 - \sigma_i^{t_i}) = 0$, the model is allowed to dismiss the further refinement $UT(h_i^{t_i-1})$ for $h_i^{t_i}$ at the step t_i. Then, the model reaches a local equilibrium for the corresponding token that the input $h_i^{t_i-1}$ is similar to the output $h_i^{t_i}$. In other words, the model ponders the significance of the further refinement via our lazy transition that a token representation is *lazy* to absorb the information if the further refinement is trivial. In sequence modeling, all the equilibrium token representations are learned and concatenated for the required sequence representation that the model oscillates around a *relaxed* equilibrium.

Our contributions are: *1)* we present a lazy transition that is placed on top of UT to build LT (lazy transformer). Our lazy transition dynamically forms a refinement path for a token at each step by pondering the step importance and the local equilibrium. Eventually, LT is encouraged to oscillate around a *relaxed* equilibrium in sequence modeling; *2)* we provide an empirical study to quantitatively analyze how the *relaxed* equilibrium impacts NMT in performance, deep models, and zero-shot inferring; *3)* we show our model can consistently improve the performance of pre-training and two tasks of varying complexity, where standard Transformer fails; *4)* our empirical study shows that stable and smooth refinements at the early iteration steps are significant, which results in a strong equilibrium and a stable oscillation.

2 Related Work

Iterative Refinement in Transformer, Tied Transformer, and Universal Transformer One core backbend of Transformer (Vaswani et al., 2017) is iterative refinements (Ebski et al., 2018) that are finished by forming a residual structure around each sub-layer: $h_i^l = h_i^{l-1} + f^l(h_i^{l-1})$, where l denotes depth and $f(\cdot)$ represents a sub-layer (e.g., an attention layer (Parikh et al., 2016; Lin et al., 2017)). Following tied Transformer (Gulcehre et al., 2018; Xia et al., 2019; Dabre and Fujita, 2019), which share parameters across some layers, (Dehghani et al., 2019) introduce token-wise recurrence (Graves et al., 2014; Joulin and Mikolov, 2015; Kaiser and Sutskever, 2016) to signal-layer but wide Transformer and then present UT, a Turing-complete model. Theoretically, UT yields a similar recurrent inductive bias of RNN's because each token representation is refined by attending to the sequence representation of the previous step with tied parameters. We present a comparison in Appendix A. Significantly, the iterative refinement in UT is reformed to : $h_i^t = h_i^{t-1} + f(h_i^{t-1})$, where f is the same for every iteration step t, i.e., a single-layer structure that the parameters are tied throughout the iteration. In this work, we apply our lazy transition on top of a UT block. To reform iterative refinements, we are inspired by (Zhang et al., 2021; Escolano et al., 2021; Bapna et al., 2018; Wang et al., 2019) that f (or f^l) could be a more complicated network rather than a simple sub-layer, defining f as the entire UT block and reforming the iterative refinement as Eq.1.

Adaptive Computation While a token-wise recurrent model like UT can theoretically run infinitely, the model is commonly trained by setting a maximum number of iteration steps. However, the number of inference steps is flexible. (Graves, 2016) first introduce ACT (Adaptive Computation Time) to compute a scalar halting probability predicted by the model at each step for each token in RNN. Then, (Dehghani et al., 2019) adapt ACT for UT to halt the iteration before reaching the maximum number of training steps[1] in inferring. Furthermore, (Elbayad et al., 2020) present depth-adaptive decoding for tokens to model the distribution of exiting with the probability of computing each layer/step and then emitting token predictions. Our lazy transition follows this line somewhat that $(1 - \sigma_i^{t_i})$ in Eq.1 dynamically approximates the computation time for tokens. It reflects on two characteristics: *1)* $(1 - \sigma_i^{t_i}) = 0 \equiv$ stop iteration;

---

[1] In some papers, training steps refer to how many batches we use for training. In this paper, training steps mean "how many steps we iterate a model for a training batch."

2) $(1-\sigma_i^{t_i})$ computed at each step.

3 Approach

We present LT (Lazy Transformer), a token-wise recurrent model. LT only consists of a UT block and our lazy transition. In training, we iteratively run LT but constrain the computational bound to control the training process by setting a maximum number of iteration steps. However, iteration steps are dynamic in inferring.

3.1 Relaxed Equilibrium

In sequence modeling, DEQ(Bai et al., 2019) and ALBERT (Lan et al., 2020) report that a UT-based model tends to oscillate around an equilibrium. Concretely, each additional step has a smaller and smaller contribution to the current sequence representation until the model oscillates around a fixed point. Formally, we have: $\lim_{t\to+\infty} h_{1:N}^t = \lim_{t\to+\infty} UT(h_{1:N}^t) \equiv h_{1:N}^E = UT(h_{1:N}^E)$, where t is the step, $h_{1:N}^t$ is the sequence representation of a N length sequence $X_{1:N}$ at t, and $h_{1:N}^E$ is the equilibrium sequence representation. Empirically, the equilibrium phenomenon could be observed from the difference norm of sequence representations: $||UT(h_{1:N}^t) - h_{1:N}^t|| \approx ||UT(h_{1:N}^{t+1}) - UT(h_{1:N}^t)|| \equiv ||UT(h_{1:N}^{t:}) - h_{1:N}^{t:}|| < \epsilon$, where ϵ depends on the model and $t:$ denotes steps after t.

Intuitively, UT, DEQ, and ALBERT are encouraged to reach a global and sequence-level equilibrium[2] at a specific iteration step t in a dynamic programming style for outputting the equilibrium sequence representation. By contrast, we attempt a greedy strategy to independently find a local equilibrium for a token, modeling the locally optimal choice. Then, for an input sequence, we model all the local equilibriums to find a *relaxed* equilibrium instead of naively finding a global and sequence-level equilibrium. Formally, in sequence modeling, we model a *relaxed* equilibrium to obtain an equilibrium sequence representation $h_{1:N}^R$:

$$\begin{aligned} &\forall i \in N : \lim_{t_i\to+\infty} h_i^{t_i} = \lim_{t_i\to+\infty} UT(h_i^{t_i}) \\ &\equiv \forall i \in N : h_i^{R_i} = UT(h_i^{R_i}) \\ &\equiv h_{1:N}^R = UT(h_{1:N}^R) = [h_1^{R_1}, h_2^{R_2}, ..., h_N^{R_N}] \end{aligned} \tag{2}$$

where $h_i^{t_i}$ denotes i-th token representation at t_i (token-wise), $h_i^{R_i}$ is the equilibrium token representation, R stands the step of reaching the *relaxed* equilibrium, and $[\cdot]$ denotes concatenation. Similarly, we can evaluate the local equilibrium from the difference norm of token representations:

$$||UT(h_i^{t_i:}) - h_i^{t_i:}|| < \tilde{\epsilon} \tag{3}$$

Note that, in our preliminary experiment, we find that $h_{1:N}^E \neq [h_1^{R_1}, h_2^{R_2}, ..., h_N^{R_N}]$, i.e., the equilibrium sequence representation is not equivalent to the combination of all the equilibrium token representations because tokens have different ambiguous states. For the *relaxed* equilibrium, we do not have to update tokens equally at an iteration step so that an iteration step can show varying importance for different tokens, subject to the ambiguous state of the token representations. Thus, we consider adjusting the impact of the current step for different tokens throughout the iteration.

3.2 Equilibrium from Linear CKA

Although we can easily and immediately observe the equilibrium or the local equilibrium phenomenon from difference norms, we have no prior knowledge in practice that we cannot analyze the equilibrium quantitatively throughout the iteration. Hence, we consider the linear CKA exam (centered kernel alignment): $CKA(X,Y) = ||X^TY||_F^2/(||X^TX||_F||Y^TY||_F) \in (0,1]$ that is introduced by (Kornblith et al., 2019) to identify correspondences between representations in models trained from different initializations and is invariant to orthogonal transform and isotropic scaling but is not invariant to any linear transforms. For this exam, we are inspired by (Wu et al., 2020), who measure the degree of a layer's multilinguality with a CKA exam between two averages of outputted sequence representations. However, we run the exam for two averages of sequence representations $h_{1:N}$ emerged from two consecutive steps[3]. Precisely, we majorly rewrite the equilibrium to:

$$\begin{aligned} &\lim_{t\to+\infty} CKA(\tilde{h}^t, \frac{\sum_{i=1}^N UT(h_i^t)}{N}) = 1 \\ &\equiv CKA(\tilde{h}^E, \frac{\sum_{i=1}^N UT(h_i^E)}{N}) = 1 \end{aligned} \tag{4}$$

---

[2] Our preliminary experiment confirms this intuition, which will be further discussed in §Experiment.

[3] Note that, in this way, the feature space is the channel of representations, not the representations itself in the original CKA exam.

where $\tilde{h}^t = \frac{\sum_{i=1}^{N} h_i^t}{N}$. For our *relaxed* equilibrium in sequence modeling, we have:

$$\begin{aligned} &\forall i \in N : \lim_{t_i \to +\infty} CKA(h_i^{t_i}, UT(h_i^{t_i})) = 1 \\ &\equiv \forall i \in N : CKA(h_i^{R_i}, UT(h_i^{R_i})) = 1 \\ &\equiv \sum_{i=1}^{N} CKA(h_i^{R_i}, UT(h_i^{R_i})) = N \end{aligned} \tag{5}$$

Essentially, we can dynamically evaluate the local equilibrium by giving the exam to token representations throughout the iteration:

$$CKA(h_i^{t_i:}, UT(h_i^{t_i:})) \approx 1 \quad (6)$$

It reflects the correspondence and interdependence between UT's input and output. Note that, although the global equilibrium does not expect the local equilibrium, this exam also gives an intuition of how a token representation changes throughout the iteration.

3.3 Lazy Transition

To leverage the *relaxed* equilibrium (Eq.2 and Eq.5), our lazy transition uses a residual structure to form iterative refinements (Ebski et al., 2018) for h_i at each step in order to obtain $h_i^{R_i}$. Recall that, $UT(h_i^{t_i-1})$ is the deep refinement we can obtain at step t_i, and $CKA(\cdot)$ returns $(0, 1]$. We form the iterative refinement (Eq.1) to:

$$\begin{aligned} h_i^{t_i} &= h_i^{t_i-1} + (1 - \sigma_i^{t_i}) UT(h_i^{t_i-1}) \\ \sigma_i^{t_i} &= CKA(h_i^{t_i-1}, UT(h_i^{t_i-1})) \end{aligned} \tag{7}$$

Concretely, the model is based on the correspondence and interdependence between UT's input $h_i^{t_i-1}$ and output $UT(h_i^{t_i-1})$. When $\sigma_i^{t_i}$ is close to 1 at step t_i, $h_i^{t_i:}$ is only oscillating around $h_i^{t_i}$, and UT cannot provide useful information for better representations anymore. Then, the model is encouraged to dismiss UT and then outputs h_i's equilibrium token representation: $h_i^{R_i} (\equiv h_i^{t_i-1} \equiv h_i^{t_i} \equiv h_i^{t_i:})$, for the the *relaxed* equilibrium. It is similar to the reset gate in GRU that dynamically forget the previous state, but our lazy transition attempts to dismiss the newly obtained information $UT(h_i^{t_i-1})$ that is unimportant. Therefore, our lazy transition provides implicit step information, similar to GRU that can identify the current position and handle input sentences of varying length. Since there is no variable for identifying steps, the model can run varying steps in inferring. On the other hand, this could be viewed as a linear interpolation: $h_i^{t_i} = \sigma_i^{t_i} h_i^{t_i-1} + (1 - \sigma_i^{t_i})(h_i^{t_i-1} + UT(h_i^{t_i-1}))$, where $\sigma_i^{t_i}$ decides how much the model updates $h_i^{t_i-1}$ at step t_i from the pre-refined representation[4]: $h_i^{t_i-1} + UT(h_i^{t_i-1})$.

Meanwhile, since $h_i^{t_i}$ is informed by $UT(h_i^{t_i-1})$ without any step-specific parameter, the benefits are twofold: *1)* our lazy transition does not hurt the global receptive field of UT, only adjusting the contribution of a step; *2)* the recurrent inductive bias of UT is inherited because all the parameters are tied throughout the iteration. Our empirical study confirms these two benefits (see §Experiment).

3.4 Lazy Transformer

In sequence modeling, since our model does not provide any position information, in order for the model to make use of the order of the sequence, we inject position information at each step. Therefore, our LT (lazy Transformer) is formed as: $h_{1:N}^{t_{1:N}} = h_{1:N}^{t_{1:N}-1} + (1 - \sigma_{1:N}^{t_{1:N}}) UT(h_{1:N}^{t_{1:N}-1} + PE_{1:N})$, where $h_i^{t_i}$ computed by Eq.7 is the i-th token representation of a N length sequence representation $h_{1:N}$ and $PE_{1:N}$ is the sinusoidal position encoding for identifying positions as defined in (Vaswani et al., 2017). Recall that $1 - \sigma_i^{t_i}$ collapses to 0 when the model is researching the local equilibrium of h_i. The model can simply copy the equilibrium token representation to the next step for speed.

Instantiation LT can be instantiated, used, and trained as the same as a vanilla Transformer block or a UT block. Concretely, we can instantiate and train: *1)* a LT encoder with the objective of MLM (masked language modeling) (Devlin et al., 2019; Lan et al., 2020); *2)* a LT decoder with the objective of GPT (generative pre-training) (Radford et al., 2018; Alec Radford, 2020); *3)* a LT encoder-decoder (consisting of a LT encoder and a LT decoder) in a *seq2seq* (Graves, 2013) manner.

3.5 Comparison

Readers can refer to Appendix C for details.

Lazy Transition vs. GRU They have different motivations. GRU aims to learn a segment-level representation by accumulating the information from all the tokens, whereas LT is encouraged to ponder the importance of a step for different tokens and then to oscillate around the *relaxed* equilibrium.

---

[4] In other words, we assume $\sigma_i^{t_i} = 0$ that all the newly computed information $UT(h_i^{t_i-1})$should be added to $h_i^{t_i-1}$.

Meanwhile, compared to GRU, which forgets the previously computed state via the reset gate, our lazy transition is allowed to dismiss the newly computed information that is trivial.

Lazy Transition vs. Adaptive Computation Adaptive computation methods like ACT (Graves, 2016) and Adaptive-depth Transformer (Elbayad et al., 2020) learn a generator to output a probability of exiting based on the step output. We argue that these methods are agonistic for the model's convergence because they do not consider the information flow from the input to the corresponding output. By contrast, our method leverages the model's convergence and applies CKA to ponder the correspondence and interdependence between inputs and outputs, where in our case, the model's convergence is the *relaxed* equilibrium.

Lazy Transformer vs. UT, DEQ, and ALBERT LT is parallel to UT (Dehghani et al., 2019), DEQ (Bai et al., 2019), and ALBERT (Lan et al., 2020). We share the idea of recurrence over depth, but we have three main differences: *1)* previous methods require an explicit step encoding for each iteration, whereas we let our lazy transition handle iterations implicitly; *2)* we ponder the significance of a step for different tokens, whereas previous methods refine tokens equally at a step; *3)* we consider the local and token-level equilibrium in addition to the sequence-level equilibrium.

4 Experiment

We divide our empirical studies and experiments into two genres: *1)* we experiment with NMT (our main task) to confirm the effectiveness of our methods for large-scale sequence modeling and further quantitatively justify our hypotheses and assumptions; *2)* we attempt pre-training tasks and two somewhat rare but challenging tasks: the Learning to Execute task (Zaremba and Sutskever, 2014) and the LAMBADA (Paperno et al., 2016) task, to observe the performance on tasks of varying complexity. All the links of datasets, libraries, scripts, and tools marked with ⋄ are listed in Appendix H. We open source code on GitHub.

Training Our code is implemented on Tensorflow 2.6 (Abadi et al., 2016) with 4 NVIDIA TITAN Xp 12G GPU. We implement our model based on the codebase of official UT from tensor2tensor⋄[5] and official CKA⋄. We use the default setting: *universal_transformer_base* from tensor2tensor. Concretely, we use Adam optimizer (Kingma and Ba, 2015) with parameters $\beta_1 = 0.9$,$\beta_2 = 0.997$ and $\epsilon = 10^{-9}$, and a dynamic learning rate with $warm\_up = 8000$ (Vaswani et al., 2017) ($learning\_rate \in (0, 7e^{-4}]$) is employed. We set dropout regularization with a drop rate $rate = 0.1$ and label smoothing with $gamma = 0.1$ (Mezzini, 2018). For data feeding efficiency, each batch of similar-length sequences are padded to the same length and may have a different number of elements in each batch.

Reimplementation and Reconfiguration We reimplement some models on our machine with the same batch size. We compare the reimplemented results to the reported results on the same test set to ensure the difference is less than 5% (or 1 in BLEU). Then, we can confirm the reimplementation and reconfiguration.

4.1 Neural Machine Translation

Dataset and Preprocessing We train a LT encoder-decoder model for machine translation. To be comparable, we share two NMT tasks: *1)* $English \rightarrow German$ of WMT 2014⋄ (Bojar et al., 2014); *2)* $English \rightarrow Romanian$ of WMT 2016⋄ (Bojar et al., 2016). Following the standard evaluation, the model is evaluated on *newstest2014* for $English \rightarrow German$ and *newstest2016* for $English \rightarrow Romanian$. We use the Moses tokenizer⋄ developed by (Koehn et al., 2007) for tokenization and use fastBPE⋄ to learn shared 32K BPE (Sennrich et al., 2016) for a language pair. Data filtering is finished by FAIR tool⋄ (Ng et al., 2019). We use *sacreBleu*⋄ (Post, 2018) with standard settings[6] to evaluate the quality of translation.

Model Configuration The model configurations are identical to base-UT (Dehghani et al., 2019). Specifically, we set model dimension, word embedding, head, and FFN filter to 1024, 1024, 16, and 4096, which results in the same number of parameters (62M) as base-Transformer

---

[5] Note that, the newest UT implementation uses pre-normalization $y = x + f(ln(x))$ instead of reported post-normalization $y = ln(x + f(x))$. UT with pre-normalization shows slight degradation in performance ($\approx 1\%$) but improves stability in training, initialization, and scalability, where x denotes the input, $f(.)$ stands for a sub-layer, and ln is a layer-normalization unit.

(Vaswani et al., 2017). Beam search is configured with beam size 4 and length penalty 0.6. We train the model for 100k iterations. We use $\{T\_enc\_step, T\_dec\_step\} \implies \{I\_enc\_step, I\_dec\_step\}$ to denote a model that runs the maximum T_enc_step and T_dec_step steps in the encoder and decoder respectively for training and runs the maximum I_enc_step and I_dec_step steps in the encoder and decoder respectively for inferring. For instance, $\{6, 6\} \implies \{6, 6\}$ means we set the maximum step to 6 both in the encoder and decoder for training and inferring.

4.1.1 Base Model

In this experiment, we set $\{6, 6\} \implies \{6, 6\}$ (**base-LT**), which is identical to the baseline model: base-UT. Also, it is equivalent to base-Transformer that has 6 layers in both the encoder and decoder. For comparison, we place GRU [7] on top of the UT block for evaluation (base-UT + GRU), similar to that we use our lazy transition, and we also train another UT with ACT (base-UT + ACT). All of these models *require* step encodings for the identification of steps. For the evaluation of how our lazy transition handles iterations without explicit encodings, we instantiate another UT without step encodings (base-UT w/o SE), a similar model that naively repeats one layer without step identifications (Dabre and Fujita, 2019).

Table 1 shows the results on NMT tasks. base-LT outperforms base-UT (row 3&7) by 4%. By observing row 2&3, the performance of UT significantly degrades without using step encodings, which indicates a mechanism for step identification is beneficial for UT. Meanwhile, we find that applying ACT to UT (row 5) can improve the performance on NMT, but GRU (row 6) seems to have no effect.

We observe the equilibrium phenomena in models by giving the CKA exam (Eq.6) in the encoder and decoder. Visualizations are presented in Appendix E. In our case study, all the tokens in base-UT (Appendix E.1 (c,d)) run to an equilibrium synchronously because every step shows similar importance to all the tokens, i.e., all the tokens have similar CKA scores at every step throughout the iteration. It confirms that base-UT tends to find a global equilibrium (Eq.4) for all the tokens, as discussed before. Furthermore, this process is unstable that CKA scores change dramatically at the early steps[8], resulting in unstable refinements (under-refining or over-refining) for some tokens and hurting tokens' local equilibrium. Meanwhile, we are aware that base-UT + ACT (Appendix E.3), base-UT w/o SE (Appendix E.2), and base-UT + GRU (Appendix E.4) show a similar behavior to base-UT throughout the iteration. base-UT + GRU is even more irregular than base-UT at the early steps. Also, we suspect that ACT and GRU have no power to adjust the importance of a step for each token throughout the iteration in NMT.

Compared to that, base-LT (Appendix E.1 (a,b)) enables each token to smoothly find its local equilibrium independently and then turns to oscillate around the *relaxed* equilibrium (Eq.2) together. Specifically, we observe that CKA scores of a step ($\sigma_i^{t_i}$ in Eq.7) differ from one token to the others at every step in the early 4 iterations, which answers our question in §Introduction that a step can show varying importance for all the tokens. Then, base-LT tends to refine token representations based on the sequence-level characteristics at the late 2 steps to oscillate around the *relaxed* equilibrium, resulting in similar CKA scores.

4.1.2 Deep model

Given the nature of the iteration-based model, we can run infinite steps in the encoder and decoder. Therefore, we test the performance beyond 6 steps. In this experiment, we share a challenge with (Bapna et al., 2018; Wang et al., 2019) to train deep models. According to their works, NMT can get significant benefits from many layers in the encoder but not in the decoder. Similarly, we assume we can obtain benefits from running many steps in the encoder. For comparison, we config-

---

[7] We use orthogonal kernels for GRU to solve an optimization problem. See Appendix B for details.

[8] e.g., from step 1 to step 2, the average of absolute difference is 0.221, which is only 0.105 in base-LT.

ure models with $\{20, 6\} \implies \{20, 6\}$ (**20-LT**), which is similar to the 20-layer model in (Bapna et al., 2018; Wang et al., 2019). Beyond 20 steps in the encoder, we further configure a model with $\{40, 6\} \implies \{40, 6\}$ (**40-LT**).

We show the results of deep models in Table 1. Running a large number of steps in the encoder can consistently improve the performance of LT, and deep LT outperforms baseline models. Similar to base-LT, we also consider the CKA exam for the equilibrium phenomena (Appendix E.5) that we obtain similar conclusions to base-LT. It indicates our method is a potential new development for deep models without introducing additional parameters.

Besides, we find UT can get benefits from deep settings, but the performance is not very strong. Intuitively, it is caused by the global equilibrium strategy observed in base-UT that CKA scores change dramatically at the early steps. Therefore, 20-UT cannot smoothly run to an equilibrium, which results in a suboptimal choice. The CKA exam confirms our intuition and draws a similar conclusion of base-UT. By contrast, instead of searching a global equilibrium from scratch, LT searches local equilibriums for tokens at the early steps, which results in varying contributions for different token representations, and then turns to find a global equilibrium for all tokens that we observe a similar behavior to UT. We conjure that LT tends to focus on token-specific characteristics first and then on sequence-specific characteristics.

Table 2: Partial results of zero-shot inferring. Training steps are in bold. SE denotes step encodings. † denotes the best performance. See texts for description.

4.1.3 Zero-shot Inferring

In the above experiments, we set the inference steps as the same as the training steps, sharing the same strategy with previous works (Dehghani et al., 2019; Lan et al., 2020; Bai et al., 2019). We are interested in an asymmetric strategy that the inference steps is different from the training steps. Thus, some steps are zero-shot inferring without explicit training. Recall that the model oscillates around an equilibrium point and outputs similar representations (if iterating). We assume these similar representations can be used for prediction, and we expect similar performance. On the other hand, we visualize the equilibrium phenomena to observe the equilibrium, and zero-shot inferring can quantitatively examine the equilibrium. For this test, we reuse our trained models[9] for $En \rightarrow De$ but change the setting to $\{6, 6\} \implies \{[1, 12], [1, 12]\}$, $\{20, 6\} \implies \{[15, 26], [1, 12]\}$, and $\{40, 6\} \implies \{[35, 46], [1, 12]\}$ respectively. For metrics, we compute avg and std for $nonzero$ (> 1) outputs, where avg indicates how strong the equilibrium point is and std tells us how far the model is oscillating around the point.

We show a part of experimental results in Table 2 (see all the results in Appendix F). We observe that models can achieve competitive performance from zero-shot inferring for some steps close to the training step, and the best performance does not precisely exist at the training step, except for base-UT + ACT. Essentially, we observe and confirm some conclusions as mentioned earlier. **1)** LT's behavior is regularized around the equilibrium when comparing base-LT $std: 5.03$ with base-UT $std: 6.32$ and 20-LT $std: 1.65$ with 20-UT $std: 4.62$. Specifically, LT's lazy transition controls the refinements throughout the iteration that token representations from one step can jointly compose a sequence representation yielding similar performance to the others, whereas UT is

---

[9] Interestingly, we find the reported sinusoidal step encodings for UT support this test without bringing noises to untrained inference steps. However, some absolute methods or look-up methods are problematic.

encouraged to compose the final sequence representations at the training step and lacks a mechanism to control the refinements explicitly. **2)** UT does not oscillate around a strong equilibrium point, i.e., having a suboptimal equilibrium, because base-UT avg : 22.16 and 20-UT avg : 26.03 are not strong. By contrast, LT is stably oscillating around a strong equilibrium and can compose relatively strong sequence representations in different inference steps because base-LT and 20-LT achieve avg : 24.52 and avg : 28.89 respectively. **3)** In both UT and LT, deep models generally find a stronger and more stable equilibrium than base models. **4)** base-UT + GRU fails in this test, which results in low avg : 17.46 and high std : 9.13. We suspect this failure causes by a very irregular behavior at the first step, as the CKA exam indicates in Appendix E.4. **5)** base-UT + ACT outperforms base-UT on avg. However, base-UT is slightly more stable than base-UT + ACT. Besides, base-UT + ACT generally has a larger gradient norm than others, which may impact the stability and convergence in training. *6)* Due to the halting mechanism in ACT, base-UT + ACT seems to halt the process instead of oscillating around the equilibrium because the performance is constant after some steps. **7)** base-UT significantly outperforms base-UT w/o SE on stability, which indicates a mechanism for step identifications is an essential component for stability.

Limitation We do not find a solution to pick the inference step for the best performance, because we do not recognize any pattern. Meanwhile, we could dynamically select a step for a tradeoff between speed and performance by simply copying equilibrium token representations from the previous steps to the next steps. We will leave this for our future work. Besides, we find LT and UT are not stable when translating sentences longer than 50 words. The BLEU score varies from 5 to 60 for different sentences (see Appendix G). We will conduct further experiments to probe this problem.

4.2 Pre-training Task

ALBERT (Lan et al., 2020) study the application of UT in pre-training. Since LT is extended from UT, we study LT in pre-training, sharing the framework of ALBERT. Concretely, our setting is identical to base ALBERT, denoting it as 12-base-ALBERT. We set the model dimension, word embedding dimension, and the maximum number of steps to 768, 128, and 12. Note that in the original ALBERT, they denote steps as layers. As recommended, we generate masked span for the MLM targets using the random strategy from (Joshi et al., 2020), and we use LAMB optimizer$\diamond$ with a learning rate of 0.00176 (You et al., 2020) instead of Adam optimizer. The only change is that we use our LT to replace UT in 12-base-ALBERT, and we denote our model as 12-base-LT. Following the instructions, we pre-train models on BooksCorpus$\diamond$ (Zhu et al., 2015) and English Wikipedia$\diamond$ (Devlin et al., 2019) for 140k steps. Then, we fine-tune on MNLI$\diamond$ (Williams et al., 2018) and SQuAD(v1.1 and v2.0)$\diamond$ (Rajpurkar et al., 2016, 2018). We report the performance on the dev set as the same as (Devlin et al., 2019; Lan et al., 2020).

Model	SQuAD1.1 (F1)	SQuAD2.0 (F1)	MNLI (Acc)
12-base-ALBERT (Lan et al., 2020)	89.3	80.0	81.6
⋆12-base-ALBERT	89.4	80.0	81.4
⋆12-base-ALBERT-ACT	89.5	80.5	81.6
⋆12-base-ALBERT-GRU	86.9	77.8	78.6
OURS: 12-base-LT	89.8	81.1	82.1
⋆24S-base-ALBERT	89.6	80.9	81.7
OURS: 24-base-LT	90.1	81.7	82.6

Table 3: LT in pre-training. ⋆ *denotes the baseline models that are reimplemented.*
