PMI has been introduced by Church and Hanks (1990) as word assosiatio ratio, and since then been used extensively to model semantic similarity. Among several desirable properties, it correlates well with human judgments (Recchia and Jones, 2009).

2.2 Taxonomic normalizations

As pointed out in earlier work, query transitions tend to correlate with taxonomic relations such as generalization and specialization (Lau and Horvitz, 1999; Rieh and Xie, 2006). Boldi et al. (2009) show how knowledge of transition types can positively impact query reformulation. We would like to exploit this information as well. However, rather than building a dedicated supervised classifier for this task we try to capture it directly at the source. First, we notice how string features; e.g., length, and edit distance already model this phenomenon to some extent, and in fact are part of the features used in Boldi et al. (2009). However, these measures are not always accurate and it is easy to find counterexamples both at the term level (e.g., "camping" to "outdoor activities" is a generalization) and character level ("animal pictures" to "cat pictures" is a specialization). Secondly, we propose that by manipulating PMI we can directly model taxonomic relations to some extent.

Rather than using raw PMI values we renormalize them. Notice that it is not obvious in our context how to interpret the relation between strings co-occurring less frequently than random. Such noisy events will yield negative PMI values since $p(w_i, w_j) < p(w_i)p(w_j)$. We enforce zero PMI values for such cases. If PMI is thus constrained to non-negative values, normalization will bound PMI to the range between 0 and 1.

The first type of normalization, called *joint normalization*, uses the negative log joint probability and is defined as

$$\mathrm{PMI(J)}(w_i, w_j) = \mathrm{PMI}(w_i, w_j)/{-\log}(\mathrm{p}(w_i, w_j)).$$

The jointly normalized PMI(J) is a symmetric measure between w_i and w_j in the sense that $\mathrm{PMI(J)}(w_i, w_j) = \mathrm{PMI(J)}(w_j, w_i)$. Intuitively it is a measure of the amount of shared information between the two strings relative to the sum of individual strings information. The advantages of the joint normalization of PMI have been noticed before (Bouma, 2009).

To capture asymmetries in the relation between two strings, we introduce two non-symmetric normalizations which also bound the measure between 0 and 1. The second normalization is called *specialization normalization* and is defined as

$$\mathrm{PMI(S)}(w_i, w_j) = \mathrm{PMI}(w_i, w_j)/ - \log(\mathrm{p}(w_i)).$$

The reason we call it specialization is that PMI(S) favors pairs where the second string is a specialization of the first one. For instance, PMI(S) is at its maximum when $\mathrm{p}(w_i, w_j) = \mathrm{p}(w_j)$ and that means the conditional probability $\mathrm{p}(w_i|w_j)$ is 1 which is an indication of a specialization relation.

The last normalization is called the *generalization normalization* and is defined in the reverse direction as

$$\mathrm{PMI(G)}(w_i, w_j) = \mathrm{PMI}(w_i, w_j)/-\log(\mathrm{p}(w_j)).$$

Again, PMI(G) is a measure between 0 and 1 and is at its maximum value when $\mathrm{p}(w_j|w_i)$ is 1.

The three normalizations provide a richer representation of the association between two strings. Furthermore, jointly, they model in an information-theoretic sense the generalization-specialization dimension directly. As an example, for the query transition "apple" to "mac os" PMI(G)=0.2917 and PMI(S)=0.3686; i.e., there is more evidence for a specialization. Conversely for the query transition "ferrari models" to "ferrari" we get PMI(G)=1 and PMI(S)=0.5558; i.e., the target is a "perfect" generalization of the source[1].

2.3 Syntactic measures

Let V be a finite vocabulary and ξ be the null symbol. An edit operation: insertion, deletion or substitution, is a pair $(a, b) \in \{V \cup \{\xi\} \times V \cup \{\xi\}\} \setminus \{(\xi, \xi)\}$. An alignment between two sequences w_i and w_j is a sequence of edit operations $\omega = (a_1, b_1), ..., (a_n, b_n)$. Given a non-negative cost function c, the cost of an alignment is $c(\omega) = \sum_{i=1}^{n} c(\omega_i)$. The Levenshtein distance, or edit distance, defined over V, $d_V(w_i, w_j)$ between two sequences is the cost of the least expensive sequence of edit operations which transforms w_i into w_j (Levenshtein, 1966). The distance computation can be performed via dynamic programming in time $\mathrm{O}(|w_i||w_j|)$. Similarity at the string, i.e., character or term, level is an indicator of semantic similarity. Edit distance captures the amount of overlap between the queries as sequences of symbols and has been previously used in information retrieval (Boldi et al., 2009; Jones et al., 2006).

We use two basic Levenshtein distance models. The first, called Edit1 (E1), employs a unit cost function for each of the three operations. That is, given a finite vocabulary T containing all terms occurring in queries:

$$\forall a, b \in T, c_{\mathrm{E1}}(a, b) = 1 \text{ if}(a \neq b), 0 \text{ else}.$$

The second, called Edit2 (E2), uses unit costs for insertion and deletion, but computes the character-based edit distance between two terms to decide on the substitution cost. If two terms are very similar at the character level, then the cost of substitution is lower. Given a finite vocabulary T of terms and a finite vocabulary A of characters, the cost function is defined as:

$$\forall a, b \in T, c_{E2}(a, b) = d_A(a, b) \text{ if} a \wedge b \neq \xi, 1 \text{ else}.$$

where $d_A(a, b)$ is linearly scaled between 0 and 1 dividing by $\max(|a|, |b|)$.

We also investigate a variant of the edit distance algorithm in which the terms in the input sequences are sorted, alphabetically, before the distance computation. The motivation behind this variant is the observation that linear order in queries is not always meaningful. For example, it seems reasonable to assume that "brooklyn pizza" and "pizza brooklyn" denote roughly the same user intent. However, the pair has an edit distance of two (delete-insert), while the distance between "brooklyn pizza" and the less relevant "brooklyn college" is only one (substitute). The sorted variant relaxes the ordering constraint.

2.4 Generalized measures

In this section we extend the edit distance framework introduced in Section 2.3 with the semantic similarity measures described in Section 2.1, using the taxonomic normalizations defined in Section 2.2.

Extending the Levenshtein distance framework to take into account semantic similarities between terms is conceptually simple. As in the Edit2 model above we use a modified cost function. We introduce a *cost matrix* encoding individual costs for term substitution operations; the cost is defined in terms of the normalized PMI measures of Section 2.2, recall that these measures range between 0 and 1. Given a normalized similarity measure f, an entry in a cost matrix S for a term pair (w_i, w_j) is defined as:

$$s(w_i, w_j) = 2 - 2f(w_i, w_j) + \epsilon$$

[1] The values are computed from Web counts.

We call these models SEdit (SE), where S specifies the cost matrix used. Given a finite term vocabulary T and cost matrix S, the cost function is defined as:

$$\forall a, b \in T, c_{SE}(a, b) = s(a, b) \text{ if} a \wedge b \neq \xi, 1 \text{ else.}$$

The cost function has the following properties. Since insertion and deletion have unit cost, a term is substituted only if a substitution is "cheaper" than deleting and inserting another term, namely, if the similarity between the terms is not zero. The ϵ correction, coupled with unit insertion and deletion cost, guarantees that for an unrelated term pair a combination of insertion and deletion will always be less costly then a substitution. Thus in the computation of the optimal alignment, each operation cost ranges between 0 and 2.

As a remark on efficiency, we notice that here the semantic similarities are computed between terms, rather than full queries. At the term level, caching techniques can be applied more effectively to speed up feature computation. The cost function is implemented as a pre-calculated matrix, in the next section we describe how the matrix is estimated.

2.5 Cost matrix estimation

In our experiments we evaluated two different sources to obtain the PMI-based cost matrices. In both cases, we assumed that the cost of the substitution of a term with itself (i.e. identity substitution) is always 0. The first technique uses a probabilistic clustering model trained on queries and clicked documents from user query logs. The second model estimates cost matrices directly from user session logs, consisting of approximately 1.3 billion U.S. English queries. A session is defined as a sequence of queries from the same user within a controlled time interval. Let q_s and q_t be a query pair observed in the session data where q_t is issued immediately after q_s in the same session. Let $q'_s = q_s \setminus q_t$ and $q'_t = q_t \setminus q_s$, where $\setminus$ is the set difference operator. The co-occurrence count of two terms w_i and w_j from a query pair q_s, q_t is denoted by $n_{i,j}(q_s, q_t)$ and is defined as:

$$n_{i,j}(q_s, q_t) = \begin{cases} 1 \text{ if } w_i = w_j \wedge w_i \in q_s \wedge w_j \in q_t \\ 1/(|q'_s|\,|q'_t|) \text{ if } w_i \in q'_s \wedge w_j \in q'_t \\ 0 \text{ else.} \end{cases}$$

In other words, if a term occurs in both queries, it has a co-occurrence count of 1. For all other term pairs, a normalized co-occurrence count is computed in order to make sure the sum of co-occurrence counts for a term $w_i \in q_s$ sums to 1 for a given query pair. The normalization is an attempt to avoid the under representation of terms occurring in both queries.

The final co-occurrence count of two arbitrary terms w_i and w_j is denoted by $N_{i,j}$ and it is defined as the sum over all query pairs in the session logs, $N_{i,j} = \sum_{q_s,q_t} n_{i,j}(q_s, q_t)$. Let $N = \sum_{w_i,w_j} N_{i,j}$ be the sum of co-occurrence counts over all term pairs. Then we define a joint probability for a term pair as $\mathrm{p}(w_i, w_j) = \frac{N_{i,j}}{N}$. Similarly, we define the single-occurrence counts and probabilities of the terms by computing the marginalized sums over all term pairs. Namely, the probability of a term w_i occurring in the source query is $\mathrm{p}(i, \cdot) = \sum_{w_j} N_{i,j}/N$ and similarly the probability of a term w_j occurring in the target query is $\mathrm{p}(\cdot, j) = \sum_{w_i} N_{i,j}/N$. Plugging in these values in Eq. (1), we get the $\mathrm{PMI}(w_i, w_j)$ for term pair w_i and w_j, which are further normalized as described in Section 2.2.

More explanation and evaluation of the features described in this section can be found in Ciaramita et al. (2010).

3 Learning to Rank from Co-Click Data

3.1 Extracting Weak Labels from Co-Clicks

Several studies have shown that implicit feedback from clickstream data is a weaker signal than human relevance judgements. Joachims (2002) or Agrawal et al. (2009) presented techniques to convert clicks into labels that can be used for machine learning. Our goal is not to elicit relevance judgments from user clicks, but rather to relate queries by pivoting on commonly clicked search results. The hypothesis is that two queries are related if they lead to user clicks on the same documents for a large amount of documents. This approach is similar to the method proposed by Fitzpatrick and Dent (1997) who attempt to measure the relatedness between two queries by using the normalized intersection of the top 200 retrieval results. We add click information to this setup, thus strengthening the preference for precision over recall in the extraction of related queries.

Table 1: Statistics of co-click data sets.

	train	dev	test
number of queries	250,000	2,500	100
average number of rewrites per query	4,500	4,500	30
percentage of rewrites with $\geq$ 10 coclicks	0.2	0.2	43

In our experiments we created two ground-truth ranking scenarios from the co-click signals. In a first scenario, called *bipartite ranking*, we extract a set of positive and a set of negative query-rewrite pairs from the user logs data. We define positive pairs as queries that have been co-clicked with at least 10 different results, and negative pairs as query pairs with fewer than 10 co-clicks. In a second scenario, called *multipartite ranking*, we define a hierarchy of levels of "goodness", by combining rewrites with the same number of co-clicks at the same level, with increasing ranks for higher number of co-clicks. Statistics on the co-click data prepared for our experiments are given in Table 1.

For training and development, we collected query-rewrite pairs from user query logs that contained at least one positive rewrite. The training set consists of about 1 billion of query-rewrite pairs; the development set contains 10 million query-rewrite pairs. The average number of rewrites per query is around 4,500 for the training and development set, with a very small amount of 0.2% positive rewrites per query. In order to confirm the validity of our co-click hypothesis, and for final evaluation, we held out another sample of query-rewrite pairs for manual evaluation. This dataset contains 100 queries for each of which we sampled 30 rewrites in descending order of co-clicks, resulting in a high percentage of 43% positive rewrites per query. The query-rewrite pairs were annotated by 3 raters as follows: First the raters were asked to rank the rewrites in descending order of relevance using a graphical user interface. Second the raters assigned rank labels and binary relevance scores to the ranked list of rewrites. This labeling strategy is similar to the labeling strategy for synonymy judgements proposed by Rubenstein and Goodenough (1965). Inter-rater agreements on binary relevance judgements, and agreement between rounded averaged human relevance scores and assignments of positive/negative labels by the co-click threshold of 10 produced a Kappa value of 0.65 (Siegel and Castellan, 1988).

3.2 Learning-to-Rank Query Rewrites

3.2.1 Notation

Let $S = \{(x_q, y_q)\}_{q=1}^n$ be a training sample of queries, each represented by a set of rewrites $x_q = \{x_{q1}, \ldots, x_{q,n(q)}\}$, and set of rank labels $y_q = \{y_{q1}, \ldots, y_{q,n(q)}\}$, where $n(q)$ is the number of rewrites for query q. For full rankings of all rewrites for a query, a total order on rewrites is assumed, with rank labels taking on values $y_{qi} \in \{1, \ldots, n(q)\}$. Rewrites of equivalent rank can be specified by assuming a partial order on rewrites, where a multipartite ranking involves $r < n(q)$ relevance levels such that $y_{qi} \in \{1, \ldots, r\}$, and a bipartite ranking involves two rank values $y_{qi} \in \{1, 2\}$ with relevant rewrites at rank 1 and non-relevant rewrites at rank 2.

Let the rewrites in x_q be identified by the integers $\{1, 2, \ldots, n(q)\}$, and let a permutation π_q on x_q be defined as a bijection from $\{1, 2, \ldots, n(q)\}$ onto itself. Let Π_q denote the set of all possible permutations on x_q, and let π_{qi} denote the rank position of x_{qi}. Furthermore, let (i, j) denote a pair of rewrites in x_q and let $\mathcal{P}_q$ be the set of all pairs in x_q.

We associate a feature function $\phi(x_{qi})$ with each rewrite $i = 1, \ldots, n(q)$ for each query q. Furthermore, a partial-order feature map as used in Yue et al. (2007) is created for each rewrite set as follows:

$$\phi(x_q, \pi_q) = \frac{1}{|\mathcal{P}_q|} \sum_{(i,j)\in\mathcal{P}_q} \phi(x_{qi}) - \phi(x_{qj}) \text{sgn}(\frac{1}{\pi_{qi}} - \frac{1}{\pi_{qj}}).$$

The goal of learning a ranking over the rewrites x_q for a query q can be achieved either by sorting the rewrites according to the rewrite-level ranking function $f(x_{qi}) = \langle w, \phi(x_{qi}) \rangle$, or by finding the permutation that scores highest according to a query-level ranking function $f(x_q, \pi_q) = \langle w, \phi(x_q, \pi_q) \rangle$.

In the following, we will describe a variety of well-known ranking objectives, and extensions thereof, that are used in our experiments. Optimization is done in a stochastic gradient descent (SGD) framework. We minimize an empirical loss objective

$$\min_w \sum_{x_q, y_q} \ell(w)$$

by stochastic updating

$$w_{t+1} = w_t - \eta_t g_t$$

where η_t is a learning rate, and g_t is the gradient

$$g_t = \nabla \ell(w)$$

where

$$\nabla \ell(w) = \left\langle \frac{\partial}{\partial w_1}\ell(w), \frac{\partial}{\partial w_2}\ell(w), \ldots, \frac{\partial}{\partial w_n}\ell(w) \right\rangle .$$

3.2.2 Listwise Hinge Loss

Standard ranking evaluation metrics such as (Mean) Average Precision (Manning et al., 2008) are defined on permutations of whole lists and are not decomposable over instances. Joachims (2005), Yue et al. (2007), or Chakrabarti et al. (2008) have proposed multivariate SVM models to optimize such listwise evaluation metrics. The central idea is to formalize the evaluation metric as a prediction loss function L, and incorporate L via margin rescaling into the hinge loss function, such that an upper bound on the prediction loss is achieved (see Tsochantaridis et al. (2004), Proposition 2).

The loss function is given by the following listwise hinge loss:

$$\ell_{lh}(w) = (L(y_q, \pi_q^*) - \langle w, \phi(x_q, y_q) - \phi(x_q, \pi_q^*)\rangle)_+$$

where π_q^* is the maximizer of the $\max_{\pi_q \in \Pi_q \setminus y_q} L(y_q, \pi_q^*) + \langle w, \phi(x_q, \pi_q^*)\rangle$ expression, $(z)_+ = \max\{0, z\}$ and $L(y_q, \pi_q) \in [0, 1]$ denotes a prediction loss of a predicted ranking π_q compared to the ground-truth ranking y_q.[2]

In this paper, we use Average Precision (AP) as prediction loss function s.t.

$$L_{AP}(y_q, \pi_q) = 1 - AP(y_q, \pi_q)$$

where AP is defined as follows:

$$\begin{aligned} AP(y_q, \pi_q) &= \frac{\sum_{j=1}^{n(q)} Prec(j) \cdot (|y_{qj} - 2|)}{\sum_{j=1}^{n(q)} (|y_{qj} - 2|)}, \\ Prec(j) &= \frac{\sum_{k:\pi_{qk} \leq \pi_{qj}} (|y_{qk} - 2|)}{\pi_{qj}}. \end{aligned}$$

Note that the ranking scenario is in this case bipartite with $y_{qi} \in \{1, 2\}$.

The derivatives for ℓ_{lh} are as follows:

$$\frac{\partial}{\partial w_k}\ell_{lh} = \begin{cases} 0 \text{ if } \left(\langle w, \phi(x_q, y_q) - \phi(x_q, \pi_q^*)\rangle\right) \\ \qquad > L(y_q, \pi_q^*), \\ -(\phi_k(x_q, y_q) - \phi_k(x_q, \pi_q^*)) \text{ else.} \end{cases}$$

SGD optimization involves computing π_q^* for each feature and each query, which can be done efficiently using the greedy algorithm proposed by Yue et al. (2007). We will refer to this method as the *SVM-MAP* model.

3.2.3 Pairwise Hinge Loss for Bipartite and Multipartite Ranking

Joachims (2002) proposed an SVM method that defines the ranking problem as a pairwise classification problem. Cortes et al. (2007) extended this method to a magnitude-preserving version by penalizing a pairwise misranking by the magnitude of the difference in preference labels. A position-sensitive penalty for pairwise ranking SVMs was proposed by Riezler and De Bona (2009) and Chapelle and Keerthi (2010), and earlier for perceptrons by Shen and Joshi (2005). In the latter approaches, the magnitude of the difference in inverted ranks is accrued for each misranked pair. The idea is to impose an increased penalty for misrankings at the top of the list, and for misrankings that involve a difference of several rank levels.

Similar to the listwise case, we can view the penalty as a prediction loss function, and incorporate it into the hinge loss function by rescaling the margin by a pairwise prediction loss function $L(y_{qi}, y_{qj})$. In our experiments we used a position-sensitive prediction loss function

$$L(y_{qi}, y_{qj}) = |\frac{1}{y_{qi}} - \frac{1}{y_{qj}}|$$

defined on the difference of inverted ranks. The margin-rescaled pairwise hinge loss is then defined as follows:

$$\begin{aligned} \ell_{ph}(w) = \sum_{(i,j) \in \mathcal{P}_q} &(L(y_{qi}, y_{qj}) - \\ &\langle w, \phi(x_{qi}) - \phi(x_{qj})\rangle \operatorname{sgn}(\frac{1}{y_{qi}} - \frac{1}{y_{qj}}))_+ \end{aligned}$$

[2] We slightly abuse the notation y_q to denote the permutation on x_q that is induced by the rank labels. In case of full rankings, the permutation π_q corresponding to ranking y_q is unique. For multipartite and bipartite rankings, there is more than one possible permutation for a given ranking, so that we let π_q denote a permutation that is consistent with ranking y_q.

Table 2: Experimental evaluation of *random* and *best feature* baselines, and *log-linear*, *SVM-MAP*, *SVM-bipartite*, *SVM-multipartite*, and *SVM-multipartite-margin-rescaled* learning-to-rank models on manually labeled test set.

	MAP	NDCG@10	AUC	Prec@1	Prec@3	Prec@5
Random	51.8	48.7	50.4	45.6	45.6	46.6
Best-feature	71.9	70.2	74.5	70.2	68.1	68.7
SVM-bipart.	73.7	73.7	74.7	79.4	70.1	70.1
SVM-MAP	74.3	75.2	75.3	76.3	71.8	72.0
Log-linear	74.7	75.1	75.7	75.3	72.2	71.3
SVM-pos.-sens.	75.7	76.0	76.6	82.5	72.9	73.0
SVM-multipart.	**76.5**	**77.3**	**77.2**	**83.5**	**74.2**	**73.6**

The derivative of ℓ_{ph} is calculated as follows:

$$\frac{\partial}{\partial w_k}\ell_{lp} = \begin{cases} 0 \text{ if } (\langle w, \phi(x_{qi}) - \phi(x_{qj})\rangle \\ \qquad \text{sgn}(\frac{1}{y_{qi}} - \frac{1}{y_{qj}})) > L(y_{qi}, y_{qj}), \\ -(\phi_k(x_{qi}) - \phi_k(x_{qj}))\text{sgn}(\frac{1}{y_{qi}} - \frac{1}{y_{qj}}) \\ \quad \text{else.} \end{cases}$$

Note that the effect of inducing a position-sensitive penalty on pairwise misrankings applies only in case of full rankings on $n(q)$ rank levels, or in case of multipartite rankings involving $2 < r < n(q)$ rank levels. Henceforth we will refer to margin-rescaled pairwise hinge loss for multipartite rankings as the *SVM-pos.-sens.* method.

Bipartite ranking is a special case where $L(y_{qi}, y_{qj})$ is constant so that margin rescaling does not have the effect of inducing position-sensitivity. This method will be referred to as the *SVM-bipartite* model.

Also note that for full ranking or multipartite ranking, predicting a low ranking for an instance that is ranked high in the ground truth has a domino effect of accruing an additional penalty at each rank level. This effect is independent of margin-rescaling. The method of pairwise hinge loss for multipartite ranking with constant margin will henceforth be referred to as the *SVM-multipartite* model.

Computation in SGD optimization is dominated by the number of pairwise comparisons $|\mathcal{P}_q|$ for each query. For full ranking, a comparison of $|\mathcal{P}_q| = \binom{n(q)}{2}$ pairs has to be done. In the case of multipartite ranking at r rank levels, each including $|l_i|$ rewrites, pairwise comparisons between rewrites at the same rank level can be ignored. This reduces the number of comparisons to $|\mathcal{P}_q| = \sum_{i=1}^{r-1}\sum_{j=i+1}^{r}|l_i||l_j|$. For bipartite ranking of p positive and n negative instances, $|\mathcal{P}_q| = p \cdot n$ comparisons are necessary.

3.2.4 Log-linear Models for Bipartite Ranking

A probabilistic model for bipartite ranking can be defined as the conditional probability of the set of relevant rewrites, i.e., rewrites at rank level 1, given all rewrites at rank levels 1 and 2. A formalization in the family of log-linear models yields the following logistic loss function ℓ_{llm} that was used for discriminative estimation from sets of partially labeled data in Riezler et al. (2002):

$$\ell_{llm}(w) = -\log \frac{\sum_{x_{qi} \in x_q | y_{qi}=1} e^{\langle w, \phi(x_{qi})\rangle}}{\sum_{x_{qi} \in x_q} e^{\langle w, \phi(x_{qi})\rangle}}.$$

The gradient of ℓ_{llm} is calculated as a difference between two expectations:

$$\frac{\partial}{\partial w_k}\ell_{llm} = -p_w\left[\phi_k | x_q; y_{qi} = 1\right] + p_w\left[\phi_k | x_q\right].$$

The SGD computation for the log-linear model is dominated by the computation of expectations for each query. The logistic loss for bipartite ranking is henceforth referred to as the *log-linear* model.

4 Experimental Results

In the experiments reported in this paper, we trained linear ranking models on 1 billion query-rewrite pairs using 60 dense features, combined of the building blocks of syntactic and semantic similarity metrics under different estimations of cost matrices. Development testing was done on a data set that was held-out from the training set. Final testing was carried out on the manually labeled dataset. Data statistics for all sets are given in Table 1.

Table 3: P-values computed by approximate randomization test for 15 pairwise comparisons of result differences.

	Best-feature	SVM-bipart.	SVM-MAP	Log-linear	SVM-pos.-sens.	SVM-multipart.
Best-feature	-	< 0.005	< 0.005	< 0.005	< 0.005	< 0.005
SVM-bipart.	-	-	$\mathbf{0.324}$	< 0.005	< 0.005	< 0.005
SVM-MAP	-	-	-	$\mathbf{0.374}$	< 0.005	< 0.005
Log-linear	-	-	-	-	$\mathbf{0.053}$	< 0.005
SVM-pos.-sens.	-	-	-	-	-	< 0.005
SVM-multipart.	-	-	-	-	-	-

Model selection was performed by adjusting meta-parameters on the development set. We trained each model at constant learning rates $\eta \in \{1, 0.5, 0.1, 0.01, 0.001\}$, and evaluated each variant after every fifth out of 100 passes over the training set. The variant with the highest MAP score on the development set was chosen and evaluated on the test set. This early stopping routine also served for regularization.

Evaluation results for the systems are reported in Table 2. We evaluate all models according to the following evaluation metrics: Mean Average Precision (MAP), Normalized Discounted Cumulative Gain with a cutoff at rank 10 (NDCG@10), Area-under-the-ROC-curve (AUC), Precision@n[3]. As baselines we report a random permutation of rewrites (*random*), and the single dense feature that performed best on the development set (*best-feature*). The latter is the log-probability assigned to the query-rewrite pair by the probabilistic clustering model used for cost matrix estimation (see Section 2.5). P-values are reported in Table 3 for all pairwise comparisons of systems (except the random baseline) using an Approximate Randomization test where stratified shuffling is applied to results on the query level (see Noreen (1989)). The rows in Tables 2 and 3 are ranked according to MAP values of the systems. *SVM-multipartite* outperforms all other ranking systems under all evaluation metrics at a significance level ≥ 0.995. For all other pairwise comparisons of result differences, we find result differences of systems ranked next to each other to be not statistically significant. All systems outperform the *random* and *best-feature* baselines with statistically significant result differences. The distinctive advantage of the *SVM-multipartite* models lies in the possibility to rank rewrites with very high co-click numbers even higher than rewrites with reasonable numbers of co-clicks. This preference for ranking the top co-clicked rewrites high seems the best avenue for transferring co-click information to the human judgements encoded in the manually labeled test set. Position-sensitive margin rescaling does not seem to help, but rather seems to hurt.

5 Discussion

We presented an approach to learn rankings of query rewrites from large amounts of user query log data. We showed how to use the implicit co-click feedback about rewrite quality in user log data to train ranking models that perform well on ranking query rewrites according to human quality standards. We presented large-scale experiments using SGD optimization for linear ranking models. Our experimental results show that an SVM model for multipartite ranking outperforms other linear ranking models under several evaluation metrics. In future work, we would like to extend our approach to other models, e.g., sparse combinations of lexicalized features.

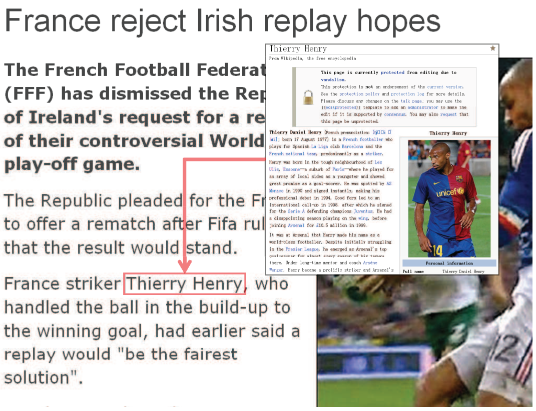
Abstract

This paper address the problem of entity linking. Specifically, given an entity mentioned in unstructured texts, the task is to link this entity with an entry stored in the existing knowledge base. This is an important task for information extraction. It can serve as a convenient gateway to encyclopedic information, and can greatly improve the web users' experience. Previous learning based solutions mainly focus on classification framework. However, it's more suitable to consider it as a ranking problem. In this paper, we propose a learning to rank algorithm for entity linking. It effectively utilizes the relationship information among the candidates when ranking. The experiment results on the TAC 2009[1] dataset demonstrate the effectiveness of our proposed framework. The proposed method achieves 18.5% improvement in terms of accuracy over the classification models for those entities which have corresponding entries in the Knowledge Base. The overall performance of the system is also better than that of the state-of-the-art methods.

1 Introduction

The entity linking task is to map a named-entity mentioned in a text to a corresponding entry stored in the existing Knowledge Base. The Knowledge Base can be considered as an encyclopedia for entities. It contains definitional, descriptive or relevant information for each entity. We can acquire the knowledge of entities by looking up the Knowledge Base. Wikipedia is an online encyclopedia, and now it becomes one of the largest repositories of encyclopedic knowledge. In this paper, we use Wikipedia as our Knowledge Base.

Entity linking can be used to automatically augment text with links, which serve as a convenient gateway to encyclopedic information, and can greatly improve user experience. For example, Figure 1 shows news from BBC.com. When a user is interested in ”Thierry Henry”, he can acquire more detailed information by linking *”Thierry Henry”* to the corresponding entry in the Knowledge Base.



France reject Irish replay hopes

The French Football Federat
(FFF) has dismissed the Rep
of Ireland's request for a re
of their controversial World
play-off game.

The Republic pleaded for the Fr
to offer a rematch after Fifa rul
that the result would stand.

France striker Thierry Henry, who handled the ball in the build-up to the winning goal, had earlier said a replay would "be the fairest solution".

Thierry Daniel Henry (French pronunciation: [tjɛʁi ɑ̃ʁi]; born 17 August 1977) is a French footballer who plays for Spanish La Liga club Barcelona and the French national team, predominantly as a striker.

Henry was born in the tough neighbourhood of Les Ulis, Essonne—a suburb of Paris—where he played for an array of local sides as a youngster and showed great promise as a goal-scorer. He was spotted by AS Monaco in 1990 and signed instantly, making his professional debut in 1994. Good form led to an international call-up in 1998, after which he signed for the Serie A defending champions Juventus. He had a disappointing season playing on the wing, before joining Arsenal for £10.5 million in 1999.

It was at Arsenal that Henry made his name as a world-class footballer. Despite initially struggling in the Premier League, he emerged as Arsenal's top goal-scorer for almost every season of his tenure there. Under long-time mentor and coach Arsène Wenger, Henry became a prolific striker and Arsenal's

Figure 1: Entity linking example

Entity linking is also useful for some information extraction (IE) applications. We can make use of information stored in the Knowledge Base to assist the IE problems. For example, to answer the question *”When was the famous basketball player Jordan born?”*, if the Knowledge Base contains the en-

tity of basketball player Michael Jordan and his information (such as infobox[2] in Wikipedia), the correct answer *”February 17, 1963”* can be easily retrieved.

Entity linking encounters the problem of entity ambiguity. One entity may refer to several entries in the Knowledge Base. For example, the entity ”Michael Jordan” can be linked to the basketball player or the professor in UC Berkeley.

Previous solutions find that classification based methods are effective for this task (Milne and Witten, 2008). These methods consider each candidate entity independently, and estimate a probability that the candidate entry corresponds to the target entity. The candidate with the highest probability was chosen as the target entity. In this way, it’s more like a ranking problem rather than a classification problem. Learning to rank methods take into account the relations between candidates, which is better than considering them independently. Learning to rank methods are popular in document information retrieval, but there are few studies on information extraction. In this paper, we investigate the application of learning to rank methods to the entity linking task. And we compare several machine learning methods for this task. We investigate the pairwise learning to rank method, Ranking Perceptron (Shen and Joshi, 2005), and the listwise method, ListNet (Cao et al., 2007). Two classification methods, SVM and Perceptron, are developed as our baselines. In comparison, learning to rank methods show significant improvements over classification methods, and ListNet achieves the best result. The best overall performance is also achieved with our proposed framework.

This paper is organized as follows. In the next section we will briefly review the related work. We present our framework for entity linking in section 3. We then describe in section 4 learning to rank methods and features for entity linking. A top1 candidate validation module will be explained in section 5. Experiment results will be discussed in section 6. Finally, we conclude the paper and discusses the future work in section 7.

2 Related Work

There are a number of studies on named entity disambiguation, which is quite relevant to entity linking. Bagga and Baldwin (1998) used a Bag of Words (BOW) model to resolve ambiguities among people. Mann and Yarowsky (2003) improved the performance of personal names disambiguation by adding biographic features. Fleischman (2004) trained a Maximum Entropy model with Web Features, Overlap Features, and some other features to judge whether two names refer to the same individual. Pedersen (2005) developed features to represent the context of an ambiguous name with the statistically significant bigrams.

These methods determined to which entity a specific name refer by measuring the similarity between the context of the specific name and the context of the entities. They measured similarity with a BOW model. Since the BOW model describes the context as a term vector, the similarity is based on co-occurrences. Although a term can be one word or one phrase, it can’t capture various semantic relations. For example, ”Michael Jordan now is the boss of Charlotte Bobcats” and ”Michael Jordan retired from NBA”. The BOW model can’t describe the relationship between *Charlotte Bobcats* and *NBA*. Malin and Airoldi (2005) proposed an alternative similarity metric based on the probability of walking from one ambiguous name to another in a random walk within the social network constructed from all documents. Minkov (2006) considered extended similarity metrics for documents and other objects embedded in graphs, facilitated via a lazy graph walk, and used it to disambiguate names in email documents. Bekkerman and McCallum (2005) disambiguated web appearances of people based on the link structure of Web pages. These methods tried to add background knowledge via social networks. Social networks can capture the relatedness between terms, so the problem of a BOW model can be solved to some extent. Xianpei and Jun (2009) proposed to use Wikipedia as the background knowledge for disambiguation. By leveraging Wikipedia’s semantic knowledge like social relatedness between named entities and associative relatedness between concepts, they can measure the similarity between entities more accurately. Cucerzan (2007) and

[2] Infoboxes are tables with semi-structured information in some pages of Wikipedia

Bunescu (2006) used Wikipedia's category information in the disambiguation process. Using different background knowledge, researcher may find different efficient features for disambiguation.

Hence researchers have proposed so many efficient features for disambiguation. It is important to integrate these features to improve the system performance. Some researchers combine features by manual rules or weights. However, it is not convenient to directly use these rules or weights in another data set. Some researchers also try to use machine learning methods to combine the features. Milne and Witten (2008) used typical classifiers such as Naive Bayes, C4.5 and SVM to combine features. They trained a two-class classifier to judge whether a candidate is a correct target. And then when they try to do disambiguation for one query, each candidate will be classified into the two classes: correct target or incorrect target. Finally the candidate answer with the highest probability will be selected as the target if there are more than one candidates classified as answers. They achieve great performance in this way with three efficient features. The classifier based methods can be easily used even the feature set changed. However, as we proposed in Introduction, it's not the best way for such work. We'll detail the learning to rank methods in the next section.

3 Framework for Entity Linking

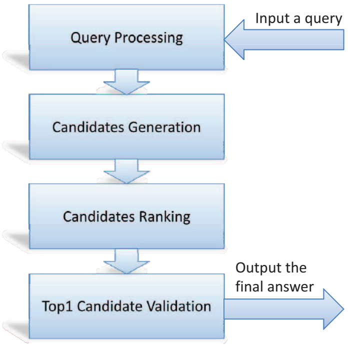

Figure 2: The framework for entity linking

Entity linking is to align a named-entity mentioned in a text to a corresponding entry stored in the existing Knowledge Base. We proposed a framework to solve the "entity linking" task. As illustrated in Figure 2, when inputting a query which is an entity mentioned in a text, the system will return the target entry in Knowledge Base with four modules:

1. Query Processing. First, we try to correct the spelling errors in the queries by using query spelling correction supplied by Google. Second, we expand the query in three ways: expanding acronym queries from the text where the entity is located, expanding queries with the corresponding redirect pages of Wikipedia and expanding queries by using the anchor text in the pages from Wikipedia.

2. Candidates Generation. With the queries generated in the first step, the candidate generation module retrieves the candidates from the Knowledge Base. The candidate generation module also makes use of the disambiguation pages in Wikipedia. If there is a disambiguation page corresponding to the query, the linked entities listed in the disambiguation page are added to the candidate set.

3. Candidates Ranking. In the module, we rank all the candidates with learning to rank methods.

4. Top1 Candidate Validation. To deal with those queries without appropriate matching, we finally add a validation module to judge whether the top one candidate is the target entry.

The detail information of ranking module and validation module will be introduced in next two sections.

4 Learning to Rank Candidates

In this section we first introduce the learning to rank methods, and then describe the features for ranking methods.

4.1 Learning to rank methods

Learning to rank methods are popular in the area of document retrieval. There are mainly two types of learning to rank methods: pairwise and listwise. The pairwise approach takes as instances object pairs in a ranking list for a query in learning. In this way, it transforms the ranking problem to the classification problem. Each pair from ranking list is labeled based on the relative position or with the score of ranking objects. Then a classification model can be trained on the labeled data and then be used for ranking. The pairwise approach has advantages in that the existing methodologies on classification can be applied directly. The listwise approach takes candidate lists for a query as instances to train ranking models. Then it trains a ranking function by minimizing a listwise loss function defined on the predicted list and the ground truth list.

To describe the learning to rank methods, we first introduce some notations:

- Query set Q = .
- Each query is associated with a list of objects(in document retrieval, the objects should be documents), .
- Each object list has a labeled score list represents the relevance degree between the objects and the query.
- Features vectors from each query-object pair, .
- Ranking function f, for each it outputs a score . After the training phase, to rank the objects, just use the ranking function f to output the score list of the objects, and rank them with the score list.

In the paper we will compare two different learning to rank approaches: Ranking Perceptron for pairwise and ListNet for listwise. A detailed introduction on Ranking Perceptron (Shen and Joshi, 2005) and ListNet (Cao et al., 2007) is given.

4.1.1 Ranking Perceptron

Ranking Perceptron is a pairwise learning to rank method. The score function is defined as .

For each pair , is computed. With a given margin function and a positive rate , if , an update is performed:

After iterating enough times, we can use the function to rank candidates.

4.1.2 ListNet

ListNet takes lists of objects as instances in learning. It uses a probabilistic method to calculate the listwise loss function.

ListNet transforms into probability distributions both the scores of the objects assigned by the oracle ranking function and the real score of the objects given by human.

Let denote a permutation on the objects. In ListNet algorithm, the probability of with given scores is defined as:

Then the top k probability of $\mathcal{G}$ can be calculated as:

$$\mathcal{G}$$

The ListNet uses a listwise loss function with Cross Entropy as metric:

$$\mathcal{G}$$

Denote as the ranking function based on Neural Network model . The gradient of with respect to parameter can be calculated as:

$$\mathcal{G}$$

In each iteration, the is updated with in a gradient descent way. Here is the learning rate.

To train a learning to rank model, the manually evaluated score list for each query's candidate list is required. We assign 1 to the real target entity and 0 to the others.

4.2 Features for Ranking

In the section, we will introduce the features used in the ranking module. For convenience, we define some symbols first:

> Q represents a query, which contains a named entity mentioned in a text. CSet represents the candidate entries in Knowledge Base for the query Q. C represents a candidate in CSet.
>
> Q's nameString represents the name string of Q. Q's sourceText represents the source text of Q. Q's querySet represents the queries which are expansions of Q's nameString.
>
> C's title represents the title of corresponding Wikipedia article of C. C's titleExpand represents the union set of the redirect set of C and the anchor text set of C. C's article represents the Wikipedia article of C.
>
> C's nameEntitySet represents the set of all named entities in C's article labeled by Stanford NER (Finkel et al., 2005). Q's nameEntitySet represents the set of all named entities in Q's sourceText.
>
> C's countrySet represents the set of all countries in C's article, and we detect the countries from text via a manual edited country list. Q's countrySet represents the set of all countries in Q's sourceText. C's countrySetInTitle represents the set of countries exist in one of the string s from C's titleExpand.
>
> C's citySetInTitle represents the set of all cities exist in one of the string s from C's titleExpand, and we detect the cities from text via a manual edited list of famous cities. Q's citySet represents the set of all cities in Q's sourceText.
>
> Q's type represents the type of query Q. It's labeled by Stanford NER. C's type is manually labeled already in the Knowledge Base.

The features that used in the ranking module can be divided into 3 groups: Surface, Context and Special. Each of these feature groups will be detailed next.

4.2.1 Surface Features

The features in Surface group are used to measure the similarity between the query string and candidate entity's name string.

> StrSimSurface. The feature value is the maximum similarity between the Q's nameString and each string s in the set C's titleExpand. The string similarity is measured with edit distance.
>
> ExactEqualSurface. The feature value is 1 if there is a string s in set C's titleExpand same as the Q's nameString, or the Candidate C is extracted from the disambiguation page. In other case, the feature value is set to 0.
>
> StartWithQuery. The feature value is 1 if there is a string s in set C's titleExpand starting with the Q's nameString, and C's ExactEqualSurface is not 1. In other case, the feature value is set to 0.
>
> EndWithQuery. The feature value is 1 if there is a string s in set C's titleExpand ending with the Q's nameString, and C's ExactEqualSurface is not 1. In other case, the feature value is set to 0.
>
> StartInQuery. The feature value is 1 if there is a string s in set C's titleExpand that s is the prefix of the Q's nameString, and C's ExactEqualSurface is not 1. In other case, the feature value is set to 0.
>
> EndInQuery. The feature value is 1 if there is a string s in set C's titleExpand that s is the postfix of the Q's nameString, and C's ExactEqualSurface is not 1. In other case, the feature value is set to 0.
>
> EqualWordNumSurface. The feature value is the maximum number of same words between the Q's nameString and each string s in the set C's titleExpand.
>
> MissWordNumSurface. The feature value is the minimum number of different words between the Q's nameString and each string s in the set C's titleExpand.

4.2.2 Context Features

The features in Context group are used to measure the context relevance between query and the candidate entity. We mainly consider the TF-IDF similarity and named entity co-occurrence.

TFSimContext. The feature value is the TF-IDF similarity between the C's article and Q's sourceText.

TFSimRankContext. The feature value is the inverted rank of C's TFSimContext in the CSet.

AllWordsInSource. The feature value is 1 if all words in C's title exist in Q's sourceText, and in other case, the feature value is set to 0.

NENumMatch. The feature value is the number of of same named entities between C's nameEntitySet and Q's nameEntitySet. Two named entities are judged to be the same if and only if the two named entities' strings are identical.

4.2.3 Special Features

Besides the features above, we also find that the following features are quite significant in the entity linking task: country names, city names and types of queries and candidates.

CountryInTextMatch. The feature value is the number of same countries between C's countrySet and Q's countrySet.

CountryInTextMiss. The feature value is the number of countries that exist in Q's countrySet but do not exist in C's countrySet.

CountryInTitleMatch. The feature value is the number of same countries between C's countrySetInTitle and Q's countrySet.

CountryInTitleMiss. The feature value is the number of countries that exist in C's countrySetInTitle but do not exist in Q's countrySet.

CityInTitleMatch. The feature value is the number of same cities between C's citySetInTitle and Q's citySet.

TypeMatch. The feature value is 0 if C's type is not consistent with Q's type, in other case, the feature value is set to 1.

When ranking the candidates in CSet, the features' value was normalized into [0, 1] to avoid noise caused by large Integer value or small double value.

5 Top 1 Candidate Validation

To deal with those queries without target entities in the Knowledge Base, we supply a Top 1 candidate validation module. In the module, a two-class classifier is used to judge whether the top one candidate is the true target entity. The top one candidate selected from the ranking module can be divided into two classes: target and non-target, depending on whether it's the correct target link of the query. According to the performance of classification, SVM is chosen as the classifier (In practice, the libsvm package is used) and the SVM classifier is trained on the entire training set.

Most of the features used in the validation module are the same as those in ranking module, such as StrSimSurface, EqualWordNumSurface, MissWordNumSurface, TFSimContext, AllWordsInSource, NENumMatch and TypeMatch. We also design some other features, as follows:

AllQueryWordsInWikiText. The feature value is one if Q's textRetrievalSet contains C, and in other case the feature value is set to zero. The case that Q's textRetrievalSet contains C means the candidate C's article contains the Q's nameString.

CountryInTextPer. The feature is the percentage of countries from Q's countrySet exist in C's countrySet too. The feature can be seen as a normalization of CountryInTextMatch/Miss features in ranking module.

ScoreOfRank. The feature value is the score of the candidate given by the ranking module. The ScoreOfRank takes many features in ranking module into consideration, so only fewer features of ranking module are used in the classifier.

6 Experiment and Analysis

6.1 Experiment Setting

Algorithm	Accuracy	Improvement over SVM
ListNet	**0.9045**	+18.5%
Ranking Perceptron	0.8842	+15.8%
SVM	0.7636	-
Perceptron	0.7546	-1.2%

Table 1: Evaluation of different ranking algorithm

Entity linking is initiated as a task in this year's TAC-KBP[3] track, so we use the data from this track. The entity linking task in the KBP track is to map an entity mentioned in a news text to the Knowledge Base, which consist of articles from Wikipedia. The KBP track gives a sample query set which consists of 416 queries for developing. The test set consists of 3904 queries. 2229 of these queries can't be mapped to Knowledge Base, for which the systems should return NIL links. The remaining 1675 queries all can be aligned to Knowledge Base. We will firstly analyze the ranking methods with those non-NIL queries, and then with an additional validation module, we train and test with all queries including NIL queries.

As in the entity linking task of KBP track, the accuracy is taken as

$$\frac{\texttt{correct answered queries}}{\texttt{total queries}}$$

6.2 Evaluation of Machine Learning Methods in ranking

As mentioned in the section of related work, learning to rank methods in entity linking performs better than the classification methods. To justify this, some experiments are designed to evaluate the performance of our ranking module when adopting different algorithms.

To evaluate the performance of the ranking module, we use all the queries which can be aligned to a target entry in the Knowledge Base. The training set contains 285 valid queries and the test set contains 1675.

Set	Features in Set
Set1	Surface Features
Set2	Set1+TF-IDF Features
Set3	Set2+AllWordsInSource
Set4	Set3+NENumMatch
Set5	Set4+CountryInTitle Features
Set6	Set5+CountryInText Features
Set7	Set6+CityInTitleMatch
Set8	Set7+MatchType

Table 2: Feature Sets

Three algorithms are taken into comparison: ListNet, Ranking Perceptron, and classifier based methods. The classifier based methods are trained by dividing the candidates into two classes: target and non-target. Then, the candidates are ranked according to their probability of being classified as target. two different classifiers are tested here, SVM and Perceptron.

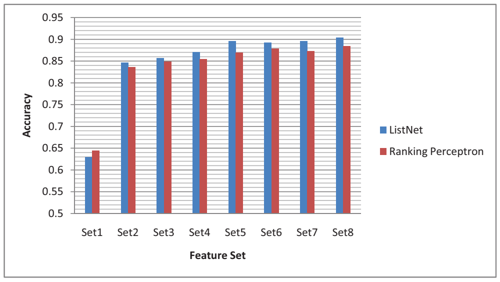

Figure 3: Comparison of ListNet and Ranking Perceptron

As shown in Table 1, the two learning to rank methods perform much better than the classification based methods. The experiment results prove our point that the learning to rank algorithms are more suitable in this work. And the ListNet shows slight improvement over Ranking Perceptron, but since the improvement is not so significant, maybe it depends on the feature set. To confirm this, we compare the two algorithms with different features, as showed in Table 2. In Figure 3, The ListNet outperforms Ranking Perceptron with all feature sets except Set1, which indicates that the listwise approach is more suitable than the pairwise approach. The pairwise approach suffers from two problems: first, the objective of learning is to minimize classification er-

[3] http://apl.jhu.edu/ paulmac/kbp.html

Systems	Accuracy of all queries	Accuracy of non-NIL queries	Accuracy of NIL queries
System1	0.8217	0.7654	0.8641
System2	0.8033	0.7725	0.8241
System3	0.7984	0.7063	0.8677
ListNet+SVM	**0.8494**	**0.79**	**0.8941**

Table 3: Evaluation of the overall performance, compared with KBP results (System 1-3 demonstrate the top three ranked systems)

rors but not to minimize the errors in ranking; second, the number of pairs generated from list varies largely from list to list, which will result in a model biased toward lists with more objects. The issues are also discussed in (Y.B. Cao et al., 2006; Cao et al., 2007). And the listwise approach can fix the problems well.

As the feature sets are added incrementally, it can be used for analyzing the importance of the features to the ranking task. Although Surface Group only takes into consideration the candidate's title and the query's name string, its accuracy is still higher than 60%. This is because many queries have quite small number of candidates, the target entry can be picked out with the surface features only. The result shows that after adding the TF-IDF similarity related features, the accuracy increases significantly to 84.5%. Although TF-IDF similarity is a simple way to measure the contextual similarity, it performs well in practice. Another improvement is achieved when adding the CountryInTitleMatch and CountryInTitleMiss features. Since a number of queries in test set need to disambiguate candidates with different countries in their titles, the features about country in the candidates' title are quite useful to deal with these queries. But it doesn't mean that the features mentioned above are the most important. Because many features correlated with each other quite closely, adding these features doesn't lead to remarkable improvement. The conclusion from the results is that the Context Features significantly improve the ranking performance and the Special Features are also useful in the entity linking task.

6.3 Overall Performance Evaluation

We are also interested in overall performance with the additional validation module. We use all the 3904 queries as the test set, including both NIL and non-NIL queries. The top three results from the KBP track (McNamee and Dang, 2009) are selected as comparison. The evaluation result in Table 3 shows that our proposed framework outperforms the best result in the KBP track, which demonstrates the effectiveness of our methods.

7 Conclusions and Future Work

This paper demonstrates a framework of learning to rank for linking entities with the Knowledge Base. Experimenting with different ranking algorithms, it shows that the learning to rank methods perform much better than the classification methods in this problem. ListNet achieves 18.5% improvement over SVM, and Ranking Perceptron gets 15.8% improvement over SVM. We also observe that the listwise learning to rank methods are more suitable for this problem than pairwise methods. We also add a validation module to deal with those entities which have no corresponding entry in the Knowledge Base. We also evaluate the proposed method on the whole data set given by the KBP track, for which we add a binary SVM classification module to validate the top one candidate. The result of experiment shows the proposed strategy performs better than all the systems participated in the entity linking task.

In the future, we will try to develop more sophisticated features in entity linking and design a typical learning to rank method for the entity linking task.

Improving the Multilingual User Experience of Wikipedia Using Cross-Language Name Search

Abstract

Although Wikipedia has emerged as a powerful collaborative Encyclopedia on the Web, it is only partially multilingual as most of the content is in English and a small number of other languages. In real-life scenarios, non-English users in general and ESL/EFL [1] users in particular, have a need to search for relevant English Wikipedia articles as no relevant articles are available in their language. The multilingual experience of such users can be significantly improved if they could express their information need in their native language while searching for English Wikipedia articles. In this paper, we propose a novel cross-language name search algorithm and employ it for searching English Wikipedia articles in a diverse set of languages including Hebrew, Hindi, Russian, Kannada, Bangla and Tamil. Our empirical study shows that the multilingual experience of users is significantly improved by our approach.

1 Introduction

Since its inception in 2001, Wikipedia has emerged as the most famous free, web-based, collaborative, and multilingual encyclopedia with over 13 million articles in over 270 languages. However, Wikipedia exhibits severe asymmetry in the distribution of its content in the languages of the world with only a small number of languages dominating (see Table 1). As a consequence, most users of the under-represented languages of the world have no choice but to consult foreign language Wikipedia articles for satisfying their information needs.

Table 1: Linguistic asymmetry of Wikipedia

Language	Speakers	Contributors	Articles
English	1500M	47.1%	3,072,373
Russian	278M	5.2%	441,860
Hebrew	10M	0.7%	97,987
Hindi	550M	0.06%	50,926
Bangla	230M	0.02%	20,342
Tamil	66M	0.04%	19,472
Kannada	47M	0.02%	7,185

Although consulting foreign language Wikipedia is not a solution for the problem of linguistic asymmetry, in the specific case of ESL/EFL users who form a sizable fraction of Internet users of the world [2], it is arguably the most practical option today. Typically, ESL/EFL users are reasonably good at reading and extracting relevant information from English content but not so good at expressing their information needs in English. In particular, getting the spellings of foreign names in English correctly is very difficult for most ESL/EFL users due to the differences in the way a foreign name is pronounced in the native languages. For instance, Japanese EFL speakers often break consonant clusters in foreign names using vowels (see Table 2) and Hindi ESL speakers find it difficult to differentiate between ‘an’, ‘en’, and ‘on’ in English names (such as ‘Clin-

[*] This work was done when the author was a summer intern at Microsoft Research India.

[1] *English as Second Language* and *English as Foreign Language*.

[2] As per some estimates, there are about 1 Billion ESL and EFL speakers in the world today and their number is growing.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 492–500,
Los Angeles, California, June 2010.

ton') and will most likely use 'an' ('Clintan').

Table 2: Influence of native language on the English spelling of names.

Wikipedia Entity	Hindi	Japanese	Kannada
Stephen Hawking	Stefan Hoking	Suchifun Houkingu	Steephan Haakimg
Paul Krugman	Pol Crugmun	Pooru Kuruguman	Paal Kragaman
Haroun al-Rashid	Haroon al-Rashid	Haruun aru-Rasheedo	Haroon al-Rasheed
Subrahmaniya Bharati	Subramaniya Bharati	Suburaamaniya Bahaarachi	Subrahmanya Bharathi

In principle, English spell-checkers (Ahmad and Kondrak, 2005) can handle the problem of incorrect spellings in the queries formed by ESL/EFL users. But in practice, there are two difficulties. Firstly, most English spell-checkers do not have a good coverage of names which form the bulk of user queries. Secondly, spelling correction of names is difficult because spelling mistakes are markedly influenced by the native language of the user. Not surprisingly, Wikipedia's inbuilt spell-checker suggests *"Suchin Housing"* as the only alternative to the query *"Suchifun Houkingu"* instead of the correct entity *"Stephen Hawking"* (See Table 3 for more examples).

The inability of ESL/EFL speakers to express their information needs correctly in English and the poor performance of spell-checkers highlight the need for a practical solution for the linguistic asymmetry problem of Wikipedia. In this work, we argue the multilingual user experience of ESL/EFL users can be significantly improved by allowing them to express their information need in their native language. While it might seem that we would need a fully functional cross-language retrieval system that supports translation of non-English queries to English, we note that a good number of the pages in Wikipedia are on people. This empirical fact allows us to improve the multilingual experience of ESL/EFL Wikipedia users by means of cross-language name search which is less resource demanding than a fully functional cross-language retrieval system.

There are several challenges that need to be addressed in order to enable cross-language name search in Wikipedia.

Table 3: Spelling suggestions by Wikipedia.

User Input	Wikipedia's Suggestion	Correct Spelling
Suchifun Houkingu	Suchin Housing	Stephen Hawking
Stefan Hoking	Stefan Ho king	Stephen Hawking
Pol Crugman	Poll Krugman	Paul Krugman
Paal Kragaman	Paul Krugman	Paul Krugman
Suburaamaniya Bahaarachi	Subramaniya Baracchi	Subrahmaniya Bharati

- Firstly, name queries are expressed by ESL/EFL users in the native languages using the orthography of those languages. Transliterating the name into Latin script using a Machine Transliteration system is an option but state-of-the-art Machine Transliteration technologies are still far away from producing the correct transliteration. Further, as pointed out by (Udupa et al., 2009a), it is not enough if a Machine Transliteration system generates a correct transliteration; it must produce the transliteration that is present in the Wikipedia title.

- Secondly, there are about 6 million titles (including redirects) in English Wikipedia which rules out the naive approach of comparing the query with every one of the English Wikipedia titles for transliteration equivalence as is done typically in transliteration mining tasks. A practical cross-language name search system for Wikipedia must be able to search millions of Wikipedia titles in a fraction of a second and return the most relevant titles.

- Thirdly, names are typically multi-word and as a consequence there might not be an exact match between the query and English Wikipedia titles. Any cross-language name search system for Wikipedia must be able to deal with multi-word names and partial matches effectively.

- Fourthly, the cross-language name search system must be tolerant to spelling variations in the query as well as the Wikipedia titles.

In this work, we propose a novel approach to cross-language name search in Wikipedia that addresses all the challenges described above. Further, our approach does not depend on either spell-checkers or Machine Transliteration. Rather we transform the problem into a geometric search problem and employ a state-of-the-art geometric algorithm for searching a very large database of names. This enables us to accurately search the relevant Wikipedia titles for a given user query in a fraction of a second even on a single processor.

1.1 Our Contributions

Our contributions can be summarized as follows:

1. We introduce a language and orthography independent geometric representation for single-word names (Section 3.1).

2. We model the problem of learning the geometric representation of names as a multi-view learning problem and employ the machinery of Canonical Correlation Analysis (CCA) to compute a low-dimensional Euclidean feature space. We map both foreign single-word names and English single-word names to points in the common feature space and the similarity between two single-word names is an exponentially decaying function of the squared geometric distance between the corresponding points (Section 3).

3. We model the problem of searching a database of names as a geometric nearest neighbor problem in low-dimensional Euclidean space and employ the well-known ANN algorithm for approximate nearest neighbors to search for the equivalent of a query name in the English Wikipedia titles (Arya et al., 1998) (Section 3.3).

4. We introduce a simple and efficient algorithm for computing the similarity scores of multi-word names from the single-word similarity scores (Section 3.4).

5. We show experimentally that our approach significantly improves the multilingual experience of ESL/EFL users (Section 4).

2 Related Work

Although approximate similarity search is well-studied, we are not aware of any non-trivial cross-language name search algorithm in the literature. However, several techniques for mining name transliterations from monolingual and comparable corpora have been studied (Pasternack and Roth, 2009), (Goldwasser and Roth, 2008), (Klementiev and Roth, 2006), (Sproat et al., 2006), (Udupa et al., 2009b). These techniques employ various transliteration similarity models. Character unigrams and bigrams were used as features to learn a discriminative transliteration model and time series similarity was combined with the transliteration similarity model (Klementiev and Roth, 2006). A generative transliteration model was proposed and used along with cross-language information retrieval to mine named entity transliterations from large comparable corpora (Udupa et al., 2009b). However, none of these transliteration similarity models are applicable for searching very large name databases as they rely on brute-force search. Not surprisingly, (Pasternack and Roth, 2009) report that *“.. testing [727 single word English names] with fifty thousand [Russian] candidates is a large computational hurdle (it takes our model about seven hours)”*.

Several algorithms for string similarity search have been proposed and applied to various problems (Jin et al., 2005). None of them are directly applicable to cross-language name search as they are based on the assumption that the query string shares the same alphabet as the database strings.

Machine Transliteration has been studied extensively in the context of Machine Translation and Cross-Language Information Retrieval (Knight and Graehl, 1998), (Virga and Khudanpur, 2003), (Kuo et al., 2006), (Sherif and Kondrak, 2007), (Ravi and Knight, 2009), (Li et al., 2009), (Khapra and Bhattacharyya, 2009). However, Machine Transliteration followed by string similarity search gives less-than-satisfactory solution for the cross-language name search problem as we will see later in Section 4.

CCA was introduced by Hotelling in 1936 and has been applied to various problems including CLIR, Text Clustering, and Image Retrieval (Hardoon et al., 2004). Recently, CCA has gained importance in the Machine Learning community as a technique for multi-view learning. CCA computes a common semantic feature space for two-view data and allows users to query a database using either of the two views. CCA has been used in bilingual lexicon extraction from comparable corpora (Gaussier et al., 2004) and monolingual corpora (Haghighi et al., 2008).

Nearest neighbor search is a fundamental problem where challenge is to preprocess a set of points in some metric space into a geometric data structure so that given a query point, its k-nearest neighbors in the set can be reported as fast as possible. It has applications in many areas including pattern recognition and classification, machine learning, data compression, data mining, document retrieval and statistics. The brute-force search algorithm can find the nearest neighbors in running time proportional to the product of the number of points and the dimension of the metric space. When the dimension of the metric space is small, there exist algorithms which give better running time than brute-force search. However, the search time grows exponentially with the dimension and none of the algorithms do significantly better than brute-force search for high-dimensional data. Fortunately, efficient algorithms exist if instead of exact nearest neighbors, we ask for approximate nearest neighbors (Arya et al., 1998).

3 Cross-Language Name Search as a Geometric Search Problem

The key idea behind our approach is the following: if we can embed names as points (or equivalently as vectors) in a suitable geometric space, then the problem of searching a very large database of names can be casted as a geometric search problem, i.e. one of finding the nearest neighbors of the query point in the database.

As illustrative examples, consider the names *Stephen* and *Steven*. A simple geometric representation for these names is the one induced by their corresponding features: $\{St, te, ep, ph, he, en\}$ and $\{St, te, ev, ve, en\}$ [3]. In this representation, each character bigram constitutes a dimension of the geometric feature space whose coordinate value is the number of times the bigram appears in the name. It is possible to find a low-dimensional representation for the names by using Principal Components Analysis or any other dimensionality reduction technique on the bigram feature vectors. However, the key point to note is that once we have an appropriate geometric representation for names, the similarity between two names can be computed as

$$K_{mono}\left(name1, name2\right) = e^{-||\phi_1 - \phi_2||^2/2\epsilon^2} \quad (1)$$

where ϕ_1 and ϕ_2 are the feature vectors of the two names and ϵ is a constant. Armed with the geometric similarity measure, we can leverage geometric search techniques for finding names similar to the query.

In the case of cross-language name search, we need a feature representation of names that is language/script independent. Once we map names in different languages/scripts to the same feature space, we can essentially treat similarity search as a geometric search problem.

3.1 Language/Script Independent Geometric Representation of Names

To obtain language/script independent geometric representation of names, we start by forming the language/script specific feature vectors as described in Section 3. Given two names, *Stephen* in Latin script and स्टीफन in Devanagari script, we form the corresponding character bigram feature vectors ϕ (using features $\{St, te, ep, ph, en\}$) and ψ (using features {स्ट, टी,िफ, फन}) respectively. We then map these vectors to a common geometric feature space using two linear transformations A and B:

$$\phi \rightarrow A^T\phi = \phi_s \in R^d \quad (2)$$

$$\psi \rightarrow B^T\psi = \psi_s \in R^d \quad (3)$$

The vectors ϕ_s and ψ_s can be viewed as language/script independent representation of the names *Stephen* and स्टीफन.

[3] Here, we have employed character bigrams as features. In principle, we can use any suitable set of features including phonetic features extracted from the strings.

3.1.1 Cross-Language Similarity of Names

In order to search a database of names in English when the query is in a native language, say Hindi, we need to be able to measure the similarity of a name in Devangari script with names in Latin script. The language/script independent representation gives a natural way to measure the similarity of names across languages. By embedding the language/script specific feature vectors ϕ and ψ in a common feature space via the projections A and B, we can compute the similarity of the corresponding names as follows:

$$K_{cross}\left(name1, name2\right) = e^{-||\phi_s - \psi_s||^2/2\epsilon^2} \qquad (4)$$

It is easy to see from Equation 4 that the similarity score of two names is small when the projections of the names are negatively correlated.

3.2 Learning Common Feature Space using CCA

Ideally, the transformations A and B should be such that similar names in the two languages are mapped to close-by points in the common geometric feature space. It is possible to learn such transformations from a training set of name transliterations in the two languages using the well-known multi-view learning framework of Canonical Correlation Analysis (Hardoon et al., 2004). By viewing the language/script specific feature vectors as two representations/views of the same semantic object, the entity whose name is written as $Stephen$ in English and as स्टीफन in Hindi, we can employ the machinery of CCA to find the transformations A and B.

Given a sample of multivariate data with two views, CCA finds a linear transformation for each view such that the correlation between the projections of the two views is maximized. Consider a sample $Z = \{(x_i, y_i)\}_{i=1}^{N}$ of multivariate data where $x_i \in R^m$ and $y_i \in R^n$ are two views of the object. Let $X = \{x_i\}_{i=1}^{N}$ and $Y = \{y_i\}_{i=1}^{N}$. Assume that X and Y are centered[4], i.e., they have zero mean. Let a and b be two directions. We can project X onto the direction a to get $U = \{u_i\}_{i=1}^{N}$ where $u_i = a^T x_i$. Similarly, we can project Y onto the direction b to get the projections $V = \{v_i\}_{i=1}^{n}$ where $v_i = b^T y_i$. The aim of CCA is to find a pair of directions (a, b) such that the projections U and V are maximally correlated. This is achieved by solving the following optimization problem:

$$\begin{aligned}\rho &= max_{(a,b)} \frac{< Xa, Xb >}{||Xa||||Xb||} \\ &= max_{(a,b)} \frac{a^T XY^T b}{\sqrt{a^T XX^T a}\sqrt{b^T YY^T b}}\end{aligned}$$

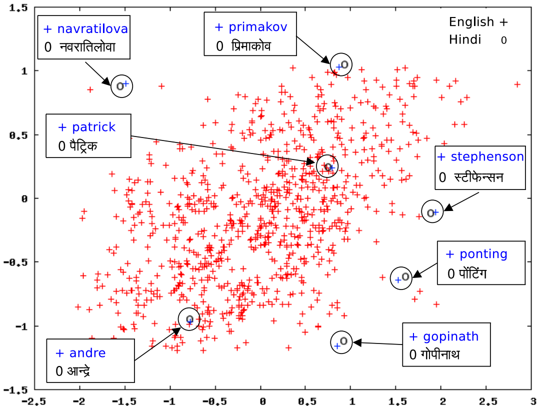
The objective function of Equation 5 can be maximized by solving the following generalized eigen value problem (Hardoon et al., 2004):

$$\begin{aligned}XY^T \left(YY^T\right)^{-1} YX^T a &= \lambda^2 XX^T a \\ \left(YY^T\right)^{-1} YX^T a &= \lambda b\end{aligned}$$

The subsequent basis vectors can be found by adding the orthogonality of bases constraint to the objective function. Although the number of basis vectors can be as high as $\min\{Rank(X), Rank(Y)\}$, in practice, only the first few basis vectors are used since the correlation of the projections is high for these vectors and small for the remaining vectors.

Let A and B be the first $d > 0$ basis vectors computed by CCA.

Figure 1: Projected names (English-Hindi).



3.2.1 Common Geometric Feature Space

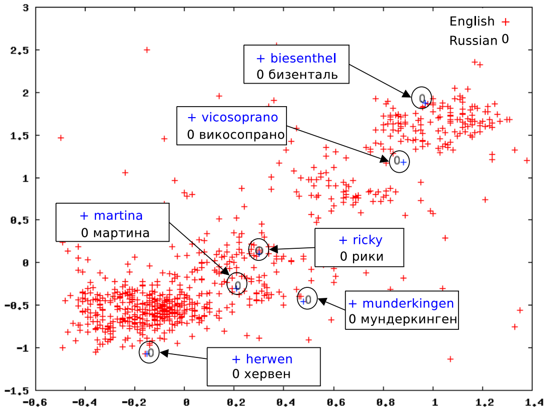
As described in Section 3.1, we represent names as points in the common geometric feature space defined by the projection matrices A and B. Figure 1

[4] If X and Y are not centered, they can be centered by subtracting the respective means.

shows a 2-dimensional common feature space computed by CCA for English (Latin script) and Hindi (Devanagari script) names. As can be seen from the figure, names that are transliterations of each other are mapped to near-by points in the common feature space.

Figure 2 shows a 2-dimensional common feature space for English (Latin script) and Russian (Cyrillic script) names. As can be seen from the figure, names that are transliterations of each other are mapped to near-by points in the common feature space.

Figure 2: Projected names (English-Russian).



3.3 Querying the Name Database

Given a database $D = \{e_i\}_{i=1}^{M}$ of single-word names in English, we first compute their language/script specific feature vectors $\phi^{(i)}$, $i = 1, \ldots, M$. We then compute the projections $\phi_s^{(i)} = A^T\phi^{(i)}$. Thus, we transform the name database D into a set of vectors $\{\phi_s^{(1)}, \ldots, \phi_s^{(M)}\}$ in R^d.

Given a query name h in Hindi, we compute its language/script specific feature vector ψ and project it on to the common feature space to get $\psi_s = B^T\psi \in R^d$. Names similar to h in the database D can be found as solutions of the k-nearest neighbor problem:

$$\begin{aligned} e_{i_k} &= argmax_{e_i \in D - \{e_{i_j}\}_{j=1}^{k-1}} K_{cross}\left(e_i, h\right) \\ &= argmax_{e_i \in D - \{e_{i_j}\}_{j=1}^{k-1}} e^{-||\phi_s^{(i)} - \psi_s||^2/2\epsilon^2} \\ &= argmin_{e_i \in D - \{e_{i_j}\}_{j=1}^{k-1}} ||\phi_s^{(i)} - \psi_s|| \end{aligned}$$

Unfortunately, computing exact k-nearest neighbors in dimensions much higher than 8 is difficult and the best-known methods are only marginally better than brute-force search (Arya et al., 1998). Fortunately, there exist very efficient algorithms for computing approximate nearest neighbors and in practice they do nearly as well as the exact nearest neighbors algorithms (Arya et al., 1998). It is also possible to control the tradeoff between accuracy and running time by specifiying a maximum approximation error bound. We employ the well-known Approximate Nearest Neighbors (aka ANN) algorithm by Arya and Mount which is known to do well in practice when $d \leq 100$ (Arya et al., 1998).

3.4 Combining Single-Word Similarities

The approach described in the previous sections works only for single-word names. We need to combine the similarities at the level of individual words into a similarity function for multi-word names. Towards this end, we form a weighted bipartite graph from the two multi-word names as follows:

We first tokenize the Hindi query name into single word tokens and find the nearest English neighbors for each of these Hindi tokens using the method outlined section 3.3. We then find out all the English Words which contain one or more of the English neighbors thus fetched. Let $E = e_1e_2 \ldots e_I$ be one such multi-word English name and $H = h_1h_2 \ldots h_J$ be the multi-word Hindi query. We form a weighted bipartite graph $G = (S \cup T, W)$ with a node s_i for the ith word e_i in E and node t_j for the jth word h_j in H. The weight of the edge (s_i, t_j) is set as $w_{ij} = K_{cross}\left(e_i, h_j\right)$.

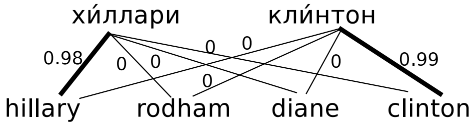
Let w be the weight of the maximum weighted bipartite matching in the graph G. We define the similarity between E and H as follows:

$$K_{cross}\left(E, H\right) = \frac{w}{|I - J| + 1}. \qquad (5)$$

The numerator of the right hand side of Equation 5 favors name pairs which have a good number of high quality matches at the individual word level whereas the denominator penalizes pairs that have disproportionate lengths.

Note that, in practice, both I and J are small and hence we can find the maximum weighted bipartite matching very easily. Further, most edge weights in

Figure 3: Combining Single-Word Similarities.



the bipartite graph are negligibly small. Therefore, even a greedy matching algorithm suffices in practice.

4 Experiments and Results

In the remainder of this section, we refer to our system by GEOM-SEARCH.

4.1 Experimental Setup

We tested our cross language name search system using six native languages, *viz.*, Russian, Hebrew, Hindi, Kannada, Tamil and Bangla. For each of these languages, we created a test set consisting of 1000 multi-word name queries and found manually the most relevant Wikipedia article for each query in the test set. The Wikipedia articles thus found and all the redirect titles that linked to them formed the gold standard for evaluating the performance of our system.

In order to compare the performance of GEOM-SEARCH with a reasonable baseline, we implemented the following baseline: We used a state-of-the art Machine Transliteration system to generate the best transliteration of each of the queries. We used the edit distance between the transliteration and the single-word English name as the similarity score. We combined single word similarities using the approach described in Section 3.4. We refer to this baseline by TRANS-SEARCH.

Note that several English Wikipedia names sometimes get the same score for a query. Therefore, we used a tie-aware mean-reciprocal rank measure to evaluate the performance (McSherry and Najork, 2008).

4.2 GEOM-SEARCH

The training and search procedure employed by GEOM-SEARCH are described below.

4.2.1 CCA Training

We learnt the linear transformations A and B that project the language/script specific feature vectors to the common feature space using the approach discussed in Section 3.2. The learning algorithm requires a training set consisting of pairs of single-word names in English and the respective native language. We used approximately $15,000$ name pairs for each native language.

A key parameter in CCA training is the number of dimensions of the common feature space. We found the optimal number of dimensions using a tuning set consisting of $1,000$ correct name pairs and $1,000$ incorrect name pairs for each native language. We found that $d = 50$ is a very good choice for each native language.

Another key aspect of training is the choice of language/script specific features. For the six languages we experimented with and also for English, we found that character bigrams formed a good set of features. We note that for languages such as Chinese, Japanese, and Korean, unigrams are the best choice. Also, for these languages, it may help to syllabify the English name.

4.2.2 Search

As a pre-processing step, we extracted a list of 1.3 million unique words from the Wikipedia titles. We computed the language/script specific feature vector for each word in this list and projected the vector to the common feature space as described in Section 3.1. The low-dimensional embeddings thus computed formed the input to the ANN algorithm.

We tokenized each query in the native language into constituent words. For each constituent, we first computed the language/script specific feature vector, projected it to the common feature space, and found the k-nearest neighbors using the ANN algorithm. We used k=100 for all our experiments.

After finding the nearest neighbors and the corresponding similarity scores, we combined the scores using the approach described in Section 3.4.

4.3 TRANS-SEARCH

The training and search procedure employed by TRANS-SEARCH are described below.

Figure 4: Top scoring English Wikipedia page retrieved by GEOM-SEARCH

4.3.1 Transliteration Training

We used a state-of-the-art CRF-based transliteration technique for transliterating the native language names (Khapra and Bhattacharyya, 2009). We used CRF++, an open-source CRF training tool, to train the transliteration system. We used exactly the same features and parameter settings as described in (Khapra and Bhattacharyya, 2009). As in the case of CCA, we use around $15,000$ single word name pairs in the training.

4.3.2 Search

The preprocessing step for TRANS-SEARCH is the same as that for GEOM-SEARCH. We transliterated each constituent of the query into English and find all single-word English names that are at an edit distance of at most 3. We computed the similarity score as described in Section 3.4.

4.4 Evaluation

We evaluated the performance of GEOM-SEARCH and TRANS-SEARCH using a tie-aware mean reciprocal rank (MRR). Table 4 compares the average time per query and the MRR of the two systems.

GEOM-SEARCH performed significantly better than the transliteration based baseline system for all the six languages. On an average, the relevant English Wikipedia page was found in the top 2 results produced by GEOM-SEARCH for all the six native languages. Clearly, this shows that GEOM-SEARCH is highly effective as a cross-langauge name search system. The good results also validate our claim that cross-language name search can improve the multi-lingual user experience of ESL/EFL users.

Table 4: MRR and average time per query (in seconds) for the two systems.

Language	GEOM		TRANS	
	Time	MRR	Time	MRR
Hin	0.51	0.686	2.39	0.485
Tam	0.23	0.494	2.16	0.291
Kan	1.08	0.689	2.17	0.522
Ben	1.30	0.495	–	–
Rus	0.15	0.563	1.65	0.476
Heb	0.65	0.723	–	–

5 Conclusions

GEOM-SEARCH, a geometry-based cross-language name search system for Wikipedia, improves the multilingual experience of ESL/EFL users of Wikipedia by allowing them to formulate queries in their native languages. Further, it is easy to integrate a Machine Translation system with GEOM-SEARCH. Such a system would find the relevant English Wikipedia page for a query using GEOM-SEARCH and then translate the relevant Wikipedia pages to the native language using the Machine Translation system.

Abstract

Most work on language acquisition treats word segmentation—the identification of linguistic segments from continuous speech—and word learning—the mapping of those segments to meanings—as separate problems. These two abilities develop in parallel, however, raising the question of whether they might interact. To explore the question, we present a new Bayesian segmentation model that incorporates aspects of word learning and compare it to a model that ignores word meanings. The model that learns word meanings proposes more adult-like segmentations for the meaning-bearing words. This result suggests that the non-linguistic context may supply important information for learning word segmentations as well as word meanings.

1 Introduction

Acquiring a language entails mastering many learning tasks simultaneously, including identifying where words begin and end in continuous speech and learning meanings for those words. It is common to treat these tasks as separate, sequential processes, where segmentation is a prerequisite to word learning but otherwise there are few if any dependencies. The earliest evidence of segmentation, however, is for words bordering a child's own name (Bortfeld et al., 2005). In addition, infants begin learning their first words before they achieve adult-level competence in segmentation. These two pieces of evidence raise the question of whether the tasks of meaning learning and segmentation might mutually inform one another.

To explore this question we present a joint model that simultaneously identifies word boundaries and attempts to associate meanings with words. In doing so we make two contributions. First, by modeling the two levels of structure in parallel we simulate a more realistic situation. Second, a joint model allows us to explore possible synergies and interactions. We find evidence that our joint model performs better on a segmentation task than an alternative model that does not learn word meanings.

The picture in Figure 1 depicts a language learning situation from our corpus (originally from Fernald and Morikawa, 1993; recoded in Frank et al., 2009) where a mother talks while playing with various toys. Setting down the dog and picking up the hand puppet of a pig, she asks, "Is that the pig?" Starting out, a young learner not only does not know that the word "pig" refers to the puppet but does not even know that "pig" is a word at all. Our model simulates the learning task, taking as input the unsegmented phonemic representation of the speech along with the set of objects in the non-linguistic context as shown in Figure 1 (a), and infers both a segmentation and a word-object mapping as in Figure 1 (b).

One can formulate the word learning task as that of finding a reasonably small set of reusable word-meaning pairs consistent with the underlying communicative intent. Infant directed speech often refers to objects in the immediate environment, and early word learning seems to involve associating frequently co-occurring word-object pairs (Akhtar and Montague, 1999; Markman, 1990). Several computational models are based on this idea that a word

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 501–509,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

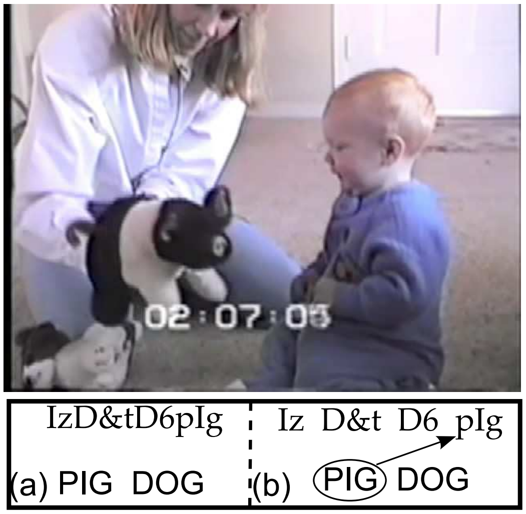

Figure 1: (a) The input to our system for the utterance "Is that the pig?" consists of an unsegmented sequence of phonemes and the set of objects representing the non-linguistic context. These objects were manually identified by inspecting the associated video, a frame from which is shown above. (b) The gold-standard segmentation and word-object assignments of the same utterance, against which the output of our system is evaluated (all words except "pIg" are mapped to a special "null" object, as explained in the text).

that frequently occurs in the presence of an object and not so frequently in its absence is likely to refer to that object (Frank et al., 2009a; Siskind, 1996; Yu and Ballard, 2007). Importantly, all these models assume words are pre-segmented in the input.

While the word segmentation task relates less clearly to the communicative content, it can be formulated according to a similar objective, that of attempting to explain the sound sequences in the input in terms of some reasonably small set of reusable units, or words. Computational models have successfully addressed the problem in much this way (Johnson and Goldwater, 2009; Goldwater et al., 2009; Brent, 1999), and the general approach is consistent with experimental observations that humans are sensitive to statistics of sound sequences (Saffran et al., 1996; Frank et al., 2007).

The two tasks can be integrated in a relatively seamless way, since, as we have just formulated them, they have a common objective, that of finding a minimal, consistent set of reusable units. However, the two deal with different types of information with different dependencies. The basic idea is that learning a vocabulary that both meets the constraints of the word-learning task and is consistent with the objective of the segmentation task can yield a better segmentation. That is, we hope to find a synergy in the joint inference of meaning and segmentation.

Note that to the best of our knowledge there is very little computational work that combines word form and word meaning learning (Frank et al. 2006 takes a first step but their model is applicable only to small artificial languages). Frank et al. (2009a) and Regier (2003) review pure word learning models and, in addition to the papers we have already cited, Brent (1999) presents a fairly comprehensive review of previous pure segmentation models. However, none of the models reviewed make any attempt to jointly address the two problems. Similarly, in the behavioral literature on development, we are aware of only one segmentation study (Graf-Estes et al., 2007) that involves non-linguistic context, though this study treats the two tasks sequentially rather than jointly.

We now describe our model and inference procedure and follow with evaluation and discussion.

2 Model Definition

Cross-situational meaning learning in our joint word learning and segmenting model is inspired by the model of Frank et al. (2009a). Our model can be viewed as a variant of the Latent Dirichlet Allocation (LDA) topic model of Blei et al. (2003), where topics are drawn from the objects in the non-linguistic context. The model associates each utterance with a single referent object, the topic, and every word in the utterance is either generated from a distribution over words associated with that object or else from a distribution associated with a special "null" object shared by all utterances. Note that in this paper we use "topic" to denote the referent object of an utterance, otherwise we depart from topic modeling convention and use the term "object" instead.

Segmentation is based on the unigram model proposed by Brent (1999) and reformulated by Goldwater et al. (2009) in terms of a Dirichlet process. Since both LDA and the unigram segmenter are based on unigram distributions it is relatively straightforward

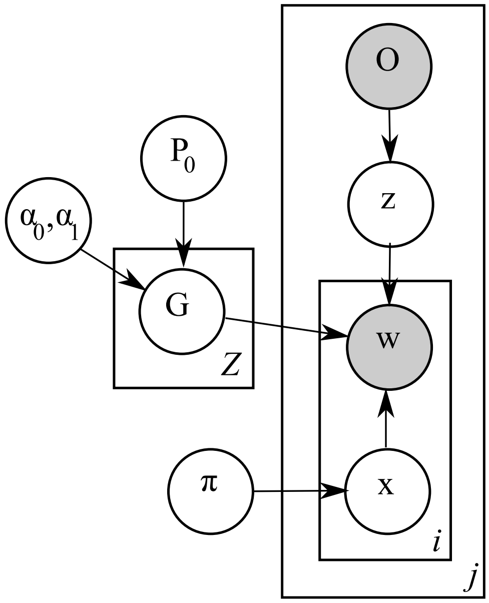

Figure 2: Topical Unigram Model: O_j is the set of objects in the non-linguistic context of the j^{th} utterance, z_j is the utterance topic, w_{ji} is the i^{th} word of the utterance, x_{ji} is the category of the word (referring or non-referring), and the other variables are distribution parameters.

to integrate the two to simultaneously infer word boundaries and word-object associations.

Figure 2 illustrates a slightly simplified form of the model, and the the relevant distributions are as follows:

$$\begin{aligned} z|O &\sim Uniform(O) \\ G_z|z,\alpha_0,\alpha_1,P_0 &\sim \begin{cases} DP(\alpha_1,P_0) & \text{if } z \neq 0 \\ DP(\alpha_0,P_0) & \text{otherwise} \end{cases} \\ \pi &\sim Beta(1,1) \\ x|\pi &\sim Bernoulli(\pi) \\ w|G,z,x &\sim \begin{cases} G_z & \text{if } x=1 \\ G_0 & \text{if } x=0 \end{cases} \end{aligned}$$

Note that $Uniform(O)$ denotes a discrete uniform distribution over the elements of the set O. P_0 is described later.

Briefly, each utterance has a single topic z_j, drawn from the objects in the non-linguistic context O_j, and then for each word w_{ji} we first flip a coin x_{ji} to determine if it refers to the topic or not. Then, depending on x_{ji} the word is either drawn from a distribution specific to the topic ($x_{ji} = 1$) or from a distribution associated with the "null" object ($x_j i = 0$). In slightly greater detail but still glossing over the details of how the multinomial parameters are generated, the generative story proceeds as follows:

1. For each utterance, indexed by j
2. (a) Pick a single topic z_j uniformly from the set of objects in the environment O_j
   (b) For each word w_{ji} of the utterance
   (c) i. Determine if it refers to z_j or not by setting x_{ji} to 1 (referring) with probability π, and to 0 (non-referring) otherwise.
       ii. if x_{ji} is 1, draw w_{ji} from the topic specific distribution over words G_{z_j}.
       iii. otherwise, draw w_{ji} from G_0, the distribution over words associated with the "null" object.

This generative story is a simplification since it does not describe how we model utterance boundaries. It is important for segmentation purposes to explicitly model utterance boundaries since, unlike utterance-internal word boundaries, we assume utterance boundaries are observed. Thus, the story is complicated by the fact that there is a chance each time we generate a word that we also generate an utterance boundary. The choice of whether to terminate the utterance or not is captured by a $Bernoulli(\gamma)$ random variable $\$_{ji}$ indicating whether the i^{th} word was the last word of the j^{th} utterance.

$$\begin{aligned} \gamma &\sim Beta(1,1) \\ \$|\gamma &\sim Bernoulli(\gamma) \end{aligned}$$

The G_z multinomial parameters are generated from a Dirichlet process with base distribution over words, P_0, which describes how new word types are generated from their constituent phonemes. Phonemes are generated sequentially, i.i.d. uniformly from m phonemic types. In addition, there is a probability $p_\#$ of generating a word boundary.

$$P_0(w) = (1 - p_\#)^{|w|-1} p_\# \frac{1}{m^{|w|}}$$

The concentration parameters α_0 and α_1 also play a critical role in the generation of words and word types. Any given word has a certain probability of either being produced from the set of previously seen word types, or from an entirely new one. The greater the concentration parameter, the more likely the model is to appeal to the base distribution P_0 to introduce a new word type.

Like Frank et al. (2009a), we distinguish between two coarse grammatical categories, referring and non-referring. Referring words are generated by the topic, while non-referring words are drawn from G_0, a distribution associated with the "null" object. The distinction ensures sparse word-object maps that obey the principle of mutual exclusion. Otherwise all words in the utterance would be associated with the topic object, resulting in a very large set of words for each object that is very likely to overlap with the words for other objects. As a further bias toward a small lexicon, we employ different concentration parameters (α_0 and α_1) for the non-referring and referring words, using a much smaller value for the referring words. Intuitively, there should be a relatively small prior probability of introducing a new word-object pair, corresponding to a small α_1 value. On the other hand, most other words don't refer to the topic object (or any other object for that matter), corresponding to a much larger α_0 value.

Note that this topical unigram model is a straightforward generalization of the unigram segmentation model (Goldwater et al., 2009) to the case of multiple topics. In fact, if all words were assumed to refer to the same object (or to no object at all) the models would be identical.

Unlike LDA, each "document" has only one topic, which is necessitated by the fact that in our model documents correspond single utterances. The utterances in our corpus of child directed speech are often only four or five words long, whereas the general LDA model assumes documents are much larger. Thus, there may not be enough words to infer a useful utterance specific distribution over topics. Consequently, rather than inferring a separate topic distribution for each utterance, we simply assume a uniform distribution over objects in the non-linguistic context. In effect, we rely entirely on the non-linguistic context and word-object associations to infer topics. Though necessitated by data sparsity issues, we also note that it is very rare in our corpus for utterances to refer to more than one object in the non-linguistic context, so the choice of a single topic may also be a more accurate model. In fact, even with multi-sentence documents, LDA may perform better if only one topic is assumed per sentence (Gruber et al., 2007).

3 Inference

We use a collapsed Gibbs sampling procedure, integrating over all possible G_z, π, and γ values and then iteratively sample values for each variable conditioned on the current state of all other variables. We visit each utterance once per iteration, sample a topic, and then visit each possible word boundary location to sample the boundary and word categories simultaneously according to their joint probability.

A single topic is sampled for each utterance, conditioned on the words and their current determinations as referring or non-referring. Since z_j is drawn from a uniform distribution, this probability is simply proportionate to the conditional probability of the words given z_j and the x_{ji} variables.

$$P(z_j|\mathbf{w_j},\mathbf{x_j},\mathbf{h}^{-j}) \propto \frac{\Gamma(\sum_w^{W_j} n_{w,z_j}^{(\mathbf{h}^-)} + \alpha_1 P_0(w))}{\Gamma(\sum_w^{W_j} n_{w,z_j}^{(\mathbf{h})} + \alpha_1 P_0(w))} \cdot \prod_w^{W_j} \frac{\Gamma(n_{w,z_j}^{(\mathbf{h})} + \alpha_1 P_0(w))}{\Gamma(n_{w,z_j}^{(\mathbf{h}^-)} + \alpha_1 P_0(w))}$$

Here, $P(z_j|\mathbf{w_j},\mathbf{x_j},\mathbf{h^{-j}})$ is the probability of topic z_j given the current hypothesis $\mathbf{h}$ for all variables excluding those for the current utterance. Also, $n_{w,z_j}^{(\mathbf{h}^{-j})}$ is the count of occurrences of word type w that refer to topic z_j among the current variable assignments, and W_j is the set of word types appearing in utterance j. The vectors of word and category variables in utterance j are represented as $\mathbf{w_j}$ and $\mathbf{x_j}$, respectively. Note that only referring words have any bearing on the appropriate selection of z_j and so all factors involving only non-referring words are absorbed by the constant of proportionality.

The word categories can be sampled conditioned on the current word boundary states according to the following conditional probability, where $n_{x_{ji}}^{(\mathbf{h}^{-ji})}$ is the number of words categorized according to label

x_{ji} over the entire corpus excluding word w_{ji}.

$$\begin{aligned} P(x_{ji}|w_{ji}, z_j, \mathbf{h}^{-ji}) &\propto P(w_{ji}|z_j, x_{ji}, \mathbf{h}^{-ji}) \\ &\quad \cdot P(x_{ji}|\mathbf{h}^{-ji}) \\ &= \frac{n^{(\mathbf{h}^{-ji})}_{w_{ji},x_{ji}z_j} + \alpha_{x_{ji}} P_0(w_{ji})}{n^{(\mathbf{h}^{-ji})}_{\bullet,x_{ji}z_j} + \alpha_{x_{ji}}} \cdot \frac{n^{(\mathbf{h}^{-ji})}_{x_{ji}} + 1}{n^{(\mathbf{h}^{-ji})}_{\bullet} + 2} \end{aligned} \qquad (1)$$

In practice, however, we actually sample the word category variables jointly with the boundary states, using a scheme similar to that outlined in Goldwater et al. (2009). We visit each possible word boundary location (any point between two consecutive phonemes) and compute probabilities for the hypotheses for which the phonemic environment makes up either one word or two. As illustrated below there are two sets of cases: those where we treat the segment as a single word, and those where we treat it as two words.

$$\begin{array}{ccc} \overset{x_1}{\ldots\#w_1\#\ldots} & \text{vs.} & \overset{x_2 \quad x_3}{\ldots\#w_2\#w_3\#\ldots} \\ \uparrow & & \uparrow \end{array}$$

The probabilities of the hypotheses can be derived by application of equation 1. Since the $\mathbf{x}$ variables can each describe two possible events, there are a total of six different cases to consider for each boundary assignment: two cases without and four with a word boundary.

The probability of each of the two cases without a word boundary can be computed as follows:

$$\begin{aligned} P(w_1, x_1|z, \mathbf{h}^-) &= \frac{n^{(\mathbf{h}^-)}_{w_1,x_1z} + \alpha_{x_1} P_0(w_1)}{n^{(\mathbf{h}^-)}_{\bullet,x_1z} + \alpha_{x_1}} \\ &\quad \cdot \frac{n^{(\mathbf{h}^-)}_{x_1} + 1}{n^{(\mathbf{h}^-)}_{\bullet} + 2} \cdot \frac{n^{(\mathbf{h}^-)}_{\$_1} + 1}{n^{(\mathbf{h}^-)}_{\bullet} + 2} \end{aligned}$$

Here $\mathbf{h}^-$ signifies the current hypothesis for all variables excluding those for the current segment and $n^{(\mathbf{h}^-)}_{\$_1}$ is the count for $\mathbf{h}^-$ of either utterance final words if w_1 is utterance final or non-utterance final words if w_1 is also not utterance final.

In the four cases with a word boundary, we have two words and two categories to sample.

$$\begin{aligned} P(w_2, x_2, w_3, x_3|z, \mathbf{h}^-) &= \frac{n^{(\mathbf{h}^-)}_{w_2,x_2z} + \alpha_{x_2} P_0(w_2)}{n^{(\mathbf{h}^-)}_{\bullet,x_2z} + \alpha_{x_2}} \\ &\quad \cdot \frac{n^{(\mathbf{h}^-)}_{x_2} + 1}{n^{(\mathbf{h}^-)}_{\bullet} + 2} \cdot \frac{n^{(\mathbf{h}^-)}_{\$_2=0} + 1}{n^{(\mathbf{h}^-)}_{\bullet} + 2} \\ &\quad \cdot \frac{n^{(\mathbf{h}^-)}_{w_3,x_3z} + \delta_{x_2}(x_3)\delta_{w_2}(w_3) + \alpha_{x_3} P_0(w_3)}{n^{(\mathbf{h}^-)}_{\bullet,x_3z} + \delta_{x_2}(x_3) + \alpha_{x_3}} \\ &\quad \cdot \frac{n^{(\mathbf{h}^-)}_{x_3} + \delta_{x_2}(x_3) + 1}{n^{(\mathbf{h}^-)}_{\bullet} + 3} \cdot \frac{n^{(\mathbf{h}^-)}_{\$_3} + \delta_{\$_2}(\$_3) + 1}{n^{(\mathbf{h}^-)}_{\bullet} + 3} \end{aligned}$$

Here $\delta_x(y)$ is 1 if $x = y$ and 0 otherwise.

4 Results & Model Comparisons

4.1 Corpus

Our training corpus (Fernald and Morikawa, 1993; Frank et al., 2009b) consists of about 22,000 words and 5,600 utterances. Video recordings consisting of mother-child play over pairs of toys were orthographically transcribed, and each utterance was annotated with the set of objects present in the non-linguistic context. The object referred to by the utterance, if any, was noted, as described in Frank et al. (2009b). We used the VoxForge dictionary to map orthographic words to phoneme sequences in a process similar to that described in Brent (1999).

Figure 1 (a) presents an example of the coding of phonemic transcription and non-linguistic context for a single utterance. The input to the system consists solely of the phonemic transcription and the objects in the non-linguistic context.

4.2 Evaluation

We ran the sampler ten times for 100,000 iterations with parameter settings of $\alpha_1 = 0.01$, $\alpha_0 = 20$, and $p_{\#} = 0.5$, keeping only the final sample for evaluation. We defined the word-object pairs for a sample as the words in the referring category that were paired at least once with a particular topic. These pairs were then compared against a gold standard set of word-object pairs, while segmentation performance was evaluated by comparing the final boundary assignments against the gold standard segmentation.

4.2.1 Word Learning

To explore the contribution of word boundaries to the joint word learning and segmenting task, we compare our full joint model against a variant that only infers topics, using the gold standard segmentation as input. In this way we also reproduce the usual assumption of a sequential relationship between segmentation and word learning and test the necessity of the simplifying assumption. The results are shown in Table 2. We compare them with three different metric types: topic accuracy; precision, recall, and F-score of the word-object pairs; and Kullback-Liebler (KL) divergence.

First, treating utterances with no referring words as though they have no topic, we compute the accuracy of the inferred topics. Note that we don't report accuracy for the the variant with no non-linguistic context, since in this case the objects are interchangeable, and we have a problem identifying which cluster corresponds to which topic. Table 2 shows that the joint segmentation and word learning model gets the topic right for 81% of the utterances. The variant that assumes pre-segmented input does comparably well with an accuracy of 79%. Surprisingly, it seems that knowing the gold segmentation doesn't add very much, at least for the topic inference task.

To evaluate how well we discovered the word-object map, we manually compiled a list of all the nouns in the corpus that named one of the 30 objects. We used this set of nouns, cross-referenced with their topic objects, as a gold standard set of word-object pairs. By counting the co-occurrences, we also compute a gold standard probability distribution for the words given the topic, $P(w|z, x = 1)$.

Precision, recall and F-score are computed as per Frank et al. (2009a). In particular, precision is the fraction of gold pairs among the sampled set and recall is the fraction of sampled pairs among the gold standard pairs.

$$\text{p} = \frac{|\text{Sampled} \cap \text{Gold}|}{|\text{Sampled}|}, \qquad \text{r} = \frac{|\text{Sampled} \cap \text{Gold}|}{|\text{Gold}|}$$

KL divergence is a way of measuring the difference between distributions. Small numbers generally indicate a close match and is zero only when the two are equal. Using the empirical distribution over gold topics $P(z)$, we use the standard formula for KL divergence to compare the gold standard distribution P against the inferred distribution Q. I.e., we compute $D_{KL}(P(w, z)||Q(w, z))$.

Object	Words			
BOX	thebox	box		
BRUSH	brush			
BUNNY	rabbit	Rosie		
BUS	bus			
CAR	car	thecar

DOUGH	dough			
ERNIE	Ernie			

Table 1: Subset of an inferred word-object mapping. For clarity, the proposed words have been converted to standard English orthography.

	p	r	f	KL	acc
Joint	**0.21**	0.45	0.28	2.78	**0.81**
Gold Seg	**0.21**	**0.60**	**0.31**	**1.82**	0.79

Table 2: Word Learning Performance. Comparing precision, recall, and F-score of word-object pairs, $D_{KL}(P(w, z)||Q(w, z))$, and accuracy of utterance topics for the full joint model and a variant that only infers meanings given a gold standard segmentation.

The model learns fairly meaningful word-object associations; results are shown in Table 2. As in the case of topic accuracy, the joint and word learning only variants perform similarly, this time with somewhat better performance for the easier task with an F-score and KL divergence of 0.31 and 1.82 vs. 0.28 and 2.78 for the joint task.

Table 1 illustrates the sort of word-object pairs the model discovers. As can be seen, many of the errors are due to the segmentation, usually under-segmentation errors where it segments two words as one. This is a general problem with the unigram segmenter on which our model is based (Goldwater et al., 2009). Yet, even though these segmentation errors are also counted as word learning errors, they are often still meaningful in the sense that the true referring word is a subsequence.

So, word segmentation has an impact on word learning. Yet, the joint model still tends to uncover reasonable meanings. The next question is whether these meanings have an impact on the segmentation.

	NoCon	Random	Joint
Referring Nouns	0.36	0.35	**0.50**
Neighbors	0.33	0.33	**0.37**
Utt Final Nouns	0.36	0.36	**0.52**
Entire Corpus	0.53	0.53	**0.54**

Table 3: Segmentation performance. F-score for three subsets and the full corpus for three variants: the model without non-linguistic context, the model with random topics, and the full joint model.

4.2.2 Word Segmentation

To measure the impact of word learning on segmentation, we again compare the model on the full joint task against two other variants: one where topics are randomly selected, and one that ignores the non-linguistic context. For the random topics variant, we choose each topic during initialization according to the empirical distribution over gold topics and treat these topic assignments as observed variables for subsequent iterations. The variant that ignores non-linguistic context draws topics uniformly from the entire set of objects ever discussed in the corpus, another test of the contribution of the non-linguistic context to segmentation. We report token F-score, computed as per Goldwater et al. (2009), where any segment proposed by the model is a true positive only if it matches the gold segmentation and is a false positive otherwise. Any segment in the gold data not found by the model is a false negative.

Table 3 shows the segmentation performance for various subsets as well as for the entire corpus. Because we are primarily interested in synergies between word learning and segmentation, we focus on the words most directly impacted by the meanings: gold standard referring nouns and their neighboring words.

The model behaves the same with randomized topics as without context; it learns none of the gold standard pairs (no matter how we identify clusters with topics for the contextless case). On all subsets, the full joint model outperforms the other two variants. In particular, the greatest gain is for the referring nouns, with a 21% reduction in error. Also, similar to the findings of Bortfeld et al. (2005) regarding 6 month olds' abilities to segment words adjoining a familiar name, we also find that neighboring words benefit from sharing a word boundary with a learned word.

The model performs exceptionally well on utterance final referring nouns, with a 24% reduction in error. This may explain certain psycholinguistic observations. Frank et al. (2006) performed an artificial language experiment with humans subjects demonstrating that adults were able to learn words at the same time as they learned to segment the language. However, subjects did much better on a word learning task when the meaning bearing words were consistently placed at the end of utterances. There are several possible reasons why this might have been the case. For instance, it is common in English for the object noun to occur at the end of the sentence, and since the subjects were all English speakers, they may have found it easier to learn an artificial language with a similar pattern. However, our model predicts another simple possibility: the segmentation task is easier at the end because one of the two word boundaries is already known (the utterance boundary itself).

4.3 Discussion

The word learning model generally prefers a very sparse word-to-object map. This is enforced by using a concentration parameter α_1 that is quite small relative to the α_0 parameter, and it biases the model so that the distributions over referring words are very different from that over non-referring words. A small concentration parameter biases the estimator to prefer a small set of word types. In contrast, the relatively large concentration parameter for the non-referring words tends to result in most of the words receiving highest probability as non-referring words. The model thus categorizes words accordingly. It is in part due to this tendency towards sparse word-object maps that the model enforces mutual exclusivity, a phenomenon well documented among natural word learners (Markman, 1990).

Aside from contributing to mutual exclusivity and specialization among the topical word distributions, the small concentration parameter also has important implications for the segmentation task. A very small value for α_1 discourages the learner from acquiring more word types for each meaning than absolutely necessary, thereby forcing the segmenter to use fewer types to explain the sequence of phonemes. A model without any notion of meaning cannot maintain separate distributions for different topics, and must in some sense treat all words as non-referring. A segmenting model without meanings cannot share the word learner's reluctance to propose new meaning-bearing word types and might propose three separate types for "your book", "a book", and "the book". However, with a small enough prior on new referring word types, the word learner that discovers a common referent for all three sequences and, preferring fewer referring word types, is more likely to discover the common subsequence "book". With a single word-object pair ("book", BOOK), the word learner could explain reference for all three sequences instead of using the three separate pairs ("yourbook", BOOK), ("abook", BOOK), and ("thebook", BOOK).

While relying on non-linguistic context helps segment the meaning-bearing words, the overall improvement is small in our current corpus. One reason for this small improvement was that only 9% of the tokens in the corpus were referring words. In corpora containing a larger variety of objects – and in cases where sub- and super-ordinate labels like "eyes" and "ears" are coded – this percentage is likely to be much higher, leading to a greater boost in overall segmentation performance.

We should acknowledge that the decisions entailed in enriching the annotations are neither trivial nor without theoretic implication, however. It is not immediately obvious how to represent the non-linguistic correlates of verbs, for instance. Developmentally, verbs are typically acquired much later than nouns, and it has been argued that this may be due to the difficulty of producing a cognitive representation of the associated meaning (Gentner and Boroditsky, 2001). Even among concrete nouns, not all are equal. Children tend to have a bias toward whole objects when mapping novel words to their non-linguistic counterparts (Markman, 1990). Decisions about more sophisticated encoding of non-linguistic information may thus require more knowledge about children's representations of the world around them

5 Conclusion and Future Work

We find (1) that it is possible to jointly infer both meanings and a segmentation in a fully unsupervised way and (2) that doing so improves the segmentation performance of our model. In particular, we found that although the word learning side suffered from segmentation errors, and performed worse than a model that learned from a gold standard segmentation, the loss was only slight. On the other hand, segmentation performance for the meaning bearing words improved a great deal. The first result suggests that is not necessary to assume fully segmented input in order to learn word meanings, and that the segmentation and word learning tasks can be effectively modeled in parallel, allowing us to explore potential developmental interactions. The second result suggests that synergies do actually exist and argue not only that we can model the two as parallel processes, but that doing so could prove fruitful.

Our model is relatively simple both in terms of word learning and in terms of word segmentation. For instance, social cues and shared attention, or discourse effects, might all play a role (Frank et al., 2009b). Shared features or other relationships can also potentially impact how quickly one might generalize a label to multiple instances (Tenenbaum and Xu, 2000). There are many ways to elaborate on the word learning task, with additional potential synergistic implications.

We might also elaborate the linguistic structures we incorporate into the word learning model. For instance, Johnson (2008) explores synergies in syllable and morphological structures in word segmentation. Aspects of linguistic structure, such as morphology, may contribute to word meaning learning beyond its contribution to word segmentation performance.

Acknowledgments

This research was funded by NSF awards 0544127 and 0631667 to Mark Johnson and by NSF DDRIG 0746251 to Michael C. Frank. We would also like to thank Anne Fernald for providing the corpus and Maeve Cullinane for help in coding it.

Abstract

For millions of people in less resourced regions of the world, text messages (SMS) provide the only regular contact with their doctor. Classifying messages by medical labels supports rapid responses to emergencies, the early identification of epidemics and everyday administration, but challenges include text-brevity, rich morphology, phonological variation, and limited training data. We present a novel system that addresses these, working with a clinic in rural Malawi and texts in the Chichewa language. We show that modeling morphological and phonological variation leads to a substantial average gain of F=0.206 and an error reduction of up to 63.8% for specific labels, relative to a baseline system optimized over word-sequences. By comparison, there is no significant gain when applying the same system to the English translations of the same texts/labels, emphasizing the need for subword modeling in many languages. Language independent morphological models perform as accurately as language specific models, indicating a broad deployment potential.

1 Introduction

The whole world is texting, but rarely in English. Africa has seen the greatest recent uptake of cellphones, with an 8-fold increase over the last 5 years and saturation possible in another 5 (Buys et al., 2009). This is a leapfrog technology – for the majority of new users cellphones are the *only* form of remote communication, surpassing landlines, (non-mobile) internet access and even grid electricity, with costs making texts the dominant communication method. This has led social development organizations to leverage mobile technologies to support health (Leach-Lemens, 2009), banking (Peevers et al., 2008), access to market information (Jagun et al., 2008), literacy (Isbrandt, 2009) and emergency response (Munro, 2010). The possibility to automate many of these services through text-classification is huge, as are the potential benefits – those with the least resources have the most to gain.

However, the data presents many challenges, as text messages are brief, most languages have rich morphology, spellings may be overly-phonetic, and there is often limited training data. We partnered with a medical clinic in rural Malawi and FrontlineSMS:Medic, whose text message management systems serve a patient population of over 2 million in less developed regions of the world. The system allows remote community health workers (CHWs) to communicate directly with more qualified medical staff at centralized clinics, many for the first time.

We present a short-message classification system that incorporates morphological and phonological/orthographic variation, with substantial improvements over a system optimized on word-sequences alone. The average gain is F=0.206 with an error reduction of up to 63.8% for specific labels. For 6 of the 9 labels this more than *doubles* the accuracy. By comparison, there is *not* a significant gain in accuracy when applying the same system to the English translations of the same texts/labels, emphasizing the need for modeling subword structures, but also highlighting why morphology has been peripheral in text classification until now.

2 Language and data

Chichewa is a Bantu language with about 13 million speakers in Southern Africa including 65% of Malawians. We limit examples to the nouns: *odwala* 'patient', *mankhwala* 'medicine'; verb: *fun* 'want'; and the 1st person pronoun/marker: *ndi-* 'I'. Chichewa is closely related to many neighboring languages – more than 100 million people could recognize *ndifuna* as 'I want'.

The morphological complexity is average with about 2-3 morpheme boundaries per word, but this is rich and complex compared to estimates for English, Spanish and Chinese with average of 0.33, 0.85 and 0.01 morpheme boundaries per word. A typical verb is *ndimakafunabe*, 'I am still wanting', consisting of six morphemes, *ndi-ma-ka-fun-a-be*, expressing: 1st person Subject; present tense; noun-class (gender) agreement with the Object; 'want'; verb part-of-speech; and incompletive aspect.

2.1 Labels

The text messages are coded for 0-9 labels in 3 groupings (with counts):

Administrative: related to the clinic:

1. Patient-related (394)
2. Clinic-admin: meetings, supplies etc (169)
3. Technological: phone-credit, batteries etc (21)

Requests: from Community Health Workers:

4. Response: any action requested by CHW (124)
5. Request for doctor (62)
6. Medical advice: CHW asking for advice (23)

Illness: changes of interest to monitoring bodies:

7. TB: tuberculosis (44)
8. HIV: HIV, AIDS and/or treatments (45)
9. Death: reported death of a patient (30)

The groupings correspond to the three main stakeholders of the messages: the clinic itself, interested in classifying messages according to internal work-practices; the Community Health Workers and their patients, acting as the direct care-givers outside the clinic; and broader bodies like the World Health Organization who are interested in monitoring diseases and early identification of epidemics (biosurveillance). The labels are the three most frequent labels required by each of these user groups.

We analyzed 4 months of texts messages with approximately 1,500 labels from 600 messages, consisting of 8,000 words and 30,000 morphemes. While this is small, the final system is being piloted at a clinic in rural Malawi, where users can define new labels at any time according to changing work-practices, new diseases etc. If more than 4 months of manually labeling were required it could limit the utility and user acceptance.

All the messages were translated into English by a medical practitioner, allowing us to make cross-linguistic comparisons of our system.

2.2 Variation

The variation in the data is large. There are >40 forms for 'patient' and only 32% are *odwala*. Of the rest, >50% occur only once. The variation results from morphology: *ndi-odwala*; phonology: *odwa<u>r</u>a*, *ndi<u>w</u>odwala*, and compounding: *ndatindidziwewodwala*. There are also >10 spellings for the English borrowing: *patient*, *pachenti* etc, and 3 for the synonym *matenda*.

Similarly, there are >20 forms for 'medicine'. For *fun* 'want', there are >30 forms with >80% occuring only once. There are >200 forms containing *ndi* and no one form accounts for more than 5% of the instances.

The co-occurrence of *ndi* and *fun* within a word is a strong non-redundant predictor for several labels, but >75% of forms occur only once and >85% of the forms are non-contiguous, as above and in the most frequent *ndi-ma-funa* 'I currently want'.

By contrast, in the English translations 'needing' occurs just once but all other forms of 'patient', 'medicine' and '(I) want/need' are frequent.

This brief introduction to the language and data should make it clear that specialized methods are required for modeling variation in text messages, especially in many languages where text messaging is the dominant form of digital communication.

3 Morphological models

We compared language specific and language independent morphological models, comparing 3 methods (with *ndimafuna* as an example):

Stemmed: {*ndi, fun*}
Segmented: {*ndi, ma, fun, a*}
Morph-config: {*ndi-ma, ndi-fun, ndi-a, ma-fun...*}

We also looked at character ngrams, as used by Hidalgo et al. (2006) for morphological variation in English and Spanish. The results converged with those of the segmented model, which is not surprising as the most frequent features would be similar and increasing data items would overcome the sparcity. We leave more sophisticated character ngram modeling for future work.

3.1 Language specific

For the language specific morphological models we implemented a morphological parser as a set of context-free grammars for all possible prefixes and suffixes according to the formal definitions of Chichewa morphology in Mchombo (2004).

We identified stems by parsing potential prefixes and suffixes, segmenting a word w into n morphemes $w_{m,0}, \ldots, w_{m,n-1}$ leaving a stem w_s with length $len(w_s)$ and corpus frequency of $f(w_s)$, such that $len(w_s) > 0$ (ie, there must be a stem). Where multiple parses could be applied, we minimized $len(w_s)$, then maximized n.

3.2 Language independent

For the language independent morphological models we adapted the word-segmenter of Goldwater, Griffiths and Johnson (2009), to morphological parsing (see Related Work for other algorithms we tested/considered). It was suited to our task because a) it is largely nonparametric, meaning that it can be deployed as a black-box before language-specific properties are known b) it favored recall over precision (see the Results for discussion) and c) using a segmentation algorithm, rather than explicitly modeling morphology, also addresses compounds.

This model uses a *Hierarchical Dirichlet Process* (HDP) (Teh et al., 2005). Every morpheme in the corpus m_i is drawn from a distribution G which consists of possible morphemes (the affixes and stems) and probabilities associated with each morpheme. G is generated from a Dirichlet Process (DP) distribution $DP(\alpha_0, P_0)$, with morphemes sampled from P_0 and their probabilities determined by a concentration parameter α_0. The context-sensitive model where H_m is the DP for a specific morpheme is:

$$\begin{array}{lll} m_i|m_{i-1} = m, H_m & \sim H_m & \forall m \\ H_m|\alpha_1, G & \sim DP(\alpha_1, G) & \forall m \\ G|\alpha_0, P & \sim DP(\alpha_0, P_0) & \end{array}$$

Note that this part of our model is identical to the bigram HDP in Goldwater et al. (2009), except that we possess a set of morphemes, not words. Because word boundaries are already marked in the majority of the messages, we constrain the model to treat all existing word boundaries in the corpus as morpheme boundaries, thus constraining the model to morpheme and compound segmentation.

Unlike word-segmentation, not all tokens in the morpheme lexicon are equal, as we want to model stems separately from affixes in the stemmed models. We assume a) the free morphemes (stems and through compounding) are the least frequent and therefore have the lowest final probability, $P(m)$, in the HDP model; and b) each word w must have at least one free morpheme, the stem w_s ($w_s \neq \emptyset$).[1]

The token-optimal process for identifying stems is straightforward and efficient. The words are sorted by the $argmin$ probabilities of $P(w_{m,0}), \ldots, P(w_{m,n-1})$. For each word w, unless w_s can be identified by a previously observed free morpheme, w_s is identified as $argmin(P(w_{m,0}), \ldots, P(w_{m,n-1}))$ and w_s is added to our lexicon of free morphemes. This algorithm iterates over the words with one extra pass to mark all free morphemes in each word (assuming that there might be compounds we missed on the first pass). The cost, where M is the total number of morphemes and W the total number of words, is $O(log(W) + M)$.

This process has the potential to miss free morphemes that only happened to occur in compounds with less-probable stems, but this did not occur in our data.

4 Phonological/Orthographic Models

We compared three models of phonological/orthographic variation:

Chichewa: Chichewa specific
Script: Roman script specific
Indep: language independent

We refer to these using the term 'phonology' very broadly. The majority of the variation stems from

[1] Note that identifying stems must be a separate step – if we allowed multiple free morphemes for each word to enter the lexicon without penalty in the HDP model it would converge on a zero-penalty distribution where *all* morphemes were free.

the phonology, but also from phonetic variation as expressed in a given writing system, and variation in the writing system itself arising from fluent speakers with varying literacy.

4.1 Chichewa specific

For the language specific normalization, we applied a set of heuristics to the data, based on the variation given in (Paas, 2005) and our own knowledge of how Bantu languages are expressed in Roman scripts. The heuristics were used to normalize all alternates, eg: $\{iwo \rightarrow i\emptyset o\}$ and $\{r \rightarrow l\}$, resulting in *ndiwodwara* → *ndiodwala*.

The heuristics represented forms for phonemes with the same potential place of articulation ('c/k'), forms with an adjacent place-of-articulation that are common phonological alternates ('l/r', 'e,i'), voicing alternations ('s/z'), or language-internal phonological processes like the insertion of a glide between vowels that the morphology has made adjacent (like we pronounce but don't spell in 'go(w)ing' in English).

We also implemented hard-coded acronym-recovery methods for acronyms associated with the 'Illness' labels: 'HIV', 'TB', 'AIDS', 'ARV'.

4.2 Script specific

The script specific techniques used the same sets of alternates in the language specific model, but normalized such that the heuristic H was applied to a word w in the corpus C resulting in an alternate w', iff $w' \in C$. This method limits the alternates to those whose existence is supported by the data. It is therefore more conservative than the previous method.

For more general acronym identification, we adapted the method of Schwartz & Hearst (2003). We created a set of candidate acronyms by identifying capitalized sequences in non-capitalized contexts and period-delimited single character sequences. All case-insensitive sequences that were segmented by consistent non-alphabetic characters were then identified as acronyms, provided that they ended in a non-alphabetic character. We could not define a similar acronym-start boundary, as prefixes were often added to acronyms, even when the acronyms themselves contained spaces, eg: '*aT. B.*'.

4.3 Language independent

For complete language independence we applied a noise-reduction algorithm to the stream of characters in order to learn the heuristics that represented potential phonological alternates by identifying all minimal pairs of characters sequences (sequences that alternated by one character, include the absence of a character).

Given all sequences of characters, we identified all pairs of sequences of length $> l$ that differed by one character c_1, where c_1 could be null. We then ranked the pairs of alternating sequences by descending length and applied a threshold t, selecting the t longest sequences, creating alternating patterns from all pairs. Regardless of l or t, the resulting heuristics did not resemble those in 4.1 or 4.2.

We did not implement any acronym identification methods, for obvious reasons.

5 Results

The results are compared to a baseline system optimized over word sequences (words and ngrams but no subword modeling). All results presented here are from a MaxEnt model using a leave-one-out cross-validation.

For the English translations of the texts there was no phonological/orthographic variation beyond that resulting from morphology, so we only applied the language independent morphological models.

5.1 Morphology

With the exception of the unsupervised stemming, all the morphological models led to substantial gains in accuracy. As Table 1 shows, the most accurate system used the language specific segmentation, with an average accuracy of F=0.476, a macro-average gain of 22.4%.

The greatest increase in accuracy occured where verbs were the best predictors – the words with the most complex morphology. The 'Response' label showed the greatest relative gain in accuracy for those with a non-zero baseline, where the accuracy increased 4-fold from F=0.113 to F=0.442. It is expected that a label predicated on requests for action should rely on the isolation of verb stems, but this is still a very substantial gain. In contrast to this 391.2% gain in accuracy for Chichewa, the gain for

	Baseline	Stemmed		Segmented		Morph-Config		Gain

TB	0.235	0.357	0	0.414	0.200	0.386	0.327	+17.8	+09.2
Death	0.235	0.333	0.229	0.500	0.667	0.462	0.723	+48.8	+48.8
Average.	0.252	0.370	0.163	0.476	0.425	0.455	0.427	+22.4	+17.4

Table 1: Morphology results: F-values for leave-one-out cross-validation comparing different morphological models. *Indep* = language independent, *Chich* = specific to Chichewa, ( ) = not significant ($\rho > 0.05, \chi^2$), *Final* = Gain of the 'Morph-Config, Indep' model over the Baseline.

English, while still relying on the isolation of verb stems, only increased the accuracy by 5.4%.

The unsupervised stemming underperformed the baseline model by 8.9%, due to over-segmentation. Compared to the Chichewa stemmer, we estimate that the unsupervised stemmer had 90-95% recall and 40-50% precision, resulting in over-stemmed tokens. However, this seemed to be favor the *segmented* and *morph-config* models, as unnecessary segmentation can be recovered when the tokens are sequenced or re-configured, with the supervised model arriving at the optimal weights for each candidate token or sequence. This can be seen by comparing the stemmed and morph-config results for the Chichewa-specific and language independent results. The difference in stemming is 20.7% but for the morph-config models it is only 2.8%. A loss in segmentation recall could not be recovered in the same way, as adjacent non-segmented morphemes will remain one token. This leads us to conclude that recall should be weighted more highly than precision in unsupervised morphological models applied to supervised classification tasks.

5.2 Phonology

For the phonological models the results in Table 2 show that the script-specific model was the most accurate with an average of F=0.443, a gain of 19.1% over the baseline.

There are correlations between morphological variation and phonological variation, with the gains similar for each label in Table 1 and Table 2. This is because much phonological variation often arises from the morphology, as in *ndiwodwala* where the glide *w* is pronounced and variably written between the vowels made adjacent through morphology. It is also because more morphologically complex words are longer and simply have more potential for phonological and written variation. The were greater gains in identifying the 'TB' and 'HIV' labels here than in the morphological models as the result of acronym identification.

The language independent model did not perform well. Despite changing the data considerably, there was little change in the accuracy, indicating that the changes it made were largely random with respect to the target concepts. The most frequent alternations in large contexts were noun-class prefixes differing by a single character, which has the potential to change the meaning, and this seemed to negate any gains from normalization.

While language independent results would have been ideal, a system with script-specific assumptions is realistic. It is likely that text messages are regularly sent in 1000s of languages but less than 10 scripts, and our definition of 'script specific' would be considered 'language independent' elsewhere. For example, in the Morpho Challenge (see

	Baseline	**Model**			**Gain**

Related Work) Arabic data was converted to Roman script, and it is likely that the methods could be adapted with some success to any alphabetic script.

5.3 Combined results

Table 3 gives the final results, comparing the systems over the original text messages and the English translations of the same messages. The most accurate results were achieved by applying the phonological normalization before the morphological segmentation, giving a (macro) average of 0.459 which is an increase of 20.6% over the baseline. The increase in accuracy was not cumulative – the combined system outperforms both the standalone phonological and morphological systems, but with a comparatively modest gain.

The final English system is 9.2% more accurate than the final Chichewa system, but the Chichewa system has closed the gap considerably as the English baseline system was 25.7% more accurate than the baseline Chichewa system. Assuming that the potential accuracy is approximately equal (given both languages are encoding exactly the same information) we conclude that we have made substantial gains in accuracy but there are further large gains to be made. Therefore, while we have not solved the problem of text message classification in morphologically rich languages, we have been able to make promising gains in an exciting new area of research.

5.4 Practical effectiveness

The FrontlineSMS system currently allows users to filter messages by keywords, similar to many email clients. Because of the large number of variants per word this is sub-optimal in many languages. We defined a second baseline to model an idealized version of the current system that assumes oracle knowledge of the keyword/label and the optimal order in which to apply rules created from this knowledge. The only constraint was that we excluded words that occurred only once. In essence, it is a MaxEnt model that includes seen test items and assigns a label according to the single strongest feature for each test item.

Here, we evaluated the systems according to Micro-F, recall and precision, as these give a better gauge of the frequency of error per incoming text, and therefore the usability for someone needing to correct mislabeled texts. We also calculated the Micro-F for each label/non-label decision to give exact figures per classification decision. The results are in Table 4. The Micro-F is 0.684 as compared to 0.403 for the keyword system. The higher precision is also promising, indicating that when we assign a label we are more often correct. By adjusting the precision and recall through label confidence thresholds, 90% precision can be achieved with 35.3% recall.[2] In terms of usability, the Label/no-Label re-

Table 3: Final Results, comparing the systems in Chichewa and the English translations.

sults are very promising, reducing errors from 1 in 4 to 1 in 20.

The learning rates in Figure 1 show that the learners are converging on accurate models after only seeing a handful of text messages. This figure also makes it clear that subword processing gives relatively little gain to the English translations. The disparity between the final model and the baseline widens as more items are seen, indicating that the failure of the word-optimal baseline model is not just due to a lack of training items.

5.5 Other models investigated

Much recent work in text classification has been in machine-learning, comparing models over constant features. We tested SVMs and joint learning strategies. The gains were significant but small and did not closed the gap between systems with and without subword modeling. We therefore omit these for space and scope.

However, one interesting result came from extending the feature space with topics derived from *Latent Dirichlet Allocation* (LDA) using similar methods to Ramage et al. (2009). This produced significant gains (micro-F=0.029), halving the remaining gap with the English system, but only when the topics were derived from modeling non-contiguous morpheme sequences, not words-alone or segmented morphemes. We found that the different surface forms of each word cooccurred *less* often than chance (0.46 as often as chance for the different forms of *odwala*) forming disjunctive distributions. We suspect that this acts as a bias against robust unsupervised clustering of the different forms.

6 Related Work

To our best knowledge, no prior researchers have worked on subword models for text message categorization, or any NLP task with the Chichewa, but we build on many recent developments in computational morphology and NLP for Bantu languages.

Badenhorst et al. (2009) found substantial variation in a speech recognition corpus for 9 Southern Bantu languages, where accurate models could also be built with limited data. Morphological segmentation improved Swahili-English machine translation in De Pauw et al. (2009), even in the absense of gold standard reference segmentations, as was the case here. The complexity and necessity of modeling non-contiguous morphemes in Bantu languages is discussed by Pretorius et al. (2009).

Computational morphology (Goldsmith, 2001; Creutz, 2006; Kurimo et al., 2008; Johnson and Goldwater, 2009; Goldwater et al., 2009) has begun to play a prominent role in machine translation and speech recognition for morphologically rich languages (Goldwater and McClosky, 2005; Tachbelie et al., 2009). In the current-state-of-the-art, a combination of the *ParaMor* (Monson et al., 2008) and *Morfessor* (Creutz, 2006) algorithms achieved

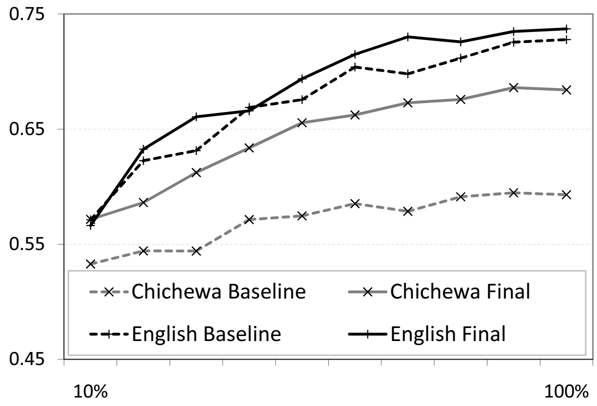

Figure 1: The learning rate, comparing micro-F for the Chichewa and English systems on different training set sizes. A random stratified sample was used for subsets.

the most accurate results in 2008 Morpho Challenge Workshop (Kurimo et al., 2008). *ParaMor* assumes a single affix and is not easily adapted to more complex morphologies, but we were able to test and evaluate *Morfessor* and the earlier *Linguistica* (Goldsmith, 2001). Both were more accurate for segmentation than our adaptation of Goldwater et al. (2009), but with lower recall. For the reasons discussed in Section 5.3 this meant less accuracy in classification. Goldwater et al. have also used the Pitman-Yor algorithm for morphological modeling (Goldwater et al., 2006). In results too recent to test here, Pitman-Yor has been used for segmentation with accuracy comparable to the HDP model but with greater efficiency (Mochihashi et al., 2009). Biosurveillance systems currently use simple rule-based pre-processing for subword models. Dara et al. (2008) found only modest gains, although the data was limited to English.

For text message classification, prior work is limited to identifying SPAM (Healy et al., 2005; Hidalgo et al., 2006; Cormack et al., 2007), where specialized algorithms and feature representations were also found to improve accuracy. For written variation, Kobus et al. (2008) focussed on SMS-specific abbreviations in French. Unlike their data, SMS-specific abbreviations were not present in our data. This is consistent with the reports on SMS practices in the related isiXhosa language (Deumert and Masinyana, 2008), but it may also be because the data we used contained professional communications not personal messages.

	Label class		**Label/No-Label**

Prec.	0.265	0.796	0.570	0.972
Rec.	0.842	0.599	0.953	0.929

Table 4: Micro-F, precision and recall, compared with the oracle keyword system. *KWF* = Oracle Keyword Filter.

7 Conclusions

We have demonstrated that subword modeling in Chichewa leads to significant gains in classifying text messages according to medical labels, reducing the error from 1 in 4 to 1 in 20 in a system that should generalize to other languages with similar morphological complexity.

The rapid expansion of cellphone technologies has meant that digital data is now being generated in 100s, if not 1000s, of languages that have not previously been the focus of language technologies. The results here therefore represent just one of a large number of potential new applications for short-message classification systems.

Automatic Diacritization for Low-Resource Languages Using a Hybrid Word and Consonant CMM

Abstract

We are interested in diacritizing Semitic languages, especially Syriac, using only diacritized texts. Previous methods have required the use of tools such as part-of-speech taggers, segmenters, morphological analyzers, and linguistic rules to produce state-of-the-art results. We present a low-resource, data-driven, and language-independent approach that uses a hybrid word- and consonant-level conditional Markov model. Our approach rivals the best previously published results in Arabic (15% WER with case endings), without the use of a morphological analyzer. In Syriac, we reduce the WER over a strong baseline by 30% to achieve a WER of 10.5%. We also report results for Hebrew and English.

1 Introduction

Abjad writing systems omit vowels and other diacritics. The ability to restore these diacritics is useful for personal, industrial, and governmental purposes—especially for Semitic languages. In its own right, the ability to diacritize can aid language learning and is necessary for speech-based assistive technologies, including speech recognition and text-to-speech. Diacritics are also useful for tasks such as segmentation, morphological disambiguation, and machine translation, making diacritization important to Natural Language Processing (NLP) systems and intelligence gathering. In alphabetic writing systems, similar techniques have been used to restore accents from plain text (Yarowsky, 1999) and could be used to recover missing letters in the compressed writing styles found in email, text, and instant messages.

We are particularly interested in diacritizing Syriac, a low-resource dialect of Aramaic, which possesses properties similar to Arabic and Hebrew. This work employs conditional Markov models (CMMs) (Klein and Manning, 2002) to diacritize Semitic (and other) languages and requires only diacritized texts for training. Such an approach is useful for languages (like Syriac) in which annotated data and linguistic tools such as part-of-speech (POS) taggers, segmenters, and morphological analyzers are not available. Our main contributions are as follows: (1) we introduce a hybrid word and consonant CMM that allows access to the diacritized form of the previous words; (2) we introduce new features available in the proposed model; and (3) we describe an efficient, approximate decoder. Our models significantly outperform existing low-resource approaches across multiple related and unrelated languages and even achieve near state-of-the-art results when compared to resource-rich systems.

In the next section, we review previous work relevant to our approach. Section 3 then motivates and describes the models and features used in our framework, including a description of the decoder. We describe our data in Section 4 and detail our experimental setup in Section 5. Section 6 presents our results. Finally, Section 7 briefly discusses our conclusions and offers ideas for future work.

2 Previous Work

Diacritization has been receiving increased attention due to the rising interest in Semitic languages, cou-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 519–527,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

pled with the importance of diacritization to other NLP-related tasks. The existing approaches can be categorized based on the amount of resources they require, their basic unit of analysis, and of course the language they are targeting. Probabilistic systems can be further divided into generative and conditional approaches.

Existing methodologies can be placed along a continuum based on the quantity of resources they require—a reflection of their cost. Examples of resources used include morphological analyzers (Habash and Rambow, 2007; Ananthakrishnan et al., 2005; Vergyri and Kirchhoff, 2004; El-Sadany and Hashish, 1989), rules for grapheme-to-sound conversion (El-Imam, 2008), transcribed speech (Vergyri and Kirchhoff, 2004), POS tags (Zitouni et al., 2006; Ananthakrishnan et al., 2005), and a list of prefixes and suffixes (Nelken and Shieber, 2005). When such resources exist for a particular language, they typically improve performance. For instance, Habash and Rambow's (2007) approach reduces the error rate of Zitouni et al.'s (2006) by as much as 30% through its use of a morphological analyzer. In fact, such resources are not always available. Several data-driven approaches exist that require only diacritized texts (e.g., Kübler and Mohamed, 2008; Zitouni et al., 2006; Gal, 2002) which are relatively inexpensive to obtain: most literate speakers of the target language could readily provide them.

Apart from the quantity of resources required, diacritization systems also differ in their basic unit of analysis. A consonant-based approach treats each consonant[1] in a word as a potential host for one or more (possibly null) diacritics; the goal is to predict the correct diacritic(s) for each consonant (e.g., Kübler and Mohamed, 2008). Zitouni et al. (2006) extend the problem to a sequence labeling task wherein they seek the best *sequence* of diacritics for the consonants. Consequently, their approach has access to previously chosen diacritics.

Alternatively, the basic unit of analysis can be the full, undiacritized word. Since morphological analyzers produce analyses of undiacritized words, diacritization approaches that employ them typically fall into this category (e.g., Habash and Rambow, 2007; Vergyri and Kirchoff, 2004). Word-based, low-resource solutions tend to treat the problem as word-level sequence labeling (e.g., Gal, 2002).

Unfortunately, word-based techniques face problems due to data sparsity: not all words in the test set are seen during training. In contrast, consonant-based approaches rarely face the analogous problem of previously unseen consonants. Thus, one low-resource solution to data sparsity is to use consonant-based techniques for unknown words (Ananthakrishnan et al., 2005; Nelken and Shieber, 2005).

Many of the existing systems, especially recent ones, are probabilistic or contain probabilistic components. Zitouni et al. (2006) show the superiority of their conditional-based approaches over the best-performing generative approaches. However, the instance-based learning approach of Kübler and Mohamed (2008) slightly outperforms Zitouni et al. (2006). In the published literature for Arabic, the latter two have the best low-resource solutions. Habash and Rambow (2007) is the state-of-the-art, high-resource solution for Arabic. To our knowledge, no work has been done in this area for Syriac.

3 Models

In this work, we are concerned with diacritization for Syriac for which a POS tagger, segmenter, and other tools are not readily available, but for which diacritized text is obtainable.[2] Use of a system dependent on a morphological analyzer such as Habash and Rambow's (2007) is therefore not cost-effective. Furthermore, we seek a system that is applicable to a wide variety of languages. Although Kübler and Mohamed's (2008) approach is competitive to Zitouni et al.'s (2006), instance-based approaches tend to suffer with the addition of new features (their own experiments demonstrate this). We desire to add linguistically relevant features to improve performance and thus choose to use a conditional model. However, unlike Zitouni et al. (2006), we use a hybrid word- and consonant-level approach based on the following observations (statistics taken from the Syriac training and development sets explained in Section 4):

[1] We refer to all graphemes present in undiacritized texts as consonants.

[2] Kiraz (2000) describes a morphological analyzer for Syriac that is not publicly available and is costly to reproduce.

1. Many undiacritized words are unambiguous: 90.8% of the word types and 63.5% of the tokens have a single diacritized form.

2. Most undiacritized word types have only a few possible diacritizations: the average number of possible diacritizations is 1.11.

3. Low-frequency words have low ambiguity: Undiacritized types occurring fewer than 5 times have an average of 1.05 possible diacritizations.

4. Diacritized words not seen in the training data occur infrequently at test time: 10.5% of the diacritized test tokens were not seen in training.

5. The diacritics of previous words can provide useful morphological information such as person, number, and gender.

Contrary to observations 1 and 2, consonant-level approaches dedicate modeling capacity to an exponential (in the number of consonants) number of possible diacritizations of a word. In contrast, a word-level approach directly models the (few) diacritized forms seen in training. Furthermore, word-based approaches naturally have access to the diacritics of previous words if used in a sequence labeler, as per observation 5. However, without a "backoff" strategy, word-level models cannot predict a diacritized form not seen in the training data. Also, low-frequency words by definition have less information from which to estimate parameters. In contrast, abundant information exists for each diacritic in a consonant-level system. To the degree to which they hold, observations 3 and 4 mitigate these latter two problems. Clearly a hybrid approach would be advantageous.

To this end we employ a CMM in which we treat the problem as an instance of sequence labeling at the word level with less common words being handled by a consonant-level CMM. Let $\mathbf{u}$ be the undiacriatized words in a sentence. Applying an order o Markov assumption, the distribution over sequences of diacritized words $\mathbf{d}$ is:

$$P\left(\mathbf{d}|\mathbf{u}\right) = \prod_{i=1}^{\|\mathbf{d}\|} P\left(d_i|\mathbf{d}_{i-o\ldots i-1}, \mathbf{u}; \boldsymbol{\omega}, \boldsymbol{\gamma}, \alpha\right) \quad (1)$$

in which the local conditional distribution of a diacritized word is an interpolation of a word-level model ($\boldsymbol{\omega}_{u_i}$) and a consonant-level model ($\boldsymbol{\gamma}$):

$$\begin{aligned} &P\left(d_i|\mathbf{d}_{i-o\ldots i-1}, \mathbf{u}; \boldsymbol{\omega}, \boldsymbol{\gamma}, \alpha\right) = \\ &\quad \alpha P\left(d_i|\mathbf{d}_{i-o\ldots i-1}, \mathbf{u}; \boldsymbol{\omega}_{u_i}\right) + \\ &\quad (1-\alpha) P\left(d_i|\mathbf{d}_{i-o\ldots i-1}, \mathbf{u}; \boldsymbol{\gamma}\right) \end{aligned}$$

We let the consonant-level model be a standard CMM, similar to Zitouni et al. (2006), but with access to previously diacritized words. Note that the order of this "inner" CMM need not be the same as that of the outer CMM.

The parameter α reflects the degree to which we trust the word-level model. In the most general case, α can be a function of the undiacritized words and the previous o diacritized words. Based on our earlier enumerated observations, we use a simple delta function for α: we let α be 0 when $\mathbf{u}_i$ is rare and 1 otherwise. We leave discussion for what constitutes a "rare" undiacritized type for Section 5.2.

Figure 1b presents a graphical model of a simple example sentence in Syriac. The diacritization for non-rare words is predicted for a whole word, hence the random variable D for each such word. These diacritized words D_i depend on previous D_{i-1} as per equation (1) for an order-1 CMM (note that the capitalized A, I, and O are in fact consonants in this transliteration). Because "NKTA" and "RGT" are rare, their diacritization is represented by a consonant-level CMM: one variable for each possible diacritic in the word. Importantly, these consonant-level models have access to the previously diacritized word (D_4 and D_6, respectively).

We use log-linear models for all local distributions in our CMMs, i.e., we use maximum entropy (maxent) Markov models (McCallum et al., 2000; Berger et al., 1996). Due to the phenomenon known as *d*-separation (Pearl and Shafer, 1988), it is possible to independently learn parameters for each word model $\boldsymbol{\omega}_{u_i}$ by training only on those instances for the corresponding word. Similarly, the consonant model can be learned independent of the word models. We place a spherical normal prior centered at zero with a standard deviation of 1 over the weights of all models and use an L-BFGS minimizer to find the MAP estimate of the weights for all the models (words and consonant).

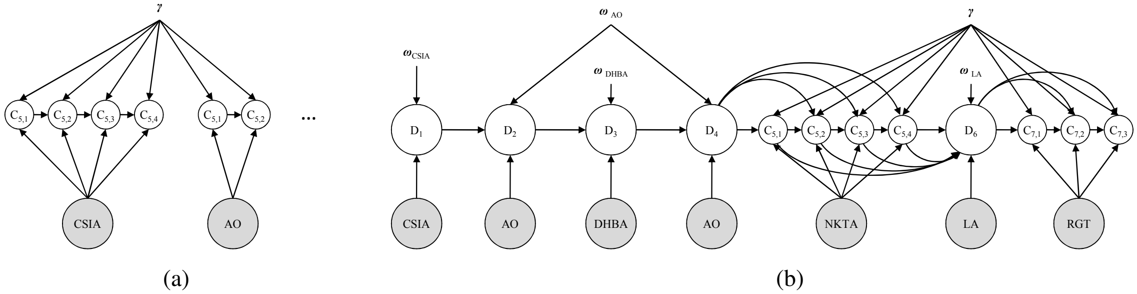

Figure 1: Graphical models of Acts 20:33 in Syriac, *CSIA AO DHBA AO NKTA LA RGT* 'silver or gold or garment I have not coveted,' using Kiraz's (1994) transliteration for (a) the initial portion of a consonant-level-only model and (b) a combined word- and consonant-level model. For clarity, both models assume a consonant-level Markov order of 1; (b) shows a word-level Markov order of 1. For simplicity, the figure further assumes that additional features come only from the current (undiacritized) word.

Note that Zitouni et al.'s (2006) model is a special case of equation (1) where all words are rare, the word-level Markov order (o) is 0, and the consonant-level Markov order is 2. A simplified version of Zitouni's model is presented in Figure 1a.

3.1 Features

Our features are based on those found in Zitouni et al. (2006), although we have added a few of our own which we consider to be one of the contributions of this paper. Unlike their work, our consonant-level model has access to previously diacritized words, allowing us to exploit information noted in observation 5.

Each of the word-level models shares the same set of features, defined by the following templates:

- The prefixes and suffixes (up to 4 characters) of the previously *diacritized* words.
- The string of the actual diacritics, including the null diacritic, from each of the previous o diacritized words and n-grams of these strings; a similar set of features is extracted but without the null diacritics.
- Every possible (overlapping) n-gram of all sizes from $n = 1$ to $n = 5$ of undiacritized words contained within the window defined by 2 words to the right and 2 to the left. These templates yield 15 features for each token.
- The count of how far away the current token is from the beginning/end of the sentence up to the Markov order; also, their binary equivalents.

The first two templates rely on diacritizations of previous words, in keeping with observation 5.

The consonant-level model has the following feature templates:

- The current consonant.
- Previous diacritics (individually, and n-grams of diacritics ending in the diacritic prior to the current consonant, where n is the consonant-level Markov order).
- Conjunctions of the first two templates.
- Indicators as to whether this is the first or last consonant.
- The first three templates independently conjoined with the current consonant.
- Every possible (overlapping) n-gram of all sizes from $n = 1$ to $n = 11$ consisting of consonants contained within the window defined by 5 words to the right and 5 to the left.
- Same as previous, but available diacritics are included in the window.
- Prefixes and suffixes (of up to length 4) of previously diacritized words conjoined with previous diacritics in the current token, both individually and n-grams of such.

This last template is only possible because of our model's dependency on previous diacritized words.

3.2 Decoder

Given a sentence consisting of undiacritized words, we seek the most probable sequence of diacritized words, i.e., $\arg\max_{\mathbf{d}} P(\mathbf{d}|\mathbf{u}...)$. In sentences containing no rare words, the well-known Viterbi algorithm can be used to find the optimum.

However, as can be seen in Figure 1b, predictions in the consonant-level model (e.g., $C_{5,1...4}$) depend on previously diacritized words (D_4), and some diacritized words (e.g., D_6) depend on diacritics in the previous rare word ($C_{5,1...4}$). These dependencies introduce an exponential number of states (in the length of the word) for rare words, making exact decoding intractable. Instead, we apply a non-standard beam during decoding to limit the number of states for rare words to the n-best (locally). This is accomplished by using an independent "inner" n-best decoder for the consonant-level CMM to produce the n-best diacritizations for the rare word given the previous diacritized words and other features. These become the only states to and from which transitions in the "outer" word-level decoder can be made. We note this is the same type of decoding that is done in pipeline models that use n-best decoders (Finkel et al., 2006). Additionally, we use a traditional beam-search of width 5 to further reduce the search space both in the outer and inner CMMs.

4 Data

Although our primary interest is in the Syriac language, we also experimented with the Penn Arabic Treebank (Maamouri et al., 2004) for the sake of comparison with other approaches. We include Hebrew to provide results for yet another Semitic language. We also apply the models to English to show that our method and features work well outside of the Semitic languages. A summary of the datasets, including the number of diacritics, is found in Figure 2. The number of diacritics shown in the table is less than the number of possible predictions since we treat contiguous diacritics between consonants as a single prediction.

For our experiments in Syriac, we use the New Testament portion of the Peshitta (Kiraz, 1994) and treat each verse as if it were a sentence. The diacritics we predict are the five short vowels, as well as *Sĕ̊yāmē*, *Rukkākhā*, *Quššāyā*, and *linea ocultans*.

lang	diacs	train	dev	test
Syriac	9	87,874	10,747	11,021
Arabic	8	246,512	42,105	51,664
Hebrew	17	239,615	42,133	49,455
English	5	1,004,073	80,156	89,537

Figure 2: Number of diacritics and size (in tokens) of each dataset

For Arabic, we use the training/test split defined by Zitouni et al. (2006). We group all words having the same P index value into a sentence. We build our own development set by removing the last 15% of the sentences of the training set. Like Zitouni, when no solution exists in the treebank, we take the first solution as the gold tag. Zitouni et al. (2006) report results on several different conditions, but we focus on the most challenging of the conditions: we predict the standard three short vowels, three *tanween*, *sukuun*, *shadda*, and all case endings. (Preliminary experiments show that our models perform equally favorably in the other scenarios as well.)

For Hebrew, we use the Hebrew Bible (Old Testament) in the Westminster Leningrad Codex (Zefania XML Project, 2009). As with Syriac, we treat each verse as a sentence and remove the paragraph markers (*pe* and *samekh*). There is a large number of diacritics that could be predicted in Hebrew and no apparent standardization in the literature. For these reasons, we attempt to predict as many diacritics as possible. Specifically, we predict the diacritics whose unicode values are 05B0-B9, 05BB-BD, 05BF, 05C1-C2, and 05C4. We treat the following list of punctuation as consonants: *maqaf*, *paseq*, *sof pasuq*, *geresh*, and *gershayim*. The cantillation marks are removed entirely from the data.

Our English data comes from the Penn Treebank (Marcus et al., 1994). We used sections 0–20 as training data, 21–22 as development data, and 23–24 as our test set. Unlike words in the Semitic languages, English words can begin with a vowel, requiring us to prepend a prosthetic consonant to every word; we also convert all English text to lowercase.

5 Experiments

For all feature engineering and tuning, we trained and tested on training and development test sets, respectively (as specified above). Final results are reported by folding the development test set into the training data and evaluating on the blind test set. We retain only those features that occur more than once.

For each approach, we report the Word Error Rate (WER) (i.e., the percentage of words that were incorrectly diacritized), along with the Diacritic Error Rate (DER) (i.e., the percentage of diacritics, including the null diacritic, that were incorrectly predicted). We also report both WER and DER for only those words that were not seen during training (UWER and UDER, respectively). We found that precision, recall, and f-score were nearly perfectly correlated with DER; hence, we omit this information for brevity.

5.1 Models for Evaluation

In previous work, Kübler et al. (2008) report the lowest error rates of the low-resource models. Although their results are not directly comparable to Zitouni et al. (2006), we have independently confirmed that the former slightly outperforms the latter using the same diacritics and on the same dataset (see Figure 4), thereby providing the strongest published baseline for Arabic on a common dataset. We denote this model as `kübler` and use it as a strong baseline for all datasets.

For the Arabic results, we additionally include Zitouni et al.'s (2006) lexical model (`zitouni-lex`) and their model that uses a segmenter and POS tagger (`zitouni-all`), which are not immediately available to us for Syriac. For yet another point of reference for Arabic, we provide the results from the state-of-the-art (resource-rich) approach of Habash and Rambow (2007) (`habash`). This model is at an extreme advantage, having access to a full morphological analyzer. Note that for these three models we simply report their published results and do not attempt to reproduce them.

Since `kübler` is of a different model class than ours, we consider an additional baseline that is a consonant-level CMM with access to the same information, namely, only those consonants within a window of 5 to either side (`ccmm`). This is equivalent to a special case of our hybrid model wherein both the word-level and the consonant-level Markov order are 0. The features that we extract from this window are the windowed n-gram features.

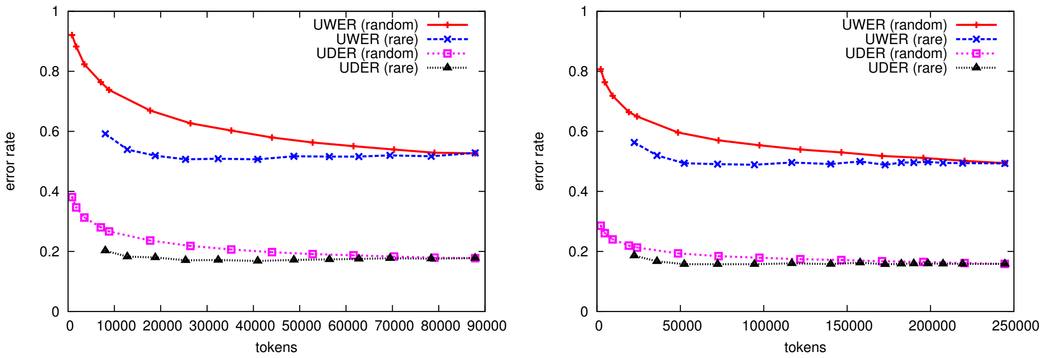
In order to assess the utility of previous diacritics and how effectively our features leverage them, we build a model based on the methodology from Section 3 but specify that all words are rare, effectively creating a consonant-only model that has access to the diacritics of previous words. We call this model `cons-only`. We note that the main difference between this model and `zitouni-lex` are features that depend on previous diacritized words.

Finally, we present results using our full hybrid model (`hybrid`). We use a Markov order of 2 at the word and consonant level for both `hybrid` and `cons-only`.

5.2 Consonant-Level Model and Rare Words

The hybrid nature of `hybrid` naturally raises the question of whether or not the inner consonant model should be trained only on rare words or on all of the data. In other words, is the distribution of diacritics different in rare words? If so, the consonant model should be trained only on rare words. To answer this question, we trained our consonant-level model (`cons-only`) on words occurring fewer than n times. We swept the value of the threshold n and compared the results to the same model trained on a random selection of words. As can be seen in Figure 3, the performance on unknown words (both UWER and UDER) using a model trained on rare words can be much lower than using a model trained on the same amount of randomly selected data. In fact, training on rare words can lead to a lower error rate on unknown words than training on all tokens in the corpus. This suggests that the distribution of diacritics in rare words is different from the distribution of diacritics in general. This difference may come from foreign words, especially in the Arabic news corpus.

While this phenomenon is more pronounced in some languages and with some models more than others, it appears to hold in the cases we tried. We found the WER for unknown words to be lowest for a threshold of 8, 16, 32, and 32 for Syriac, Arabic, Hebrew, and English, respectively.



(a) Syriac

(b) Arabic

Figure 3: Learning curves showing impact on consonant-level models when training on rare tokens for Syriac and Arabic. Series marked “rare” were trained with the least common tokens in the dataset.

	Approach	WER	DER	UWER	UDER
Syriac	kübler	15.04	5.23	64.65	18.21
	ccmm	13.99	4.82	**54.54**	**15.18**
	cons-only	12.31	5.03	55.68	19.09
	hybrid	**10.54**	**4.29**	55.16	18.86
Arabic	zitouni-lex	25.1	8.2	NA	NA
	kübler	23.61	7.25	66.69	20.51
	ccmm	22.63	6.61	57.71	16.10
	cons-only	**15.02**	**5.15**	48.10	15.76
	hybrid	17.87	5.67	**47.85**	**15.63**
	zitouni-all	18.0	5.5	NA	NA
	habash	14.9	4.8	NA	NA
Hebrew	kübler	30.60	12.96	89.52	36.86
	ccmm	29.67	12.05	80.02	**29.39**
	cons-only	23.39	10.92	75.70	33.34
	hybrid	**22.18**	**10.71**	**74.38**	32.40
English	kübler	10.54	4.38	**54.96**	**16.31**
	ccmm	11.60	4.71	58.55	16.34
	cons-only	8.71	3.87	58.93	17.85
	hybrid	**5.39**	**2.38**	57.24	16.51

Figure 4: Results for all languages and approaches

6 Discussion of Results

Since Syriac is of primary interest to us, we begin by examining the results from this dataset. Syriac appears to be easier to diacritize than Arabic, considering it has a similar number of diacritics and only one-third the amount of data. On this dataset, **`hybrid`** has the lowest WER and DER, achieving nearly 30% and 18% reduction in WER and DER, respectively, over **`kübler`**; it reduces both error rates over **`cons-only`** by more than 14%. These results attest to the effectiveness of our model in accounting for the observations made in Section 3.

A similar pattern holds for the Hebrew and English datasets, namely that **`hybrid`** reduces the WER over **`kübler`** by 28% to upwards of 50%; **`cons-only`** also consistently and significantly outperforms **`kübler`** and **`ccmm`**. However, the reduction in error rate for our **`cons-only`** and **`hybrid`** models tends to be lower for DER than WER in all languages except for English. In the case of **`hybrid`**, this is probably because it is inherently word-based. Having access to entire previous diacritized words may be a contributing factor as well, especially in **`cons-only`**.

When comparing model classes (**`kübler`** and **`ccmm`**), it appears that performance is comparable across all languages, with the maxent approach enjoying a slight advantage except in English. Interestingly, the maxent solution usually handles unknown words better, although it does not specifically target this case. Both models outperform **`zitouni-lex`** in Arabic, despite the fact that they use a much simpler feature set, most notably, the lack of previous diacritics. In the case of **`ccmm`** this may be attributable in part to our use of an L-BFGS optimizer, convergence criteria, feature selection, or other potential differences not noted in Zitouni et al. (2006). We note that the maxent-based approaches are much more time and memory intensive.

Using the Arabic data, we are able to compare our methods to several other published results.

The **cons-only** model significantly outperforms **zitouni-all** despite the additional resources to which the latter has access. This is evidence supporting our hypothesis that the diacritics from previous words in fact contain useful information for prediction. This empirically suggests that the independence assumptions in consonant-only models are too strict.

Perhaps even more importantly, our low-resource method approaches the performance of **habash**. We note that the differences may not be statistically significant, and also that Habash and Rambow (2007) omit instances in the data that lack solutions. In fact, **cons-only** has a lower WER than all but two of the seven techniques used by Habash and Rambow (2007), which use a morphological analyzer.

Interestingly, **hybrid** does worse than **cons-only** on this dataset, although it is still competitive with **zitouni-all**. We hypothesize that the observations from Section 3 do not hold as strongly for this dataset. For this reason, using a smooth interpolation function (rather than the abrupt one we employ) may be advantageous and is an interesting avenue for future research.

One last observation is that the approaches that use diacritics from previous words (i.e., **cons-only** and **hybrid**) usually have lower sentence error rates (not shown in Figure 4). This highlights an advantage of observation 5: that dependencies on previously diacritized words can help ensure a consistent tagging within a sentence.

7 Conclusions and Future Work

In this paper, we have presented a low-resource solution for automatic diacritization. Our approach is motivated by empirical observations of the ambiguity and frequency of undiacritized and diacritized words as well as by the hypothesis that diacritics from previous words provide useful information. The main contributions of our work, based on these observations, are (1) a hybrid word-level CMM combined with a consonant-level model for rare words, (2) a consonant-level model with dependencies on previous diacritized words, (3) new features that leverage these dependencies, and (4) an efficient, approximate decoder for these models. As expected, the efficacy of our approach varies across languages, due to differences in the actual ambiguity and frequency of words in these languages. Nevertheless, our models consistently reduce WER by 15% to nearly 50% over the best performing low-resource models in the literature. In Arabic, our models approach state-of-the-art despite not using a morphological analyzer. Arguably, our results have brought diacritization very close to being useful for practical application, especially when considering that we evaluated our method on the most difficult task in Arabic, which has been reported to have double the WER (Zitouni et al., 2006).

The success of this low-resource solution naturally suggests that where more resources are available (e.g., in Arabic), they could be used to further reduce error rates. For instance, it may be fruitful to incorporate a morphological analyzer or segmentation and part-of-speech tags.

In future work, we would like to consider using CRFs in place of MEMMs. Also, other approximate decoders used in pipeline approaches could be explored as alternatives to the one we used (e.g., Finkel et al., 2006). Additionally, we wish to include our model as a stage in a pipeline that segments, diacritizes, and labels morphemes. Since obtaining data for these tasks is substantially more expensive, we hope to use active learning to obtain more data.

Our framework is applicable for any sequence labeling task that can be done at either a word or a sub-word (e.g., character) level. Segmentation and lemmatization are particularly promising tasks to which our approach could be applied.

Finally, for the sake of completeness, we note that more recent work has been done based on our baseline models that has emerged since the preparation of the current work, particularly Zitouni et al. (2009) and Mohamed et al. (2009). We wish to address any improvements captured by this more recent work such as the use of different data sets and addressing problems with the *hamza* to decrease error rates.

Acknowledgments

We thank Imed Zitouni, Nizar Habash, Sandra Kübler, and Emad Mohamed for their assistance in reconstructing datasets, models, and features.

Abstract

Word Segmentation is the foremost obligatory task in almost all the NLP applications where the initial phase requires tokenization of input into words. Urdu is amongst the Asian languages that face word segmentation challenge. However, unlike other Asian languages, word segmentation in Urdu not only has space omission errors but also space insertion errors. This paper discusses how orthographic and linguistic features in Urdu trigger these two problems. It also discusses the work that has been done to tokenize input text. We employ a hybrid solution that performs an n-gram ranking on top of rule based maximum matching heuristic. Our best technique gives an error detection of 85.8% and overall accuracy of 95.8%. Further issues and possible future directions are also discussed.

1 Introduction

All language processing applications require input text to be tokenized into words for further processing. Languages like English normally use white spaces or punctuation marks to identify word boundaries, though with some complications, e.g. the word "e.g." uses a period in between and thus the period does not indicate a word boundary. However, many Asian languages like Thai, Khmer, Lao and Dzongkha do not have word boundaries and thus do not use white space to consistently mark word endings. This makes the process of tokenization of input into words for such languages very challenging.

Urdu is spoken by more than 100 million people, mostly in Pakistan and India[1]. It is an Indo-Aryan language, written using Arabic script from right to left, and Nastalique writing style (Hussain, 2003). Nastalique is a cursive writing system, which also does not have a concept of space. Thus, though space is used in typing the language, it serves other purposes, as discussed later in this paper. This entails that space cannot be used as a reliable delimiter for words. Therefore, Urdu shares the word segmentation challenge for language processing, like other Asian languages.

This paper explains the problem of word segmentation in Urdu. It gives details of work done to investigate linguistic typology of words and motivation of using space in Urdu. The paper then presents an algorithm developed to automatically process the input to produce consistent word segmentation, and finally discusses the results and future directions.

2 Urdu Writing System

Urdu is written in cursive Arabic script. Characters in general join with the neighbors within a word and in doing so acquire different shapes. Logically, a character can acquire up to four shapes, i.e. initial, medial, final position in a connected sequence or an isolated form. The characters having this four-way shaping are known as *joiners*. However, another set of characters only join with characters before them but do not join with character after them, and are termed as *non-joiners*. The non-joiners only have final and isolated forms. For example Arabic Letter Farsi Yeh ی is a joiner and has four shapes ﯾ, ﯿ, ﯽ and ی respectively and Arabic letter Dal د is a non-joiner and has two forms د and ـد only. The shape that these characters acquire depends upon the context.

Table 1 lists the orthographic rules that Urdu characters follow. For example, the table shows that in the middle of a word, if the character is a non-joiner, it acquires final shape when following a

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 528–536,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

joiner and isolated shape when following a non-joiner. This joining behavior results in formation of multiple connected portions within a word, each called a *ligature*.

Word	J-Shape	Example	NJ-Shape	Example
Start	I	مسجد	I_s	دجال
Middle	M after J	نمره	F after J	بندر
	I after NJ	دمبا	I_s after J	نادر
End	F after J	عجم	F after J	بند
	I_s after NJ	کام	I_s after NJ	رد

J = Joiners, NJ = Non-Joiners
I = Initial, I_s = Isolated, M = Medial, F = Final
Underlined = Shape in Consideration				

Table 1: Orthographic Rules for Urdu

The concept of space as a word boundary marker is not present in Urdu writing. As an Urdu learner, a person is not taught to leave a space between words, but only to generate correct shaping while writing. Thus, the concept of space is only learnt later on when the person learns how to use a computer. However, space is introduced as a tool to control the correct letter shaping and not to consistently separate words. For example, the native speaker learns to insert a space within the word ضرورت مند ("needy") to generate the correct shape of ت. Without space it appears as ضرورتمند which is visually incorrect. On contrary, the user finds it unnecessary to insert a space between the two words اردومرکز ("Urdu Center"), because the correct shaping is produced automatically as the first word ends with a non-joiner. Therefore اردومرکز and اردو مرکز look identical.

Though space character is not present in Urdu, with increasing usage of computer it is now being used, both to generate correct shaping (as discussed above) and also to separate words (a habit being carried over to Urdu from English literate computer users). This makes space an unreliable cue for word boundary. The problem is further obfuscated by the lack of a clear definition of a work in Urdu in some contexts. The next section discusses these issues.

3 Segmentation Issues in Urdu Text

The segmentation challenges can be divided into two categories, challenges caused due to joiner and non-joiner characters.

3.1 Space Omission

As discussed, for words ending with non-joiners correct shaping is generated even when space is not typed and thus, many times a user omits the space. Though there is no visible implication, from the perspective of computational processing not typing a space merges current word with the next word. Figure 1 below illustrates an example, where the phrase has eight words (or tokens) each ending with a non-joiner and thus the whole phrase can be written without a space and is still visibly same and equally readable.

قافلے کے صدر احمد شیر ڈوگر نے کہا

(a)

قافلےکےصدراحمدشیرڈوگرنےکہا

(b)

Figure 1: All Words Ending with Non-Joiners (a) with Spaces, (b) without Spaces between Words ("Troop Leader Ahmed Sher Dogar Said")

Another frequent set of space omissions are caused due to variation in the definition of a word in Urdu. There are certain function words in Urdu which may be combined with other function words and content words by some writers but may be written separately by others. Shape variation may also occur in some of these cases, but is overlooked by the writers. Table 2 gives some examples of such cases. Though the merged form is not considered correct diction, it is still frequently used and thus has to be handled. It is not considered spelling error but a writing variation.

POS	Combined	Separated	Translation
P_n+CM	آپکا	آپ کا	Yours
D+ NN	اسوقت	اس وقت	at that time
CM+ NN	کیطرف	کی طرف	Towards
V+TA	کریگی	کرے گی	will do
CM + P	کیلیے	کے لیے	For
P_n = Pronoun, D = Demonstrative, NN = Noun, CM = Case Marker, V=Verb, P = Particle			

Table 2: Multiple Words Written in Connected Form Causing Shaping Changes

Due to reasonable frequency of such cases, these may be considered as acceptable alternatives, and thus Urdu word segmentation system would need to deal with both forms and consider them equivalent. This process is productively applicable and not limited to a few pre-determined cases. Additional complication in the process arises from the fact that in some cases (last two cases in Table 2) the spellings also change when two words are written in combined form, due to the way these characters are encoded. Urdu considers ی and ے both logically same characters at a certain level, though with different shapes to indicated different vowels (Hussain, 2004). In combined form they render the same shape. However, Unicode terms ے as a non-joiner with no medial shape. Thus, the Urdu writers use ی to generate the medial position of ے in combined form.

3.2 Space Insertion

When multiple morphemes are juxtaposed within a word, many of them tend to retain their shaping as separate ligatures. If ending characters are joiners, space is usually inserted by writers to prevent them from joining and thus to retain the separate ligature identity. This causes an extra space within a word. Though this creates the visually acceptable form, it creates two tokens from a single word in the context of its processing. If the writers do not type a space between these two morphemes within a word they would join and create a visually incorrect shape. Such examples are common in Urdu[2]. Few of these cases are given in Table 3.

Class	A	B	Translation
i	شادی شدہ	شادیشدہ	Married
ii	موم بتی	مومبتی	Candle
iii	خواہ مخواہ	خواہمخواہ	Unnecessarily
iv	ٹیلی فون	ٹیلیفون	Telephone
v	پی ایچ ڈی	پیایچڈی	PhD

i= Affixation, ii = Compounding ,
iii = Reduplication, iv = Foreign Word,
v = Abbreviations			

Table 3: (A) Separated Form (Correct Shaping, but Two Tokens), (B) Combined Form (Erroneous Shaping, with one Token)

As categorized in Table 3, the space insertion problem is caused due to multiple reasons. Data analyzed shows that space is inserted (i) to keep affixes separate from the stem, (ii) in some cases, to keep two words compounded together from visually merging, (iii) to keep reduplicated words from combining, (iv) to enhance readability of some foreign words written in Urdu, and (v) to keep English letters separate and readable when English abbreviations are transliterated.

3.3 Extent of Segmentation Issues in Urdu

In an earlier work on Urdu spell checking (Naseem and Hussain, 2007) report that a significant number of spelling errors[3] are due to irregular use of space, as discussed above. The study does a spelling check of an Urdu corpus. The errors reported by the spelling checker are manually analyzed. A total of 975 errors are found and of which 736 errors were due to irregular use of space (75.5%) and 239 errors are non-space-related errors (24.5%). Of the space related errors, majority of errors (672 or 70% of total errors) are due to space omission and 53 errors (5%) were due to space insertion. Thus irregular use of space causes an extremely high percentage of all errors and has to be addressed for all language processing applications for Urdu.

A study of Urdu words was also conducted as part of the current work. Text was used from popular Urdu online news sites (www.bbc.co.uk/urdu and http://search.jang.com.pk/). A data of 5,000 words from both corpora was observed and space insertion and omission cases were counted. These counts are given in Table 4. Counts for Space Insertion are sub-divided into the four categories identified earlier.

Problem	BBC	Jang	Total
Space Omission	373	563	936
Space Insertion			
Affixation	298	467	765
Reduplication	52	76	128
Compounding	133	218	351
Abbreviation	263	199	462
Total	1119	1523	2642

Table 4: Space Omission and Insertion Counts from Online BBC and Jang Urdu News Websites

The data shows that a significantly high percentage of errors related to space, with significant errors

[2] Though Unicode recommends using Zero Width Non-Joiner character in these context, this is not generally known by Urdu typists and thus not practiced; Further, this character is not available on most Urdu keyboards.

[3] Errors based on tokenization on space and punctuation markers

related to both omission and insertion. Within insertion errors, affixation, compounding and abbreviation related errors are more significant (because reduplication is a less frequent phenomenon).

In summary, the space related errors are significant and must be addressed as a precursor to any significant language and speech processing of the language

3.4 Ambiguity in Defining Urdu Word

Another confounding factor in this context it that there is no clear agreement on word boundaries of Urdu in some cases.

Compound words are hard to categorize as single or multiple words. Urdu forms compounds in three ways: (i) by placing two words together, e.g. ماں باپ ("parents", literally "father mother"), (ii) by putting a combining mark between them[4], e.g. وزیر اعظم ("prime minister"), and (iii) by putting the conjunction و between two words, e.g. نظم و ضبط ("Discipline").

Similarly certain cases of reduplication are also considered a single word by a native speaker, e.g. فرفر ("fluently") and برابر ("equal"), while others are not, e.g. آہستہ آہستہ ("slowly"). There are also cases which are ambiguous, as there is no agreement even within native speakers.

Moreover, certain function words, normally case markers, postpositions and auxiliaries, may be written joined with other words in context or separately. The words like کے لیے may also be written in joined form کیلیے, and the different forms may be perceived as multiple or single words respectively.

This is demonstrated by the results of a study done with 30 native speakers of Urdu (including university students, language researchers and language teachers). The subjects were asked to mark whether they considered some text a single word or a sequence of two words. Some relevant results are given in Table 5. The table indicates that for the types of phenomena in Table 4, the native speakers do not always agree on the word boundary, that certain cases are very ambiguous, and that writing with or without space also changes the perception of where the word boundary should lie.

Word(s)	# of Words		Category
	1	2	
وزیرمملکت	24	6	Compounding with conjunctive diacritic
حکومتِ پاکستان	17	13	-do-
صورتِ حال	28	2	-do-
صورتحال	28	2	-do-
امن وامان	25	5	Compounding with conjunctive character و
نشو ونما	29	1	-do-
عقیدت مندی	30	0	Suffixation
جرائم پیشہ	22	8	-do-
جگہ جگہ	3	27	Reduplication
ساتھ ساتھ	3	27	-do-
ہوگی	15	15	Space omission between two auxiliaries
جائیگا	18	12	Space omission between verb and auxiliary
جائے گا	5	25	Same as above but without space omission

Table 5: Survey on Word Definition

As the word boundary is ambiguously perceived, it is not always clear when to mark it. To develop a more consistent solution, the current work tags the different levels of boundaries, and it is left up to the application provider using the output to decide which tags to translate to word level boundaries. Free morphemes are placed and identified at first level. At second level we identify strings that are clearly lexicalized as a single word. Compounds, reduplication and abbreviations are dealt at third level.

4 Summary of Existing Techniques

Rule based techniques have been extensively used for word segmentation. Techniques including longest matching (Poowarawan, 1986; Rarunrom, 1991) try to match longest possible dictionary look-up. If a match is found at n^{th} letter next look-up is performed starting from $n+1$ index. Longest matching with word binding force is used for Chinese word segmentation (Wong and Chang, 1997). However, the problem with this technique is that it consistently segments a letter sequence the same way, and does not take the context into account.

[4] The diacritics (called *zer-e-izafat* or *hamza-e-izafat*) are optional, and are not written in the example given.

Thus, shorter word sequences are never generated, even where they are intended.

Maximum matching is another rule based technique that was proposed to solve the shortcomings of longest matching. It generates all possible segmentations out of a given sequence of characters using dynamic programming. It then selects the best segmentation based on some heuristics. Most popularly used heuristic selects the segmentation with minimum number of words. This heuristic fails when alternatives have same number of words. Some additional heuristics are then often applied, including longest match (Sornlertlamvanich, 1995). Many variants of maximum matching have been applied (Liang, 1986; Li et al., 1991; Gu and Mao, 1994; Nie et al., 1994).

There is a third category of rule based techniques, which also use additional linguistic information for generating intermediate solutions which are then eventually mapped onto words. For example, rule based techniques have also been applied to languages like Thai and Lao to determine syllables, before syllables are eventually mapped onto words, e.g. see (Phissamy et al., 2007).

There has been an increasing application of statistical methods, including n-grams, to solve word segmentation. These techniques are based at letters, syllables and words, and use contextual information to resolve segmentation ambiguities, e.g. (Aroonmanakul, 2002; Krawtrakul et al., 1997). The limitation of statistical methods is that they only use immediate context and long distance dependencies cannot be directly handled. Also the performance is based on training corpus. Nevertheless, statistical methods are considered to be very effective to solve segmentation ambiguities.

Finally, another class of segmentation techniques applies several types of features, e.g. Winnow and RIPPER algorithms (Meknavin et al., 1997; Blum 1997). The idea is to learn several sources of features that characterize the context in which each word tends to occur. Then these features are combined to remove the segmentation ambiguities (Charoenpornsawat and Kijsirikul 1998).

5 Segmentation Model for Urdu

Although many other languages share the same problem of word boundary identification for language processing, Urdu problem is unique due to its cursive script and its irregular use of space to create proper shaping. Though other languages only have space omission challenge, Urdu has both omission and insertion problems further confounding the issue.

We employ a combination of techniques to investigate an effective algorithm to achieve Urdu segmentation. These techniques are incorporated based on knowledge of Urdu linguistic and writing system specific information for effective segmentation. For space omission problem a rule based maximum matching technique is used to generate all the possible segmentations. The resulting possibilities are ranked using three different heuristics, namely min-word, unigram and bigram techniques.

For space insertion, we first sub-classify the problem based on linguistic information, and then use different techniques for the different cases. Space insertion between affixes is done by extracting all possible affixes from Urdu corpus. Some affixes in Urdu are also free morphemes so it is important to identify in segmentation process whether or not they are part of preceding or following word. For example ناک is also a free morpheme (“nose”) and a suffix that makes adjective from noun, e.g. in word خطر ناک (“dangerous”). This is done based on the part of speech information of the words in the context.

Reduplication is handled using edit distance algorithm. In Urdu the reduplicated morpheme is either the same or a single edit-distance from the base morpheme, e.g. فرفر has same string repeated, برابر has one insertion, and ٹھیک ٹھاک has one substitution. Thus, if a string is less than two edits from its neighbor it is an instance of reduplication[5]. As the examples suggest, the reduplication may not only be limited to word initial position and may also occur word medially. However, if the length of base word is less than four, it is further to avoid function words (case markers, postpositions, aux-

[5] Insertion, deletion and substitution are all considered contributing a single edit distance here.

iliaries, etc.) from being mistakenly identified as a case of reduplication, e.g. کیا گیا ("was done") has two words with a single edit distance but is not a reduplicated sequence.

Urdu does not abbreviate strings, but abbreviations from English are frequently transliterated into Urdu. This sequence can be effectively recognized by developing a simple finite automaton. The automaton treats marks all such co-occurring morphemes because they are likely to be an English abbreviation transliterated into Urdu, e.g. پی ایچ ڈی ("PhD"). If such morphemes are preceding proper names then these are not combined as they are more likely to be the initials of an abbreviated name, e.g. این ڈی شاکر ("N. D. Shakir"). This approach confuses the morpheme کے (genitive case marker) of Urdu with the transliteration of English letter "k". If we write پی ایچ ڈی کے بعد ("after PhD"), it is interpreted as "P H D K after". This has to be explicitly handled.

As classification of compounds into one or two word sequences is unclear, unambiguous cases are explicitly handled via lexical look-up. An initial lexicon of 1850 compound words has been developed for the system based on a corpus of Urdu. Common foreign words are also included in this list.

5.1 Algorithm

The segmentation process starts with preprocessing, which involves removing diacritics (as they are optionally used in Urdu and not considered in the current algorithm because they are frequently incorrectly marked by users[6]) and normalizing the input text to remove encoding ambiguities[7]. Input is then tokenized based on space and punctuation characters in the input stream. As has been discussed, space does not necessarily indicate word boundary. However presence of space does imply word or morpheme boundary in many cases, which can still be useful. The tokenization process gives what we call an Orthographic Word (OW). OW is used instead of "word" because one OW may eventually give multiple words and multiple OWs may combine to give a single word. Keeping space related information also keeps the extent of problem to be solved within a reasonable computational complexity. For example input string نادر خان درانی (the name of the first author) with spaces giving three OWs, creates 2 x 1 x 7 = 14 possible segmentations when sent separately to the maximum matching module (space omission error removal - see Figure 2). However, if we remove the spaces from the input and send input as a single OW نادرخاندرانی to maximum matching process, we get 77 possible segmentations. This number grows exponentially with the length of input sentence. Throwing away space character means we are losing important information so we keep that intact to our use.

After pre-processing a series of modules further process the input string and convert the OWs into a sequence of words. This is summarized in Figure 2 and explained below.

Each OW is sent to a module which deals with space omission errors. This module extracts all possible morpheme segmentations out of an OW. Ten best segmentations of these are selected based on minimum-word heuristic. This heuristic prefers segmentations with minimum number of morphemes. Such a heuristic is important to prevent the search space to explode. We observed that using 10-best segmentations proved to be sufficient in most cases as OW normally encapsulates two or three Urdu words but as a heuristic we also added a feature which increases this number of 10-best segmentations to 15, 20, 25-best and so on depending upon number of characters in an OW. Ten best segmentations for each OW are merged with the extracted segmentations of other OWs. Up till here we have successfully resolved all space omission errors and the input sentence has been segmented into morphemes. The 10^n (where 'n' is No. of OWs) segmentations are then passed on to space insertion error removal module. This module has several sub-modules that handle different linguistic phenomena like reduplication, affixation, abbreviations and compounding.

[6] The word اعلیٰ is written with the super-script Alef placed on Lam and Yay characters. The latter variation is correct but the former incorrect variation is also common in the corpus.

[7] Unicode provides multiple codes for a few letters, and both composed and decomposed forms for others. These have to be mapped onto same underlying encoding sequence for further processing. See http://www.crulp.org/software/langproc/urdunormalization.htm for details.

The reduplication identification module employs single edit distance algorithm to see if adjacent morphemes are at single edit-distance of each other. If the edit distance is less than two, then the reduplication is identified and marked.

N-Gram Based Ranking

Figure 2: Urdu Word Segmentation Process

For example the module will correctly recognize consecutively occurring OWs بھولا and بھالا as a case of reduplication. Reduplication is also applied earlier in space omission error module as there may also be a case of reduplication within a single OW. This module handles such cases, by dividing words in halves and identifying possible reduplications. Thus, if the words are written without space, e.g. بھولابھالا (innocent) they are still identified and tagged as reduplicated words بھولا and بھالا.

This list of words is then fed into an automaton which recognizes the sequence of abbreviations generated by transliterating English letters.

A complete affix list is compiled, and in the next stage the short listed word sequences are processed through a process which looks through this list to determine if any of the OWs may be combined. Part of speech information of stem is also used to confirm if OWs can be merged.

Urdu compounds are finally identified. This is done by using a compound list generated through the corpus. As compounding is arbitrary, where speakers are not certain in many cases that a sequence of morphemes form a single compound or not, the segmentation process leaves this level to the discretion of the user. Whichever compounds are listed in a compound lexicon are treated as a single compound word. Those not listed are not tagged as compounds. User may enhance this list arbitrarily. The lexicon is initialized with a list of non-controversial compound, as verified from published dictionaries.

Eventually, all the segmentations are re-ranked. We used three different re-ranking methods namely minimum-word heuristic, unigram and bi-gram based sequence probabilities, comparative analysis.

Based on the segmentation process, the output sequence contains the following tagging. As discussed earlier, the word segmentation may be defined based on this tagging by the individual application using this process.

Phenomenon	Tags	Examples
Word	<W></W>	<W>اعلان</W>
Root	<R></R>	<W><R>ضرورت</R> <S>مند</S></W>
Suffix	<S></S>	<W><R>حیرت</R> <S>انگیز</S></W>
Prefix	<P></P>	<W><P>بد</P> <R>تہذیبی</R></W>
XY Compounds	<C1></C1>	<C1><W>انشاء</W> <W>اللہ</W></C1>
X-e-Y Compounds	<C2></C2>	<C2><W>وزیر</W> <W>اعلی</W></C2>
X-o-Y Compounds	<C3></C3>	<C3><W>گرد</W> <W>و</W> <W>نواح</W></C3>
Reduplication	<Rd></Rd>	<Rd><W>ٹھیک</W> <W>ٹھاک</W></Rd>
Abbreviations	<A></A>	<A><W>پی</W> <W>سی</W> </A>

Figure 3: Urdu Word Segmentation Tag Set

A regular word is tagged using <w> …</w> pair. Roots, suffixes and prefixes are also tagged within a word. Reduplication, compounding and abbreviations are all considered to be multi-word tags and relevant words are grouped within these tags. Three different kind of compounding is separately tagged.

6 Results

The algorithm was tested on a very small, manually segmented corpus of 2367 words. The corpus we selected contained 404 segmentation errors with 221 cases of space omissions and 183 cases of space insertions. In space insertion category there were 66 cases of affixation, 63 cases of compounding, 32 cases of reduplication and 22 cases of abbreviations. The results for all three techniques are shown below:

Categories	Errors	%ages
Affixation	59/66	89.39
Reduplication	27/32	84.37
Abbreviations	19/22	86.36
Compounds	28/63	44.44
Total	133/183	72.67

Table 6: Percentages of Number of Errors Detected in Different Categories of Space Insertion Error

There were 221 cases of space omission errors where multiple words were written in a continuum. Given below is a table that shows how many of these were correctly identified by each of the used techniques. Clearly, statistical techniques outperform a simple minimum number of words heuristic. Bigrams are likely to produce better results if the training corpus is improved. Our training corpus contained manually segmented 70K words. The bigram probabilities are obtained using SRILM-Toolkit (Stolcke, 2002).

Categories	Errors	%ages
Maximum Matching	186/221	84.16
Unigram	214/221	96.83
Bigram	209/221	94.5

Table 7: %age of No. of Errors Detected in Space Omission with Different Ranking Techniques

Following table gives cumulative results for correctly identified space omission and insertion errors.

Categories	Errors	%ages
Maximum Matching	323/404	79.95
Unigram	347/404	85.8
Bigram	339/404	83.9

Table 8: %age of No. of Errors Detected Cumulatively

Final table counts total number of words (reduplication, compounds and abbreviations cases are inclusive) in test corpus and total number of correctly identified words after running the entire segmentation process.

Categories	Detected	%ages
Maximum Matching	2209/2367	93.3
Unigram	2269/2367	95.8
Bigram	2266/2367	95.7

Table 9: Percentage of Correctly Detected Words

7 Future Work

This work presents a preliminary effort on word segmentation problem in Urdu. It is a multi-dimensional problem. Each dimension requires a deeper study and analysis. Each sub-problem has been touched in this work and a basic solution for all has been devised. However to improve on results each of these modules require a separate analysis and study. Statistics is only used in ranking of segmentations. In future work bi-gram statistics can be used to merge morphemes. More data can be tagged to find out joining probabilities for the affixes that occur as free morpheme. Such analysis will reveal whether an affix is more inclined towards joining or occurs freely more frequently. Similarly a corpus can be tagged on compounds. For each morpheme its probability to occur in compound can be calculated. If two or more morphemes with higher compounding probabilities co-occur they can be joined together. Similarly corpus can be tagged for abbreviations.

Ranking of segmentations and affix merging can be improved if POS tags are also involved with bigram probabilities. Use of POS tags with n-gram technique is proven to be very helpful in solving unknown word problems. Our model does not explicitly handle unknown words. Currently the maximum matching module splits an unknown OW into smaller Urdu morphemes. For example کولیسینکوف(Kolesnikov) is erroneously split into کولی،سین،کو،ف. More serious problems occur in cases when OW is a mixture of known and unknown words. For example in case فریزرکوجاناہے ("Fraser must go"). All these are to be addressed in future work.

Enabling Monolingual Translators: Post-Editing vs. Options

Philipp Koehn
University of Edinburgh

Edinburgh, EH8 9AB
Scotland, United Kingdom
pkoehn@inf.ed.ac.uk

Abstract

We carried out a study on monolingual translators with no knowledge of the source language, but aided by post-editing and the display of translation options. On Arabic-English and Chinese-English, using standard test data and current statistical machine translation systems, 10 monolingual translators were able to translate 35% of Arabic and 28% of Chinese sentences correctly on average, with some of the participants coming close to professional bilingual performance on some of the documents.

While machine translation systems have advanced greatly over the last decade, nobody seriously expects human-level performance any time soon, except for very constraint settings. But are todays systems good enough to enable monolingual speakers of the target language without knowledge of the source language to generate correct translations? And what type of assistance from machine translation is most helpful for such translators?

We carried out a study that involved monolingual translators who had no knowledge of Chinese and Arabic to translate documents from the NIST 2008[1] test sets, being assisted by statistical machine translation systems trained on data created under the GALE[2] research program.

Our study shows that monolingual translators were able to translate 35% of Arabic and 28% of Chinese sentences, under a strict standard of correctness that scored professional bilingual translations as 61% and 66% correct for Arabic and Chinese, respectively. We found also large variability among the participants and between the documents in the study, indicating the importance of general language skills and domain knowledge. The results suggest that a skilled monolingual translator can compete with a bilingual translator, when using todays machine translation systems.

1 Related Work

The use of human translators in combination with machine translation is as old as the emergence of the first effective machine translation systems. Typically, this takes the form of a human translator post-editing machine translation output, and rarely of a human translator guiding the decisions of a machine translation system. Recent examples of using post-editing of machine translation in tools for translation tools are the Google Translator Toolkit (Galvez and Bhansali, 2009) and the WikiBabel project (Kumaran et al., 2008).

A recent seminal effort on building interactive machine translation systems (Langlais et al., 2000; Barrachina et al., 2009) looked at a tighter integration of machine translation and human translation by developing a prediction model that interactively suggests translations to the human translator, taking her prior translation decisions into account. This approach was recently re-implemented and extended by Koehn (2009).

Our study uses both post-editing and the extended interactive machine translation approach as types of assistance for translations. In our case, however, we look at monolingual translators, while prior work has focused on bilingual translators.

Another effort to enable monolingual translators looked at a more linguistically motivated tool using syntactic analysis to inform their translation decisions (Albrecht et al., 2009).

The quality of the translations produced by

monolingual translators was previously explored by Callison-Burch (2005) in a submission to the NIST 2005 evaluation campaign, but not properly evaluated. The idea of using post-editing by monolingual speakers without access to the source as a metric to evaluate machine translation quality of different systems was explored by Callison-Burch et al. (2009) in the WMT 2009 shared task.

2 Human Translation

Except for constraint settings with a very limited domain, translation quality by trained humans is much higher than automatic translation methods. Especially for the commercially most relevant field of publication-quality translation of official reports, product manuals, promotion material, web sites, and so on, machine translation currently plays at most a supportive role.

2.1 Translation Tools

The main draw-back of relying on professional human translators is their high cost. A number of technological advances in the industry have increased the productivity of translators, and thus lowered their cost, over the last two decades. The pervasive use of computers and the Internet has reduced the cost of management, and helped a industry where translation is outsources many times over: from the original customer to a translation agency, from a translation agency to freelance translators, and maybe some additional levels in between.

The use of computers has also led to the adoption of tools such as translation memories[3] (databases of translated material that are queried for fuzzy matches, i.e. translated sentences similar to the one to be processed), monolingual and bilingual concordances (showing words used in context, and their translations), terminology databases, online dictionaries and thesauri, and basic editing tools such as word processors and spell checkers (Desilets, 2009).

The use of machine translation has not yet made great inroads into the toolbox of professional translators. Being reduced to mere post-editors of badly machine translated texts is not an appealing prospect, and machine translation is generally considered (rightly or wrongly) not yet good enough to increase productivity. More innovative use of machine translations such as interactive machine translation (Langlais et al., 2000) has not advanced much beyond the research stage. There is rich potential for improvements and entirely new tools.

2.2 Translation Skills

A fully qualified professional translator has to have two sets of skills when translating a text. On the one hand the language skills to generally understand the source language and to write well in the target language, and on the other hand the domain knowledge to understand the content of a possibly very specialized technical document. Both skill sets may be hard to find, especially in combination.

In fact, it is common practice in the translation industry to differentiate translators according to their qualifications. For instance, junior translators may produce the first draft, and senior translators edit it — which they will be able to do much faster than a translation from scratch by themselves.

Human translation is also performed in a non-professional environment by generally less qualified volunteer translators. To give just a few example: there are vibrant communities that concern themselves with the translation of Wikipedia articles[4] (Kumaran et al., 2008), open source software documentation,[5] movie subtitles,[6] and even material such as the TED conference talks.[7]

Research has shown that less qualified translators are able to increase their productivity and quality disproportionally when given automatic assistance (Koehn and Haddow, 2009). Assistance may be as limited as offering machine translation in a post-editing environment, as for instance provided by Google Translator Toolkit[8] (Galvez and Bhansali, 2009) which provides a special function to translate Wikipedia articles.

In this context, our work looks at one extreme of the skill range: translators that have no knowledge of the source language. While we would not expect them to compete with professional translators that have this knowledge, their inferior performance may

Figure 1: Translation Options shown to the monolingual translator. The machine translation of the Arabic input sentence is: *The us house of representatives adopted thursday a law calls for the withdrawal of us combat troops from iraq by the first of april 2008, defying once again president george bush who opposed to setting any date.*

be remedied as suggested above: their texts may be edited by a more qualified translator, or their domain knowledge may augment the language skills of a collaborating translator.

From the view of human translation, the main question that this paper is trying to answer is: how well can monolingual translators perform, given the current quality of machine translation, and what types of assistance offered by a machine translation system is most helpful?

3 Machine Translation

Statistical machine translation has made great progress over the last two decades, with changing models, learning methods, decoding algorithms, decision rules, etc. While there is increasing effort to build grammar-based translation models that take into account the recursive nature of language, currently the most popular models are still phrase-based.

3.1 Phrase-Based Models

In phrase based models, the input is segmented into text chunks (that do not have to correspond to linguistic phrases), each is translated and may be reordered, and the output is assembled with the help of a language model. The translations for individual phrases are called translation options. Typically, up to 20 translation options for each input phrase are considered during decoding.

The large number of translation options and their even larger combinatorial arrangement creates a search space that is too large to exhaustively explore, creating the need for a heuristic search algorithm. During the heuristic search a search graph is constructed. This search graph can be converted into a word lattice, which is useful for n-best list generation, or in our case interactive machine translation.

3.2 Interactive Machine Translation

The by-products of phrase-based models have been used in a type of computer aided translation tool called interactive machine translation. In these setups, the human translator is creating the translation, but receives suggestions how to complete the sentence or is offered alternative translation options for the input words and phrases.

The translation options that the decoder is using are ranked based on their probability and presented to the human translator, as done by Koehn (2009). Sentence completion prediction is based on the search graph (Barrachina et al., 2009). If the human translator starts a translation that diverges from the suggestion, the interactive translation tool quickly computes a approximate match in the search graph and uses this as a starting point for further predictions.

In our experiments, we offer both translation options and interactive sentence completion predictions to the user. See Figure 1 for an example.

3.3 Arabic and Chinese

This paper is using machine translation systems for Arabic–English and Chinese–English that were developed in the context of the recent GALE research program funded by DARPA.

The choice of these two languages pairs has two motivations: first, a lot of resources have gone into improving translation quality for these language pairs. An important question is how the improvements in translation quality can be utilized.

The second motivation for choosing Arabic–English and Chinese–English is that they are undecipherably foreign for a typical European or American speaker of English. The fact that both languages are written in a different script already makes it impossible to spot cognates, except for the occasional number. In our study, the test subjects had to practically exclusively rely on the given sentence translations or phrase translations options.

3.4 Evaluation of Machine Translation

Chinese–English is considered significantly harder than Arabic–English, as measured by automatic metrics (which measure similarity to a human reference translation), human evaluation metrics such as HTER (which measures the number of editing steps necessary to correct the output into an acceptable translation), or human judgment on the correctness of the translation, its fluency or adequacy (which is typically measured on a scale from 1 to 5).

All these metrics have been criticized in the past as too simple, biased towards statistical systems, non-repeatable, having low intra and inter-annotator agreement, or plainly too expensive to use. How to properly evaluate machine translation quality is still an open problem.

From the view of machine translation evaluation, this paper explores the question if current machine translation systems have reached the goal to bring across the meaning of a foreign text. The ability of a monolingual target language speaker to produce correct translations (based on her understanding of the machine translation output) is a test for this goal. It sets aside the problems of clumsy wordings and grammatical errors. To relate this to traditional error metrics in machine translation: we focus on the adequacy opposed to the fluency of translation.

Language	Sentences	Words
Arabic	9,320,356	228,712,189
Chinese	2,039,399	49,564,193

Table 1: Training data: number of sentences and English words in the parallel training data

4 Experiment

We trained translation models using Moses (Koehn et al., 2007) on the bilingual data provided by the LDC, with additional monolingual data from the English Gigaword corpus for an interpolated 5-gram language model. Basic statistics about the corpus are given in Table 1. The systems are close to the state of the art.

We used four news stories for each of the two languages for the monolingual translators. The news stories were selected from the evaluation sets of the 2008 machine translation evaluation campaign organized by NIST. See Table 2 for details. The news stories are rather short (around 10 sentences each), since we opted for a variety of stories rather than long stories.

The evaluation set comes with four reference translations. This allowed us to use one of the reference translation as gold standard for the evaluation, and the other three reference translations as competitors for the monolingual translations.

We recruited 10 monolingual translators, students at the University of Edinburgh for the study. None of the students had knowledge of either Chinese or Arabic. Each translator was given all eight stories to translate, half of the stories with only the machine translation output (Post-editing task) and half of the stories with interactive assistance as described in Section 3.2: prediction of sentence completion and translation options (Options).

In both cases, we also displayed the Arabic or Chinese source sentence to the translator, which may show some clues regarding punctuation, numbers, or the length of source words. The translators had no knowledge of the source script.

After all the translations were completed, we assessed the translation quality. Since we did not have access to bilingual speakers for this, we resorted to the standard manual setup, where human judges are asked to assess the quality of each sentence transla-

Story	Headline	Sent.	Words
1: Chinese	White House Pushes for Nuclear Inspectors to Be Sent as Soon as Possible to Monitor North Korea's Closure of Its Nuclear Reactors	6	207
2: Chinese	Torrential Rains Hit Western India, 43 People Dead	10	204
3: Chinese	Research Shows a Link between Arrhythmia and Two Forms of Genetic Variation	7	247
4: Chinese	Veteran US Goalkeeper Keller May Retire after America's Cup	10	367
5: Arabic	Britain: Arrests in Several Cities and Explosion of Suspicious Car	7	224

Table 2: News stories used in the experiment with headlines from the reference translation

Assistance	Arabic	Chinese
Bilingual	61±6%	66±6%
Postediting	35±4%	26±4%
Options	34±4%	30±4%

Table 3: Correctness of translations (with 95% confidence interval) under the two types of assistance, compared against professional reference translations

tion compared to a reference translation in context — the first reference translation in the NIST evaluation set which was produced by a professional translation agency.

We used a strict evaluation metric: a binary judgment, if the translation is correct. Correct was defined as *a fluent translation that contains the same meaning in the document context*. The reference translation was shown with its document context (two sentences before and after). We used a variant of the web-based evaluation tool of the 2009 Workshop on Statistical Machine Translation.

5 Results

The headline results are displayed in Table 3. The bilingual translations which were taken from the other three reference sets score surprisingly low: only about two thirds of the sentences were deemed to be correct by our judges. This is a better result than the monolingual translators performance, who translate around one third of the sentences correctly, except for a statistically significant worse showing for post-editing Chinese–English.

Translator	Arabic	Chinese
bi1	67±10%	65±11%
bi2	49±10%	67±10%
bi3	67±10%	67±9%
mono1	48±11%	31±11%
mono2	29±10%	21±8%
mono3	26±10%	12±7%
mono4	50±11%	26±11%
mono5	25±10%	25±10%
mono6	26±9%	18±9%
mono7	23±10%	29±10%
mono8	50±11%	50±10%
mono9	42±10%	37±11%
mono10	25±9%	32±10%

Table 4: Correctness by translator (note: different bilingual translators for Arabic and Chinese)

Translation speed of the monolingual translators varied, but it was mostly around 500 words per hour (7 seconds per word), which is roughly comparable to the lower end of professional translation speed.

Table 4 shows the performance of the individual translators. The 95% confidence intervals are very wide, due to the few sentences that were translated by each translator, but some monolingual translators are significantly better than others. Some of the monolingual translators seem to compete head-to-head with the professional bilingual translators: three monolingual translators perform as well as one of the bilingual translators for Arabic–English, albeit one has to be cautioned by the wide confidence intervals. See also Figure 2 for a graphical display.

Story	BLEU	Bilingual	Post-ed.	Options
1: Chinese	42.8	76±16%	32±13%	40±13%
2: Chinese	24.8	70±10%	39±8%	33±9%
3: Chinese	35.1	61±12%	19±8%	17±7%
4: Chinese	26.7	64±11%	12±6%	36±9%
5: Arabic	43.6	60±14%	10±6%	13±7%
6: Arabic	48.5	57±13%	34±9%	43±9%
7: Arabic	60.5	72±10%	45±8%	36±9%
8: Arabic	55.7	50±13%	45±10%	39±10%

Table 5: Correctness by story and BLEU score of MT

	Length	Bilingual	Post-ed.	Options
Arabic	≤15 words	81±16%	56±15%	48±16%
Arabic	16–30 words	54±10%	41±8%	37±7%
Arabic	>30 words	62±8%	27±6%	29±6%
Chinese	≤15 words	60±12%	48±10%	21±9%
Chinese	16–30 words	73±13%	25±9%	32±10%
Chinese	>30 words	68±8%	17±5%	33±6%

Table 6: Correctness by sentence length

Similarly, performance on the different stories varies (Table 5, Figure 3): For instance, the monolingual translators struggled with the Chinese medical and sports stories (no. 3 and 4) and the Arabic car explosion story (no. 5), while even on average, they are close to bilingual translation quality on the Arabic stories 6 and 8. Note that correctness correlates mildly with BLEU.

Surprisingly, we did not find a consistent effect of sentence length on the quality of the translations (see Table 6). We expected to find worse translations among the longer sentences, but this is not the case for the all conditions.

6 Analysis

Our results have shown that monolingual translators are often able to produce correct translation when post-editing output from current Arabic–English and Chinese–English machine translation systems. For Chinese–English, they are better when given additional assistance in form of translation options and interactive machine translation.

We give in Figure 4 examples for translations by machine translation, as well as monolingual and bilingual translators.

One puzzle is the low score for the professional human translators, as only two thirds of their trans-

(a) Critical judges

REF: *Torrential Rains Hit Western India, 43 People Dead*

BI: *Heavy Rains Plague Western India Leaving 43 Dead*

(b) Mistakes by the professional translators

REF: *Over just two days on the 29th and 30th, rainfall in Mumbai reached 243 mm.*

BI: *The rainfall in Mumbai had reached 243 cm over the two days of the 29th and 30th alone.*

(c) Bad English by monolingual translators

MONO: *The western region of india heavy rain killed 43 people.*

(d) Mistranslated / untranslated name

REF: *Johndroe said that the two leaders ...*

MT: *Strong zhuo, pointing out that the two presidents ...*

MONO: *Qiang Zhuo pointed out that the two presidents ...*

(e) Wrong relationship between entities

REF: *The next match against Colombia will probably be the US team's and Keller's last performance in this America's Cup competition.*

MT: *The colombian team for the match, and it is very likely that the united states and kai in the americas cup final performance.*

MONO6: *The Colombian team and the United States are very likely to end up in the Americas Cup as the final performance.*

MONO8: *The next match against Colombia is likely to be the United States' and Keller's final performance in the current Copa America.*

(f) Badly muddled machine translation

REF: *In the current America's cup, he has, just as before, been given an important job to do by head coach Bradley, but he clearly cannot win the match singlehanded. The US team, made up of "young guards,"...*

MT: *He is still being head coach bradley appointed to important, it's even a fist ", four young guards at the beginning of the ", the united states is...*

MONO: *He is still being considered important by head coach Bradley who appointed him. It is a fight with "four young guards at the beginning of their careers", but the United States...*

Figure 4: Examples of translations

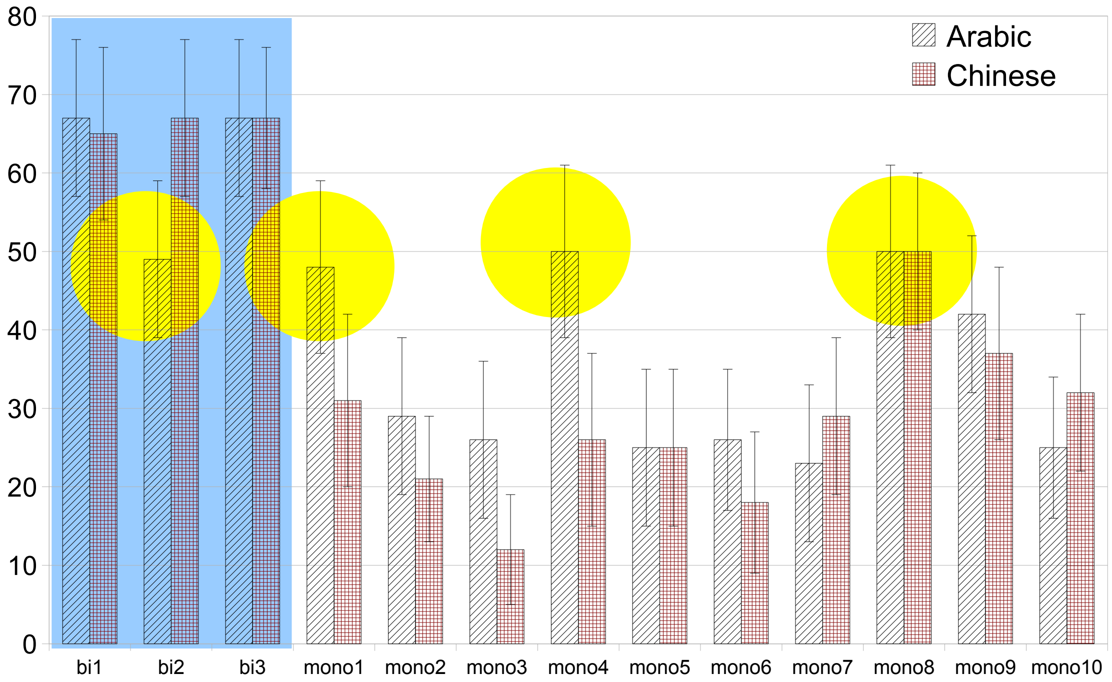

Figure 2: Quality of different bilingual and monolingual translators: For Arabic, three monolingual translators are as good as the worst bilingual translator (around 50% of sentences judged as correct). For detailed numbers, see Table 4.

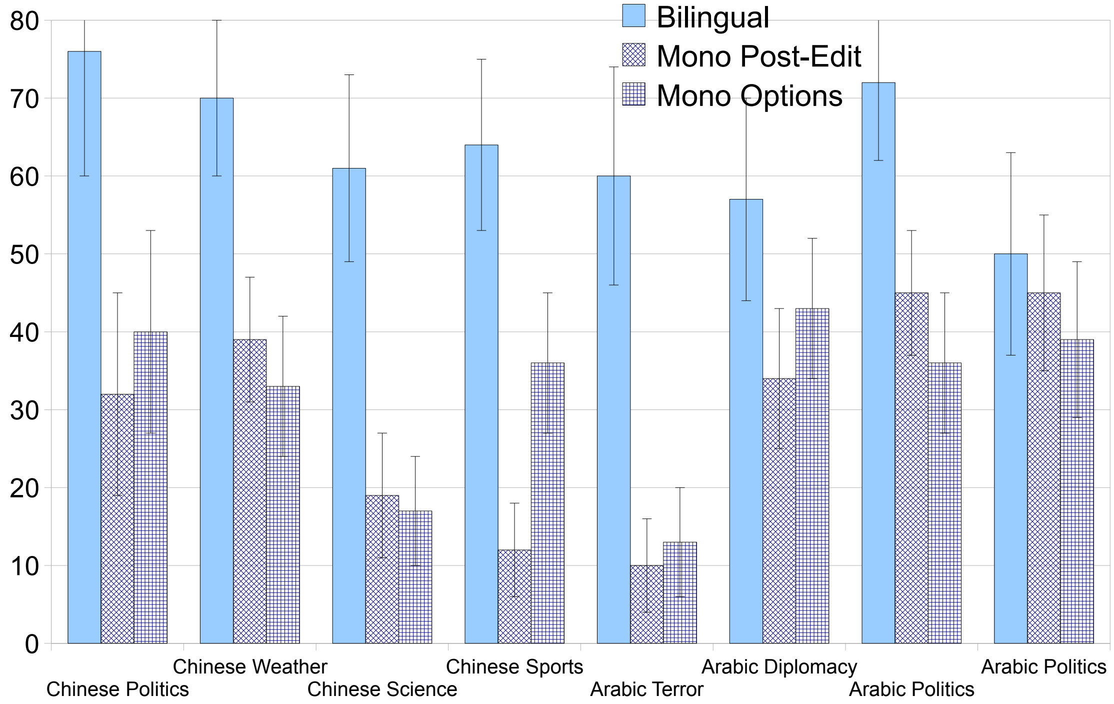

Figure 3: Translation quality of monolingual translators differs significantly between stories: For the last Ararbic politics stories average performance is close to bilingual quality, while it is bad for the Chinese science and sports as well as the Arabic terror story. For detailed numbers, please see Table 5.

lations were deemed to be correct. The example (a) shows such a translation, and it is hard to tell why it was deemed wrong by all three judges who looked at it. There are real mistakes in the professional translations, as example (b) shows, which mistakes the rain fall amount as *243cm* instead of *243mm*.

Some monolingual translators, by the way, also had problems with that number. The machine translation system is not very well in translating numbers, which could be relatively easily addressed.

Sometimes monolingual translators are just not thorough enough in their efforts, as example (c) shows, where the output does have the correct meaning elements, but it is just not correct English. These type of examples explain the big difference between the different monolingual translators.

A severe problem for monolingual translators are untranslated or mistranslated names. In example (d) *Johndroe* was referred to by monolingual translators as *Qiang Zhuo* or *Strong Zhuo*. The statistical machine translation system we used has no special name transliteration component, so often a name remains untranslated. Without given the right translation as a choice, the monolingual is in no position of completing a correct translation.

The monolingual translators' world and domain knowledge helps them a great deal to piece together translations, but sometimes it is not enough, as example (e) shows. There is some connection between *final performance*, *United States* and *Columbia*, but it is not the final performance for both teams as MONO6 renders it. Translator MONO8 got it right, but other translators made different mistakes.

Finally, there are some cases, as example (f) shows, where the machine translation is just so bad, that monolingual translators have no chance to render a proper translation of the sentence, especially when only post-editing.

7 Conclusion

We approached this study from two directions: the motivation to enable monolingual translators and the need for a way to assess the quality of todays machine translation systems.

Coming from a human translator's perspective, we asked what type of assistance machine translation can provide for a human translator. We compared the use of interactive machine translation against post-editing, and found no significant difference for Arabic (34% vs. 35%), but better performance with richer assistance for Chinese (30% vs. 26%). We believe that there is ample opportunity to provide additional assistance and we will explore this in future work.

Coming from a machine translation perspective, we asked if current systems are good enough to bring across the meaning of documents, even if generating output language with grammatical and idiomatic mistakes. Given the harsh metric we use to assess translation quality (complete correctness of a sentence), we showed that monolingual translators were able to produce translations that were on average 35% (Arabic) and 28% (Chinese) correct, compared to 61% (Arabic) and 66% (Chinese) correctness for professional bilingual translations.

Arguable, the method we use to assess the preservation of meaning in machine translation is superior to subjective adequacy judgments: it separates the task of defining the meaning of a machine translation from the assessment of its correctness.

We identified name and number translation as important aspects to improve performance on this task.

We also learned that there are significant difference between human translators, which indicates that general language skills and effort are very important. We also learned that the performance varies significantly for different documents in a way that hints at the importance of domain knowledge. In conclusion, a good monolingual translator has good language skills in the target language and understands the domain. In this case, this study suggests, she may be as good as a professional bilingual translator.

Acknowledgement

This work was supported in part by the GALE program of the Defense Advanced Research Projects Agency, Contract No. HR0011-06-C-0022, and in part by the EuroMatrixPlus project funded by the European Commission (7th Framework Programme). This study was made possible by the work of the monolingual translators.

Abstract

State-of-the-art Machine Translation (MT) systems are still far from being perfect. An alternative is the so-called Interactive Machine Translation (IMT) framework. In this framework, the knowledge of a human translator is combined with a MT system. The vast majority of the existing work on IMT makes use of the well-known *batch learning* paradigm. In the batch learning paradigm, the training of the IMT system and the interactive translation process are carried out in separate stages. This paradigm is not able to take advantage of the new knowledge produced by the user of the IMT system. In this paper, we present an application of the *online learning* paradigm to the IMT framework. In the online learning paradigm, the training and prediction stages are no longer separated. This feature is particularly useful in IMT since it allows the user feedback to be taken into account. The online learning techniques proposed here incrementally update the statistical models involved in the translation process. Empirical results show the great potential of online learning in the IMT framework.

1 Introduction

Information technology advances have led to the need for more efficient translation methods. Current MT systems are not able to produce ready-to-use texts. Indeed, MT systems usually require human post-editing to achieve high-quality translations.

One way of taking advantage of MT systems is to combine them with the knowledge of a human translator in the IMT paradigm, which is a special type of the computer-assisted translation paradigm (Isabelle and Church, 1997). An important contribution to IMT technology was pioneered by the *TransType* project (Foster et al., 1997; Langlais et al., 2002) where data driven MT techniques were adapted for their use in an interactive translation environment.

Following the TransType ideas, Barrachina et al. (2009) proposed a new approach to IMT, in which fully-fledged statistical MT (SMT) systems are used to produce full target sentence hypotheses, or portions thereof, which can be partially or completely accepted and amended by a human translator. Each partial, correct text segment is then used by the SMT system as additional information to achieve improved suggestions. Figure 1 illustrates a typical IMT session.

source($\mathbf{f}$): Para ver la lista de recursos
reference($\hat{\mathbf{e}}$): To view a listing of resources

inter.-0	$\mathbf{e}_p$						
	$\mathbf{e}_s$	*To*	*view*	*the*	*resources*	*list*	
inter.-1	$\mathbf{e}_p$	To	view				
	k			$\boxed{\textbf{a}}$			
	$\mathbf{e}_s$				*list*	*of*	*resources*
inter.-2	$\mathbf{e}_p$	To	view	a	list		
	k				$\boxed{\textbf{i}}$		
	$\mathbf{e}_s$				*ng*	*resources*	
inter.-3	$\mathbf{e}_p$	To	view	a	listing		
	k					$\boxed{\textbf{o}}$	
	$\mathbf{e}_s$					*f*	*resources*
accept	$\mathbf{e}_p$	To	view	a	listing	of	resources

Figure 1: IMT session to translate a Spanish sentence into English. In interaction-0, the system suggests a translation ($\mathbf{e}_s$). In interaction-1, the user moves the mouse to accept the first eight characters ”To view ” and presses the $\boxed{\textbf{a}}$ key (k), then the system suggests completing the sentence with ”*list of resources*” (a new $\mathbf{e}_s$). Interactions 2 and 3 are similar. In the final interaction, the user accepts the current suggestion.

In this paper, we also focus on the IMT framework. Specifically, we present an IMT system that is able to learn from user feedback. For this purpose, we apply the *online learning* paradigm to the IMT framework. The online learning techniques that we propose here allow the statistical models involved in the translation process to be incrementally updated.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 546–554,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

Figure 2 (inspired from (Vidal et al., 2007)) shows a schematic view of these ideas. Here, $\mathbf{f}$ is the input sentence and $\mathbf{e}$ is the output derived by the IMT system from $\mathbf{f}$. By observing $\mathbf{f}$ and $\mathbf{e}$, the user interacts with the IMT system until the desired output $\hat{\mathbf{e}}$ is produced. The input sentence $\mathbf{f}$ and its desired translation $\hat{\mathbf{e}}$ can be used to refine the models used by the system. In general, the model is initially obtained through a classical batch training process from a previously given training sequence of pairs ($\mathbf{f}_i$,$\mathbf{e}_i$) from the task being considered. Now, the models can be extended with the use of valuable user feedback.

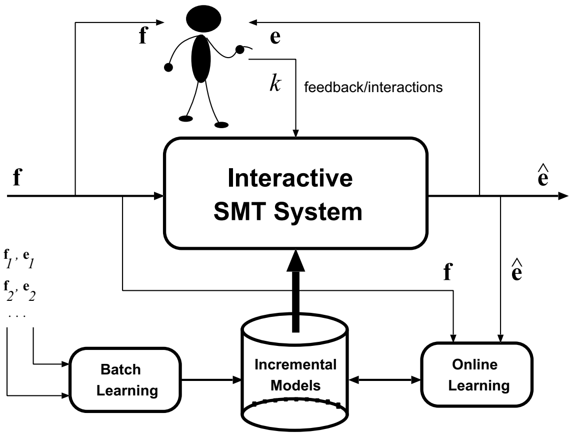

Figure 2: An Online Interactive SMT system

2 Interactive machine translation

IMT can be seen as an evolution of the SMT framework. Given a sentence $\mathbf{f}$ from a source language $\mathcal{F}$ to be translated into a target sentence $\mathbf{e}$ of a target language $\mathcal{E}$, the fundamental equation of SMT (Brown et al., 1993) is the following:

$$\hat{\mathbf{e}} = \underset{\mathbf{e}}{\text{argmax}} \{Pr(\mathbf{e} \mid \mathbf{f})\} \tag{1}$$

$$= \underset{\mathbf{e}}{\text{argmax}} \{Pr(\mathbf{f} \mid \mathbf{e}) \, Pr(\mathbf{e})\} \tag{2}$$

where $Pr(\mathbf{f} \mid \mathbf{e})$ is approximated by a *translation model* that represents the correlation between the source and the target sentence and where $Pr(\mathbf{e})$ is approximated by a *language model* representing the well-formedness of the candidate translation $\mathbf{e}$.

State-of-the-art statistical machine translation systems follow a loglinear approach (Och and Ney, 2002), where direct modelling of the posterior probability $Pr(\mathbf{e} \mid \mathbf{f})$ of Equation (1) is used. In this case, the decision rule is given by the expression:

$$\hat{\mathbf{e}} = \underset{\mathbf{e}}{\text{argmax}} \left\{ \sum_{m=1}^{M} \lambda_m h_m(\mathbf{e}, \mathbf{f}) \right\} \tag{3}$$

where each $h_m(\mathbf{e}, \mathbf{f})$ is a feature function representing a statistical model and λ_m its weight.

Current MT systems are based on the use of phrase-based models (Koehn et al., 2003) as translation models. The basic idea of Phrase-based Translation (PBT) is to segment the source sentence into phrases, then to translate each source phrase into a target phrase, and finally to reorder the translated target phrases in order to compose the target sentence. If we summarize all the decisions made during the phrase-based translation process by means of the hidden variable $\tilde{a}_1^K$, we obtain the expression:

$$Pr(\mathbf{f}|\mathbf{e}) = \sum_{K, \tilde{a}_1^K} Pr(\tilde{f}_1^K, \tilde{a}_1^K \mid \tilde{e}_1^K) \tag{4}$$

where each $\tilde{a}_k \in \{1 \ldots K\}$ denotes the index of the target phrase $\tilde{e}$ that is aligned with the k-th source phrase $\tilde{f}_k$, assuming a segmentation of length K.

According to Equation (4), and following a maximum approximation, the problem stated in Equation (2) can be reframed as:

$$\hat{\mathbf{e}} \approx \arg\max_{\mathbf{e}, \mathbf{a}} \{p(\mathbf{e}) \cdot p(\mathbf{f}, \mathbf{a} \mid \mathbf{e})\} \tag{5}$$

In the IMT scenario, we have to find an extension $\mathbf{e}_s$ for a given prefix $\mathbf{e}_p$. To do this we reformulate Equation (5) as follows:

$$\hat{\mathbf{e}}_s \approx \arg\max_{\mathbf{e}_s, \mathbf{a}} \{p(\mathbf{e}_s \mid \mathbf{e}_p) \cdot p(\mathbf{f}, \mathbf{a} \mid \mathbf{e}_p, \mathbf{e}_s)\} \tag{6}$$

where the term $p(\mathbf{e}_p)$ has been dropped since it does depend neither on $\mathbf{e}_s$ nor on $\mathbf{a}$.

Thus, the search is restricted to those sentences $\mathbf{e}$ which contain $\mathbf{e}_p$ as prefix. It is also worth mentioning that the similarities between Equation (6) and Equation (5) (note that $\mathbf{e}_p\mathbf{e}_s \equiv \mathbf{e}$) allow us to use the same models whenever the search procedures are adequately modified (Barrachina et al., 2009).

Following the loglinear approach stated in Equation (3), Equation (6) can be rewriten as:

$$\hat{\mathbf{e}}_s = \underset{\mathbf{e}_s, \mathbf{a}}{\text{argmax}} \left\{ \sum_{m=1}^{M} \lambda_m h_m(\mathbf{e}, \mathbf{a}, \mathbf{f}) \right\} \tag{7}$$

which is the approach that we follow in this work.

A common problem in IMT arises when the user sets a prefix ($\mathbf{e}_p$) which cannot be found in the phrase-based statistical translation model. Different solutions have been proposed to deal with this problem. The use of word translation graphs, as a compact representation of all possible translations of a source sentence, is proposed in (Barrachina et al., 2009). In (Ortiz-Martínez et al., 2009), a technique based on the generation of partial phrase-based alignments is described. This last proposal has also been adopted in this work.

3 Related work

In this paper we present an application of the online learning paradigm to the IMT framework. In the online learning setting, models are trained sample by sample. Our work is also related to model adaptation, although model adaptation and online learning are not exactly the same thing.

The online learning paradigm has been previously applied to train discriminative models in SMT (Liang et al., 2006; Arun and Koehn, 2007; Watanabe et al., 2007; Chiang et al., 2008). These works differ from the one presented here in that we apply online learning techniques to train generative models instead of discriminative models.

In (Nepveu et al., 2004), dynamic adaptation of an IMT system via cache-based model extensions to language and translation models is proposed. The work by Nepveu et al. (2004) constitutes a domain adaptation technique and not an online learning technique, since the proposed cache components require pre-existent models estimated in batch mode. In addition to this, their IMT system does not use state-of-the-art models.

To our knowledge, the only previous work on online learning for IMT is (Cesa-Bianchi et al., 2008), where a very constrained version of online learning is presented. This constrained version of online learning is not able to extend the translation models due to technical problems with the efficiency of the learning process. In this paper, we present a purely statistical IMT system which is able to incrementally update the parameters of all of the different models that are used in the system, including the translation model, breaking with the above mentioned constraints. What is more, our system is able to learn from scratch, that is, without any preexisting model stored in the system. This is demonstrated empirically in section 5.

4 Online IMT

In this section we propose an online IMT system. First, we describe the basic IMT system involved in the interactive translation process. Then we introduce the required techniques to incrementally update the statistical models used by the system.

4.1 Basic IMT system

The basic IMT system that we propose uses a log-linear model to generate its translations. According to Equation (7), we introduce a set of seven feature functions (from h_1 to h_7):

- **n-gram language model (h_1)**
  $h_1(\mathbf{e}) = \log(\prod_{i=1}^{|\mathbf{e}|+1} p(e_i|e_{i-n+1}^{i-1}))$, [1] where $p(e_i|e_{i-n+1}^{i-1})$ is defined as follows:

$$p(e_i|e_{i-n+1}^{i-1}) = \frac{\max\{c_X(e_{i-n+1}^{i}) - D_n, 0\}}{c_X(e_{i-n+1}^{i-1})} + \frac{D_n}{c_X(e_{i-n+1}^{i-1})} N_{1+}(e_{i-n+1}^{i-1}\bullet) \cdot p(e_i|e_{i-n+2}^{i-1}) \quad (8)$$

where $D_n = \frac{c_{n,1}}{c_{n,1}+2c_{n,2}}$ is a fixed discount ($c_{n,1}$ and $c_{n,2}$ are the number of n-grams with one and two counts respectively), $N_{1+}(e_{i-n+1}^{i-1}\bullet)$ is the number of unique words that follows the history e_{i-n+1}^{i-1} and $c_X(e_{i-n+1}^{i})$ is the count of the n-gram e_{i-n+1}^{i}, where $c_X(\cdot)$ can represent true counts $c_T(\cdot)$ or modified counts $c_M(\cdot)$. True counts are used for the higher order n-grams and modified counts for the lower order n-grams. Given a certain n-gram, its modified count consists in the number of different words that precede this n-gram in the training corpus.

Equation (8) corresponds to the probability given by an n-gram language model with an interpolated version of the Kneser-Ney smoothing (Chen and Goodman, 1996).

[1] $|\mathbf{e}|$ is the length of $\mathbf{e}$, e_0 denotes the *begin-of-sentence* symbol, $e_{|\mathbf{e}|+1}$ denotes the *end-of-sentence* symbol, $e_i^j \equiv e_i...e_j$

- **target sentence-length model (h_2)**
$h_2(\mathbf{e},\mathbf{f}) = \log(p(|\mathbf{f}|\,|\,|\mathbf{e}|)) = \log(\phi_{|\mathbf{e}|}(|\mathbf{f}|+0.5) - \phi_{|\mathbf{e}|}(|\mathbf{f}|-0.5))$, where $\phi_{|\mathbf{e}|}(\cdot)$ denotes the cumulative distribution function (cdf) for the normal distribution (the cdf is used here to integrate the normal density function over an interval of length 1). We use a specific normal distribution with mean $\mu_{|\mathbf{e}|}$ and standard deviation $\sigma_{|\mathbf{e}|}$ for each possible target sentence length $|\mathbf{e}|$.

- **inverse and direct phrase-based models (h_3, h_4)**
$h_3(\mathbf{e},\mathbf{a},\mathbf{f}) = \log(\prod_{k=1}^{K} p(\tilde{f}_k|\tilde{e}_{\tilde{a}_k}))$, where $p(\tilde{f}_k|\tilde{e}_{\tilde{a}_k})$ is defined as follows:

$$p(\tilde{f}_k|\tilde{e}_{\tilde{a}_k}) = \beta \cdot p_{phr}(\tilde{f}_k|\tilde{e}_{\tilde{a}_k}) + (1-\beta).p_{hmm}(\tilde{f}_k|\tilde{e}_{\tilde{a}_k}) \quad (9)$$

In Equation (9), $p_{phr}(\tilde{f}_k|\tilde{e}_{\tilde{a}_k})$ denotes the probability given by a statistical phrase-based dictionary used in regular phrase-based models (see (Koehn et al., 2003) for more details). $p_{hmm}(\tilde{f}_k|\tilde{e}_{\tilde{a}_k})$ is the probability given by an HMM-based (intra-phrase) alignment model (see (Vogel et al., 1996)):

$$p_{hmm}(\tilde{f}|\tilde{e}) = \epsilon \sum_{a_1^{|\tilde{f}|}} \prod_{j=1}^{|\tilde{f}|} p(\tilde{f}_j|\tilde{e}_{a_j}) \cdot p(a_j|a_{j-1},|\tilde{e}|) \quad (10)$$

The HMM-based alignment model probability is used here for smoothing purposes as described in (Ortiz-Martínez et al., 2009).

Analogously h_4 is defined as:
$h_4(\mathbf{e},\mathbf{a},\mathbf{f}) = \log(\prod_{k=1}^{K} p(\tilde{e}_{\tilde{a}_k}|\tilde{f}_k))$

- **target phrase-length model (h_5)**
$h_5(\mathbf{e},\mathbf{a},\mathbf{f}) = \log(\prod_{k=1}^{K} p(|\tilde{e}_k|))$, where $p(|\tilde{e}_k|) = \delta(1-\delta)^{|\tilde{e}_k|}$. h_5 implements a target phrase-length model by means of a geometric distribution with probability of success on each trial δ. The use of a geometric distribution penalizes the length of target phrases.

- **source phrase-length model (h_6)**
$h_6(\mathbf{e},\mathbf{a},\mathbf{f}) = \log(\prod_{k=1}^{K} p(|\tilde{f}_k|\,|\,|\tilde{e}_{\tilde{a}_k}|))$,
where $p(|\tilde{f}_k|\,|\,|\tilde{e}_{\tilde{a}_k}|) = \delta(1-\delta)^{abs(|\tilde{f}_k|-|\tilde{e}_{\tilde{a}_k}|)}$ and $abs(\cdot)$ is the absolute value function. A geometric distribution is used to model this feature (it penalizes the difference between the source and target phrase lengths).

- **distortion model (h_7)**
$h_7(\mathbf{a}) = \log(\prod_{k=1}^{K} p(\tilde{a}_k|\tilde{a}_{k-1}))$, where $p(\tilde{a}_k|\tilde{a}_{k-1}) = \delta(1-\delta)^{abs(b_{\tilde{a}_k}-l_{\tilde{a}_{k-1}})}$, $b_{\tilde{a}_k}$ denotes the beginning position of the source phrase covered by $\tilde{a}_k$ and $l_{\tilde{a}_{k-1}}$ denotes the last position of the source phrase covered by $\tilde{a}_{k-1}$. A geometric distribution is used to model this feature (it penalizes the reorderings).

The log-linear model, which includes the above described feature functions, is used to generate the suffix $\mathbf{e}_s$ given the user-validated prefix $\mathbf{e}_p$. Specifically, the IMT system generates a partial phrase-based alignment between the user prefix $\mathbf{e}_p$ and a portion of the source sentence $\mathbf{f}$, and returns the suffix $\mathbf{e}_s$ as the translation of the remaining portion of $\mathbf{f}$ (see (Ortiz-Martínez et al., 2009)).

4.2 Extending the IMT system from user feedback

After translating a source sentence $\mathbf{f}$, a new sentence pair $(\mathbf{f},\mathbf{e})$ is available to feed the IMT system (see Figure 1). In this section we describe how the log-linear model described in section 4.1 is updated given the new sentence pair. To do this, a set of *sufficient statistics* that can be incrementally updated is maintained for each feature function $h_i(\cdot)$. A sufficient statistic for a statistical model is a statistic that captures all the information that is relevant to estimate this model.

Regarding feature function h_1 and according to equation (8), we need to maintain the following data: $c_{k,1}$ and $c_{k,2}$ given any order k, $N_{1+}(\cdot)$, and $c_X(\cdot)$ (see section 4.1 for the meaning of each symbol). Given a new sentence $\mathbf{e}$, and for each k-gram e_{i-k+1}^{i} of $\mathbf{e}$ where $1 \le k \le n$ and $1 \le i \le |\mathbf{e}|+1$, we modify the set of sufficient statistics as it is shown in Algorithm 1. The algorithm checks the changes in the counts of the k-grams to update the set of sufficient statistics. Sufficient statistics for D_k are updated following the auxiliar procedure shown in Algorithm 2.

Feature function h_2 requires the incremental calculation of the mean $\mu_{|\mathbf{e}|}$ and the standard deviation $\sigma_{|\mathbf{e}|}$ of the normal distribution associated to a target sentence length $|\mathbf{e}|$. For this purpose the procedure described in (Knuth, 1981) can be used. In this procedure, two quantities are maintained for each normal distribution: $\mu_{|\mathbf{e}|}$ and $S_{|\mathbf{e}|}$. Given a new sentence

```
input  : $n$ (higher order), $e_{i-k+1}^{i}$ ($k$-gram),
         $\mathcal{S} = \{\forall j(c_{j,1}, c_{j,2}), N_{1+}(\cdot), c_X(\cdot)\}$
         (current set of sufficient statistics)
output : $\mathcal{S}$ (updated set of sufficient statistics)
begin
    if $c_T(e_{i-k+1}^{i}) = 0$ then
        if $k - 1 \geq 1$ then
            updD($\mathcal{S}$,$k$-1,$c_M(e_{i-k+2}^{i-1})$,$c_M(e_{i-k+2}^{i-1})$+1)
            if $c_M(e_{i-k+2}^{i-1}) = 0$ then
                $N_{1+}(e_{i-k+2}^{i-1}) = N_{1+}(e_{i-k+2}^{i-1}) + 1$
            $c_M(e_{i-k+2}^{i-1}) = c_M(e_{i-k+2}^{i-1}) + 1$
            $c_M(e_{i-k+2}^{i}) = c_M(e_{i-k+2}^{i}) + 1$
        if $k = n$ then
            $N_{1+}(e_{i-k+1}^{i-1}) = N_{1+}(e_{i-k+1}^{i-1}) + 1$
    if $k = n$ then
        updD($\mathcal{S}$,$k$,$c_T(e_{i-k+1}^{i})$,$c_T(e_{i-k+1}^{i}) + 1$)
    $c_T(e_{i-k+1}^{i-1})$=$c_T(e_{i-k+1}^{i-1}) + 1$
    $c_T(e_{i-k+1}^{i})$=$c_T(e_{i-k+1}^{i}) + 1$
end
```

Algorithm 1: Pseudocode for updating the sufficient statistics of a given k-gram

```
input  : $\mathcal{S}$ (current set of sufficient statistics),$k$
         (order), $c$ (current count), $c'$ (new count)
output : $(c_{k,1}, c_{k,2})$ (updated sufficient statistics)
begin
    if $c = 0$ then
        if $c' = 1$ then $c_{k,1} = c_{k,1} + 1$
        if $c' = 2$ then $c_{k,2} = c_{k,2} + 1$
    if $c = 1$ then
        $c_{k,1} = c_{k,1} - 1$
        if $c' = 2$ then $c_{k,2} = c_{k,2} + 1$
    if $c = 2$ then $c_{k,2} = c_{k,2} - 1$
end
```

Algorithm 2: Pseudocode for the updD procedure

pair $(\mathbf{f}, \mathbf{e})$, the two quantities are updated using a recurrence relation:

$$\mu_{|\mathbf{e}|} = \mu'_{|\mathbf{e}|} + (|\mathbf{f}| - \mu'_{|\mathbf{e}|})/c(|\mathbf{e}|) \tag{11}$$

$$S_{|\mathbf{e}|} = S'_{|\mathbf{e}|} + (|\mathbf{f}| - \mu'_{|\mathbf{e}|})(|\mathbf{f}| - \mu_{|\mathbf{e}|}) \tag{12}$$

where $c(|\mathbf{e}|)$ is the count of the number of sentences of length $|\mathbf{e}|$ that have been seen so far, and $\mu'_{|\mathbf{e}|}$ and $S'_{|\mathbf{e}|}$ are the quantities previously stored ($\mu_{|\mathbf{e}|}$ is initialized to the source sentence length of the first sample and $S_{|\mathbf{e}|}$ is initialized to zero). Finally, the standard deviation can be obtained from S as follows: $\sigma_{|\mathbf{e}|} = \sqrt{S_{|\mathbf{e}|}/(c(|\mathbf{e}|) - 1)}$.

Feature functions h_3 and h_4 implement inverse and direct smoothed phrase-based models respectively. Since phrase-based models are symmetric models, only an inverse phrase-based model is maintained (direct probabilities can be efficiently obtained using appropriate data structures, see (Ortiz-Martínez et al., 2008)). The inverse phrase model probabilities are estimated from the phrase counts:

$$p(\tilde{f}|\tilde{e}) = \frac{c(\tilde{f}, \tilde{e})}{\sum_{\tilde{f}'} c(\tilde{f}', \tilde{e})} \tag{13}$$

According to Equation (13), the set of sufficient statistics to be stored for the inverse phrase model consists of a set of phrase counts ($c(\tilde{f}, \tilde{e})$ and $\sum_{\tilde{f}'} c(\tilde{f}', \tilde{e})$ must be stored separately). Given a new sentence pair $(\mathbf{f}, \mathbf{e})$, the standard phrase-based model estimation method uses a word alignment matrix between $\mathbf{f}$ and $\mathbf{e}$ to extract the set of phrase pairs that are *consistent* with the word alignment matrix (see (Koehn et al., 2003) for more details). Once the consistent phrase pairs have been extracted, the phrase counts are updated. The word alignment matrices required for the extraction of phrase pairs are generated by means of the HMM-based models used in the feature functions h_3 and h_4.

Inverse and direct HMM-based models are used here for two purposes: to smooth the phrase-based models via linear interpolation and to generate word alignment matrices. The weights of the interpolation can be estimated from a development corpus. Equation (10) shows the expression of the probability given by an inverse HMM-based model. The probability includes lexical probabilities $p(f_j|e_i)$ and alignment probabilities $p(a_j|a_{j-1}, l)$. Since the alignment in the HMM-based model is determined by a hidden variable, the EM algorithm is required to estimate the parameters of the model (see (Och and Ney, 2003)). However, the standard EM algorithm is not appropriate to incrementally extend our HMM-based models because it is designed to work in batch training scenarios. To solve this problem, we apply the incremental view of the EM algorithm described in (Neal and Hinton, 1998). According to (Och and Ney, 2003), the lexical probability for a pair of words is given by the expression:

$$p(f|e) = \frac{c(f|e)}{\sum_{f'} c(f'|e)} \tag{14}$$

where $c(f|e)$ is the *expected* number of times that the word e is aligned to the word f. The alignment probability is defined in a similar way:

$$p(a_j|a_{j-1}, l) = \frac{c(a_j|a_{j-1}, l)}{\sum_{a'_j} c(a'_j|a_{j-1}, l)} \tag{15}$$

where $c(a_j|a_{j-1}, l)$ denotes the expected number of times that the alignment a_j has been seen after the previous alignment a_{j-1} given a source sentence composed of l words.

Given the equations (14) and (15), the set of sufficient statistics for the inverse HMM-based model consists of a set of expected counts (numerator and denominator values are stored separately). Given a new sentence pair $(\mathbf{f}, \mathbf{e})$, we execute a new iteration of the incremental EM algorithm on the new sample and collect the contributions to the expected counts.

The parameters of the direct HMM-based model are estimated analogously to those of the inverse HMM-based model. Once the direct and the inverse HMM-based model parameters have been modified due to the presentation of a new sentence pair to the IMT system, both models are used to obtain word alignments for the new sentence pair. The resulting direct and inverse word alignment matrices are combined by means of the *symmetrization* alignment operation (Och and Ney, 2003) before extracting the set of consistent phrase pairs.

HMM-based alignment models are used here because, according to (Och and Ney, 2003) and (Toutanova et al., 2002), they outperform IBM 1 to IBM 4 alignment models while still allowing the exact calculation of the likelihood for a given sentence pair.

The δ parameters of the geometric distributions associated to the feature functions h_5, h_6 and h_7 are left fixed. Because of this, there are no sufficient statistics to store for these feature functions.

Finally, the weights of the log-linear combination are not modified due to the presentation of a new sentence pair to the system. These weights can be adjusted off-line by means of a development corpus and well-known optimization techniques.

5 Experiments

This section describes the experiments that we carried out to test our online IMT system.

5.1 Experimental setup

The experiments were performed using the XEROX XRCE corpus (SchlumbergerSema S.A. et al., 2001), which consists of translations of Xerox printer manuals involving three different pairs of languages: French-English, Spanish-English, and German-English. The main features of these corpora are shown in Table 1. Partitions into training, development and test were performed. This corpus is used here because it has been extensively used in the literature on IMT to report results.

IMT experiments were carried out from English to the other three languages.

5.2 Assessment criteria

The evaluation of the techniques presented in this paper were carried out using the *Key-stroke and mouse-action ratio* (KSMR) measure (Barrachina et al., 2009). This is calculated as the number of keystrokes plus the number of *mouse movements* plus one more count per sentence (aimed at simulating the user action needed to accept the final translation), the sum of which is divided by the total number of reference characters. In addition to this, we also used the well-known BLEU score (Papineni et al., 2001) to measure the translation quality of the first translation hypothesis produced by the IMT system for each source sentence (which is automatically generated without user intervention).

5.3 Online IMT results

To test the techniques proposed in this work, we carried out experiments in two different scenarios. In the first one, the first 10 000 sentences extracted from the training corpora were interactively translated by means of an IMT system without any preexistent model stored in memory. Each time a new sentence pair was validated, it was used to incrementally train the system. Figures 3a, 3b and 3c show the evolution of the KSMR with respect to the number of sentence pairs processed by the IMT system; the results correspond to the translation from English to Spanish, French and German, respectively. In addi-

		En	Sp	En	Fr	En	Ge

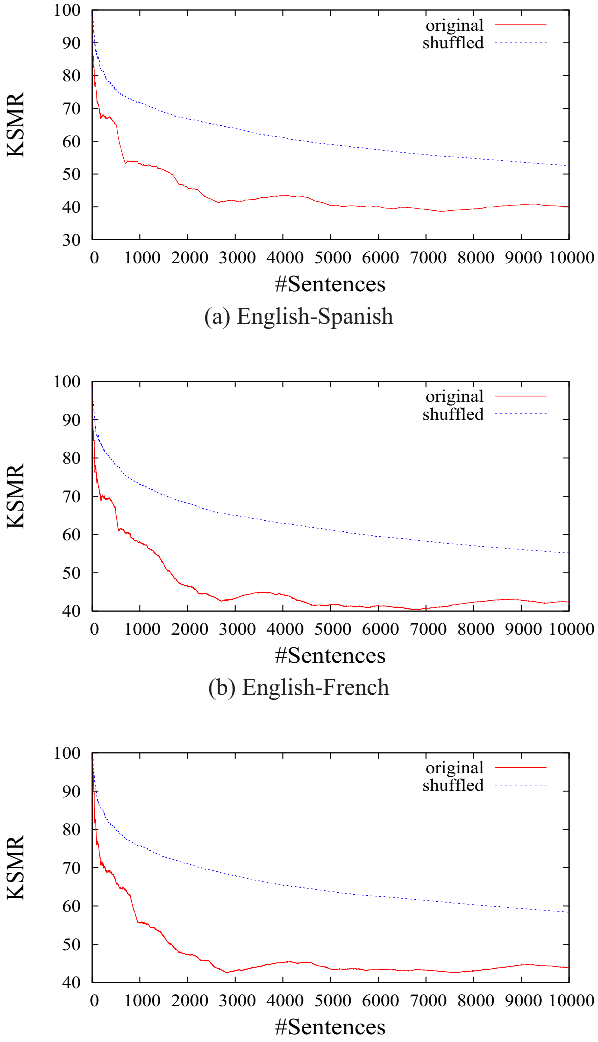
	Perplexity (3-grams)	107.0	59.6	192.6	135.4	92.8	169.2

Table 1: XEROX corpus statistics for three different language pairs (from English (En) to Spanish (Sp), French (Fr) and German (Ge))

tion, for each language pair we interactively translated the original portion of the training corpus and the same portion of the original corpus after being randomly shuffled.

As these figures show, the results clearly demonstrate that the IMT system is able to learn from scratch. The results were similar for the three languages. It is also worthy of note that the obtained results were better in all cases for the original corpora than for the shuffled ones. This is because, in the original corpora, similar sentences appear more or less contiguosly (due to the organization of the contents of the printer manuals). This circumstance increases the accuracy of the online learning, since with the original corpora the number of *lateral effects* ocurred between the translation of similar sentences is decreased. The online learning of a new sentence pair produces a lateral effect when the changes in the probability given by the models not only affect the newly trained sentence pair but also other sentence pairs. A lateral effect can cause that the system generates a wrong translation for a given source sentence due to undesired changes in the statistical models.

The accuracy were worse for shuffled corpora, since shuffling increases the number of lateral effects that may occur between the translation of similar sentences (because they no longer appear contiguously). A good way to compare the quality of different online IMT systems is to determine their robustness in relation to sentence ordering. However, it can generally be expected that the sentences to be translated in an interactive translation session will be in a non-random order.



(a) English-Spanish

(b) English-French

(c) English-German

Figure 3: KSMR evolution translating a portion of the training corpora

Alternatively, we carried out experiments in a different learning scenario. Specifically, the XEROX test corpora were interactively translated from the English language to the other three languages, comparing the performance of a batch IMT system with that of an online IMT system. The batch IMT system is a conventional IMT system which is not able to take advantage of user feedback after each translation while the online IMT system uses the new sentence pairs provided by the user to revise the statistical models. Both systems were initialized with a log-linear model trained in batch mode by means of the Xerox training corpora. The weights of the log-linear combination were adjusted for the development corpora by means of the downhill-simplex algorithm. Table 2 shows the obtained results. The table shows the BLEU score and the KSMR for the batch and the online IMT systems (95% confidence intervals are shown). The BLEU score was calculated from the first translation hypothesis produced by the IMT system for each source sentence. The table also shows the average online learning time (LT) for each new sample presented to the system[2]. All the improvements obtained with the online IMT system were statistically significant. Also, the average learning times clearly allow the system to be used in a real-time scenario.

	IMT system	BLEU	KSMR	LT (s)
En-Sp	batch	55.1± 2.3	18.2± 1.1	-
	online	60.6± 2.3	15.8± 1.0	0.04
En-Fr	batch	33.7± 2.0	33.9± 1.3	-
	online	42.2± 2.2	27.9± 1.3	0.09
En-Ge	batch	20.4± 1.8	40.3± 1.2	-
	online	28.0± 2.0	35.0± 1.3	0.07

Table 2: BLEU and KSMR results for the Xerox test corpora using the batch and the online IMT systems. The average online learning time (LT) in seconds is shown for the online system

Finally, in Table 3 a comparison of the KSMR results obtained by the online IMT system with state-of-the-art IMT systems is reported (95% confidence intervals are shown). We compared our system with those presented in (Barrachina et al., 2009): the alignment templates (AT), the stochastic finite-state transducer (SFST), and the phrase-based (PB) approaches to IMT. The results were obtained using the same Xerox training and test sets (see Table 1) for the four different IMT systems. Our system outperformed the results obtained by these systems.

	AT	PB	SFST	Online
En-Sp	23.2±1.3	16.7±1.2	21.8±1.4	15.8± 1.0
En-Fr	40.4±1.4	35.8±1.3	43.8±1.6	27.9± 1.3
En-Ge	44.7±1.2	40.1±1.2	45.7±1.4	35.0± 1.3

Table 3: KSMR results comparison of our system and three different state-of-the-art batch systems

6 Conclusions

We have presented an online IMT system. The proposed system is able to incrementally extend the statistical models involved in the translation process, breaking technical limitations encountered in other works. Empirical results show that our techniques allow the IMT system to learn from scratch or from previously estimated models.

One key aspect of the proposed system is the use of HMM-based alignment models trained by means of the incremental EM algorithm.

The incremental adjustment of the weights of the log-linear models and other parameters have not been tackled here. For the future we plan to incorporate this functionality into our IMT system.

The incremental techniques proposed here can also be exploited to extend SMT systems (in fact, our proposed IMT system is based on an incrementally updateable SMT system). For the near future we plan to study possible aplications of our techniques in a fully automatic translation scenario.

Finally, it is worthy of note that the main ideas presented here can be used in other interactive applications such as Computer Assisted Speech Transcription, Interactive Image Retrieval, etc (see (Vidal et al., 2007) for more information). In conclusion, we think that the online learning techniques proposed here can be the starting point for a new generation of interactive pattern recognition systems that are able to take advantage of user feedback.

The Best Lexical Metric for Phrase-Based Statistical MT System Optimization

Daniel Cer, Christopher D. Manning and Daniel Jurafsky
Stanford University
Stanford, CA 94305, USA

Abstract

Translation systems are generally trained to optimize BLEU, but many alternative metrics are available. We explore how optimizing toward various automatic evaluation metrics (BLEU, METEOR, NIST, TER) affects the resulting model. We train a state-of-the-art MT system using MERT on many parameterizations of each metric and evaluate the resulting models on the other metrics and also using human judges. In accordance with popular wisdom, we find that it's important to train on the same metric used in testing. However, we also find that training to a newer metric is only useful to the extent that the MT model's structure and features allow it to take advantage of the metric. Contrasting with TER's good correlation with human judgments, we show that people tend to prefer BLEU and NIST trained models to those trained on edit distance based metrics like TER or WER. Human preferences for METEOR trained models varies depending on the source language. Since using BLEU or NIST produces models that are more robust to evaluation by other metrics and perform well in human judgments, we conclude they are still the best choice for training.

1 Introduction

Since their introduction, automated measures of machine translation quality have played a critical role in the development and evolution of SMT systems. While such metrics were initially intended for evaluation, popular training methods such as minimum error rate training (MERT) (Och, 2003) and margin infused relaxed algorithm (MIRA) (Crammer and Singer, 2003; Watanabe et al., 2007; Chiang et al., 2008) train translation models toward a specific evaluation metric. This makes the quality of the resulting model dependent on how accurately the automatic metric actually reflects human preferences.

The most popular metric for both comparing systems and tuning MT models has been BLEU. While BLEU (Papineni et al., 2002) is relatively simple, scoring translations according to their n-gram overlap with reference translations, it still achieves a reasonable correlation with human judgments of translation quality. It is also robust enough to use for automatic optimization. However, BLEU does have a number of shortcomings. It doesn't penalize n-gram scrambling (Callison-Burch et al., 2006), and since it isn't aware of synonymous words or phrases, it can inappropriately penalize translations that use them.

Recently, there have been efforts to develop better evaluation metrics. Metrics such as *Translation Edit Rate* (TER) (Snover et al., 2006; Snover et al., 2009) and METEOR[1] (Lavie and Denkowski, 2009) perform a more sophisticated analysis of the translations being evaluated and the scores they produce tend to achieve a better correlation with human judgments than those produced by BLEU (Snover et al., 2009; Lavie and Denkowski, 2009; Przybocki et al., 2008; Snover et al., 2006).

Their better correlations suggest that we might obtain higher quality translations by making use of these new metrics when training our models. We expect that training on a specific metric will produce the best performing model according to that met-

[1] METEOR: Metric for Evaluation of Translation with Explicit ORdering.

ric. Doing better on metrics that better reflect human judgments seems to imply the translations produced by the model would be preferred by human judges.

However, there are four potential problems. First, some metrics could be susceptible to systematic exploitation by the training algorithm and result in model translations that have a high score according to the evaluation metric but that are of low quality.[2] Second, other metrics may result in objective functions that are harder to optimize. Third, some may result in better generalization performance at test time by not encouraging overfitting of the training data. Finally, as a practical concern, metrics used for training cannot be too slow.

In this paper, we systematically explore these four issues for the most popular metrics available to the MT community. We examine how well models perform both on the metrics on which they were trained and on the other alternative metrics. Multiple models are trained using each metric in order to determine the stability of the resulting models. Select models are scored by human judges in order to determine how performance differences obtained by tuning to different automated metrics relates to actual human preferences.

The next sections introduce the metrics and our training procedure. We follow with two sets of core results, machine evaluation in section 5, and human evaluation in section 6.

2 Evaluation Metrics

Designing good automated metrics for evaluating machine translations is challenging due to the variety of acceptable translations for each foreign sentence. Popular metrics produce scores primarily based on matching sequences of words in the system translation to those in one or more reference translations. The metrics primarily differ in how they account for reorderings and synonyms.

2.1 BLEU

BLEU (Papineni et al., 2002) uses the percentage of n-grams found in machine translations that also occur in the reference translations. These n-gram precisions are calculated separately for different n-gram lengths and then combined using a geometric mean. The score is then scaled by a brevity penalty if the candidate translations are shorter than the references, $BP = \min(1.0, e^{1-len(R)/len(T)})$. Equation 1 gives BLEU using n-grams up to length N for a corpus of candidate translations T and reference translations R. A variant of BLEU called the NIST metric (Doddington, 2002) weights n-gram matches by how informative they are.

$$\text{BLEU:}N = \left(\prod_{n=1}^{N} \frac{n\text{-grams}(T \bigcap R)}{n\text{-grams}(T)} \right)^{\frac{1}{N}} BP \quad (1)$$

While easy to compute, BLEU has a number of shortcomings. Since the order of matching n-grams is ignored, n-grams in a translation can be randomly rearranged around non-matching material or other n-gram breaks without harming the score. BLEU also does not explicitly check whether information is missing from the candidate translations, as it only examines what fraction of candidate translation n-grams are in the references and not what fraction of references n-grams are in the candidates (i.e., BLEU ignores n-gram recall). Finally, the metric does not account for words and phrases that have similar meanings.

2.2 METEOR

METEOR (Lavie and Denkowski, 2009) computes a one-to-one alignment between matching words in a candidate translation and a reference. If a word matches multiple other words, preference is given to the alignment that reorders the words the least, with the amount of reordering measured by the number of crossing alignments. Alignments are first generated for exact matches between words. Additional alignments are created by repeatedly running the alignment procedure over unaligned words, first allowing for matches between word stems, and then allowing matches between words listed as synonyms in WordNet. From the final alignment, the candidate translation's unigram precision and recall is calculated, $P = \frac{\text{matches}}{\text{length trans}}$ and $R = \frac{\text{matches}}{\text{length ref}}$. These two are then combined into a weighted harmonic mean (2). To penalize reorderings, this value is then scaled by a fragmentation penalty based on the number of chunks the two sentences would need to be broken

[2] For example, BLEU computed without the brevity penalty would likely result in models that have a strong preference for generating pathologically short translations.

into to allow them to be rearranged with no crossing alignments, $P_{\beta,\gamma} = 1 - \gamma \left(\frac{\text{chunks}}{\text{matches}}\right)^{\beta}$.

$$F_{\alpha} = \frac{PR}{\alpha P + (1-\alpha)R} \tag{2}$$

$$\text{METEOR}_{\alpha,\beta,\gamma} = F_{\alpha} \cdot P_{\beta,\gamma} \tag{3}$$

Equation 3 gives the final METEOR score as the product of the unigram harmonic mean, F_{α}, and the fragmentation penalty, $P_{\beta,\gamma}$. The free parameters α, β, and γ can be used to tune the metric to human judgments on a specific language and variation of the evaluation task (e.g., ranking candidate translations vs. reproducing judgments of translations adequacy and fluency).

2.3 Translation Edit Rate

TER (Snover et al., 2006) searches for the shortest sequence of edit operations needed to turn a candidate translation into one of the reference translations. The allowable edits are the insertion, deletion, and substitution of individual words and swaps of adjacent sequences of words. The swap operation differentiates TER from the simpler word error rate (WER) metric (Nießen et al., 2000), which only makes use of insertions, deletions, and substitutions. Swaps prevent phrase reorderings from being excessively penalized. Once the shortest sequence of operations is found,[3] TER is calculated simply as the number of required edits divided by the reference translation length, or average reference translation length when multiple are available (4).

$$\text{TER} = \frac{\text{min edits}}{\text{avg ref length}} \tag{4}$$

TER-Plus (TERp) (Snover et al., 2009) extends TER by allowing the cost of edit operations to be tuned in order to maximize the metric's agreement with human judgments. TERp also introduces three new edit opertions: word stem matches, WordNet synonym matches, and multiword matches using a table of scored paraphrases.

3 MERT

MERT is the standard technique for obtaining a machine translation model fit to a specific evaluation metric (Och, 2003). Learning such a model cannot be done using gradient methods since the value of the objective function only depends on the translation model's argmax for each sentence in the tuning set. Typically, this optimization is performed as a series of line searches that examines the value of the evaluation metric at critical points where a new translation argmax becomes preferred by the model. Since the model score assigned to each candidate translation varies linearly with changes to the model parameters, it is possible to efficiently find the global minimum along any given search direction with only $O(n^2)$ operations when n-best lists are used.

Using our implementation of MERT that allows for pluggable optimization metrics, we tune models to BLEU:N for $N = 1 \ldots 5$, TER, two configurations of TERp, WER, several configurations of METEOR, as well as additive combinations of these metrics. The TERp configurations include the default configuration of TERp and TERpA: the configuration of TERp that was trained to match human judgments for NIST Metrics MATR (Matthew Snover and Schwartz, 2008; Przybocki et al., 2008). For METEOR, we used the standard METEOR English parameters ($\alpha = 0.8, \beta = 2.5, \gamma = 0.4$), and the English parameters for the ranking METEOR ($\alpha = 0.95, \beta = 0.5, \gamma = 0.5$),[4] which was tuned to maximize the metric's correlation with WMT-07 human ranking judgements (Agarwal and Lavie, 2008). The default METEOR parameters favor longer translations than the other metrics, since high α values place much more weight on unigram recall than precision. Since this may put models tuned to METEOR at a disadvantage when being evaluated by the other metrics, we also use a variant of the standard English model and of ranking METEOR with α set to 0.5, as this weights both recall and precision equally.

For each iteration of MERT, 20 random restarts were used in addition to the best performing point discovered during earlier iterations of training.[5]

[3] Since swaps prevent TER from being calculated exactly using dynamic programming, a beam search is used and this can overestimate the number of required edits.

[4] Agarwal and Lavie (2008) report $\gamma = 0.45$, however the 0.8.2 release of METEOR uses $\gamma = 0.5$ for ranking English.

[5] This is not necessarily identical with the point returned by the most recent MERT iteration, but rather can be any point

Since MERT is known to be sensitive to what restart points are provided, we use the same series of random restart points for each model. During each iteration of MERT, the random seed is based on the MERT iteration number. Thus, while a different set of random points is selected during each MERT iteration, on any given iteration all models use the same set of points. This prevents models from doing better or worse just because they received different starting points. However, it is still possible that certain random starting points are better for some evaluation metrics than others.

4 Experiments

Experiments were run using Phrasal (Cer et al., 2010), a left-to-right beam search decoder that achieves a matching BLEU score to Moses (Koehn et al., 2007) on a variety of data sets. During decoding we made use of a stack size of 100, set the distortion limit to 6, and retrieved 20 translation options for each unique source phrase.

Using the selected metrics, we train both Chinese to English and Arabic to English models.[6] The Chinese to English models are trained using NIST MT02 and evaluated on NIST MT03. The Arabic to English experiments use NIST MT06 for training and GALE dev07 for evaluation. The resulting models are scored using all of the standalone metrics used during training.

4.1 Arabic to English

Our Arabic to English system was based on a well ranking 2009 NIST submission (Galley et al., 2009). The phrase table was extracted using all of the allowed resources for the constrained Arabic to English track. Word alignment was performed using the Berkeley cross-EM aligner (Liang et al., 2006). Phrases were extracted using the grow heuristic (Koehn et al., 2003). However, we threw away all phrases that have a $P(e|f) < 0.0001$ in order to reduce the size of the phrase table. From the aligned data, we also extracted a hierarchical reordering model that is similar to popular lexical reordering models (Koehn et al., 2007) but that models swaps containing more than just one phrase (Galley and Manning, 2008). A 5-gram language model was created with the SRI language modeling toolkit (Stolcke, 2002) using all of the English material from the parallel data employed to train the phrase table as well as Xinhua Chinese English Parallel News (LDC2002E18).[7] The resulting decoding model has 16 features that are optimized during MERT.

4.2 Chinese to English

For our Chinese to English system, our phrase table was built using 1,140,693 sentence pairs sampled from the GALE Y2 training data. The Chinese sentences were word segmented using the 2008 version of Stanford Chinese Word Segmenter (Chang et al., 2008; Tseng et al., 2005). Phrases were extracted by running GIZA++ (Och and Ney, 2003) in both directions and then merging the alignments using the grow-diag-final heuristic (Koehn et al., 2003). From the merged alignments we also extracted a bidirectional lexical reordering model conditioned on the source and the target phrases (Koehn et al., 2007). A 5-gram language model was created with the SRI language modeling toolkit (Stolcke, 2002) and trained using the Gigaword corpus and English sentences from the parallel data. The resulting decoding model has 14 features to be trained.

5 Results

As seen in tables 1 and 2, the evaluation metric we use during training has a substantial impact on performance as measured by the various other metrics. There is a clear block structure where the best class of metrics to train on is the same class that is used during evaluation. Within this block structure, we make three primary observations. First, the best performing model according to any specific metric *configuration* is usually not the model we trained to that configuration. In the Chinese results, the model trained on BLEU:3 scores 0.74 points higher on BLEU:4 than the model actually trained to BLEU:4. In fact, the BLEU:3 trained model outperforms all other models on BLEU:N metrics. For the Arabic results, training on NIST scores 0.27 points higher

returned during an earlier iteration of MERT.

[6] Given the amount of time required to train a TERpA model, we only present TERpA results for Chinese to English.

[7] In order to run multiple experiments in parallel on the computers available to us, the system we use for this work differs from our NIST submission in that we remove the Google n-gram language model. This results in a performance drop of less than 1.0 BLEU point on our dev data.

on BLEU:4 than training on BLEU:4, and outperforms all other models on BLEU:N metrics.

Second, the edit distance based metrics (WER, TER, TERp, TERpA)[8] seem to be nearly interchangeable. While the introduction of swaps allows the scores produced by the TER metrics to achieve better correlation with human judgments, our models are apparently unable to exploit this during training. This maybe due to the monotone nature of the reference translations and the fact that having multiple references reduces the need for reorderings. However, it is possible that differences between training to WER and TER would become more apparent using models that allow for longer distance reorderings or that do a better job of capturing what reorderings are acceptable.

Third, with the exception of BLEU:1, the performance of the BLEU, NIST, and the METEOR α=.5 models appears to be more robust across the other evaluation metrics than the standard METEOR, METEOR ranking, and edit distance based models (WER, TER, TERp, an TERpA). The latter models tend to do quite well on metrics similar to what they were trained on, while performing particularly poorly on the other metrics. For example, on Chinese, the TER and WER models perform very well

[8] In our implementation of multi-reference WER, we use the length of the references that result in the lowest sentence level WER to divide the edit costs. In contrast, TER divides by the average reference length. This difference can sometimes result in WER being lower than the corresponding TER. Also, as can be seen in the Arabic to English results, TERp scores sometimes differ dramatically from TER scores due to normalization and tokenization differences (e.g., TERp removes punctuation prior to scoring, while TER does not).

on other edit distance based metrics, while performing poorly on all the other metrics except NIST. While less pronounced, the same trend is also seen in the Arabic data. Interestingly enough, while the TER, TERp and standard METEOR metrics achieve good correlations with human judgments, models trained to them are particularly mismatched in our results. The edit distance models do terribly on METEOR and METEOR ranking, while METEOR and METEOR ranking models do poorly on TER, TERp, and TERpA.

Table 3: Chinese to English MERT iterations and training times, given in hours:mins and excluding decoder time.

5.1 Other Results

On the training data, we see a similar block structure within the results, but there is a different pattern among the top performers. The tables are omitted, but we observe that, for Chinese, the BLEU:5 model performs best on the training data according to all higher order BLEU metrics (4-7). On Arabic, the BLEU:6 model does best on the same higher order BLEU metrics (4-7). By rewarding higher order n-gram matches, these objectives actually find minima that result in more 4-gram matches than the models optimized directly to BLEU:4. However, the fact that this performance advantage disappears on the evaluation data suggests these higher order models also promote overfitting.

Models trained on additive metric blends tend to smooth out performance differences between the classes of metrics they contain. As expected, weighting the metrics used in the additive blends results in models that perform slightly better on the type of metric with the highest weight.

Table 3 reports training times for select Chinese to English models. Training to TERpA is very computationally expensive due to the implementation of the paraphrase table. The TER family of metrics tends to converge in fewer MERT iterations than those trained on other metrics such as BLEU, METEOR or even WER. This suggests that the learning objective provided by these metrics is either easier to optimize or they more easily trap the search in local minima.

5.2 Model Variance

One potential problem with interpreting the results above is that learning with MERT is generally assumed to be noisy, with different runs of the algorithm possibly producing very different models. We explore to what extent the results just presented were affected by noise in the training procedure. We perform multiple training runs using select evaluation metrics and examining how consistent the resulting models are. This also allows us to determine whether the metric used as a learning criteria influences the stability of learning. For these experiments, Chinese to English models are trained 5 times using a different series of random starting points. As before, 20 random restarts were used during each MERT iteration.

In table 4, models trained to BLEU and METEOR are relatively stable, with the METEOR:0.5 trained models being the most stable. The edit distance models, WER and TERp, vary more across training runs, but still do not exceed the interesting cross metric differences seen in table 1. The instability of WER and TERp, with TERp models having a standard deviation of 1.3 in TERp and 2.5 in BLEU:4, make them risky metrics to use for training.

6 Human Evaluation

The best evaluation metric to use during training is the one that ultimately leads to the best translations according to human judges. We perform a human evaluation of select models using Amazon Mechanical Turk, an online service for cheaply performing simple tasks that require human intelligence. To use the service, tasks are broken down into individual units of work known as human intelligence tasks (HITs). HITs are assigned a small amount of money that is paid out to the workers that complete them. For many natural language annotation tasks, including machine translation evaluation, it is possible to obtain annotations that are as good as those pro-

duced by experts by having multiple workers complete each HIT and then combining their answers (Snow et al., 2008; Callison-Burch, 2009).

We perform a pairwise comparison of the translations produced for the first 200 sentences of our Chinese to English test data (MT03) and our Arabic to English test data (dev07). The HITs consist of a pair of machine translated sentences and a single human generated reference translation. The reference is chosen at random from those available for each sentence. Capitalization of the translated sentences is restored using an HMM based truecaser (Lita et al., 2003). Turkers are instructed to "…select the machine translation generated sentence that is easiest to read and best conveys what is stated in the reference". Differences between the two machine translations are emphasized by being underlined and bold faced.[9] The resulting HITs are made available only to workers in the United States, as pilot experiments indicated this results in more consistent preference judgments. Three preference judgments are obtained for each pair of translations and are combined using weighted majority vote.

As shown in table 5, in many cases the quality of the translations produced by models trained to different metrics is remarkably similar. Training to the simpler edit distance metric WER produces translations that are as good as those from models tuned to the similar but more advanced TERp metric that allows for swaps. Similarly, training to TERpA, which makes use of both a paraphrase table and edit costs

[9] We emphasize relative differences between the two translations rather than the difference between each translation and the reference in order to avoid biasing evaluations toward edit distance metrics.

tuned to human judgments, is no better than TERp.

For the Chinese to English results, there is a statistically significant human preference for translations that are produced by training to BLEU:4 and a marginally significant preferences for training to NIST over the default configuration of TERp. This contrasts sharply with earlier work showing that TER and TERp correlate better with human judgements than BLEU (Snover et al., 2009; Przybocki et al., 2008; Snover et al., 2006). While it is assumed that, by using MERT, "improved evaluation measures lead directly to improved machine translation quality" (Och, 2003), these results show improved correlations with human judgments are **not always** sufficient to establish that tuning to a metric will result in higher quality translations. In the Arabic results, we see a similar pattern where NIST is preferred to TERp, again with marginal signficance. Strangely, however, there is no real difference between TERp vs. BLEU:4.

For Arabic, training to ranking METEOR is worse than BLEU:4, with the differences being very significant. The Arabic results also trend toward suggesting that BLEU:4 is better than either standard METEOR and METEOR α 0.5. However, for the Chinese models, training to standard METEOR and METEOR α 0.5 is about as good as training to BLEU:4. In both the Chinese and Arabic results, the METEOR α 0.5 models are at least as good as those trained to standard METEOR and METEOR ranking. In contrast to the cross evaluation metric results, where the differences between the α 0.5 models and the standard METEOR models were always fairly dramatic, the human preferences suggest there is often not much of a difference in the true quality of the translations produced by these models.

7 Conclusion

Training to different evaluation metrics follows the expected pattern whereby models perform best on the same type of metric used to train them. However, models trained using the n-gram based metrics, BLEU and NIST, are more robust to being evaluated using the other metrics.

Edit distance models tend to do poorly when evaluated on other metrics, as do models trained using METEOR. However, training models to METEOR can be made more robust by setting α to 0.5, which balances the importance the metric assigns to precision and recall.

The fact that the WER, TER and TERp models perform very similarly suggests that current phrase-based translation systems lack either the features or the model structure to take advantage of swap edit operations. The situation might be improved by using a model that does a better job of both capturing the structure of the source and target sentences and their allowable reorderings, such as a syntactic tree-to-string system that uses contextually rich rewrite rules (Galley et al., 2006), or by making use of larger more fine grained feature sets (Chiang et al., 2009) that allow for better discrimination between hypotheses.

Human results indicate that edit distance trained models such as WER and TERp tend to produce lower quality translations than BLEU or NIST trained models. Tuning to METEOR works reasonably well for Chinese, but is not a good choice for Arabic. We suspect that the newer RYPT metric (Zaidan and Callison-Burch, 2009), which directly makes use of human adequacy judgements of substrings, would obtain better human results than the automated metrics presented here. However, like other metrics, we expect performance gains still will be sensitive to how the mechanics of the metric interact with the structure and feature set of the decoding model being used.

BLEU and NIST's strong showing in both the machine and human evaluation results indicates that they are still the best general choice for training model parameters. We emphasize that improved metric correlations with human judgments do not imply that models trained to a metric will result in higher quality translations. We hope future work on developing new evaluation metrics will explicitly explore the translation quality of models trained to them.

Abstract

Adaptor grammars extend probabilistic context-free grammars to define prior distributions over trees with "rich get richer" dynamics. Inference for adaptor grammars seeks to find parse trees for raw text. This paper describes a variational inference algorithm for adaptor grammars, providing an alternative to Markov chain Monte Carlo methods. To derive this method, we develop a stick-breaking representation of adaptor grammars, a representation that enables us to define adaptor grammars with recursion. We report experimental results on a word segmentation task, showing that variational inference performs comparably to MCMC. Further, we show a significant speed-up when parallelizing the algorithm. Finally, we report promising results for a new application for adaptor grammars, dependency grammar induction.

1 Introduction

Recent research in unsupervised learning for NLP focuses on Bayesian methods for probabilistic grammars (Goldwater and Griffiths, 2007; Toutanova and Johnson, 2007; Johnson et al., 2007). Such methods have been made more flexible with nonparametric Bayesian (NP Bayes) methods, such as Dirichlet process mixture models (Antoniak, 1974; Pitman, 2002). One line of research uses NP Bayes methods on whole tree structures, in the form of **adaptor grammars** (Johnson et al., 2006; Johnson, 2008b; Johnson, 2008a; Johnson and Goldwater, 2009), in order to identify recurrent subtree patterns.

Adaptor grammars provide a flexible distribution over parse trees that has more structure than a traditional context-free grammar. Adaptor grammars are used via posterior inference, the computational problem of determining the posterior distribution of parse trees given a set of observed sentences. Current posterior inference algorithms for adaptor grammars are based on MCMC sampling methods (Robert and Casella, 2005). MCMC methods are theoretically guaranteed to converge to the true posterior, but come at great expense: they are notoriously slow to converge, especially with complex hidden structures such as syntactic trees. Johnson (2008b) comments on this, and suggests the use of **variational inference** as a possible remedy.

Variational inference provides a deterministic alternative to sampling. It was introduced for Dirichlet process mixtures by Blei and Jordan (2005) and applied to infinite grammars by Liang et al. (2007). With NP Bayes models, variational methods are based on the stick-breaking representation (Sethuraman, 1994). Devising a stick-breaking representation is a central challenge to using variational inference in this setting.

The rest of this paper is organized as follows. In §2 we describe a stick-breaking representation of adaptor grammars, which enables variational inference (§3) and a well-defined incorporation of recursion into adaptor grammars. In §4 we give an empirical comparison of the algorithm to MCMC inference and describe a novel application of adaptor grammars to unsupervised dependency parsing.

2 Adaptor Grammars

We review adaptor grammars and develop a stick-breaking representation of the tree distribution.

2.1 Definition of Adaptor Grammars

Adaptor grammars capture syntactic regularities in sentences by placing a nonparametric prior over the distribution of syntactic trees that underlie them. The model exhibits "rich get richer" dynamics: once a tree is generated, it is more likely to reappear.

Adaptor grammars were developed by Johnson et al. (2006). An adaptor grammar is a tuple $\boldsymbol{A} = \langle \boldsymbol{G}, \mathcal{M}, \boldsymbol{a}, \boldsymbol{b}, \boldsymbol{\alpha} \rangle$, which contains: (i) a context-free grammar $\boldsymbol{G} = \langle \mathcal{W}, \mathcal{N}, \boldsymbol{R}, S \rangle$ where $\mathcal{W}$ is the set of

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 564–572,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

terminals, $\mathcal{N}$ is the set of nonterminals, $\boldsymbol{R}$ is a set of production rules, and $S \in \mathcal{N}$ is the start symbol—we denote by $\boldsymbol{R}_A$ the subset of $\boldsymbol{R}$ with left-hand side A; (ii) a set of adapted nonterminals, $\mathcal{M} \subseteq \mathcal{N}$; and (iii) parameters $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{\alpha}$, which are described below.

An adaptor grammar assumes the following generative process of trees. First, the multinomial distributions $\boldsymbol{\theta}$ for a PCFG based on $\boldsymbol{G}$ are drawn from Dirichlet distributions. Specifically, multinomial $\boldsymbol{\theta}_A \sim \mathrm{Dir}(\alpha_A)$ where $\boldsymbol{\alpha}$ is collection of Dirichlet parameters, indexed by $A \in \mathcal{N}$.

Trees are then generated top-down starting with S. Any non-adapted nonterminal $A \in \mathcal{N} \setminus \mathcal{M}$ is expanded by drawing a rule from $\boldsymbol{R}_A$. There are two ways to expand $A \in \mathcal{M}$:

1. With probability $(n_z - b_A)/(n_A + a_A)$ we expand A to subtree z (a tree rooted at A with a yield in $\mathcal{W}^*$), where n_z is the number of times the tree z was previously generated and n_A is the total number of subtrees (tokens) previously generated root being A. We denote by $\boldsymbol{a}$ the *concentration parameters* and $\boldsymbol{b}$ the *discount parameters*, both indexed by $A \in \mathcal{M}$. We have $a_A \geq 0$ and $b_A \in [0, 1]$.
2. With probability $(a_A + k_A b_A)/(n_A + a_A)$, A is expanded as in a PCFG by a draw from $\boldsymbol{\theta}_A$ over $\boldsymbol{R}_A$, where k_A is the number of subtrees (types) previously generated with root A.

For the expansion of adapted nonterminals, this process can be explained using the Chinese restaurant process (CRP) metaphor: a "customer" (corresponding to a partially generated tree) enters a "restaurant" (corresponding to a nonterminal) and selects a "table" (corresponding to a subtree) to attach to the partially generated tree. If she is the first customer at the table, the PCFG $\langle \boldsymbol{G}, \boldsymbol{\theta} \rangle$ produces the new table's associated "dish" (a subtree).[1]

When adaptor grammars are defined using the CRP, the PCFG $\boldsymbol{G}$ has to be non-recursive with respect to the adapted nonterminals. More precisely, for $A \in \mathcal{N}$, denote by $\mathrm{Reachable}(\boldsymbol{G}, A)$ all the nonterminals that can be reached from A using a partial derivation from $\boldsymbol{G}$. Then we restrict $\boldsymbol{G}$ such that for all $A \in \mathcal{M}$, we have $A \notin \mathrm{Reachable}(\boldsymbol{G}, A)$. Without this restriction, we might end up in a situation where the generative process is ill-defined: in the CRP terminology, a customer could enter a restaurant and select a table whose dish is still in the process of being selected.[2] In the more general form of adaptor grammars with arbitrary adaptors, the problem amounts to mutually dependent definitions of distributions which rely on the others to be defined. We return to this problem in §3.1.

Inference The inference problem is to compute the posterior distribution of parse trees given observed sentences $\boldsymbol{x} = \langle x_1, \ldots, x_n \rangle$. Typically, inference with adaptor grammars is done with Gibbs sampling. Johnson et al. (2006) use an embedded Metropolis-Hastings sampler (Robert and Casella, 2005) inside a Gibbs sampler. The proposal distribution is a PCFG, resembling a tree substitution grammar (TSG; Joshi, 2003). The sampler of Johnson et al. is based on the representation of the PY process as a distribution over partitions of integers. This representation is not amenable to variational inference.

2.2 Stick-Breaking Representation

To develop a variational inference algorithm for adaptor grammars, we require an alternative representation of the model in §2.1. The CRP-based definition implicitly marginalizes out a random distribution over trees. For variational inference, we construct that distribution.

We first review the Dirichlet process and its stick-breaking representation. The Dirichlet process defines a distribution over distributions. Samples from the Dirichlet process tend to deviate from a *base distribution* depending on a *concentration parameter*. Let $G \sim \mathrm{DP}(G_0, a)$ be a distribution sampled from the Dirichlet process with base distribution G_0

[1] We note that our construction deviates from the strict definition of adaptor grammars (Johnson et al., 2006): (i) in our construction, we assume (as prior work does in practice) that the adaptors in $\boldsymbol{A} = \langle \boldsymbol{G}, \mathcal{M}, \boldsymbol{a}, \boldsymbol{b}, \boldsymbol{\alpha} \rangle$ follow the Pitman-Yor (PY) process (Pitman and Yor, 1997), though in general other stochastic processes might be used; and (ii) we place a symmetric Dirichlet over the parameters of the PCFG, $\boldsymbol{\theta}$, whereas Johnson et al. used a fixed PCFG for the definition (though they experimented with a Dirichlet prior).

[2] Consider the simple grammar with rules { S → S S, S → a }. Assume that a customer enters the restaurant for S. She sits at a table, and selects a dish, a subtree, which starts with the rule S → S S. Perhaps the first child S is expanded by S → a. For the second child S, it is possible to re-enter the "S restaurant" and choose the first table, where the "dish" subtree is still being generated.

and concentration parameter a. The distribution G is discrete, which means it puts positive mass on a countable number of atoms drawn from G_0. Repeated draws from G exhibit the "clustering property," which means that they will be assigned to the same value with positive probability. Thus, they exhibit a partition structure. Marginalizing out G, the distribution of that partition structure is given by a CRP with parameter a (Pitman, 2002).

The stick-breaking process gives a constructive definition of G (Sethuraman, 1994). With the stick-breaking process (for the PY process), we first sample "stick lengths" $\boldsymbol{\pi} \sim \mathrm{GEM}(a, b)$ (in the case of Dirichlet process, we have $b = 0$). The GEM partitions the interval $[0, 1]$ into countably many segments. First, draw $v_i \sim \mathrm{Beta}(1 - b, a + ib)$ for $i \in \{1, \ldots\}$. Then, define $\pi_i \triangleq v_i \prod_{j=1}^{i-1}(1 - v_j)$. In addition, we also sample infinitely many "atoms" independently $z_i \sim G_0$. Define G as:

$$G(z) = \textstyle\sum_{i=1}^{\infty} \pi_i \delta(z_i, z) \qquad (1)$$

where $\delta(z_i, z)$ is 1 if $z_i = z$ and 0 otherwise. This random variable is drawn from a Pitman-Yor process. Notice the discreteness of G is laid bare in the stick-breaking construction.

With the stick-breaking representation in hand, we turn to a constructive definition of the distribution over trees given by an adaptor grammar. Let $A_1, \ldots, A_K$ be an enumeration of the nonterminals in $\mathcal{M}$ which satisfies: $i \leq j \Rightarrow A_j \notin \mathrm{Reachable}(\boldsymbol{G}, A_i)$. (That this exists follows from the assumption about the lack of recursiveness of adapted nonterminals.) Let $\mathrm{Yield}(z)$ be the yield of a tree derivation z. The process that generates observed sentences $\boldsymbol{x} = \langle x_1, \ldots, x_n \rangle$ from the adaptor grammar $\boldsymbol{A} = \langle \boldsymbol{G}, \mathcal{M}, \boldsymbol{a}, \boldsymbol{b}, \boldsymbol{\alpha} \rangle$ is as follows:

1. For each $A \in \mathcal{N}$, draw $\boldsymbol{\theta}_A \sim \mathrm{Dir}(\alpha_A)$.
2. For A from A_1 to A_K, define G_A as follows:
   (a) Draw $\boldsymbol{\pi}_A \mid a_A, b_A \sim \mathrm{GEM}(a_A, b_A)$.
   (b) For $i \in \{1, \ldots\}$, grow a tree $z_{A,i}$ as follows:
      i. Draw $A \rightarrow B_1 \ldots B_n$ from $\boldsymbol{R}_A$.
      ii. $z_{A,i} =$

      iii. While $\mathrm{Yield}(z_{A,i})$ has nonterminals:
         A. Choose an unexpanded nonterminal B from yield of $z_{A,i}$.
         B. If $B \in \mathcal{M}$, expand B according to G_B (defined on previous iterations of step 2).
         C. If $B \in \mathcal{N} \setminus \mathcal{M}$, expand B with a rule from $\boldsymbol{R}_B$ according to $\mathrm{Mult}(\boldsymbol{\theta}_B)$.
   (c) For $i \in \{1, \ldots\}$, define $G_A(z_{A,i}) = \pi_{A,i}$
3. For $i \in \{1, \ldots, n\}$ draw z_i as follows:
   (a) If $S \in \mathcal{M}$, draw $z_i \mid G_S \sim G_S$.
   (b) If $S \notin \mathcal{M}$, draw z_i as in 2(b) (omitted for space).
4. Set $x_i = \mathrm{Yield}(z_i)$ for $i \in \{1, \ldots, n\}$.

Here, there are four collections of hidden variables: the PCFG multinomials $\boldsymbol{\theta} = \{\boldsymbol{\theta}_A \mid A \in \mathcal{N}\}$, the stick length proportions $\boldsymbol{v} = \{\boldsymbol{v}_A \mid A \in \mathcal{M}\}$ where $\boldsymbol{v}_A = \langle v_{A,1}, v_{A,2}, \ldots \rangle$, the adapted nonterminals' subtrees $\boldsymbol{z}_A = \{z_{A,i} \mid A \in \mathcal{M}; i \in \{1, \ldots\}\}$ and the derivations $\boldsymbol{z}_{1:n} = z_1, \ldots, z_n$. The symbol $\boldsymbol{z}$ refers to the collection of $\{\boldsymbol{z}_A \mid A \in \mathcal{M}\}$, and $\boldsymbol{z}_{1:n}$ refers to the derivations of the data $\boldsymbol{x}$.

Note that the distribution in 2(c) is defined with the GEM distribution, as mentioned earlier. It is a sample from the Pitman-Yor process (or the Dirichlet process), which is later used in 3(a) to sample trees for an adapted non-terminal.

3 Variational Inference

Variational inference is a deterministic alternative to MCMC, which casts posterior inference as an optimization problem (Jordan et al., 1999; Wainwright and Jordan, 2008). The optimized function is a bound on the marginal likelihood of the observations, which is expressed in terms of a so-called "variational distribution" over the hidden variables. When the bound is tightened, that distribution is close to the posterior of interest. Variational methods tend to converge faster than MCMC, and can be more easily parallelized over multiple processors in a framework such as MapReduce (Dean and Ghemawat, 2004).

The variational bound on the likelihood of the data is:

$$\begin{aligned}\log p(\boldsymbol{x} \mid \boldsymbol{a}, \boldsymbol{\alpha}) \geq H(q) + \sum_{A \in \mathcal{M}} \mathbb{E}_q[\log p(\boldsymbol{v}_A \mid a_A)] \\ + \sum_{A \in \mathcal{M}} \mathbb{E}_q[\log p(\boldsymbol{\theta}_A \mid \boldsymbol{\alpha}_A)] \\ + \sum_{A \in \mathcal{M}} \mathbb{E}_q[\log p(\boldsymbol{z}_A \mid \boldsymbol{v}, \boldsymbol{\theta})] + \mathbb{E}_q[\log p(\boldsymbol{z} \mid \boldsymbol{v}_A)]\end{aligned}$$

Expectations are taken with respect to the variational distribution $q(\boldsymbol{v}, \boldsymbol{\theta}, \boldsymbol{z})$ and $H(q)$ is its entropy.

Before tightening the bound, we define the functional form of the variational distribution. We use the mean-field distribution in which all of the hidden variables are independent and governed by individual variational parameters. (Note that in the true posterior, the hidden variables are highly coupled.) To account for the infinite collection of random variables, for which we cannot define a variational distribution, we use the truncated stick distribution (Blei and Jordan, 2005). Hence, we assume that, for all $A \in \mathcal{M}$, there is some value N_A such that $q(v_{A,N_A} = 1) = 1$. The assigned probability to parse trees in the stick will be 0 for $i > N_A$, so we can ignore $z_{A,i}$ for $i > N_A$. This leads to a factorized variational distribution:

$$q(\boldsymbol{v}, \boldsymbol{\theta}, \boldsymbol{z}) = \prod_{A \in \mathcal{M}} \left(q(\boldsymbol{\theta}_A) \prod_{i=1}^{N_A} q(v_{A,i}) \times q(z_{A,i}) \right) \times \prod_{i=1}^{n} q(z_i) \tag{2}$$

It is natural to define the variational distributions over $\boldsymbol{\theta}$ and $\boldsymbol{v}$ to be Dirichlet distributions with parameters $\boldsymbol{\tau}_A$ and Beta distributions with parameters $\gamma_{A,i}$, respectively. The two distributions over trees, $q(z_{A,i})$ and $q(z_i)$, are more problematic. For example, with $q(z_i \mid \boldsymbol{\phi})$, we need to take into account different subtrees that could be generated by the model and use them with the proper probabilities in the variational distribution $q(z_i \mid \boldsymbol{\phi})$. We follow and extend the idea from Johnson et al. (2006) and use *grammatons* for these distributions. Grammatons are "mini-grammars," inspired by the grammar $\boldsymbol{G}$.

For two strings in $s, t \in \mathcal{W}^*$, we use "$t \subseteq s$" to mean that t is a substring of s. In that case, a grammaton is defined as follows:

Definition 1. *Let $\boldsymbol{A} = \langle \boldsymbol{G}, \mathcal{M}, \boldsymbol{a}, \boldsymbol{b}, \boldsymbol{\alpha} \rangle$ be an adaptor grammar with $\boldsymbol{G} = \langle \mathcal{W}, \mathcal{N}, \boldsymbol{R}, S \rangle$. Let s be a finite string over the alphabet of $\boldsymbol{G}$ and $A \in \mathcal{N}$. Let $\mathcal{U}$ be the set of nonterminals $\mathcal{U} \triangleq \mathrm{Reachable}(\boldsymbol{G}, A) \cap (\mathcal{N} \setminus \mathcal{M})$. The grammaton $\boldsymbol{G}(A, s)$ is the context-free grammar with the start symbol A and the rules*

$$R_A \cup \left(\bigcup_{B \in \mathcal{U}} R_B \right) \cup \bigcup_{A \to B_1 \dots B_n \in R_A} \; \bigcup_{i \in \{i | B_i \in \mathcal{M}\}} \{B_i \to t \mid t \subseteq s\}.$$

Using a grammaton, we define the distributions $q(z_{A,i} \mid \boldsymbol{\phi}_A)$ and $q(z_i \mid \boldsymbol{\phi})$. This requires a preprocessing step (described in detail in §3.3) that defines, for each $A \in \mathcal{M}$, a list of strings $\boldsymbol{s}_A = \langle s_{A,1}, \dots, s_{A,N_A} \rangle$. Then, for $q(z_{A,i} \mid \boldsymbol{\phi}_A)$ we use the grammaton $\boldsymbol{G}(A, s_{A,i})$ and for $q(z_i \mid \boldsymbol{\phi})$ we use the grammaton $\boldsymbol{G}(A, x_i)$ where x_i is the ith observed sentence. We parametrize the grammaton with weights $\boldsymbol{\phi}_A$ (or $\boldsymbol{\phi}$) for each rule in the grammaton. This makes the variational distributions over the trees for strings $\boldsymbol{s}$ (and trees for $\boldsymbol{x}$) globally normalized weighted grammars. Choosing such distributions is motivated by their ability to make the variational bound tight (similar to Cohen et al., 2008, and Cohen and Smith, 2009). In practice we do not have to use rewrite rules for all strings $t \subseteq s$ in the grammaton. It suffices to add rewrite rules only for the strings $t = s_{A,i}$ that have some grammaton attached to them, $\boldsymbol{G}(A, s_{A,i})$.

The variational distribution above yields a variational inference algorithm for approximating the posterior by estimating $\gamma_{A,i}$, $\boldsymbol{\tau}_A$, $\boldsymbol{\phi}_A$ and $\boldsymbol{\phi}$ iteratively, given a fixed set of hyperparameters $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{\alpha}$. Let r be a PCFG rule. Let $\tilde{f}(r, s_{B,k}) = \mathbb{E}_{q(z_k | \boldsymbol{\phi}_{B,k})}[f(r; z_k)]$, where $f(r; z_k)$ counts the number of times that rule r is applied in the derivation z_k. Let $A \to \beta$ denote a rule from $\boldsymbol{G}$. The quantity $\tilde{f}(r, s_{B,k})$ is computed using the inside-outside (IO) algorithm. Fig. 1 gives the variational inference updates.

Variational EM We use variational EM to fit the hyperparameters. Variational EM is an EM algorithm where the E step is replaced by variational inference (Fig. 1). The M-step optimizes the hyperparameters ($\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{\alpha}$) with respect to expected sufficient statistics under the variational distribution. We use Newton-Raphson for each (Boyd and Vandenberghe, 2004); Fig. 2 gives the objectives.

3.1 Note about Recursive Grammars

With recursive grammars, the stick-breaking process representation gives probability mass to events which are ill-defined. In step 2(iii)(c) of the stick-breaking representation, we assign nonzero probability to an event in which we choose to expand the current tree using a subtree with the same index that we are currently still expanding (see footnote 2). In short, with recursive grammars, we can get "loops" inside the trees.

We would still like to use recursion in the cases which are not ill-defined. In the case of recursive grammars, there is no problem with the stick-breaking representation and the order by which we enumerate the nonterminals. This is true because the stick-breaking process separates allocating the probabilities for each index in the stick and allocating the atoms for each index in the stick.

Our variational distributions give probability 0 to any event which is ill-defined in the sense mentioned above. Optimizing the variational bound in this case is equivalent to optimizing the same variational bound with a model p' that (i) starts with p, (ii) assigns probability 0 to ill-defined events, and (iii) renormalizes:

Proposition 2. *Let $p(\boldsymbol{x}, \boldsymbol{z})$ be a probability distribution, where $z \in \mathcal{Z}$, and let $\mathcal{S} \subset \mathcal{Z}$. Let $Q = \{q \mid q(z) = 0, \forall z \in \mathcal{S}\}$, a set of distributions. Then:*

$$\underset{q \in Q}{\operatorname{argmax}} \, \mathbb{E}_q[\log p(\boldsymbol{x}, \boldsymbol{z})] \quad = \quad \underset{q}{\operatorname{argmax}} \, \mathbb{E}_q[\log p'(\boldsymbol{x}, \boldsymbol{z})]$$

where $p'(\boldsymbol{x}, \boldsymbol{z})$ is a probability distribution defined as $p'(\boldsymbol{x}, \boldsymbol{z}) = p(\boldsymbol{x}, \boldsymbol{z}) / \sum_{\boldsymbol{z} \in \mathcal{S}} p(\boldsymbol{x}, \boldsymbol{z})$ for $\boldsymbol{z} \in \mathcal{S}$ and 0 otherwise.

For this reason, our variational approximation allows the use of recursive grammars. The use of recursive grammars with MCMC methods is problematic, since it has no corresponding probabilistic interpretation, enabled by zeroing events that are ill-defined in the variational distribution. There is no underlying model such as p', and thus the inference algorithm is invalid.

3.2 Time Complexity

The algorithm in Johnson et al. (2006) works by sampling from a PCFG containing rewrite rules that rewrite to a whole tree fragment. This requires a procedure that uses the inside-outside algorithm. Despite the grammar being bigger (because of the rewrite rules to a string), the asymptotic complexity of the IO algorithm stays $O(|\mathcal{N}|^2|x_i|^3 + |\mathcal{N}|^3|x_i|^2)$ where $|x_i|$ is the length of the ith sentence.[3]

$$\begin{aligned}
\gamma^1_{A,i} &= 1 - b_A + \textstyle\sum_{B \in \mathcal{M}} \sum_{k=1}^{N_B} \tilde{f}(A \to s_{A,i}, s_{B,k}) \\
\gamma^2_{A,i} &= a_A + i b_A \\
&\quad + \textstyle\sum_{j=1}^{i-1} \sum_{B \in \mathcal{M}} \sum_{k=1}^{N_B} \tilde{f}(A \to s_{A,j}, s_{B,k}) \\
\tau_{A,A \to \beta} &= \textstyle\sum_{B \in \mathcal{M}} \sum_{k=1}^{N_B} \tilde{f}(A \to \beta, s_{B,k}) \\
\phi_{A,A \to s_{A,i}} &= \Psi(\gamma^1_{A,i}) - \Psi(\gamma^1_{A,i} + \gamma^2_{A,i}) \\
&\quad + \textstyle\sum_{j=1}^{i-1} \left(\Psi(\gamma^2_{A,i}) - \Psi(\gamma^1_{A,i} + \gamma^2_{A,i}) \right) \\
\phi_{A,A \to \beta} &= \Psi(\tau_{A,A \to \beta}) - \Psi\left(\textstyle\sum_{\beta} \tau_{A,A \to \beta} \right)
\end{aligned}$$

Figure 1: Updates for variational inference with adaptor grammars. Ψ is the digamma function.

Our algorithm requires running the IO algorithm for each yield in the variational distribution, for each nonterminal, and for each sentence. However, IO runs with much smaller grammars coming from the grammatons. The cost of running the IO algorithm on the yields in the sticks for $A \in \mathcal{M}$ can be taken into account parsing a string that appears in the corpus with the full grammars. This leads to an asymptotic complexity of $O(|\mathcal{N}|^2|x_i|^3 + |\mathcal{N}|^3|x_i|^2)$ for the ith sentence in the corpus each iteration.

Asymptotically, both sampling and variational EM behave the same. However, there are different constants that hide in these asymptotic runtimes: the number of iterations that the algorithm takes to converge (for which variational EM generally has an advantage over sampling) and the number of additional rewrite rules that rewrite to a string representing a tree (for which MCMC has a relative advantage, because it does not use a fixed set of strings; instead, the size of the grammars it uses grow as sampling proceeds). In §4, we see that variational EM and sampling methods are similar in the time it takes to complete because of a trade-off between these two constants. Simple parallelization, however, which is possible only with variational inference, provides significant speed-ups.[4]

3.3 Heuristics for Variational Inference

For the variational approximation from §3, we need to decide on a set of strings, $s_{A,i}$ (for $A \in \mathcal{M}$ and $i \in \{1, \ldots, N_A\}$) to define the grammatons in the

[3] This analysis is true for CNF grammars augmented with rules rewriting to a whole string, like those used in our study.

[4] Newman et al. (2009) show how to parallelize sampling algorithms, but in general, parallelizing these algorithms is more complicated than parallelizing variational algorithms and requires further approximation.

$$\begin{array}{ll} \max_{\alpha_A} & \log \Gamma(|R_A|\alpha_A) - |R_A| \log \Gamma(\alpha_A) + (\alpha_A - 1) \left(\sum_{A \to \beta \in R_A} \Psi(\tau_{A \to \beta}) - \Psi \left(\sum_{A \to \beta \in R_A} \tau_{A \to \beta} \right) \right) \\ \max_{a_A} & \sum_{i=1}^{N_A} a_A \left(\Psi(\gamma^2_{A,i}) - \Psi(\gamma^1_{A,i} + \gamma^2_{A,i}) \right) + \log \Gamma(a_A + 1 + ib_A) - \log \Gamma(ib_A + a_A) \\ \max_{b_A} & \sum_{i=1}^{N_A} ib_A \left(\Psi(\gamma^2_{A,i}) - \Psi(\gamma^1_{A,i} + \gamma^2_{A,i}) \right) + \log \Gamma(a_A + 1 + ib_A) - \log \Gamma(1 - b_A) - \log \Gamma(ib_A + a_A) \end{array}$$

Figure 2: Variational M-step updates. Γ is the gamma function.

nonparametric stick. Any set of strings will give a valid approximation, but to make the variational approximation as accurate as possible, we require that: (i) the strings in the set must be likely to be generated using the adaptor grammar as constituents headed by the relevant nonterminal, and (ii) strings that are more likely to be generated should be associated with a lower index in the stick. The reason for the second requirement is the exponential decay of coefficients as the index increases.

We show that a simple heuristic leads to an order over the strings generated by the adaptor grammars that yields an accurate variational estimation. We begin with a weighted context-free grammar $\boldsymbol{G}_{\text{heur}}$ that has the same rules as in $\boldsymbol{G}$, only the weight for all of its rules is 1. We then compute the quantity:

$$c(A, s) = \frac{1}{n} \left(\sum_{i=1}^{n} \mathbb{E}_{\boldsymbol{G}_{\text{heur}}} [f_i(z; A, s)] \right) - \rho \log |s| \quad (3)$$

where $f_i(z; A, s)$ is a function computing the count of constituents headed by A with yield s in the tree z for the sentence x_i. This quantity can be computed by using the IO algorithm on $\boldsymbol{G}_{\text{heur}}$. The term $\rho \log |s|$ is subtracted to avoid preference for shorter constituents, similar to Mochihashi et al. (2009).

While computing $c(A, s)$ using the IO algorithm, we sort the set of all substrings of s according to their expected counts (aggregated over all strings s). Then, we use the top N_A strings in the sorted list for the grammatons of A.[5]

3.4 Decoding

The variational inference algorithm gives a distributions over parameters and hidden structures (through the grammatons). We experiment with two commonly used decoding methods: Viterbi decoding and minimum Bayes risk decoding (MBR; Goodman, 1996).

To parse a string with Viterbi (or MBR) decoding, we find the tree with highest score for the grammaton which is attached to that string. For all rules which rewrite to strings in the resulting tree, we again perform Viterbi (or MBR) decoding recursively using other grammatons.

4 Experiments

We describe experiments with variational inference for adaptor grammars for word segmentation and dependency grammar induction.

4.1 Word Segmentation

We follow the experimental setting of Johnson and Goldwater (2009), who present state-of-the-art results for inference with adaptor grammars using Gibbs sampling on a segmentation problem. We use the standard Brent corpus (Brent and Cartwright, 1996), which includes 9,790 unsegmented phonemic representations of utterances of child-directed speech from the Bernstein-Ratner (1987) corpus.

Johnson and Goldwater (2009) test three grammars for this segmentation task. The first grammar is a character unigram grammar ($\boldsymbol{G}_{\text{Unigram}}$). The second grammar is a grammar that takes into consideration collocations ($\boldsymbol{G}_{\text{Colloc}}$) which includes the rules $\{$ Sentence $\rightarrow$ $\underline{\text{Colloc}}$, Sentence $\rightarrow$ $\underline{\text{Colloc}}$ Sentence, $\underline{\text{Colloc}}$ $\rightarrow$ $\underline{\text{Word}}^{+}$, $\underline{\text{Word}}$ $\rightarrow$ Char^{+} $\}$. The third grammar incorporates more prior knowledge about the syllabic structure of English ($\boldsymbol{G}_{\text{Syllable}}$). $\boldsymbol{G}_{\text{Unigram}}$ and $\boldsymbol{G}_{\text{Syllable}}$ can be found in Johnson and Goldwater (2009). Once an utterance is parsed, Word constituents denote segments.

The value of ρ (penalty term for string length) had little effect on our results and was fixed at $\rho = -0.2$. When N_A (number of strings used in the variational distributions) is fixed, we use N_A = 15,000. We report results using Viterbi and MBR decoding. Johnson and Goldwater (2009) experimented with two

[5] The requirement to select N_A in advance is strict. We experimented with dynamic expansions of the stick, in the spirit of Kurihara et al. (2006) and Wang and Blei (2009), but we did not achieve better performance and it had an adverse effect on runtime. For completeness, we give these results in §4.

		this paper		J&G 2009

Table 1: F_1 performance for word segmentation on the Brent corpus. Dir. stands for Dirichlet Process adaptor ($\boldsymbol{b} = 0$), PY stands for Pitman-Yor adaptor ($\boldsymbol{b}$ optimized), and PY+inc. stands for Pitman-Yor with iteratively increasing N_A for $A \in \mathcal{M}$ (see footnote 5). J&G 2009 are the results adapted from Johnson and Goldwater (2009); SA is sample average decoding, and MM is maximum marginal decoding.

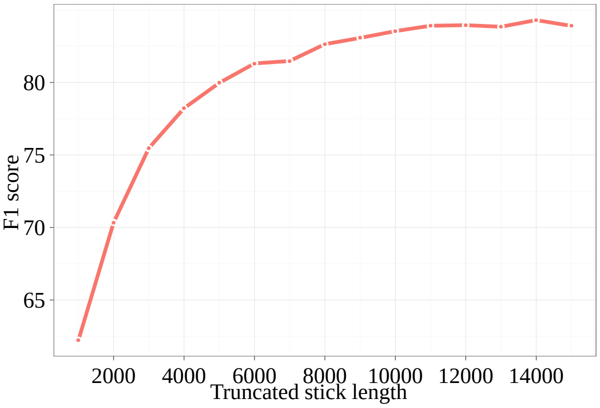

Figure 3: F_1 performance of $\boldsymbol{G}_{\text{Unigram}}$ as influenced by the length of the stick, N_{Word}.

decoding methods, sample average (SA) and maximal marginal decoding (MM), which are closely related to Viterbi and MBR, respectively. With MM, we marginalize the tree structure, rather than the word segmentation induced, similar to MBR decoding. With SA, we compute the probability of a whole tree, by averaging its count in the samples, an approximation to finding the tree with highest probability, like Viterbi.

Table 1 gives the results for our experiments. Notice that the results for the Pitman-Yor process and the Dirichlet process are similar. When inspecting the learned parameters, we noticed that the discount parameters ($\boldsymbol{b}$) learned by the variational inference algorithm for the Pitman-Yor process are very close to 0. In this case, the Pitman-Yor process is reduced to the Dirichlet process.

Similar to Johnson and Goldwater's comparisons, we see superior performance when using minimum Bayes risk over Viterbi decoding. Further notice that the variational inference algorithm obtains significantly superior performance for simpler grammars than Johnson et al., while performance using the syllable grammar is lower. The results also suggest that it is better to decide ahead on the set of strings available in the sticks, instead of working gradually and increase the size of the sticks as described in footnote 5. We believe that the reason is that the variational inference algorithm settles in a trajectory that uses fewer strings, then fails to exploit the strings that are added to the stick later. Given that selecting N_A in advance is advantageous, we may inquire if choosing N_A to be too large can lead to degraded performance, because of fragmention of the grammar. Fig. 3 suggests it is not the case, and performance stays steady after N_A reaches a certain value.

One of the advantages of variational approximation over sampling methods is the ability to run for fewer iterations. For example, with $\boldsymbol{G}_{\text{Unigram}}$ convergence typically takes 40 iterations with variational inference, while Johnson and Goldwater (2009) ran their sampler for 2,000 iterations, for which 1,000 were for burning in. The inside-outside algorithm dominates the iteration's runtime, both for sampling and variational EM. Each iteration with sampling, however, takes less time, despite the asymptotic analysis in §3.2, because of different implementations and the different number of rules that rewrite to a string. We now give a comparison of clock time for $\boldsymbol{G}_{\text{Unigram}}$ for variational inference and sampling as described in Johnson and Goldwater (2009).[6] Replicating the experiment in Johnson and Goldwater (first row in Table 1) took 2 hours and 11 minutes. With the variational approximation, we had the following: (i) the preprocessing (§3.3) step took 114 seconds; (ii) each iteration took approximately 204 seconds, with convergence after 40 iterations, leading to 8,160 seconds of pure varia-

[6] We used the code and data available at `http://www.cog.brown.edu/~mj/Software.htm`. The machine used for this comparison is a 64-bit machine with 2.6GHz CPU, 4MB of cache memory and 8GB of RAM.

tional EM processing; (iii) parsing took another 952 seconds. The total time is 2 hours and 34 minutes.

At first glance it seems that variational inference is slower than MCMC sampling. However, note that the cost of the grammar preprocessing step is amortized over all experiments with the specific grammar, and the E-step with variational inference can be parallelized, while sampling requires an update of a global set of parameters after each tree update. We ran our algorithm on a cluster of 20 1.86GHz CPUs and achieved a significant speed-up: preprocessing took 34 seconds, each variational EM iteration took 43 seconds and parsing took 208 seconds. The total time was 47 minutes, which is 2.8 times faster than sampling.

4.2 Dependency Grammar Induction

We conclude our experiments with preliminary results for unsupervised syntax learning. This is a new application of adaptor grammars, which have so far been used in segmentation (Johnson and Goldwater, 2009) and named entity recognition (Elsner et al., 2009).

The grammar we use is the dependency model with valence (DMV Klein and Manning, 2004) represented as a probabilistic context-free grammar, $\boldsymbol{G}_{\text{DMV}}$ (Smith, 2006). We note that $\boldsymbol{G}_{\text{DMV}}$ is recursive; this is not a problem (§3.1).

We used part-of-speech sequences from the *Wall Street Journal* Penn Treebank (Marcus et al., 1993), stripped of words and punctuation. We follow standard parsing conventions and train on sections 2–21 and test on section 23 (while using sentences of length 10 or less). Because of the unsupervised nature of the problem, we report results on the training set, in addition to the test set.

The nonterminals that we adapted correspond to nonterminals that define noun constituents. We then use the preprocessing step defined in §3.3 with a uniform grammar and take the top 3,000 strings for each nonterminal of a noun constituent.

The results are in Table 4.2. We report attachment accuracy, the fraction of parent-child relationships that the algorithm classified correctly. Notice that the results are not very different for Viterbi and MBR decoding, unlike the case with word segmentation. It seems like the DMV grammar, applied to this task, is more robust to changes in decoding mechanism. Adaptor grammars improve performance over classic EM and variational EM with a Dirichlet prior significantly.

	model	Vit.	MBR
train	non-Bayesian	48.2	48.3
	Dirichlet prior	48.3	48.6
	Adaptor grammar	**54.0**	†53.7
test	non-Bayesian	45.8	46.1
	Dirichlet prior	45.9	46.1
	Adaptor grammar	48.3	**50.2**

Table 2: Attachment accuracy for different models for dependency grammar induction. Bold marks best overall accuracy per evaluation set, and † marks figures that are not significantly worse (binomial sign test, $p < 0.05$).

We note that adaptor grammars are not limited to a selection of a Dirichlet distribution as a prior for the grammar rules. Our variational inference algorithm, for example, can be extended to use the logistic normal prior instead of the Dirichlet, shown successful by Cohen and Smith (2009).[7]

5 Conclusion

We described a variational inference algorithm for adaptor grammars based on a stick-breaking process representation, which solves a problem with adaptor grammars and recursive PCFGs. We tested it for a segmentation task, and showed results which are either comparable or an imporvement of state of the art. We showed that significant speed-ups can be obtained using parallelization of the algorithm. We also tested the algorithm on a novel task for adaptor grammars, dependency grammar induction. We showed that an improvement can be obtained using adaptor grammars over non-Bayesian and parametric baselines.

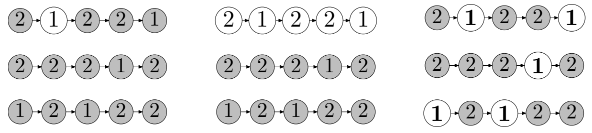
Abstract

Most existing algorithms for learning latent-variable models—such as EM and existing Gibbs samplers—are *token-based*, meaning that they update the variables associated with one sentence at a time. The incremental nature of these methods makes them susceptible to local optima/slow mixing. In this paper, we introduce a *type-based sampler*, which updates a block of variables, identified by a *type*, which spans multiple sentences. We show improvements on part-of-speech induction, word segmentation, and learning tree-substitution grammars.

1 Introduction

A long-standing challenge in NLP is the unsupervised induction of linguistic structures, for example, grammars from raw sentences or lexicons from phoneme sequences. A fundamental property of these unsupervised learning problems is multimodality. In grammar induction, for example, we could analyze subject-verb-object sequences as either *((subject verb) object)* (mode 1) or *(subject (verb object))* (mode 2).

Multimodality causes problems for token-based procedures that update variables for one example at a time. In EM, for example, if the parameters already assign high probability to the *((subject verb) object)* analysis, re-analyzing the sentences in E-step only reinforces the analysis, resulting in EM getting stuck in a local optimum. In (collapsed) Gibbs sampling, if all sentences are already analyzed as *((subject verb) object)*, sampling a sentence *conditioned* on all others will most likely not change its analysis, resulting in slow mixing.



(a) token-based (b) sentence-based (c) type-based

Figure 1: Consider a dataset of 3 sentences, each of length 5. Each variable is labeled with a *type* (1 or 2). The unshaded variables are the ones that are updated jointly by a sampler. The token-based sampler updates the variable for one token at a time (a). The sentence-based sampler updates all variables in a sentence, thus dealing with intra-sentential dependencies (b). The type-based sampler updates all variables of a particular type (1 in this example), thus dealing with dependencies due to common parameters (c).

To combat the problems associated with token-based algorithms, we propose a new sampling algorithm that operates on *types*. Our sampler would, for example, be able to change all occurrences of *((subject verb) object)* to *(subject (verb object))* in one step. These type-based operations are reminiscent of the type-based grammar operations of early chunk-merge systems (Wolff, 1988; Stolcke and Omohundro, 1994), but we work within a sampling framework for increased robustness.

In NLP, perhaps the the most simple and popular sampler is the *token-based Gibbs sampler*,[1] used in Goldwater et al. (2006), Goldwater and Griffiths (2007), and many others. By sampling only one

[1] In NLP, this is sometimes referred to as simply the collapsed Gibbs sampler.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 573–581,
Los Angeles, California, June 2010.

variable at a time, this sampler is prone to slow mixing due to the strong coupling between variables. A general remedy is to sample blocks of coupled variables. For example, the *sentence-based sampler* samples all the variables associated with a sentence at once (e.g., the entire tag sequence). However, this blocking does not deal with the strong type-based coupling (e.g., all instances of a word should be tagged similarly). The type-based sampler we will present is designed exactly to tackle this coupling, which we argue is stronger and more important to deal with in unsupervised learning. Figure 1 depicts the updates made by each of the three samplers.

We tested our sampler on three models: a Bayesian HMM for part-of-speech induction (Goldwater and Griffiths, 2007), a nonparametric Bayesian model for word segmentation (Goldwater et al., 2006), and a nonparametric Bayesian model of tree substitution grammars (Cohn et al., 2009; Post and Gildea, 2009). Empirically, we find that type-based sampling improves performance and is less sensitive to initialization (Section 5).

2 Basic Idea via a Motivating Example

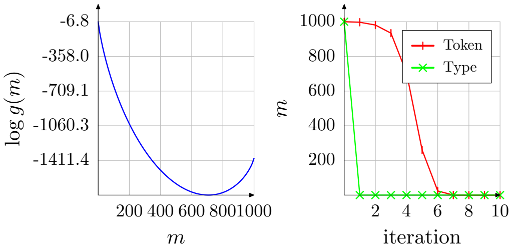
The key technical problem we solve in this paper is finding a block of variables which are both *highly coupled* and yet *tractable to sample jointly*. This section illustrates the main idea behind type-based sampling on a small word segmentation example.

Suppose our dataset $\mathbf{x}$ consists of n occurrences of the sequence *a b*. Our goal is infer $\mathbf{z} = (z_1, \dots, z_n)$, where $z_i = 0$ if the sequence is one word *ab*, and $z_i = 1$ if the sequence is two, *a* and *b*. We can model this situation with a simple generative model: for each $i = 1, \dots, n$, generate one or two words with equal probability. Each word is drawn independently based on probabilities $\theta = (\theta_a, \theta_b, \theta_{ab})$ which we endow with a uniform prior $\theta \sim \text{Dirichlet}(1, 1, 1)$.

We marginalize out θ to get the following standard expression (Goldwater et al., 2009):

$$p(\mathbf{z} \mid \mathbf{x}) \propto \frac{1^{(m)} 1^{(m)} 1^{(n-m)}}{3^{(n+m)}} \stackrel{\text{def}}{=} g(m), \qquad (1)$$

where $m = \sum_{i=1}^{n} z_i$ is the number of two-word sequences and $a^{(k)} = a(a+1) \cdots (a+k-1)$ is the *ascending factorial*.[2] Figure 2(a) depicts the resulting bimodal posterior.



(a) bimodal posterior (b) sampling run

Figure 2: (a) The posterior (1) is sharply bimodal (note the log-scale). (b) A run of the token-based and type-based samplers. We initialize both samplers with $m = n$ ($n = 1000$). The type-based sampler mixes instantly (in fact, it makes independent draws from the posterior) whereas the token-based sampler requires five passes through the data before finding the high probability region $m \approxeq 0$.

A token-based sampler chooses one z_i to update according to the posterior $p(z_i \mid \mathbf{z}_{-i}, \mathbf{x})$. To illustrate the mixing problem, consider the case where $m = n$, i.e., all sequences are analyzed as two words. From (1), we can verify that $p(z_i = 0 \mid \mathbf{z}_{-i}, \mathbf{x}) = O(\frac{1}{n})$. When $n = 1000$, this means that there is only a 0.002 probability of setting $z_i = 0$, a very unlikely but necessary first step to take to escape this local optimum. Indeed, Figure 2(b) shows how the token-based sampler requires five passes over the data to finally escape.

Type-based sampling completely eradicates the local optimum problem in this example. Let us take a closer look at (1). Note that $p(\mathbf{z} \mid \mathbf{x})$ only depends on a single integer m, which only takes one of $n+1$ values, not on the particular $\mathbf{z}$. This shows that the z_is are *exchangeable*. There are $\binom{n}{m}$ possible values of $\mathbf{z}$ satisfying $m = \sum_i z_i$, each with *the same* probability $g(m)$. Summing, we get:

$$p(m \mid \mathbf{x}) \propto \sum_{\mathbf{z}: m = \sum_i z_i} p(\mathbf{x}, \mathbf{z}) = \binom{n}{m} g(m). \qquad (2)$$

A sampling strategy falls out naturally: First, sample the number m via (2). Conditioned on m, choose

[2] The ascending factorial function arises from marginalizing Dirichlet distributions and is responsible the rich-gets-richer phenomenon: the larger n is, more we gain by increasing it.

the particular $\mathbf{z}$ uniformly out of the $\binom{n}{m}$ possibilities. Figure 2(b) shows the effectiveness of this type-based sampler.

This simple example exposes the fundamental challenge of multimodality in unsupervised learning. Both $m = 0$ and $m = n$ are modes due to the rich-gets-richer property which arises by virtue of all n examples sharing the same parameters $\boldsymbol{\theta}$. This sharing is a double-edged sword: It provides us with clustering structure but also makes inference hard. Even though $m = n$ is much worse (by a factor exponential in n) than $m = 0$, a naïve algorithm can easily have trouble escaping $m = n$.

3 Setup

We will now present the type-based sampler in full generality. Our sampler is applicable to any model which is built out of local multinomial choices, where each multinomial has a Dirichlet process prior (a Dirichlet prior if the number of choices is finite). This includes most probabilistic models in NLP (excluding ones built from log-linear features).

As we develop the sampler, we will provide concrete examples for the Bayesian hidden Markov model (HMM), the Dirichlet process unigram segmentation model (USM) (Goldwater et al., 2006), and the probabilistic tree-substitution grammar (PTSG) (Cohn et al., 2009; Post and Gildea, 2009).

3.1 Model parameters

A model is specified by a collection of multinomial parameters $\boldsymbol{\theta} = \{\theta_r\}_{r \in \mathcal{R}}$, where $\mathcal{R}$ is an index set. Each vector θ_r specifies a distribution over outcomes: outcome o has probability θ_{ro}.

- HMM: Let K is the number of states. The set $\mathcal{R} = \{(q, k) : q \in \{\mathrm{T}, \mathrm{E}\}, k = 1, \dots, K\}$ indexes the K transition distributions $\{\theta_{(\mathrm{T},k)}\}$ (each over outcomes $\{1, \dots, K\}$) and K emission distributions $\{\theta_{(\mathrm{E},k)}\}$ (each over the set of words).
- USM: $\mathcal{R} = \{0\}$, and θ_0 is a distribution over (an infinite number of) words.
- PTSG: $\mathcal{R}$ is the set of grammar symbols, and each θ_r is a distribution over labeled tree fragments with root label r.

$\mathcal{R}$	index set for parameters
$\boldsymbol{\theta} = \{\theta_r\}_{r \in \mathcal{R}}$	multinomial parameters
$\boldsymbol{\mu} = \{\mu_r\}_{r \in \mathcal{R}}$	base distributions (fixed)
$\mathcal{S}$	set of sites
$\mathbf{b} = \{b_s\}_{s \in \mathcal{S}}$	binary variables (to be sampled)
$\mathbf{z}$	latent structure (set of choices)
$\mathbf{z}^{-s}$	choices not depending on site s
$\mathbf{z}^{s:b}$	choices after setting $b_s = b$
$\Delta\mathbf{z}^{s:b}$	$\mathbf{z}^{s:b} \backslash \mathbf{z}^{-s}$: new choices from $b_s = b$
$S \subset \mathcal{S}$	sites selected for sampling
m	# sites in S assigned $b_s = 1$
$\mathbf{n} = \{n_{ro}\}$	counts (sufficient statistics of $\mathbf{z}$)

Table 1: Notation used in this paper. Note that there is a one-to-one mapping between $\mathbf{z}$ and $(\mathbf{b}, \mathbf{x})$. The information relevant for evaluating the likelihood is $\mathbf{n}$. We use the following parallel notation: $\mathbf{n}^{-s} = \mathbf{n}(\mathbf{z}^{-s}), \mathbf{n}^{s:b} = \mathbf{n}(\mathbf{z}^{s:b}), \Delta\mathbf{n}^s = \mathbf{n}(\Delta\mathbf{z}^s)$.

3.2 Choice representation of latent structure z

We represent the latent structure $\mathbf{z}$ as a set of local *choices*:[3]

- HMM: $\mathbf{z}$ contains elements of the form (T, i, a, b), denoting a transition from state a at position i to state b at position $i + 1$; and (E, i, a, w), denoting an emission of word w from state a at position i.
- USM: $\mathbf{z}$ contains elements of the form (i, w), denoting the generation of word w at character position i extending to position $i + |w| - 1$.
- PTSG: $\mathbf{z}$ contains elements of the form (x, t), denoting the generation of tree fragment t rooted at node x.

The choices $\mathbf{z}$ are connected to the parameters $\boldsymbol{\theta}$ as follows: $p(\mathbf{z} \mid \boldsymbol{\theta}) = \prod_{z \in \mathbf{z}} \theta_{z.r, z.o}$. Each choice $z \in \mathbf{z}$ is identified with some $z.r \in \mathcal{R}$ and outcome $z.o$. Intuitively, choice z was made by drawing drawing $z.o$ from the multinomial distribution $\theta_{z.r}$.

3.3 Prior

We place a Dirichlet process prior on θ_r (Dirichlet prior for finite outcome spaces): $\theta_r \sim \mathrm{DP}(\alpha_r, \mu_r)$, where α_r is a concentration parameter and μ_r is a fixed base distribution.

[3] We assume that $\mathbf{z}$ contains both a latent part and the observed input $\mathbf{x}$, i.e., $\mathbf{x}$ is a deterministic function of $\mathbf{z}$.

Let $n_{ro}(\mathbf{z}) = |\{z \in \mathbf{z} : z.r = r, z.o = o\}|$ be the number of draws from θ_r resulting in outcome o, and $n_{r\cdot} = \sum_o n_{ro}$ be the number of times θ_r was drawn from. Let $\mathbf{n}(\mathbf{z}) = \{n_{ro}(\mathbf{z})\}$ denote the vector of sufficient statistics associated with choices $\mathbf{z}$. When it is clear from context, we simply write $\mathbf{n}$ for $\mathbf{n}(\mathbf{z})$. Using these sufficient statistics, we can write $p(\mathbf{z} \mid \boldsymbol{\theta}) = \prod_{r,o} \theta_{ro}^{n_{ro}(\mathbf{z})}$.

We now marginalize out $\boldsymbol{\theta}$ using Dirichlet-multinomial conjugacy, producing the following expression for the likelihood:

$$p(\mathbf{z}) = \prod_{r \in \mathcal{R}} \frac{\prod_o (\alpha_{ro}\mu_{ro})^{(n_{ro}(\mathbf{z}))}}{\alpha_r{}^{(n_{r\cdot}(\mathbf{z}))}}, \tag{3}$$

where $a^{(k)} = a(a+1)\cdots(a+k-1)$ is the ascending factorial. (3) is the distribution that we will use for sampling.

4 Type-Based Sampling

Having described the setup of the model, we now turn to posterior inference of $p(\mathbf{z} \mid \mathbf{x})$.

4.1 Binary Representation

We first define a new representation of the latent structure based on binary variables $\mathbf{b}$ so that there is a bijection between $\mathbf{z}$ and $(\mathbf{b}, \mathbf{x})$; $\mathbf{z}$ was used to define the model, $\mathbf{b}$ will be used for inference. We will use $\mathbf{b}$ to exploit the ideas from Section 2. Specifically, let $\mathbf{b} = \{b_s\}_{s \in \mathcal{S}}$ be a collection of binary variables indexed by a set of *sites* $\mathcal{S}$.

- HMM: If the HMM has $K = 2$ states, $\mathcal{S}$ is the set of positions in the sequence. For each $s \in \mathcal{S}$, b_s is the hidden state at s. The extension to general K is considered at the end of Section 4.4.
- USM: $\mathcal{S}$ is the set of non-final positions in the sequence. For each $s \in \mathcal{S}$, b_s denotes whether a word boundary exists between positions s and $s+1$.
- PTSG: $\mathcal{S}$ is the set of internal nodes in the parse tree. For $s \in \mathcal{S}$, b_s denotes whether a tree fragment is rooted at node s.

For each site $s \in \mathcal{S}$, let $\mathbf{z}^{s:0}$ and $\mathbf{z}^{s:1}$ denote the choices associated with the structures obtained by setting the binary variable $b_s = 0$ and $b_s = 1$, respectively. Define $\mathbf{z}^{-s} \stackrel{\text{def}}{=} \mathbf{z}^{s:0} \cap \mathbf{z}^{s:1}$ to be the set of choices that do not *depend* on the value of b_s, and $\mathbf{n}^{-s} \stackrel{\text{def}}{=} \mathbf{n}(\mathbf{z}^{-s})$ be the corresponding counts.

- HMM: $\mathbf{z}^{-s}$ includes all *but* the transitions into and out of the state at s plus the emission at s.
- USM: $\mathbf{z}^{-s}$ includes all except the word ending at s and the one starting at $s+1$ if there is a boundary ($b_s = 1$); except the word covering s if no boundary exists ($b_s = 0$).
- PTSG: $\mathbf{z}^{-s}$ includes all except the tree fragment rooted at node s and the one with leaf s if $b_s = 1$; except the single fragment containing s if $b_s = 0$.

4.2 Sampling One Site

A token-based sampler considers one site s at a time. Specifically, we evaluate the likelihoods of $\mathbf{z}^{s:0}$ and $\mathbf{z}^{s:1}$ according to (3) and sample b_s with probability proportional to the likelihoods. Intuitively, this can be accomplished by removing choices that depend on b_s (resulting in $\mathbf{z}^{-s}$), evaluating the likelihood resulting from setting b_s to 0 or 1, and then adding the appropriate choices back in.

More formally, let $\Delta\mathbf{z}^{s:b} \stackrel{\text{def}}{=} \mathbf{z}^{s:b} \backslash \mathbf{z}^{-s}$ be the new choices that would be added if we set $b_s = b \in \{0, 1\}$, and let $\Delta\mathbf{n}^{s:b} \stackrel{\text{def}}{=} \mathbf{n}(\Delta\mathbf{z}^{s:b})$ be the corresponding counts. With this notation, we can write the posterior as follows:

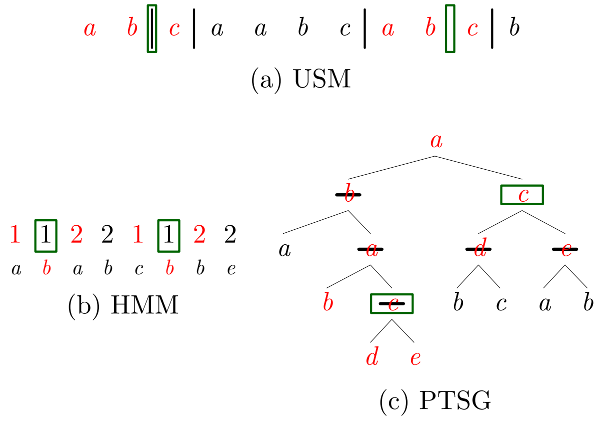
$$p(b_s = b \mid \mathbf{b} \backslash \mathbf{b}_s) \propto \tag{4}$$
$$\prod_{r \in \mathcal{R}} \frac{\prod_o (\alpha_{ro}\mu_{ro} + n_{ro}^{-s})^{(\Delta n_{ro}^{s:b})}}{(\alpha_r + n_{r\cdot}^{-s})^{(\Delta n_{r\cdot}^{s:b})}}.$$

The form of the conditional (4) follows from the joint (3) via two properties: additivity of counts ($\mathbf{n}^{s:b} = \mathbf{n}^{-s} + \Delta\mathbf{n}^{s:b}$) and a simple property of ascending factorials ($a^{(k+\delta)} = a^{(k)}(a+k)^{(\delta)}$).

In practice, most of the entries of $\Delta\mathbf{n}^{s:b}$ are zero. For the HMM, $n_{ro}^{s:b}$ would be nonzero only for the transitions into the new state (b) at position s ($z_{s-1} \to b$), transitions out of that state ($b \to z_{s+1}$), and emissions from that state ($b \to x_s$).

4.3 Sampling Multiple Sites

We would like to sample multiple sites jointly as in Section 2, but we cannot choose any arbitrary subset $S \subset \mathcal{S}$, as the likelihood will in general depend on the exact assignment of $\mathbf{b}_S \stackrel{\text{def}}{=} \{b_s\}_{s \in S}$, of which



(a) USM

(b) HMM

(c) PTSG

Figure 3: The type-based sampler jointly samples all variables at a set of sites S (in green boxes). Sites in S are chosen based on types (denoted in red). (a) HMM: two sites have the same type if they have the same previous and next states and emit the same word; they conflict unless separated by at least one position. (b) USM: two sites have the same type if they are both of the form $ab|c$ or abc; note that occurrences of the same letters with other segmentations do not match the type. (c) PTSG: analogous to the USM, only for tree rather than sequences.

there are an exponential number. To exploit the exchangeability property in Section 2, we need to find sites which look "the same" from the model's point of view, that is, the likelihood only depends on $\mathbf{b}_S$ via $m \overset{\text{def}}{=} \sum_{s \in S} b_s$.

To do this, we need to define two notions, *type* and *conflict*. We say sites s and s' have the same *type* if the counts added by setting either b_s or $b_{s'}$ are the same, that is, $\Delta\mathbf{n}^{s:b} = \Delta\mathbf{n}^{s':b}$ for $b \in \{0, 1\}$. This motivates the following definition of the *type* of site s with respect to $\mathbf{z}$:

$$t(\mathbf{z}, s) \overset{\text{def}}{=} (\Delta\mathbf{n}^{s:0}, \Delta\mathbf{n}^{s:1}), \tag{5}$$

We say that s and s' have the same type if $t(\mathbf{z}, s) = t(\mathbf{z}, s')$. Note that the actual choices added ($\Delta\mathbf{z}^{s:b}$ and $\Delta\mathbf{z}^{s':b}$) are in general different as s and s' correspond to different parts of the latent structure, but the model only depends on counts and is indifferent to this. Figure 3 shows examples of same-type sites for our three models.

However, even if all sites in S have the same type, we still cannot sample $\mathbf{b}_S$ jointly, since changing one b_s might change the type of another site s'; indeed, this dependence is reflected in (5), which shows that types depend on $\mathbf{z}$. For example, $s, s' \in S$ conflict when $s' = s + 1$ in the HMM or when s and s' are boundaries of one segment (USM) or one tree fragment (PTSG). Therefore, one additional concept is necessary: We say two sites s and s' *conflict* if there is some choice that depends on both b_s and $b_{s'}$; formally, $(\mathbf{z} \backslash \mathbf{z}^{-s}) \cap (\mathbf{z} \backslash \mathbf{z}^{-s'}) \neq \emptyset$.

Our key mathematical result is as follows:

Proposition 1 *For any set $S \subset \mathcal{S}$ of non-conflicting sites with the same type,*

$$p(\mathbf{b}_S \mid \mathbf{b} \backslash \mathbf{b}_S) \;\propto\; g(m) \tag{6}$$

$$p(m \mid \mathbf{b} \backslash \mathbf{b}_S) \;\propto\; \binom{|S|}{m} g(m), \tag{7}$$

for some easily computable $g(m)$, where $m = \sum_{s \in S} b_s$.

We will derive $g(m)$ shortly, but first note from (6) that the likelihood for a particular setting of $\mathbf{b}_S$ depends on $\mathbf{b}_S$ only via m as desired. (7) sums over all $\binom{|S|}{m}$ settings of $\mathbf{b}_S$ with $m = \sum_{s \in S} b_s$. The algorithmic consequences of this result is that to sample $\mathbf{b}_S$, we can first compute (7) for each $m \in \{0, \dots, |S|\}$, sample m according to the normalized distribution, and then choose the actual $\mathbf{b}_S$ uniformly subject to m.

Let us now derive $g(m)$ by generalizing (4). Imagine removing all sites S and their dependent choices and adding in choices corresponding to some assignment $\mathbf{b}_S$. Since all sites in S are non-conflicting and of the same type, the count contribution $\Delta\mathbf{n}^{s:b}$ is the same for every $s \in S$ (i.e., sites in S are exchangeable). Therefore, the likelihood of the new assignment $\mathbf{b}_S$ depends only on the new counts:

$$\Delta\mathbf{n}^{S:m} \overset{\text{def}}{=} m\Delta\mathbf{n}^{s:1} + (|S| - m)\Delta\mathbf{n}^{s:0}. \tag{8}$$

Using these new counts in place of the ones in (4), we get the following expression:

$$g(m) = \prod_{r \in \mathcal{R}} \frac{\prod_o (\alpha_{ro}\mu_{ro} + n_{ro}(\mathbf{z}^{-S}))^{(\Delta n_{ro}^{S:m})}}{\alpha_r + n_{r\cdot}(\mathbf{z}^{-S})^{(\Delta n_{r\cdot}^{S:m})}}. \tag{9}$$

4.4 Full Algorithm

Thus far, we have shown how to sample $\mathbf{b}_S$ given a set $S \subset \mathcal{S}$ of non-conflicting sites with the same type. To complete the description of the type-based

```
Type-Based Sampler
for each iteration $t = 1, \dots, T$:
  for each pivot site $s_0 \in \mathcal{S}$:
    $S \leftarrow \mathrm{TB}(\mathbf{z}, s_0)$ ($S$ is the type block centered at $s_0$)
    decrement $\mathbf{n}$ and remove from $\mathbf{z}$ based on $\mathbf{b}_S$
    sample $m$ according to (7)
    sample $M \subset S$ with $|M| = m$ uniformly at random
    set $b_s = \mathbb{I}[s \in M]$ for each $s \in S$
    increment $\mathbf{n}$ and add to $\mathbf{z}$ accordingly
```

Figure 4: Pseudocode for the general type-based sampler. We operate in the binary variable representation $\mathbf{b}$ of $\mathbf{z}$. Each step, we jointly sample $|S|$ variables (of the same type).

sampler, we need to specify how to choose S. Our general strategy is to first choose a *pivot site* $s_0 \in \mathcal{S}$ uniformly at random and then set $S = \mathrm{TB}(\mathbf{z}, s_0)$ for some function TB. Call S the *type block* centered at s_0. The following two criteria on TB are sufficient for a valid sampler: (A) $s_0 \in S$, and (B) the type blocks are *stable*, which means that if we change $\mathbf{b}_S$ to any $\mathbf{b}'_S$ (resulting in a new $\mathbf{z}'$), the type block centered at s_0 with respect to $\mathbf{z}'$ does not change (that is, $\mathrm{TB}(\mathbf{z}', s_0) = S$). (A) ensures ergodicity; (B), reversibility.

Now we define TB as follows: First set $S = \{s_0\}$. Next, loop through all sites $s \in \mathcal{S}$ with the same type as s_0 in some fixed order, adding s to S if it does not conflict with any sites already in S. Figure 4 provides the pseudocode for the full algorithm.

Formally, this sampler cycles over $|\mathcal{S}|$ transition kernels, one for each pivot site. Each kernel (indexed by $s_0 \in \mathcal{S}$) defines a blocked Gibbs move, i.e. sampling from $p(\mathbf{b}_{\mathrm{TB}(\mathbf{z},s_0)} \mid \cdots)$.

Efficient Implementation There are two operations we must perform efficiently: (A) looping through sites with the same type as the pivot site s_0, and (B) checking whether such a site s conflicts with any site in S. We can perform (B) in $O(1)$ time by checking if any element of $\Delta\mathbf{z}^{s:b_s}$ has already been removed; if so, there is a conflict and we skip s. To do (A) efficiently, we maintain a hash table mapping type t to a doubly-linked list of sites with type t. There is an $O(1)$ cost for maintaining this data structure: When we add or remove a site s, we just need to add or remove neighboring sites s' from their respective linked lists, since their types depend on b_s. For example, in the HMM, when we remove site s, we also remove sites $s-1$ and $s+1$.

For the USM, we use a simpler solution: maintain a hash table mapping each word w to a list of positions where w occurs. Suppose site (position) s straddles words a and b. Then, to perform (A), we retrieve the list of positions where *a*, *b*, and *ab* occur, intersecting the a and b lists to obtain a list of positions where a b occurs. While this intersection is often much smaller than the pre-intersected lists, we found in practice that the smaller amount of bookkeeping balanced out the extra time spent intersecting. We used a similar strategy for the PTSG, which significantly reduces the amount of bookkeeping.

Skip Approximation Large type blocks mean larger moves. However, such a block S is also sampled more frequently—once for every choice of a pivot site $s_0 \in S$. However, we found that empirically, $\mathbf{b}_S$ changes very infrequently. To eliminate this apparent waste, we use the following approximation of our sampler: do not consider $s_0 \in \mathcal{S}$ as a pivot site if s_0 belongs to some block which was already sampled in the current iteration. This way, each site is considered roughly once per iteration.[4]

Sampling Non-Binary Representations We can sample in models without a natural binary representation (e.g., HMMs with with more than two states) by considering random binary slices. Specifically, suppose $b_s \in \{1, \dots, K\}$ for each site $s \in \mathcal{S}$. We modify Figure 4 as follows: After choosing a pivot site $s_0 \in \mathcal{S}$, let $k = b_{s_0}$ and choose k' uniformly from $\{1, \dots, K\}$. Only include sites in one of these two states by re-defining the type block to be $S = \{s \in \mathrm{TB}(\mathbf{z}, s_0) : b_s \in \{k, k'\}\}$, and sample $\mathbf{b}_S$ restricted to these two states by drawing from $p(\mathbf{b}_S \mid \mathbf{b}_S \in \{k, k'\}^{|S|}, \cdots)$. By choosing a random k' each time, we allow $\mathbf{b}$ to reach any point in the space, thus achieving ergodicity just by using these binary restrictions.

5 Experiments

We now compare our proposed type-based sampler to various alternatives, evaluating on marginal like-

[4] A site could be sampled more than once if it belonged to more than one type block during the iteration (recall that types depend on $\mathbf{z}$ and thus could change during sampling).

lihood (3) and accuracy for our three models:

- HMM: We learned a $K = 45$ state HMM on the Wall Street Journal (WSJ) portion of the Penn Treebank (49208 sentences, 45 tags) for part-of-speech induction. We fixed α_r to 0.1 and μ_r to uniform for all r.

  For accuracy, we used the standard metric based on greedy mapping, where each state is mapped to the POS tag that maximizes the number of correct matches (Haghighi and Klein, 2006). We did not use a tagging dictionary.

- USM: We learned a USM model on the Bernstein-Ratner corpus from the CHILDES database used in Goldwater et al. (2006) (9790 sentences) for word segmentation. We fixed α_0 to 0.1. The base distribution μ_0 penalizes the length of words (see Goldwater et al. (2009) for details). For accuracy, we used word token F_1.

- PTSG: We learned a PTSG model on sections 2–21 of the WSJ treebank.[5] For accuracy, we used EVALB parsing F_1 on section 22.[6] Note this is a supervised task with latent-variables, whereas the other two are purely unsupervised.

5.1 Basic Comparison

Figure 5(a)–(c) compares the likelihood and accuracy (we use the term *accuracy* loosely to also include F_1). The initial observation is that the type-based sampler (TYPE) outperforms the token-based sampler (TOKEN) across all three models on both metrics.

We further evaluated the PTSG on parsing. Our standard treebank PCFG estimated using maximum likelihood obtained 79% F_1. TOKEN obtained an F_1 of 82.2%, and TYPE obtained a comparable F_1 of 83.2%. Running the PTSG for longer continued to improve the likelihood but actually hurt parsing accuracy, suggesting that the PTSG model is overfitting.

To better understand the gains from TYPE over TOKEN, we consider three other alternative samplers. First, annealing (TOKEN$_{\text{anneal}}$) is a commonly-used technique to improve mixing, where (3) is raised to some inverse temperature.[7] In Figure 5(a)–(c), we see that unlike TYPE, TOKEN$_{\text{anneal}}$ does not improve over TOKEN uniformly: it hurts for the HMM, improves slightly for the USM, and makes no difference for the PTSG. Although annealing does increase mobility of the sampler, this mobility is undirected, whereas type-based sampling increases mobility in purely model-driven directions.

Unlike past work that operated on types (Wolff, 1988; Brown et al., 1992; Stolcke and Omohundro, 1994), type-based sampling makes stochastic choices, and moreover, these choices are reversible. Is this stochasticity important? To answer this, we consider a variant of TYPE, TYPE$_{\text{greedy}}$: instead of sampling from (7), TYPE$_{\text{greedy}}$ considers a type block S and sets b_s to 0 for all $s \in S$ if $p(\mathbf{b}_S = (0, \dots, 0) \mid \cdots) > p(\mathbf{b}_S = (1, \dots, 1) \mid \cdots)$; else it sets b_s to 1 for all $s \in S$. From Figure 5(a)–(c), we see that greediness is disastrous for the HMM, hurts a little for USM, and makes no difference on the PTSG. These results show that stochasticity can indeed be important.

We consider another block sampler, SENTENCE, which uses dynamic programming to sample all variables in a sentence (using Metropolis-Hastings to correct for intra-sentential type-level coupling). For USM, we see that SENTENCE performs worse than TYPE and is comparable to TOKEN, suggesting that type-based dependencies are stronger and more important to deal with than intra-sentential dependencies.

5.2 Initialization

We initialized all samplers as follows: For the USM and PTSG, for each site s, we place a boundary (set $b_s = 1$) with probability η. For the HMM, we set b_s to state 1 with probability η and a random state with

[5] Following Petrov et al. (2006), we performed an initial preprocessing step on the trees involving Markovization, binarization, and collapsing of unary chains; words occurring once are replaced with one of 50 "unknown word" tokens, using base distributions $\{\mu_r\}$ that penalize the size of trees, and sampling the hyperparameters (see Cohn et al. (2009) for details).

[6] To evaluate, we created a grammar where the rule probabilities are the mean values under the PTSG distribution: this involves taking a weighted combination (based on the concentration parameters) of the rule counts from the PTSG samples and the PCFG-derived base distribution. We used the decoder of DeNero et al. (2009) to parse.

[7] We started with a temperature of 10 and gradually decreased it to 1 during the first half of the run, and kept it at 1 thereafter.

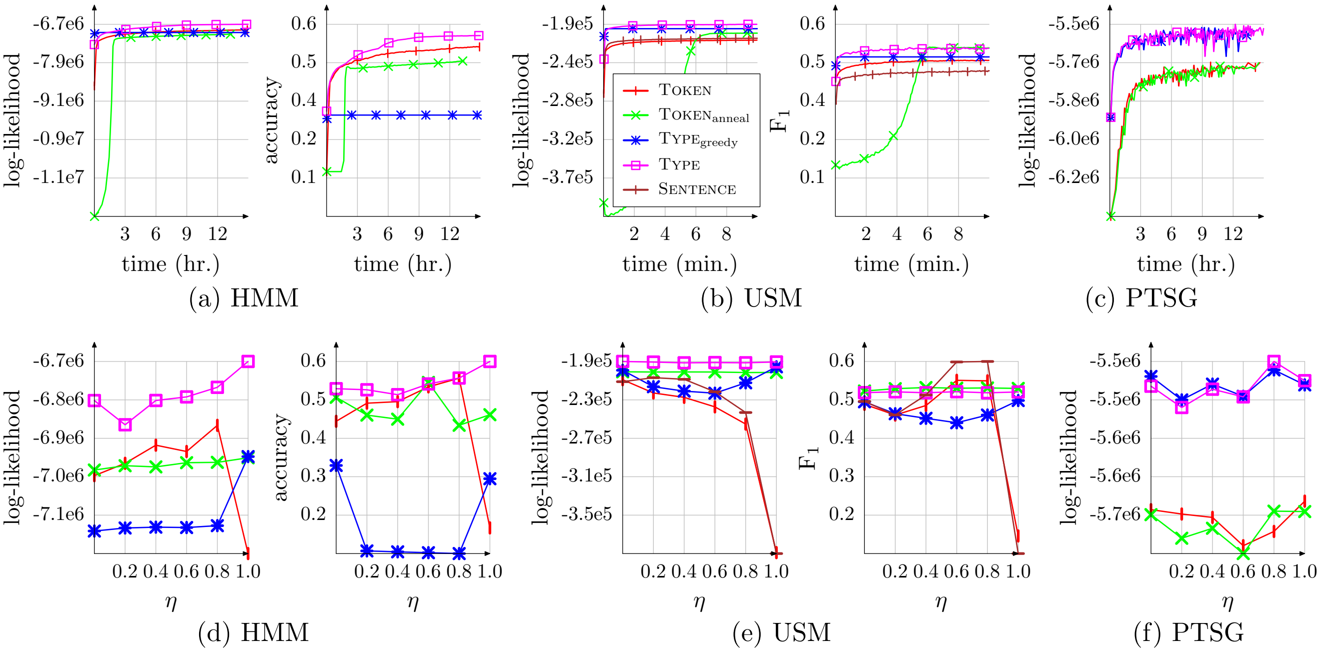


Figure 5: (a)–(c): Log-likelihood and accuracy over time. TYPE performs the best. Relative to TYPE, TYPE$_{\text{greedy}}$ tends to hurt performance. TOKEN generally works worse. Relative to TOKEN, TOKEN$_{\text{anneal}}$ produces mixed results. SENTENCE behaves like TOKEN. (d)–(f): Effect of initialization. The metrics were applied to the current sample after 15 hours for the HMM and PTSG and 10 minutes for the USM. TYPE generally prefers larger η and outperform the other samplers.

probability $1 - \eta$. Results in Figure 5(a)–(c) were obtained by setting η to maximize likelihood.

Since samplers tend to be sensitive to initialization, it is important to explore the effect of initialization (parametrized by $\eta \in [0, 1]$). Figure 5(d)–(f) shows that TYPE is consistently the best, whereas other samplers can underperform TYPE by a large margin. Note that TYPE favors $\eta = 1$ in general. This setting maximizes the number of initial types, and thus creates larger type blocks and thus enables larger moves. Larger type blocks also mean more dependencies that TOKEN is unable to deal with.

6 Related Work and Discussion

Block sampling, on which our work is built, is a classical idea, but is used restrictively since sampling large blocks is computationally expensive. Past work for clustering models maintained tractability by using Metropolis-Hastings proposals (Dahl, 2003) or introducing auxiliary variables (Swendsen and Wang, 1987; Liang et al., 2007). In contrast, our type-based sampler simply identifies tractable blocks based on exchangeability.

Other methods for learning latent-variable models include EM, variational approximations, and uncollapsed samplers. All of these methods maintain distributions over (or settings of) the latent variables of the model and update the representation iteratively (see Gao and Johnson (2008) for an overview in the context of POS induction). However, these methods are at the core all token-based, since they only update variables in a single example at a time.[8]

Blocking variables by type—the key idea of this paper—is a fundamental departure from token-based methods. Though type-based changes have also been proposed (Brown et al., 1992; Stolcke and Omohundro, 1994), these methods operated greedily, and in Section 5.1, we saw that being greedy led to more brittle results. By working in a sampling framework, we were able bring type-based changes to fruition.

[8] While EM technically updates all distributions over latent variables in the E-step, this update is performed *conditioned on* model parameters; it is this coupling (made more explicit in collapsed samplers) that makes EM susceptible to local optima.

Painless Unsupervised Learning with Features

Taylor Berg-Kirkpatrick Alexandre Bouchard-Côté John DeNero Dan Klein
Computer Science Division
University of California at Berkeley
{tberg, bouchard, denero, klein}@cs.berkeley.edu

Abstract

We show how features can easily be added to standard generative models for unsupervised learning, without requiring complex new training methods. In particular, each component multinomial of a generative model can be turned into a miniature logistic regression model if feature locality permits. The intuitive EM algorithm still applies, but with a gradient-based M-step familiar from discriminative training of logistic regression models. We apply this technique to part-of-speech induction, grammar induction, word alignment, and word segmentation, incorporating a few linguistically-motivated features into the standard generative model for each task. These feature-enhanced models each outperform their basic counterparts by a substantial margin, and even compete with and surpass more complex state-of-the-art models.

1 Introduction

Unsupervised learning methods have been increasingly successful in recent NLP research. The reasons are varied: increased supplies of unlabeled data, improved understanding of modeling methods, additional choices of optimization algorithms, and, perhaps most importantly for the present work, incorporation of richer domain knowledge into structured models. Unfortunately, that knowledge has generally been encoded in the form of conditional independence structure, which means that injecting it is both tricky (because the connection between independence and knowledge is subtle) and time-consuming (because new structure often necessitates new inference algorithms).

In this paper, we present a range of experiments wherein we improve existing unsupervised models by declaratively adding richer features. In particular, we parameterize the local multinomials of existing generative models using features, in a way which does not require complex new machinery but which still provides substantial flexibility. In the feature-engineering paradigm, one can worry less about the backbone structure and instead use hand-designed features to declaratively inject domain knowledge into a model. While feature engineering has historically been associated with discriminative, supervised learning settings, we argue that it can and should be applied more broadly to the unsupervised setting.

The idea of using features in unsupervised learning is neither new nor even controversial. Many top unsupervised results use feature-based models (Smith and Eisner, 2005; Haghighi and Klein, 2006). However, such approaches have presented their own barriers, from challenging normalization problems, to neighborhood design, to the need for complex optimization procedures. As a result, most work still focuses on the stable and intuitive approach of using the EM algorithm to optimize data likelihood in locally normalized, generative models.

The primary contribution of this paper is to demonstrate the clear empirical success of a simple and accessible approach to unsupervised learning with features, which can be optimized by using standard NLP building blocks. We consider the same generative, locally-normalized models that dominate past work on a range of tasks. However, we follow Chen (2003), Bisani and Ney (2008), and Bouchard-Côté et al. (2008), and allow each component multinomial of the model to be a miniature multi-class logistic regression model. In this case, the EM algorithm still applies with the E-step unchanged. The M-step involves gradient-based training familiar from standard supervised logistic regression (i.e., maximum entropy models). By integrating these two familiar learning techniques, we add features to unsupervised models without any

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 582–590,

specialized learning or inference.

A second contribution of this work is to show that further gains can be achieved by directly optimizing data likelihood with LBFGS (Liu et al., 1989). This alternative optimization procedure requires no additional machinery beyond what EM uses. This approach is still very simple to implement, and we found that it empirically outperforms EM.

This paper is largely empirical; the underlying optimization techniques are known, even if the overall approach will be novel to many readers. As an empirical demonstration, our results span an array of unsupervised learning tasks: part-of-speech induction, grammar induction, word alignment, and word segmentation. In each task, we show that declaring a few linguistically motivated feature templates yields state-of-the-art results.

2 Models

We start by explaining our feature-enhanced model for part-of-speech (POS) induction. This particular example illustrates our approach to adding features to unsupervised models in a well-known NLP task. We then explain how the technique applies more generally.

2.1 Example: Part-of-Speech Induction

POS induction consists of labeling words in text with POS tags. A hidden Markov model (HMM) is a standard model for this task, used in both a frequentist setting (Merialdo, 1994; Elworthy, 1994) and in a Bayesian setting (Goldwater and Griffiths, 2007; Johnson, 2007).

A POS HMM generates a sequence of words in order. In each generation step, an observed word emission y_i and a hidden successor POS tag z_{i+1} are generated independently, conditioned on the current POS tag z_i . This process continues until an absorbing stop state is generated by the transition model.

There are two types of conditional distributions in the model—emission and transition probabilities—that are both multinomial probability distributions. The joint likelihood factors into these distributions:

$$P_{\boldsymbol{\theta}}(\mathbf{Y}=\mathbf{y},\mathbf{Z}=\mathbf{z}) = P_{\boldsymbol{\theta}}(Z_1=z_1)\cdot$$
$$\prod_{i=1}^{|\mathbf{z}|} P_{\boldsymbol{\theta}}(Y_i=y_i|Z_i=z_i)\cdot P_{\boldsymbol{\theta}}(Z_{i+1}=z_{i+1}|Z_i=z_i)$$

The emission distribution $P_{\boldsymbol{\theta}}(Y_i=y_i|Z_i=z_i)$ is parameterized by conditional probabilities $\theta_{y,z,\text{EMIT}}$ for each word y given tag z. Alternatively, we can express this emission distribution as the output of a logistic regression model, replacing the explicit conditional probability table by a logistic function parameterized by weights and features:

$$\theta_{y,z,\text{EMIT}}(\mathbf{w}) = \frac{\exp\langle\mathbf{w},\mathbf{f}(y,z,\text{EMIT})\rangle}{\sum_{y'}\exp\langle\mathbf{w},\mathbf{f}(y',z,\text{EMIT})\rangle}$$

This feature-based logistic expression is equivalent to the flat multinomial in the case that the feature function $\mathbf{f}(y,z,\text{EMIT})$ consists of all indicator features on tuples (y,z,EMIT), which we call BASIC features. The equivalence follows by setting weight $w_{y,z,\text{EMIT}} = \log(\theta_{y,z,\text{EMIT}})$.[1] This formulation is known as the natural parameterization of the multinomial distribution.

In order to enhance this emission distribution, we include coarse features in $\mathbf{f}(y,z,\text{EMIT})$, in addition to the BASIC features. Crucially, these features can be active across multiple (y,z) values. In this way, the model can abstract general patterns, such as a POS tag co-occurring with an inflectional morpheme. We discuss specific POS features in Section 4.

2.2 General Directed Models

Like the HMM, all of the models we propose are based on locally normalized generative decisions that condition on some context. In general, let $\mathbf{X} = (\mathbf{Z},\mathbf{Y})$ denote the sequence of generation steps (random variables) where $\mathbf{Z}$ contains all hidden random variables and $\mathbf{Y}$ contains all observed random variables. The joint probability of this directed model factors as:

$$P_{\mathbf{w}}(\mathbf{X}=\mathbf{x}) = \prod_{i\in I} P_{\mathbf{w}}\left(X_i=x_i\middle|X_{\pi(i)}=x_{\pi(i)}\right),$$

where $X_{\pi(i)}$ denotes the parents of X_i and I is the index set of the variables in $\mathbf{X}$.

In the models that we use, each factor in the above expression is the output of a local logistic regression

[1] As long as no transition or emission probabilities are equal to zero. When zeros are present, for instance to model that an absorbing stop state can only transition to itself, it is often possible to absorb these zeros into a *base measure*. All the arguments in this paper carry with a structured base measure; we drop it for simplicity.

model parameterized by $\mathbf{w}$:

$$P_{\mathbf{w}}(X_i = d | X_{\pi(i)} = c) = \frac{\exp\langle \mathbf{w}, \mathbf{f}(d, c, t)\rangle}{\sum_{d'} \exp\langle \mathbf{w}, \mathbf{f}(d', c, t)\rangle}$$

Above, d is the generative decision value for X_i picked by the model, c is the conditioning context tuple of values for the parents of X_i, and t is the type of decision being made. For instance, the POS HMM has two types of decisions: transitions and emissions. In the emission model, the type t is EMIT, the decision d is a word and the context c is a tag. The denominator normalizes the factor to be a probability distribution over decisions.

The objective function we derive from this model is the marginal likelihood of the observations $\mathbf{y}$, along with a regularization term:

$$L(\mathbf{w}) = \log P_{\mathbf{w}}(\mathbf{Y} = \mathbf{y}) - \kappa ||\mathbf{w}||_2^2 \qquad (1)$$

This model has two advantages over the more prevalent form of a feature-rich unsupervised model, the globally normalized Markov random field.[2] First, as we explain in Section 3, optimizing our objective does not require computing expectations over the joint distribution. In the case of the POS HMM, for example, we do not need to enumerate an infinite sum of products of potentials when optimizing, in contrast to Haghighi and Klein (2006). Second, we found that locally normalized models empirically outperform their globally normalized counterparts, despite their efficiency and simplicity.

3 Optimization

3.1 Optimizing with Expectation Maximization

In this section, we describe the EM algorithm applied to our feature-rich, locally normalized models. For models parameterized by standard multinomials, EM optimizes $L(\boldsymbol{\theta}) = \log P_{\boldsymbol{\theta}}(\mathbf{Y} = \mathbf{y})$ (Dempster et al., 1977). The E-step computes expected counts for each tuple of decision d, context c, and multinomial type t:

$$e_{d,c,t} \leftarrow \mathbb{E}_{\boldsymbol{\theta}} \left[\sum_{i \in I} \mathbb{1}(X_i = d, X_{\pi(i)} = c, t) \middle| \mathbf{Y} = \mathbf{y} \right] \qquad (2)$$

These expected counts are then normalized in the M-step to re-estimate $\boldsymbol{\theta}$:

$$\theta_{d,c,t} \leftarrow \frac{e_{d,c,t}}{\sum_{d'} e_{d',c,t}}$$

Normalizing expected counts in this way maximizes the expected complete log likelihood with respect to the current model parameters.

EM can likewise optimize $L(\mathbf{w})$ for our locally normalized models with logistic parameterizations. The E-step first precomputes multinomial parameters from $\mathbf{w}$ for each decision, context, and type:

$$\theta_{d,c,t}(\mathbf{w}) \leftarrow \frac{\exp\langle \mathbf{w}, \mathbf{f}(d, c, t)\rangle}{\sum_{d'} \exp\langle \mathbf{w}, \mathbf{f}(d', c, t)\rangle}$$

Then, expected counts $\mathbf{e}$ are computed according to Equation 2. In the case of POS induction, expected counts are computed with the forward-backward algorithm in both the standard and logistic parameterizations. The only change is that the conditional probabilities $\boldsymbol{\theta}$ are now functions of $\mathbf{w}$.

The M-step changes more substantially, but still relies on canonical NLP learning methods. We wish to choose $\mathbf{w}$ to optimize the regularized expected complete log likelihood:

$$\ell(\mathbf{w}, \mathbf{e}) = \sum_{d,c,t} e_{d,c,t} \log \theta_{d,c,t}(\mathbf{w}) - \kappa ||\mathbf{w}||_2^2 \qquad (3)$$

We optimize this objective via a gradient-based search algorithm like LBFGS. The gradient with respect to $\mathbf{w}$ takes the form

$$\nabla \ell(\mathbf{w}, \mathbf{e}) = \sum_{d,c,t} e_{d,c,t} \cdot \Delta_{d,c,t}(\mathbf{w}) - 2\kappa \cdot \mathbf{w} \qquad (4)$$

$$\Delta_{d,c,t}(\mathbf{w}) = \mathbf{f}(d, c, t) - \sum_{d'} \theta_{d',c,t}(\mathbf{w}) \mathbf{f}(d', c, t)$$

This gradient matches that of regularized logistic regression in a supervised model: the difference Δ between the observed and expected features, summed over every decision and context. In the supervised case, we would observe the count of occurrences of (d, c, t), but in the unsupervised M-step, we instead substitute expected counts $e_{d,c,t}$.

This gradient-based M-step is an iterative procedure. For each different value of $\mathbf{w}$ considered during the search, we must recompute $\boldsymbol{\theta}(\mathbf{w})$, which requires computation in proportion to the size of the

[2] The locally normalized model class is actually equivalent to its globally normalized counterpart when the former meets the following three conditions: (1) The graphical model is a directed tree. (2) The BASIC features are included in $\mathbf{f}$. (3) We do not include regularization in the model ($\kappa = 0$). This follows from Smith and Johnson (2007).

parameter space. However, $\mathbf{e}$ stays fixed throughout the M-step. Algorithm 1 outlines EM in its entirety. The subroutine climb$(\cdot,\cdot,\cdot)$ represents a generic optimization step such as an LBFGS iteration.

Algorithm 1 Feature-enhanced EM

```
repeat
  Compute expected counts $\mathbf{e}$                      ▷ Eq. 2
  repeat
    Compute $\ell(\mathbf{w}, \mathbf{e})$                   ▷ Eq. 3
    Compute $\nabla\ell(\mathbf{w}, \mathbf{e})$             ▷ Eq. 4
    $\mathbf{w} \leftarrow \text{climb}(\mathbf{w}, \ell(\mathbf{w}, \mathbf{e}), \nabla\ell(\mathbf{w}, \mathbf{e}))$
  until convergence
until convergence
```

3.2 Direct Marginal Likelihood Optimization

Another approach to optimizing Equation 1 is to compute the gradient of the log marginal likelihood directly (Salakhutdinov et al., 2003). The gradient turns out to have the same form as Equation 4, with the key difference that $e_{d,c,t}$ is recomputed for every different value of $\mathbf{w}$. Algorithm 2 outlines the procedure. Justification for this algorithm appears in the Appendix.

Algorithm 2 Feature-enhanced direct gradient

```
repeat
  Compute expected counts $\mathbf{e}$                      ▷ Eq. 2
  Compute $L(\mathbf{w})$                                   ▷ Eq. 1
  Compute $\nabla\ell(\mathbf{w}, \mathbf{e})$               ▷ Eq. 4
  $\mathbf{w} \leftarrow \text{climb}(\mathbf{w}, L(\mathbf{w}), \nabla\ell(\mathbf{w}, \mathbf{e}))$
until convergence
```

In practice, we find that this optimization approach leads to higher task accuracy for several models. However, in cases where computing $e_{d,c,t}$ is expensive, EM can be a more efficient alternative.

4 Part-of-Speech Induction

We now describe experiments that demonstrate the effectiveness of locally normalized logistic models. We first use the bigram HMM described in Section 2.1 for POS induction, which has two types of multinomials. For type EMIT, the decisions d are words and contexts c are tags. For type TRANS, the decisions and contexts are both tags.

4.1 POS Induction Features

We use the same set of features used by Haghighi and Klein (2006) in their baseline globally normalized Markov random field (MRF) model. These are all coarse features on emission contexts that activate for words with certain orthographic properties. We use only the BASIC features for transitions. For an emission with word y and tag z, we use the following feature templates:

BASIC:	$\mathbb{1}(y = \cdot, z = \cdot)$
CONTAINS-DIGIT:	Check if y contains digit and conjoin with z: $\mathbb{1}(\text{containsDigit}(y) = \cdot, z = \cdot)$
CONTAINS-HYPHEN:	$\mathbb{1}(\text{containsHyphen}(x) = \cdot, z = \cdot)$
INITIAL-CAP:	Check if the first letter of y is capitalized: $\mathbb{1}(\text{isCap}(y) = \cdot, z = \cdot)$
N-GRAM:	Indicator functions for character n-grams of up to length 3 present in y.

4.2 POS Induction Data and Evaluation

We train and test on the entire WSJ tag corpus (Marcus et al., 1993). We attempt the most difficult version of this task where the only information our system can make use of is the unlabeled text itself. In particular, we do not make use of a tagging dictionary. We use 45 tag clusters, the number of POS tags that appear in the WSJ corpus. There is an identifiability issue when evaluating inferred tags. In order to measure accuracy on the hand-labeled corpus, we map each cluster to the tag that gives the highest accuracy, the many-1 evaluation approach (Johnson, 2007). We run all POS induction models for 1000 iterations, with 10 random initializations. The mean and standard deviation of many-1 accuracy appears in Table 1.

4.3 POS Induction Results

We compare our model to the basic HMM and a bigram version of the feature-enhanced MRF model of Haghighi and Klein (2006). Using EM, we achieve a many-1 accuracy of 68.1. This outperforms the basic HMM baseline by a 5.0 margin. The same model, trained using the direct gradient approach, achieves a many-1 accuracy of 75.5, outperforming the basic HMM baseline by a margin of 12.4. These results show that the direct gradient approach can offer additional boosts in performance when used with a feature-enhanced model. We also outperform the globally normalized MRF, which uses the same set of features and which we train using a direct gradient approach.

To the best of our knowledge, our system achieves the best performance to date on the WSJ corpus for totally unsupervised POS tagging.[3]

5 Grammar Induction

We next apply our technique to a grammar induction task: the unsupervised learning of dependency parse trees via the dependency model with valence (DMV) (Klein and Manning, 2004). A dependency parse is a directed tree over tokens in a sentence. Each edge of the tree specifies a directed dependency from a head token to a dependent, or argument token. Thus, the number of dependencies in a parse is exactly the number of tokens in the sentence, not counting the artificial root token.

5.1 Dependency Model with Valence

The DMV defines a probability distribution over dependency parse trees. In this head-outward attachment model, a parse and the word tokens are derived together through a recursive generative process. For each token generated so far, starting with the root, a set of left dependents is generated, followed by a set of right dependents.

There are two types of multinomial distributions in this model. The Bernoulli STOP probabilities $\theta_{d,c,\text{STOP}}$ capture the valence of a particular head. For this type, the decision d is whether or not to stop generating arguments, and the context c contains the current head h, direction δ and adjacency adj. If a head's stop probability is high, it will be encouraged to accept few arguments. The ATTACH multinomial probability distributions $\theta_{d,c,\text{ATTACH}}$ capture attachment preferences of heads. For this type, a decision d is an argument token a, and the context c consists of a head h and a direction δ.

We take the same approach as previous work (Klein and Manning, 2004; Cohen and Smith, 2009) and use gold POS tags in place of words.

5.2 Grammar Induction Features

One way to inject knowledge into a dependency model is to encode the similarity between the various morphological variants of nouns and verbs. We encode this similarity by incorporating features into both the STOP and the ATTACH probabilities. The attachment features appear below; the stop feature templates are similar and are therefore omitted.

BASIC:	$\mathbb{1}(a = \cdot, h = \cdot, \delta = \cdot)$
NOUN:	Generalize the morphological variants of nouns by using isNoun$(\cdot)$: $\mathbb{1}(a = \cdot, \text{isNoun}(h) = \cdot, \delta = \cdot)$ $\mathbb{1}(\text{isNoun}(a) = \cdot, h = \cdot, \delta = \cdot)$ $\mathbb{1}(\text{isNoun}(a) = \cdot, \text{isNoun}(h) = \cdot, \delta = \cdot)$
VERB:	Same as above, generalizing verbs instead of nouns by using isVerb$(\cdot)$
NOUN-VERB:	Same as above, generalizing with isVerbOrNoun$(\cdot)$ = isVerb$(\cdot) \vee$ isNoun$(\cdot)$
BACK-OFF:	We add versions of all other features that ignore direction or adjacency.

While the model has the expressive power to allow specific morphological variants to have their own behaviors, the existence of coarse features encourages uniform analyses, which in turn gives better accuracies.

Cohen and Smith's (2009) method has similar characteristics. They add a shared logistic-normal prior (SLN) to the DMV in order to tie multinomial parameters across related derivation events. They achieve their best results by only tying parameters between different multinomials when the corresponding contexts are headed by nouns and verbs. This observation motivates the features we choose to incorporate into the DMV.

5.3 Grammar Induction Data and Evaluation

For our English experiments we train and report directed attachment accuracy on portions of the WSJ corpus. We work with a standard, reduced version of WSJ, WSJ10, that contains only sentences of length 10 or less after punctuation has been removed. We train on sections 2-21, and use section 22 as a development set. We report accuracy on section 23. These are the same training, development, and test sets used by Cohen and Smith (2009). The regularization parameter (κ) is tuned on the development set to maximize accuracy.

For our Chinese experiments, we use the same corpus and training/test split as Cohen and Smith

[3] Haghighi and Klein (2006) achieve higher accuracies by making use of labeled prototypes. We do not use any external information.

(2009). We train on sections 1-270 of the Penn Chinese Treebank (Xue et al., 2002), similarly reduced (CTB10). We test on sections 271-300 of CTB10, and use sections 400-454 as a development set.

The DMV is known to be sensitive to initialization. We use the deterministic harmonic initializer from Klein and Manning (2004). We ran each optimization procedure for 100 iterations. The results are reported in Table 1.

5.4 Grammar Induction Results

We are able to outperform Cohen and Smith's (2009) best system, which requires a more complicated variational inference method, on both English and Chinese data sets. Their system achieves an accuracy of 61.3 for English and an accuracy of 51.9 for Chinese.[4] Our feature-enhanced model, trained using the direct gradient approach, achieves an accuracy of 63.0 for English, and an accuracy of 53.6 for Chinese. To our knowledge, our method for feature-based dependency parse induction outperforms all existing methods that make the same set of conditional independence assumptions as the DMV.

6 Word Alignment

Word alignment is a core machine learning component of statistical machine translation systems, and one of the few NLP tasks that is dominantly solved using unsupervised techniques. The purpose of word alignment models is to induce a correspondence between the words of a sentence and the words of its translation.

6.1 Word Alignment Models

We consider two classic generative alignment models that are both used heavily today, IBM Model 1 (Brown et al., 1994) and the HMM alignment model (Ney and Vogel, 1996). These models generate a hidden alignment vector $\mathbf{z}$ and an observed foreign sentence $\mathbf{y}$, all conditioned on an observed English sentence $\mathbf{e}$. The likelihood of both models takes the form:

$$P(\mathbf{y}, \mathbf{z}|\mathbf{e}) = \prod_{j} p(z_j = i|z_{j-1}) \cdot \theta_{y_j, e_i, \text{ALIGN}}$$

Model		**Inference**	**Reg**	**Eval**
POS Induction			κ	Many-1
WSJ	Basic-HMM	EM	–	63.1 (1.3)
	Feature-MRF	LBFGS	0.1	59.6 (6.9)
	Feature-HMM	EM	1.0	68.1 (1.7)
		LBFGS	1.0	**75.5** (1.1)
Grammar Induction			κ	Dir
WSJ10	Basic-DMV	EM	–	47.8
	Feature-DMV	EM	0.05	48.3
		LBFGS	10.0	**63.0**
	(Cohen and Smith, 2009)			61.3
CTB10	Basic-DMV	EM	–	42.5
	Feature-DMV	EM	1.0	49.9
		LBFGS	5.0	**53.6**
	(Cohen and Smith, 2009)			51.9
Word Alignment			κ	AER
NIST ChEn	Basic-Model 1	EM	–	38.0
	Feature-Model 1	EM	–	**35.6**
	Basic-HMM	EM	–	33.8
	Feature-HMM	EM	–	**30.0**
Word Segmentation			κ	F1
BR	Basic-Unigram	EM	–	76.9 (0.1)
	Feature-Unigram	EM	0.2	84.5 (0.5)
		LBFGS	0.2	**88.0** (0.1)
	(Johnson and Goldwater, 2009)			87

Table 1: Locally normalized feature-based models outperform all proposed baselines for all four tasks. LBFGS outperformed EM in all cases where the algorithm was sufficiently fast to run. Details of each experiment appear in the main text.

The distortion term $p(z_j = i|z_{j-1})$ is uniform in Model 1, and Markovian in the HMM. See Liang et al. (2006) for details on the specific variant of the distortion model of the HMM that we used. We use these standard distortion models in both the baseline and feature-enhanced word alignment systems.

The bilexical emission model $\theta_{y,e,\text{ALIGN}}$ differentiates our feature-enhanced system from the baseline system. In the former, the emission model is a standard conditional multinomial that represents the probability that decision word y is generated from context word e, while in our system, the emission model is re-parameterized as a logistic regression model and feature-enhanced.

Many supervised feature-based alignment models have been developed. In fact, this logistic parameterization of the HMM has been proposed before and yielded alignment improvements, but was trained using supervised estimation techniques (Varea et al., 2002).[5] However, most full translation systems to-

[4] Using additional bilingual data, Cohen and Smith (2009) achieve an accuracy of 62.0 for English, and an accuracy of 52.0 for Chinese, still below our results.

[5] Varea et al. (2002) describes unsupervised EM optimization with logistic regression models at a high level—their *dynamic training* approach—but provides no experiments.

day rely on unsupervised learning so that the models may be applied easily to many language pairs. Our approach provides efficient and consistent unsupervised estimation for feature-rich alignment models.

6.2 Word Alignment Features

The BASIC features on pairs of lexical items provide strong baseline performance. We add coarse features to the model in order to inject prior knowledge and tie together lexical items with similar characteristics.

BASIC:	$\mathbb{1}(e = \cdot, y = \cdot)$
EDIT-DISTANCE:	$\mathbb{1}(\text{dist}(y, e) = \cdot)$
DICTIONARY:	$\mathbb{1}((y, e) \in D)$ for dictionary D.
STEM:	$\mathbb{1}(\text{stem}(e) = \cdot, y = \cdot)$ for Porter stemmer.
PREFIX:	$\mathbb{1}(\text{prefix}(e) = \cdot, y = \cdot)$ for prefixes of length 4.
CHARACTER:	$\mathbb{1}(e = \cdot, \text{charAt}(y, i) = \cdot)$ for index i in the Chinese word.

These features correspond to several common augmentations of word alignment models, such as adding dictionary priors and truncating long words, but here we integrate them all coherently into a single model.

6.3 Word Alignment Data and Evaluation

We evaluate on the standard hand-aligned portion of the NIST 2002 Chinese-English development set (Ayan et al., 2005). The set is annotated with sure S and possible P alignments. We measure alignment quality using alignment error rate (AER) (Och and Ney, 2000).

We train the models on 10,000 sentences of FBIS Chinese-English newswire. This is not a large-scale experiment, but large enough to be relevant for low-resource languages. LBFGS experiments are not provided because computing expectations in these models is too computationally intensive to run for many iterations. Hence, EM training is a more appropriate optimization approach: computing the M-step gradient requires only summing over word type pairs, while the marginal likelihood gradient needed for LBFGS requires summing over training sentence alignments. The final alignments, in both the baseline and the feature-enhanced models, are computed by training the generative models in both directions, combining the result with hard union competitive thresholding (DeNero and Klein, 2007), and using agreement training for the HMM (Liang et al., 2006). The combination of these techniques yields a state-of-the-art unsupervised baseline for Chinese-English.

6.4 Word Alignment Results

For both IBM Model 1 and the HMM alignment model, EM training with feature-enhanced models outperforms the standard multinomial models, by 2.4 and 3.8 AER respectively.[6] As expected, large positive weights are assigned to both the dictionary and edit distance features. Stem and character features also contribute to the performance gain.

7 Word Segmentation

Finally, we show that it is possible to improve upon the simple and effective word segmentation model presented in Liang and Klein (2009) by adding phonological features. Unsupervised word segmentation is the task of identifying word boundaries in sentences where spaces have been removed. For a sequence of characters $\mathbf{y} = (y_1, ..., y_n)$, a segmentation is a sequence of segments $\mathbf{z} = (z_1, ..., z_{|\mathbf{z}|})$ such that $\mathbf{z}$ is a partition of $\mathbf{y}$ and each z_i is a contiguous subsequence of $\mathbf{y}$. Unsupervised models for this task infer word boundaries from corpora of sentences of characters without ever seeing examples of well-formed words.

7.1 Unigram Double-Exponential Model

Liang and Klein's (2009) unigram double-exponential model corresponds to a simple derivational process where sentences of characters $\mathbf{x}$ are generated a word at a time, drawn from a multinomial over all possible strings $\theta_{z,\text{SEGMENT}}$. For this type, there is no context and the decision is the particular string generated. In order to avoid the degenerate MLE that assigns mass only to single segment sentences it is helpful to independently generate a length for each segment from a fixed distribution. Liang and Klein (2009) constrain individual segments to have maximum length 10 and generate lengths from the following distribution: $\theta_{l,\text{LENGTH}} = \exp(-l^{1.6})$ when $1 \leq l \leq 10$. Their model is deficient since it is possible to generate

[6] The best published results for this dataset are supervised, and trained on 17 times more data (Haghighi et al., 2009).

lengths that are inconsistent with the actual lengths of the generated segments. The likelihood equation is given by:

$$P(\mathbf{Y} = \mathbf{y}, \mathbf{Z} = \mathbf{z}) = \\ \theta_{\text{STOP}} \prod_{i=1}^{|\mathbf{z}|} \left[(1 - \theta_{\text{STOP}})\, \theta_{z_i,\text{SEGMENT}} \exp(-|z_i|^{1.6}) \right]$$

7.2 Segmentation Data and Evaluation

We train and test on the phonetic version of the Bernstein-Ratner corpus (1987). This is the same set-up used by Liang and Klein (2009), Goldwater et al. (2006), and Johnson and Goldwater (2009). This corpus consists of 9790 child-directed utterances transcribed using a phonetic representation. We measure segment F1 score on the entire corpus.

We run all word segmentation models for 300 iterations with 10 random initializations and report the mean and standard deviation of F1 in Table 1.

7.3 Segmentation Features

The SEGMENT multinomial is the important distribution in this model. We use the following features:

BASIC:	$\mathbb{1}(z = \cdot)$
LENGTH:	$\mathbb{1}(\text{length}(z) = \cdot)$
NUMBER-VOWELS:	$\mathbb{1}(\text{numVowels}(z) = \cdot)$
PHONO-CLASS-PREF:	$\mathbb{1}(\text{prefix}(\text{coarsePhonemes}(z)) = \cdot)$
PHONO-CLASS-PREF:	$\mathbb{1}(\text{suffix}(\text{coarsePhonemes}(z)) = \cdot)$

The phonological class prefix and suffix features project each phoneme of a string to a coarser class and then take prefix and suffix indicators on the string of projected characters. We include two versions of these features that use projections with different levels of coarseness. The goal of these features is to help the model learn general phonetic shapes that correspond to well-formed word boundaries.

As is the case in general for our method, the feature-enhanced unigram model still respects the conditional independence assumptions that the standard unigram model makes, and inference is still performed using a simple dynamic program to compute expected sufficient statistics, which are just segment counts.

7.4 Segmentation Results

To our knowledge our system achieves the best performance to date on the Bernstein-Ratner corpus, with an F1 of 88.0. It is substantially simpler than the non-parametric Bayesian models proposed by Johnson et al. (2007), which require sampling procedures to perform inference and achieve an F1 of 87 (Johnson and Goldwater, 2009). Similar to our other results, the direct gradient approach outperforms EM for feature-enhanced models, and both approaches outperform the baseline, which achieves an F1 of 76.9.

8 Conclusion

We have shown that simple, locally normalized models can effectively incorporate features into unsupervised models. These enriched models can be easily optimized using standard NLP building blocks. Beyond the four tasks explored in this paper—POS tagging, DMV grammar induction, word alignment, and word segmentation—the method can be applied to many other tasks, for example grounded semantics, unsupervised PCFG induction, document clustering, and anaphora resolution.

Acknowledgements

We thank Percy Liang for making his word segmentation code available to us, and the anonymous reviewers for their comments.

Appendix: Optimization

In this section, we derive the gradient of the log marginal likelihood needed for the direct gradient approach. Let $\mathbf{w}_0$ be the current weights in Algorithm 2 and $\mathbf{e} = \mathbf{e}(\mathbf{w}_0)$ be the expectations under these weights as computed in Equation 2. In order to justify Algorithm 2, we need to prove that $\nabla L(\mathbf{w}_0) = \nabla \ell(\mathbf{w}_0, \mathbf{e})$.

We use the following simple lemma: if ϕ, ψ are real-valued functions such that: (1) $\phi(\mathbf{w}_0) = \psi(\mathbf{w}_0)$ for some $\mathbf{w}_0$; (2) $\phi(\mathbf{w}) \leq \psi(\mathbf{w})$ on an open set containing $\mathbf{w}_0$; and (3), ϕ and ψ are differentiable at $\mathbf{w}_0$; then $\nabla \psi(\mathbf{w}_0) = \nabla \phi(\mathbf{w}_0)$.

We set $\psi(\mathbf{w}) = L(\mathbf{w})$ and $\phi(\mathbf{w}) = \ell(\mathbf{w}, \mathbf{e}) - \sum_{\mathbf{z}} P_{\mathbf{w}_0}(\mathbf{Z} = \mathbf{z}|\mathbf{Y} = \mathbf{y}) \log P_{\mathbf{w}_0}(\mathbf{Z} = \mathbf{z}|\mathbf{Y} = \mathbf{y})$. If we can show that ψ, ϕ satisfy the conditions of the lemma we are done since the second term of ϕ depends on $\mathbf{w}_0$, but not on $\mathbf{w}$.

Property (3) can be easily checked, and property (2) follows from Jensen's inequality. Finally, property (1) follows from Lemma 2 of Neal and Hinton (1998).

Abstract

This paper describes a method for checking the acceptability of paraphrases in context. We use the Google n-gram data and a CCG parser to certify the paraphrasing grammaticality and fluency. We collect a corpus of human judgements to evaluate our system. The ultimate goal of our work is to integrate text paraphrasing into a Linguistic Steganography system, by using paraphrases to hide information in a cover text. We propose automatically generated paraphrases as a new and useful source of transformations for Linguistic Steganography, and show that our method for checking paraphrases is effective at maintaining a high level of imperceptibility, which is crucial for effective steganography.

1 Introduction

Steganography is concerned with hiding information in some cover medium, by manipulating properties of the medium in such a way that the hidden information is not easily detectable by an observer (Fridrich, 2009). The covert communication is such that the very act of communication is to be kept secret from outside observers. A related area is Watermarking, in which modifications are made to a cover medium in order to identify it, for example for the purposes of copyright. Here the changes may be known to an observer, and the task is to make the changes in such a way that the watermark cannot easily be removed.

There is a large literature on image steganography and watermarking, in which images are modified to encode a hidden message or watermark. Image stegosystems exploit the redundancy in an image representation together with limitations of the human visual system. For example, a standard image stegosystem uses the least-significant-bit (LSB) substitution technique. Since the difference between 11111111 and 11111110 in the value for red/green/blue intensity is likely to be undetectable by the human eye, the LSB can be used to hide information other than colour, without being perceptable by a human observer.[1]

A key question for any steganography system is the choice of cover medium. Given the ubiquitous nature of natural languages and electronic text, text is an obvious medium to consider. However, the literature on Linguistic Steganography, in which linguistic properties of a text are modified to hide information, is small compared with other media (Bergmair, 2007). The likely reason is that it is easier to make changes to images and other non-linguistic media which are undetectable by an observer. Language has the property that even small local changes to a text, e.g. replacing a word by a word with similar meaning, may result in text which is anomalous at the document level, or anomalous with respect to the state of the world. Hence finding linguistic transformations which can be applied reliably and often is a challenging problem for Linguistic Steganography.

In this paper we focus on steganography rather than watermarking, since we are interested in the requirement that any changes to a text be imperceptible to an observer. Figure 1 shows the Linguistic Steganography framework. First, some secret message, represented as a sequence of bits, is hidden in a

[1] The observer may also be a computer program, designed to detect statistical anomalies in the image representation which may indicate the presence of hidden information.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 591–599,

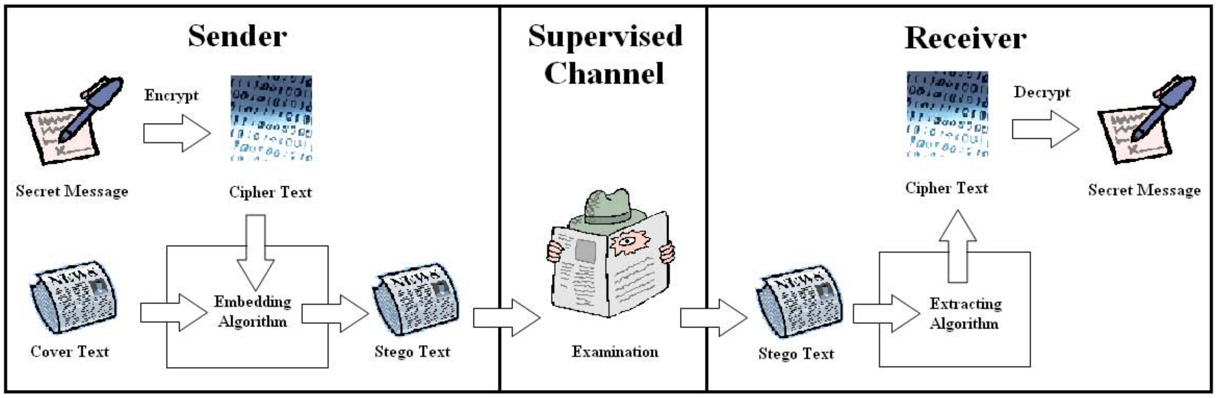

Figure 1: The Linguistic Steganography framework

cover text using the embedding algorithm, resulting in the *stego text*.[2] Next, the stego text passes the human observer, who is happy for innocuous messages to pass between the sender and receiver, but will examine the text for any suspicious looking content. Once the stego text reaches the receiver, the hidden message is recovered using the extracting algorithm.

There is a fundamental tradeoff in all steganography systems, and one that is especially apparent in the Linguistic Steganography framework: the tradeoff between *imperceptibility* and *payload*. Payload is the number of bits that can be encoded per unit of cover medium, for example per sentence in the linguistic case. The tradeoff arises because any attempt to hide additional information in the cover text, through the application of more linguistic transformations, is likely to increase the chances of raising the suspicions of the observer, by introducing anomalies into the text.

The key elements of a Linguistic Steganography system are the linguistic transformation and the embedding method. In this paper we focus on the linguistic transformation. Section 5 describes a possible embedding method for our framework, and for readers unfamiliar with linguistic steganography shows how linguistic transformations can be used to embed hidden bits in text.

Section 2 describes some of the previous transformations used in Linguistic Steganography. Note that we are concerned with transformations which are linguistic in nature, rather than dealing with superficial properties of the text, e.g. the amount of white space between words (Por et al., 2008). Our proposed method is based on the automatically acquired paraphrase dictionary described in Callison-Burch (2008), in which the application of paraphrases from the dictionary encodes secret bits. One advantage of the dictionary is that it has wide coverage, being automatically extracted; however, a disadvantage is that it contains many paraphrases which are either inappropriate, or only appropriate in certain contexts. Since we require any changes to be imperceptible to a human observer, it is crucial to our system that any uses of paraphrasing are grammatical and retain the meaning of the original cover text.

In order to test the grammaticality and meaning preserving nature of a paraphrase, we employ a simple technique based on checking whether the contexts containing the paraphrase are in the Google n-gram corpus. This technique is based on the simple hypothesis that, if the paraphrase in context has been used many times before on the web, then it is an appropriate use. We test our n-gram-based system against some human judgements of the grammaticality of paraphrases in context. We find that using larger contexts leads to a high precision system (100% when using 5-grams), but at the cost of a reduced recall. This precision-recall tradeoff reflects the inherent tradeoff between imperceptibility and payload in a Linguistic Steganography system. We also experiment with a CCG parser (Clark and Curran, 2007), requiring that the contexts surrounding the original phrase and paraphrase are assigned

[2] The message may have been encrypted initially also, as in the figure, but this is not important in this paper; the key point is that the hidden message is a sequence of bits.

the same CCG lexical categories by the parser. This method increases the precision of the Google n-gram check with a slight loss in recall.

A contribution of this paper is to advertise the Linguistic Steganography problem to the ACL community. The requirement that any linguistic transformation maintain the grammaticality and meaning of the cover text makes the problem a strong test for existing NLP technology.

2 Previous Work

2.1 Synonym Substitution

The simplest and most straightforward subliminal modification of text is to substitute selected words with their synonyms. The first lexical substitution method was proposed by Chapman and Davida (1997). Later works, such as Atallah et al. (2001a), Bolshakov (2004), Taskiran et al. (2006) and Topkara et al. (2006b), further made use of part-of-speech taggers and electronic dictionaries, such as WordNet and VerbNet, to increase the robustness of the method. Taskiran et al. (2006) attempt to use context by prioritizing the alternatives using an n-gram language model; that is, rather than randomly choose an option from the synonym set, the system relies on the language model to select the synonym. Topkara et al. (2005) and Topkara et al. (2006b) report an average embedding capacity of 0.67 bits per sentence for the synonym substitution method.

2.2 Syntactic Transformations

The second and the most widely used manipulations for linguistic steganography are syntactic transformations. This method is based on the fact that a sentence can be transformed into more than one semantically equivalent syntactic structure, using transformations such as passivization, topicalization and clefting. The first syntactic transformation method is presented by Atallah et al. (2001a). Later, Atallah et al. (2001b) embedded information in the tree structure of the text by adjusting the structural properties of intermediate representations of sentences. In other words, instead of performing lexical substitution directly to the text, the secret message is embedded into syntactic parse trees of the sentences. Liu et al. (2005), Meral et al. (2007), Murphy (2001), Murphy and Vogel (2007) and Topkara et al. (2006a) all belong to the syntactic transformation category. After embedding the secret message, modified deep structure forms are converted into the surface structure format via language generation tools. Atallah et al. (2001b) and Topkara et al. (2006a) attained the embedding capacity of 0.5 bits per sentence with the syntactic transformation method.

2.3 Semantic Transformations

The semantic transformation method is the most sophisticated approach for linguistic steganography, and perhaps impractical given the current state-of-the-art for NLP technology. It requires some sophisticated tools and knowledge to model natural language semantics. Atallah et al. (2002) used semantic transformations and embed information in text-meaning representation (TMR) trees of the text by either pruning, grafting or substituting the tree structure with information available from ontological semantic resources. Vybornova and Macq (2007) aimed to embed information by exploiting the linguistic phenomenon of presupposition, with the idea that some presuppositional information can be removed without changing the meaning of a sentence.

3 Data Resources

3.1 Paraphrase Dictionary

The cover text used for our experiments consists of newspaper sentences from Section 00 of the Penn Treebank (Marcus et al., 1993). Hence we require possible paraphrases for phrases that occur in Section 00. The paraphrase dictionary that we use was generated for us by Chris Callison-Burch, using the technique described in Callison-Burch (2008), which exploits a parallel corpus and methods developed for statistical machine translation.

Table 1 gives summary statistics of the paraphrase dictionary and its coverage on Section 00 of the Penn Treebank. The length of the extracted n-gram phrases ranges from unigrams to five-grams. The coverage figure gives the percentage of sentences which have at least one phrase in the dictionary. The coverage is important for us because it determines the payload capacity of the embedding method described in Section 5.

Table 2 lists some examples 5-gram phrases and paraphrases from the dictionary. The format of the

N-gram	Number of phrases	Coverage on section 00 (%)
Unigrams	5,856	99
Bigrams	13,473	96
Trigrams	6,574	65
Four-grams	1,604	40
Five-grams	295	10

Table 1: Statistics for the paraphrase dictionary

Original phrase	Paraphrases
the end of this year	later this year the end of the year year end
a number of people	some of my colleagues differences the European peoples party the PPE group

Table 2: Example phrases and paraphrases from the dictionary

dictionary is a mapping from phrases to sets of possible paraphrases. Each paraphrase also has a probability, based on a statistical machine translation model, but we do not use that feature here. The examples show that, while some of the paraphrases are of a high quality, some are not. For example, *differences* is unlikely to be a suitable paraphrase for *a number of people* in any context. Moreover, there are some ⟨phrase, paraphrase⟩ pairs which are only suitable in particular contexts. For example, *year end* is an unsuitable paraphrase for *the end of this year* in the sentence *The chart compares the gold price at the end of last year with the end of this year*. Barzilay and McKeown (2001) also note that the applicability of paraphrases is strongly influenced by context. Section 4 describes our method for determining if a paraphrase is suitable in a given context.

3.2 Google N-gram Data

The Google n-gram data was collected by Google Research for statistical language modelling, and has been used for many tasks such as lexical disambiguation (Bergsma et al., 2009), and contains English n-grams and their observed frequency counts, for counts of at least 40. The striking feature of the n-gram corpus is the large number of n-grams and the size of the counts, since the counts were extracted from over 1 trillion word tokens of English text on publicly accessible Web pages collected in January 2006. For example, the 5-gram phrase *the part that you were* has a count of 103. The compressed data is around 24 GB on disk.

3.3 Paraphrase Judgement Corpus

The focus of the paper is to develop an automatic system for checking the grammaticality and fluency of paraphrases in context. In order to evaluate the system, we collected some human judgements, based on 70 sentences from Section 00 of the Penn Treebank. For each sentence, we took every phrase in the sentence which is in the dictionary, and for each paraphrase of that phrase, replaced the phrase with the paraphrase to create an instance. This procedure resulted in 500 cases of paraphrases in context.

Each case was then evaluated by a human judge, using a web-based annotation system that we developed. The judges were asked to judge each case on two dimensions: a) whether the paraphrase is *grammatical* in context; and b) whether the paraphrase *retains the meaning* of the original phrase given the context. Figure 2 gives a screen shot of the annotation system.

50 of the 500 cases were judged by two judges, in order to obtain some indication of whether the grammaticality and meaning retention judgements are viable; the rest were judged by one annotator. (The 500 instances were randomly distributed among 10 native speakers, each being given 55 instances to judge.) For the meaning retention check, only 34 out of the 50 cases received the same judgement. One reason for the low agreement may be that, for 11 of the 16 disagreement cases, we were asking annota-

tors to judge the meaning retention of paraphrases which had been judged to be ungrammatical in context, which may not be a meaningful task. For the grammatical check, 42 out of the 50 cases received the same judgement, a much higher level of agreement.

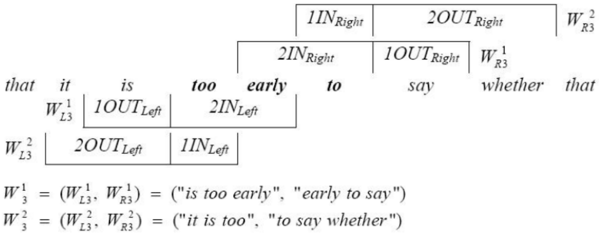
Since the meaning retention judgements were unreliable, we used only the grammatical judgements to evaluate our system. Hence we are interested in evaluating whether our n-gram and parser-based systems can determine if a paraphrase is *grammatical* in context. Meaning retention is important for the imperceptibility requirement, but grammaticality is even more so, since ungrammatical sentences will be easy for an observer to spot. However, we recognise that only testing for grammaticality does not fully test the imperceptibility properties of the system, only part of it.

For the 8 cases which received different judgements on grammaticality, the second author of this paper made the definitive judgement, which resulted in a test set of 308 paraphrases judged as grammatical in context, and 192 paraphrases judged as ungrammatical in context.

4 Proposed Method and Experiments

4.1 Google N-gram Method

The main idea for testing the use of paraphrases is to check if the various contextual n-grams appear in the Google n-gram data, or were already in the original sentence (before paraphrasing). Let us first define some notation to be used in describing the method. The leftmost and rightmost <*m*> words in the phrase/paraphrase are represented as <*m*>*IN_{Left}* and <*m*>*IN_{Right}*, respectively. Words at the left and right side of the substituted phrase are defined as <*c*>*OUT_{Left}* and <*c*>*OUT_{Right}*, where <*c*> is an integer which indicates the number of words represented. Also, we define a context window pair $W_{<n>}^{<c>} = (W_{L<n>}^{<c>}, W_{R<n>}^{<c>})$, where $W_{L<n>}^{<c>}$ is composed by <*c*>*OUTLeft* concatenated with <*n-c*>*INLeft*, and $W_{R<n>}^{<c>}$ is composed by <*n-c*>*INRight* concatenated with <*c*>*OUTRight*. Figure 3 gives an example of the context window pairs W_3^1 and W_3^2 in the sentence *Soviets said that it is* ***too early to*** *say whether that will happen* where the phrase *too early to* is being considered in context.



1IN_Right
2OUT_Right
W_{R3}^2
2IN_Right
1OUT_Right
W_{R3}^1
that it is too early to say whether that
W_{L3}^1
1OUT_Left
2IN_Left
W_{L3}^2
2OUT_Left
1IN_Left
$W_3^1 = (W_{L3}^1, W_{R3}^1)$ = ("is too early", "early to say")
$W_3^2 = (W_{L3}^2, W_{R3}^2)$ = ("it is too", "to say whether")

Figure 3: An example of the context window pair

```
INPUT: $S, P, P', n, maxC$
OUTPUT: the acceptability of paraphrase $P'$
checked by $(n, maxC)$

FOR each context size $C$ from 1 to $maxC$
    GET a context window pair $W_n^C$
    IF $O(W_n^C)$ is zero THEN
        OUTPUT paraphrase $P'$ fails
END FOR
OUTPUT paraphrase $P'$ passes
```

Figure 4: Procedure for checking acceptability

We define a *google-count function G()*. This function takes a context window pair $W_{<n>}^{<c>}$ as input and outputs a frequency count pair of $W_{<n>}^{<c>}$ recorded in the Google n-gram data. If a context window cannot be found in the Google n-gram data, the frequency count of that window is zero. Also, we define a binary *occurrence function O()*. It is used to determine whether a context window pair can be passed as acceptable. The input of this function is $W_{<n>}^{<c>}$. The function outputs one if either both $W_{L<n>}^{<c>}$ and $W_{R<n>}^{<c>}$ already occurred in the original sentence (before paraphrasing) or if the frequency counts output by *G(*$W_{<n>}^{<c>}$*)* are both greater than zero.

The two major components in our method are the paraphrase dictionary and the Google n-gram data. Once a phrase P in the cover sentence S is matched with that in the paraphrase dictionary, we test the use of its paraphrase P' by the following method. This method takes into account maximum C contextual words at both sides of the target phrase, and uses Google n-gram data as a check, where n = 2, 3, 4 or 5, and $maxC$ = 1 to $n - 1$. Each pair of (n, $maxC$) provides a separate check, by considering both left and right contexts for these values.

Figure 4 describes the procedure for checking the acceptability of paraphrasing phrase P with P' in a given sentence S, given the n-gram size and the maximum considered context size $maxC$. For example, we want to check the acceptability of the paraphrase in context shown in Figure 3 by using google tri-gram data (n = 3) and taking maximum context size equal to two into consideration ($maxC$ = 2). The procedure starts from taking context size C equal to one into account, namely checking the occurrence of W_3^1. If the paraphrase P' passes the current test, in the next iteration it will be tested by taking one more context word into account, namely W_3^2. However, If the paraphrase P' fails the current (n, C) check the checking procedure will terminate and report that the paraphrase fails. In contrast, if the paraphrase passes all the (n, C) checks where C = 1 to $maxC$, the procedure determines the paraphrase as acceptable. What is happening is that an n-gram window is effectively being shifted across the paraphrase boundary to include different amounts of context and paraphrase.

4.2 Syntactic Filter

In order to improve the grammaticality checking, we use a parser as an addition to the basic Google n-gram method. We use the Clark and Curran (2007) CCG parser to analyse the sentence before and after paraphrasing. Combinatory Categorial Grammar (CCG) is a lexicalised grammar formalism, in which CCG lexical categories — typically expressing subcategorisation information — are assigned to each word in a sentence. The grammatical check works by checking if the words in the sentence outside of the phrase and paraphrase receive the same lexical categories before and after paraphrasing. If there is any change in lexical category assignment to these words then the paraphrase is judged ungrammatical. Hence the grammar check is at the word, rather than derivation, level; however, CCG lexical categories contain a large amount of syntactic information which this method is able to exploit.

4.3 Results

The test corpus described in Section 3.3 was split into development and test data: 100 instances for development and 400 for testing. The development data was used for preliminary experiments. For the test data, 246 of the examples (61.5%) had been judged as grammatical, and 154 (38.5%) had been judged as ungrammatical by the annotators.

	Acc%	P%	R%	F%
baseline	61.5	61.5	100.0	76.2
parser	68.3	67.4	93.9	78.4

Table 3: Grammar check using CCG parser

The performance of the system is evaluated using accuracy, precision, recall and balanced F-measure. Accuracy is the percentage of correct judgements over all grammatical and ungrammatical paraphrases. Precision is the percentage of paraphrases judged grammatical by the system which are judged grammatical by the human judges, and recall is the percentage of paraphrases judged grammatical by human judges which are also judged grammatical by the system. Precision and recall are relevant in our setting because high precision implies high imperceptibility, since grammatical phrases in context are less likely to be viewed as suspicious by the observer; whereas high recall maximises the payload (given the dictionary), since high recall implies that phrases are being paraphrased where possible (and hence embedding as much information as possible).

An accuracy baseline is obtained by always returning the majority class, in this case always judging the paraphrase grammatical, which gives an accuracy of 61.5%. Table 3 gives the performance when only the CCG parser is used for checking grammaticality. As far as steganography is concerned, the precision is low, since over 30% of the paraphrases used are ungrammatical, which is likely to raise the suspicions of the observer.

Table 4 gives the results for the Google n-gram method, for various n-gram and context sizes. As the n-gram size increases — meaning that a larger part of the context is used — the accuracy falls below that of the baseline. However, from a steganography aspect, accuracy is not useful, since the trade-off between precision and recall is more relevant. As expected, with larger n-grams checking the left and right contexts, the precision increases, reaching 100% for the 5-grams. Hence, as far as grammaticality judgements are concerned, the imperceptibility requirement is completely satisified. However, the large drop in recall means that the imperceptibil-

N-gram	Context Size	Accuracy (%)	Precision (%)	Recall (%)	F-measure (%)
2-gram	1	62.0	62.1	98.0	76.0
3-gram	1	62.5	65.1	84.2	73.4
	2	67.3	72.9	74.4	73.6
4-gram	1	58.5	71.3	54.5	61.8
	2	53.2	84.7	29.3	43.5
	3	51.8	89.6	24.4	38.3
5-gram	1	54.8	85.0	32.1	46.6
	2	43.5	95.5	8.5	15.7
	3	41.0	100.0	4.1	7.8
	4	41.0	100.0	4.1	7.8

Table 4: Performance of google n-gram method

ity is achieved at the cost of a reduced payload, since many of the grammatical paraphrases that could be used to embed information are being discarded.

Table 5 shows the results for the Google n-gram method followed by the parser check; that is, if the Google n-gram method judges the paraphrase to be grammatical, then it is passed to the CCG parser for an additional check. Adding the parser generally increases the precision with a slight loss in recall. Which settings are best to use in practice would depend on how the steganography user wished to trade off imperceptibility for payload.

5 Possible embedding method

In this section, we propose a linguistic hiding method which can be integrated with an automatic paraphrasing system. It needs a large paraphrase dictionary to determine modifiable phrases and provide available paraphrases. The embedding capacity of the proposed linguistic stegosystem relies on the number of paraphrasable sentences in the cover text. If every sentence in the cover text is paraphrasable, the system can have the maximum embedding capacity equal to 1 bit per sentence which is comparable to other linguistic steganography methods using syntactic transformations and synonym substitution.

N-gram	Context Size	Accuracy (%)	Precision (%)	Recall (%)	F-measure (%)
2-gram	1	68.0	67.7	91.9	78.0
3-gram	1	67.3	70.9	79.3	74.9
	2	69.5	77.7	70.7	74.0
4-gram	1	59.5	75.6	50.4	60.5
	2	53.8	88.6	28.5	43.1
	3	52.0	92.2	24.0	38.1
5-gram	1	53.8	86.8	29.3	43.8
	2	43.3	95.2	8.1	15.0
	3	41.0	100.0	4.1	7.8
	4	41.0	100.0	4.1	7.8

Table 5: Performance of google n-gram method with the CCG parser filter

5.1 Data Embedding Procedure

First the sentences in a cover text T are identified using a sentence segmentation algorithm, giving N sentences s_1, s_2,..., s_N. The paraphrasability of each sentence is then checked using our automatic method. If a sentence contains at least one paraphrasable phrase, we call the sentence a *paraphrasable sentence* or a *non-paraphrasable sentence* otherwise. Let *D* be the maximum number of sentence boundaries between two subsequent paraphrasable sentences in *T*. Thus, for every *D* sentences within a cover text *T*, there will be at least one paraphrasable sentence. Let every unit of *D* sentences serve as one embedding unit in which a single secret bit can be embedded. If we want to embed 0 in an embedding unit, we transform all the paraphrasable sentences in this embedding unit to non-paraphrasable sentences (assuming certain properties of the dictionary; see end of this section for discussion). If we want to embed 1, we leave the embedding unit without any modifications.

Figure 5 demonstrates the embedding of the secret bitstring 101 in a cover text containing nine sentences t_1, t_2,..., t_9 defined by a sentence segmentation algorithm. First, t_1, t_3, t_4, t_7 and t_9 are determined as paraphrasable sentences and thus *D*, the

Secret Bit: 0
Secret Bit: 1
Stego Text T'

Figure 5: Embedding secret bits in a cover text using sentence segmentation method

size of an embedding unit, is 3. Next, we segment the cover text into three embedding units u_1, u_2 and u_3, each of which contains three sentences. Since we want to embed secret bits 101 in u_1, u_2 and u_3 respectively, the embedding unit u_2 should contain no paraphrasable sentence. That is, the paraphrasable phrase in t_4 should be replaced by its paraphrase. Finally, the stego text is output and sent along with the private key *D* to the other party. A private key is known only to the parties that exchange messages.

In order for this method to work, we require certain properties of the paraphrase dictionary. For example, it is crucial that, once a phrase has been paraphrased, it does not produce another phrase that can be paraphrased. This can be achieved by simply requiring that any paraphrase 'on the RHS' of the dictionary does not also appear as a phrase on the LHS. In fact, this is not so unnatural for the Callison-Burch dictionary, which consists of phrases mapped to sets of paraphrases, many of which only appear on one side.

5.2 Data Extracting Procedure

For extracting the secret data, first, the stego text T' undergoes sentence segmentation, and *N* defined sentences s'_1, s'_2,..., s'_N are obtained. According to the private key *D*, every *D* sentences are treated as an information unit, and in each unit we check the occurrence of paraphrasable sentences making use of our paraphrasing method. If an information unit contains at least one paraphrasable sentence, this information unit implies the embedding of 1. In contrast, if none of the sentences in the information unit are paraphrasable, it implies the embedding of 0. Hence, in order to recover the hidden message, the receiver requires the sentence segmentation algorithm, the paraphrase dictionary, the automatic program determining grammaticality of paraphrases in context, and the secret key D. The extraction process essentially reverses the embedding method.

6 Conclusions

The contributions of this paper are to develop an automatic system for checking the grammaticality and fluency of paraphrases in context, and the proposal of using paraphrases as a suitable transformation for Linguistic Steganography. An advantage of our proposed method is that it is somewhat language and domain independent, requiring only a paraphrase dictionary and a Google n-gram corpus, both of which are likely to be available for a range of languages in the future.

There are various practical issues in the application of Linguistic Steganography systems that we have chosen to ignore. For example, we have not discussed the choice of cover text. If a newspaper article were chosen as the cover text, then any changes could be easily found in practice by comparing the stego text with the original article, which is likely to be readily available. Another interesting question that we have not addressed is whether some languages are better suited to Linguistic Steganography than others, or whether some languages are better suited to particular linguistic transformations than others. Finally, we have only evaluated our grammatical checker and not the steganography system itself (other than giving an indication of the likely payload). How best to evaluate the imperceptibility of such a system we leave to future work.

Abstract

Producing a fluent ordering for a set of prenominal modifiers in a noun phrase (NP) is a problematic task for natural language generation and machine translation systems. We present a novel approach to this issue, adapting multiple sequence alignment techniques used in computational biology to the alignment of modifiers. We describe two training techniques to create such alignments based on raw text, and demonstrate ordering accuracies superior to earlier reported approaches.

1 Introduction

Natural language generation and machine translation systems must produce text which not only conforms to a reasonable grammatical model, but which also sounds smooth and natural to a human consumer. Ordering prenominal modifiers in noun phrases is particularly difficult in these applications, as the rules underlying these orderings are subtle and not well understood. For example, the phrase "big red ball" seems natural, while "red big ball" seems more marked, suitable only in specific contexts. There is some consensus that the order of prenominal modifiers in noun phrases is governed in part by semantic constraints, but there is no agreement on the exact constraints necessary to specify consistent orderings for any given set of modifiers. General principles of modifier ordering based on semantic constraints also fall short on larger domains, where it is not always clear how to map prenominal modifiers to proposed semantic groups.

With the recent advantages of large corpora and powerful computational resources, work on automatically ordering prenominal modifiers has moved away from approaches based on general principles, and towards learning ordering preferences empirically from existing corpora. Such approaches have several advantages: (1) The predicted orderings are based on prior evidence from 'real-world' texts, ensuring that they are therefore reasonably natural. (2) Many (if not all) prenominal modifiers can be ordered. (3) Expanding the training data with more and larger corpora often improves the system without requiring significant manual labor.

In this paper, we introduce a novel approach to prenominal modifier ordering adapted from multiple sequence alignment (MSA) techniques used in computational biology. MSA is generally applied to DNA, RNA, and protein sequences, aligning three or more biological sequences in order to determine, for example, common ancestry (Durbin et al., 1999; Gusfield, 1997; Carrillo and Lipman, 1988). MSA techniques have not been widely applied in NLP, but have produced some promising results for building a generation mapping dictionary (Barzilay and Lee, 2002), paraphrasing (Barzilay and Lee, 2003), and phone recognition (White et al., 2006).

We believe that multiple sequence alignment is well-suited for aligning linguistic sequences, and that these alignments can be used to predict prenominal modifier ordering for any given set of modifiers. Our technique utilizes simple features within the raw text, and does not require any semantic information. We achieve good performance using this approach, with results competitive with earlier work (Shaw and Hatzivassiloglou, 1999; Malouf, 2000; Mitchell, 2009) and higher recall and F-measure than that reported in Mitchell (2009) when tested on the same corpus.

2 Related work

In one of the first attempts at automatically ordering prenominal modifiers, Shaw and Hatzivassiloglou (1999) present three empirical methods to order a variety of prenominal modifier types. Their approach provides ordering decisions for adjectives, gerunds (such as “running” in “running man”), and past participles (such as “heated” in “heated debate”), as well as for modifying nouns (such as “baseball” in “baseball field”). A morphology module transforms plural nouns and comparative/superlative forms into their base forms, increasing the frequency counts for each modifier. We will briefly recap their three methods, which are categorized as the *direct evidence* method, the *transitivity* method, and the *clustering* method.

Given prenominal modifiers a and b in a training corpus, the *direct evidence* method compares frequency counts of the ordered sequences $<a,b>$ and $<b,a>$. This approach works well, but is limited by data sparsity; groups of two or more modifiers before a noun are relatively infrequent in traditional corpora, and finding the same pair of modifiers together more than once is particularly rare.

To overcome this issue, Shaw and Hatzivassiloglou’s *transitivity* and *clustering* methods make inferences about unseen orderings among prenominal modifiers. In the transitivity method, given three modifiers a,b,c, where a precedes b and b precedes c, the model concludes that a precedes c. The clustering method calculates a similarity score between modifiers based on where the modifiers occur in relation to the other modifiers in the corpus. Those modifiers that are most similar are clustered together, and ordering decisions can be made between modifiers in separate clusters. All three approaches are designed to order pairs of modifiers; it is unclear how to extend these approaches to order groups larger than a pair.

Shaw and Hatzivassiloglou find that NPs with only adjectives as modifiers (including gerunds and past participles) are considerably easier to order than those which contain both adjectives and nouns. They also find large differences in accuracy across domains; their systems achieve much lower overall accuracy on financial text (the Wall Street Journal (WSJ) corpus (Marcus et al., 1999)) than on medical discharge summaries.

Looking at all modifier pairs, the authors achieve their highest prediction accuracy of 90.7% using the transitivity technique on a medical corpus. We do not have access to this corpus, but we do have access to the WSJ corpus, which provides a way to compare our methods. On this corpus, their model produces predictions for 62.5% of all modifier pairs and achieves 83.6% accuracy when it is able to make a prediction. Random guessing on the remainder yields an overall accuracy of 71.0%.

Malouf (2000) also examines the problem of prenominal modifier ordering. He too proposes several statistical techniques, achieving results ranging from 78.3% to 91.9% accuracy. He achieves his best results by combining memory-based learning and positional probability to modifiers from the first 100 million tokens of the BNC. However, this evaluation is limited to the ordering of prenominal adjectives, which is a considerably simpler task than ordering all types of prenominal modifiers. Malouf’s approaches are also limited to ordering pairs of modifiers.

Mitchell (2009) proposes another approach, grouping modifiers into classes and ordering based on those classes. A modifier’s class is assigned based on its placement before a noun, relative to the other modifiers it appears with. Classes are composed of those modifiers that tend to be placed closer to the head noun, those modifiers that tend to be placed farther from the head noun, etc., with each class corresponding to a general positional preference. Unlike earlier work, these classes allow more than one ordering to be proposed for some pairs of modifiers.

Combining corpora of various genres, Mitchell’s system achieves a *token precision* of 89.6% (see Section 4 for discussion and comparison of various evaluation metrics). However, the model only makes predictions for 74.1% of all modifier pairs in the test data, so recall is quite low (see Tables 4 and 6).

Overall, previous work in noun-phrase ordering has produced impressive accuracies in some domains, but currently available systems tend to adapt poorly to unseen modifiers and do not generalize well to unseen domains.

3 Methods

3.1 Multiple Sequence Alignment

Multiple sequence alignment algorithms align sequences of discrete tokens into a series of columns. They attempt to align identical or easily-substitutable tokens within a column, inserting gaps when such gaps will result in a better alignment (more homogeneous token assignments within each column). For example, consider the simple alignment shown in Table 1. The two sequences 'GAACTGAT' and 'AAGTGTAT' are aligned to maximize the number of identical items that appear in the same column, substituting tokens (column 3), and inserting gaps (columns 1 and 6)[1].

A full MSA is generally constructed by iteratively aligning each new sequence with an identical or similar sequence already in the MSA (so-called "progressive alignment"). The costs of token substitution are often taken from a hand-tuned substitution matrix. A cost may also be associated with inserting a gap into the existing MSA (a "gap penalty"). Once the full MSA has been constructed, a Position Specific Score Matrix (PSSM) can be induced, in which each token (including a special gap token) is assigned a separate alignment cost for each column. An unseen sequence can then be aligned with the full MSA by Viterbi search.

Predicting sequence ordering within a noun phrase is a natural application for MSA techniques, and it seems reasonable to propose that aligning an unseen set of modifiers with such an MSA model will yield acceptable orderings. Table 2 illustrates how MSA may be applied to modifiers before a noun. Given an NP preceded by modifiers *hungry*, *big*, and *Grizzly*, alignment of the modifiers with NPs seen in the training corpus determines the prenominal ordering *big hungry Grizzly*. We then align every permutation of the NP and choose the best-scoring alignment.

G	A	C	T	G	-	A	T
-	A	G	T	G	T	A	T
1	2	3	4	5	6	7	8

Table 1: Alignment of the two DNA sequences 'GAACTGAT' and 'AAGTGTAT'.

small	clumsy	black	bear
big	-	black	cow
two-story	-	brown	house
big	clumsy	-	bull
small	fuzzy	brown	duck
large	-	green	house
big	hungry	Grizzly	bear

Table 2: Example noun-phrase alignment.

The vocabulary for a linguistic alignment is large enough to render a hand-tuned substitution matrix impractical, so we instead construct a cost function based on features of the token under consideration and those of the other tokens already aligned in a column.

We know of no prior work on methods for training such an alignment. We present and compare two training methods, each of which produces competitive ordering accuracies. Both training methods share the feature-set described in Table 3. In each case, we train an MSA by aligning each instance in the training data.

3.2 Maximum Likelihood Training

In our alignment approach, the features listed in Table 3 are grouped into several classes. All observed words are a class, all observed stems are a class (Porter, 1980), and so on. We treat each indicator feature as a separate class, and make the assumption that classes are independent of one another. This assumption is clearly false, but serves as a reasonable first approximation, similar to the independence assumption in Naïve Bayesian analysis. After aligning each instance, we estimate the probability of a feature appearing in a column as the simple maximum likelihood estimate given the observed occurrences

[1] See Durbin et al. (1999) for details on standard alignment techniques.

Identity Features	
Word	Token
Stem	Word stem, derived by the Porter Stemmer
Length	‘Binned’ length indicators: 1, 2, 3, 4, 5-6, 7-8, 9-12, 13-18, >18 characters
Indicator Features	
Capitalized	Token begins with a capital
All-caps	Entire token is capitalized
Hyphenated	Token contains a hyphen
Numeric	Entire token is numeric (e.g. 234)
Initial Numeric	Token begins with a numeral (e.g. 123, 2-sided)
Endings	Token ends with *-al*, *-ble*, *-ed*, *-er*, *-est*, *-ic*, *-ing*, *-ive*, *-ly*

Table 3: Description of the feature-set.

within its class.[2] This produces a new PSSM with which to align the next instance.

Our problem differs from alignment of biological sequences in that we have little prior knowledge of the similarity between sequences. ‘Similarity’ can be defined in many ways; for biological sequences, a simple Levenshtein distance is effective, using a matrix of substitution costs or simple token identity (equivalent to a matrix with cost 0 on the diagonal and 1 everywhere else). These matrices are constructed and tuned by domain experts, and are used both in choosing alignment order (i.e., which sequence to align next) and during the actual alignment. When aligning biological sequences, it is customary to first calculate the pairwise distance between each two sequences and then introduce new sequences into the MSA in order of similarity. In this way, identical sequences may be aligned first, followed by less similar sequences (Durbin et al., 1999).

However, we have no principled method of determining the ‘similarity’ of two words in an NP. We have no a priori notion of what the cost of substituting ‘two-story’ for ‘red’ should be. Lacking this prior knowledge, we have no optimal alignment order and we must in effect learn the substitution costs as we construct the MSA. Therefore, we choose to add instances in the order they occur in the corpus, and to iterate over the entire MSA, re-introducing each sequence. This allows a word to ‘move’ from its original column to a column which became more likely as more sequences were aligned. Each iteration is similar to a step in the EM algorithm: create a model (build up an MSA and PSSM), apply the model to the data (re-align all sequences), and repeat. Randomly permuting the training corpus did not change our results significantly, so we believe our results are not greatly dependent on the initial sequence order.

Instead of assigning substitution costs, we compute the cost of aligning a word into a particular column, as follows:

$$\mathbb{C} = \text{The set of } i \text{ feature classes, } C_i \in \mathbb{C}$$

$$j = \text{Features } 1 \ldots |C_i| \text{ from class } C_i$$

$$cnt(i,j,k) = \begin{array}{l}\text{The count of instances of} \\ \text{feature } j \text{ from class} \\ i \text{ in column } k\end{array}$$

$$\lambda_i = \begin{array}{l}\text{Laplace smoothing count} \\ \text{for feature class } C_i\end{array}$$

$$A = \text{The number of aligned instances}$$

$$f(w,i,j) = \begin{cases} 1 & \text{if word } w \text{ has feature } j \text{ from} \\ & \quad C_i, \\ 0 & \text{otherwise} \end{cases}$$

These help define feature positional probabilities for column k:

$$p(i,j,k) = \frac{cnt(i,j,k) + \lambda_i}{A + \lambda_i \cdot |C_i|} \tag{1}$$

[2] We treat two special symbols for gaps and unknown words as members of the word class.

That is, the probability of feature j from class i occurring in column k is a simple maximum-likelihood estimate — count the number of times we have already aligned that feature in the column and divide by the number of sequences aligned. We smooth that probability with simple Laplace smoothing.

We can now calculate the probability of aligning a word w into column k by multiplying the product of the probabilities of aligning each of the word's features. Taking the negative log to convert that probability into a cost function:

$$c(w, k) = -\sum_{i=1}^{|\mathbb{C}|} \sum_{j=1}^{|C_i|} \log\left(p(i, j, k) \cdot f(w, i, j)\right) \quad (2)$$

Finally, we define the cost of inserting a new column into the alignment to be equal to the number of columns in the existing alignment, thereby increasingly penalizing each inserted column until additional columns become prohibitively expensive.

$$i(j) = I \cdot \text{ Length of existing alignment} \quad (3)$$

The longest NPs aligned were 7 words, and most ML MSAs ended with 12-14 columns. We experimented with various column insertion costs and values for the smoothing λ and found no significant differences in overall performance.

3.3 Discriminative Training

We also trained a discriminative model, using the same feature-set. Discriminative training does not require division of the features into classes or the independence assumption discussed in Section 3.2. We again produced a cost vector for each column. We fixed the alignment length at 8 columns, allowing alignment of the longest instances in our test corpus.

Our training data consists of ordered sequences, but the model we are attempting to learn is a set of column probabilities. Since we have no gold-standard MSAs, we instead align the ordered NPs with the current model and treat the least cost alignment of the correct ordering as the reference for training.

We trained this model using the averaged perceptron algorithm (Collins, 2002). A perceptron learns from classifier errors, i.e., when it misorders an NP. At each training instance, we align all possible permutations of the modifiers with the MSA. If the least cost alignment does not correspond to the correct ordering of the modifiers, we update the perceptron to penalize features occurring in that alignment and to reward features occurring in the least cost alignment corresponding to the correct ordering, using standard perceptron updates.

Examining every permutation of the NP involves a non-polynomial cost, but the sequences under consideration are quite short (less than 1% of the NPs in our corpus have more than 3 modifiers, and the longest has 6; see Table 7). So exhaustive search is practical for our problem; if we were to apply MSA to longer sequences, we would need to prune heavily.[3]

4 Evaluation

We trained and tested on the same corpus used by Mitchell (2009), including identical 10-fold cross-validation splits. The corpus consists of all NPs extracted from the Penn Treebank, the Brown corpus, and the Switchboard corpus (Marcus et al., 1999; Kucera and Francis, 1967; Godfrey et al., 1992). The corpus is heavily biased toward WSJ text (74%), with approximately 13% of the NPs from each of the other corpora.

We evaluated our system using several related but distinct metrics, and on both modifier pairs and full NPs.

We define:

$\mathbb{T}$ = The set of unique orderings found in the test corpus

$\mathbb{P}$ = The set of unique orderings predicted by the system

Type Precision ($|\mathbb{P} \cap \mathbb{T}|/|\mathbb{P}|$) measures the probability that a predicted ordering is 'reasonable' (where 'reasonable' is defined as orderings which are found in the test corpus).

[3] The same issue arises when evaluating candidate orderings; see Section 4.

	Token Accuracy	Type Precision	Type Recall	Type F-measure
Mitchell	N/A	**90.3**% (2.2)	67.2% (3.4)	77.1%
ML MSA	85.5% (1.0)	84.6% (1.1)	84.7% (1.1)	84.7%
Perceptron MSA	**88.9**% (0.7)	88.2% (0.8)	**88.1**% (0.8)	**88.2**%

Table 4: Results on the combined WSJ, Switchboard, and Brown corpus; averages and standard deviations over a 10-fold cross validation. Winning scores are in bold.

Type Recall ($|\mathbb{P} \cap \mathbb{T}|/|\mathbb{T}|$) measures the percentage of 'reasonable' orderings which the system recreates.

Note that these two metrics differ only in notation from those used by Mitchell (2009).

We also define a third metric, **Token Accuracy**, which measures accuracy on each individual ordering in the test corpus, rather than on *unique* orderings. This penalizes producing orderings which are legal, but uncommon. For example, if $\{a,b\}$ occurs eight times in the test corpus as $<a,b>$ and two times as $<b,a>$, we will be limited to a maximum accuracy of 80% (presuming our system correctly predicts the more common ordering). However, even though suggesting $<b,a>$ is not strictly incorrect, we generally prefer to reward a system that produces more common orderings, an attribute not emphasized by type-based metrics. Our test corpus does not contain many ambiguous pairings, so our theoretical maximum token accuracy is 99.8%.

We define:

$$o_{1..N} = \text{All modifier orderings in the test data}$$

$$pred(o_i) = \text{The predicted ordering for modifiers in } o_i$$

$$a_i = \begin{cases} 1 & \text{if } pred(o_i) = o_i, \\ 0 & \text{otherwise} \end{cases}$$

$$\textbf{Token Accuracy} = \sum_{i=0}^{N} \frac{a_i}{N}$$

4.1 Pairwise Ordering

Most earlier work has focused on ordering pairs of modifiers. The results in Table 4 are directly comparable to those found in Mitchell (2009). Mitchell's earlier approach does not generate a prediction when the system has insufficient evidence, and allows generation of multiple predictions given conflicting evidence. In theory, generating multiple predictions could improve recall, but in practice her system appears biased toward under-predicting, favoring precision. Our approach, in contrast, forces prediction of a single ordering for each test instance, occasionally costing some precision (in particular in cross-domain trials; see Table 5), but consistently balancing recall and precision.

Our measurement of Token Accuracy is comparable to the accuracy measure reported in Shaw and Hatzivassiloglou (1999) and Malouf (2000) (although we evaluate on a different corpus). Their approaches produce a single ordering for each test instance evaluated, so for each incorrectly ordered modifier pair, there is a corresponding modifier pair in the test data that was not predicted.

Shaw and Hatzivassiloglou found financial text particularly difficult to order, and reported that their performance dropped by 19% when they included nouns as well as adjectives. Malouf's system surpasses theirs, achieving an accuracy of 91.9%. However, his corpus was derived from the BNC — he did not attempt to order financial text — and he ordered only adjectives as modifiers. In contrast, our test corpus consists mainly of WSJ text, and we test on all forms of prenominal modifiers. We believe this to be a considerably more difficult task, so our peak performance of 88.9% would appear to be — at worst — quite competitive.

Table 5 presents an evaluation of cross-domain generalization, splitting the same corpus by genre — Brown, Switchboard, and WSJ. In each trial, we train on two genres and test on

	Training	Testing	Token	Type	Type	Type
	Corpora	Corpus	Accuracy	Precision	Recall	F-measure
Mitchell	Brown+WSJ	Swbd	N/A	**94.2**%	58.2%	72.0%
	Swbd+WSJ	Brown	N/A	**87.0**%	51.2%	64.5%
	Swbd+Brown	WSJ	N/A	**82.4**%	27.2%	40.9%
ML MSA	Brown+WSJ	Swbd	74.6%	74.7%	75.3%	75.0%
	Swbd+WSJ	Brown	75.3%	74.7%	74.9%	74.8%
	Swbd+Brown	WSJ	70.2%	71.6%	71.8%	71.7%
Perceptron MSA	Brown+WSJ	Swbd	**77.2**%	78.2%	**77.6**%	**77.9**%
	Swbd+WSJ	Brown	**76.4**%	76.7%	**76.4**%	**76.5**%
	Swbd+Brown	WSJ	**77.9**%	77.5%	**77.3**%	**77.4**%

Table 5: Cross-domain generalization.

	Token Accuracy	Token Precision	Token Recall	Token F-measure
Mitchell	N/A	**94.4%**	78.6% (1.2)	85.7%
ML MSA	76.9% (1.6)	76.5% (1.4)	76.5% (1.4)	76.50%
Perceptron MSA	**86.7**% (0.9)	86.7% (0.9)	**86.7**% (0.9)	**86.7**%

Table 6: Full NP ordering accuracies; averages and standard deviations over a 10-fold cross validation. To compare directly with Mitchell (2009), we report *token* precision and recall instead of type. Our system always proposes one and only one ordering, so token accuracy, precision, and recall are identical.

the third.[4] Our results mirror those in the previous trials — forcing a prediction costs some precision (vis-a-vis Mitchell's 2009 system), but our recall is dramatically higher, resulting in more balanced performance overall.

4.2 Full NP Ordering

We now extend our analysis to ordering entire NPs, a task we feel the MSA approach should be particularly suited to, since (unlike pairwise models) it can model positional probabilities over an entire NP. To our knowledge, the only previously reported work on this task is Mitchell's (2009). We train this model on the full NP instead of on modifier pairs; this makes little difference in pairwise accuracy, but improves full-NP ordering considerably.

As seen in Table 6, both MSA models perform quite well, the perceptron-trained MSA again outperforming the maximum likelihood model. However, we were somewhat disappointed in the performance on longer sequences. We expected the MSA to encode enough global information to perform accurate full sequence ordering, but found the accuracy drops off dramatically on NPs with more modifiers. In fact, the accuracy on longer sequences is worse than we would expect by simply extending a pairwise model. For instance, ordering three modifiers requires three pairwise decisions. We predict pairwise orderings with 88% accuracy, so we would expect no worse than $(.88)^3$, or 68% accuracy on such sequences. However, the pairwise accuracy declines on longer NPs, so it underperforms even that theoretical minimum. Sparse training data for longer NPs biases the model strongly toward short sequences and transitivity (which our model does not encode) may become important when ordering several modifiers.

Modifiers	Frequency	Token	Pairwise
		Accuracy	Accuracy
2	89.1%	89.7%	89.7%
3	10.0%	64.5%	84.4%
4	0.9%	37.2%	80.7%

Table 7: Descriminative model performance on NPs of various lengths, including pairwise measures.

[4] Note that the WSJ corpus is much larger than the other two, comprising approximately 84% of the total.

5 Ablation Tests

We performed limited ablation testing on the discriminative model, removing features individually and comparing token accuracy (see Table 8). We found that few of the features provided great benefit individually; the overall system performance remains dominated by the word. The word and stem features appear to capture essentially the same information; note that performance does not decline when the word or stem features are ablated, but drops drastically when both are omitted. Performance declines slightly more when ending features are ablated as well as words and stems, so it appears that — as expected — the information captured by ending features overlaps somewhat with lexical identity. The effects of individual features are all small and none are statistically significant.

Feature(s)	Gain/Loss
Word	0.0
Stem	0.0
Capitalization	-0.1
All-Caps	0.0
Numeric	-0.2
Initial-numeral	0.0
Length	-0.1
Hyphen	0.0
-al	0.0
-ble	-0.4
-ed	-0.4
-er	0.0
-est	-0.1
-ic	+0.1
-ing	0.0
-ive	-0.1
-ly	0.0
Word and stem	-22.9
Word, stem, and endings	-24.2

6 Summary and Future Directions

We adapted MSA approaches commonly used in computational biology to linguistic problems and presented two novel methods for training such alignments. We applied these techniques to the problem of ordering prenominal modifiers in noun phrases, and achieved performance competitive with — and in many cases, superior to — the best results previously reported.

In our current work, we have focused on relatively simple features, which should be adaptable to other languages without expensive resources or much linguistic insight. We are interested in exploring richer sources of features for ordering information. We found simple morphological features provided discriminative clues for otherwise ambiguous instances, and believe that richer morphological features might be helpful even in a language as morphologically impoverished as English. Boleda et al. (2005) achieved promising preliminary results using morphology for classifying adjectives in Catalan.

Further, we might be able to capture some of the semantic relationships noted by psychological analyses (Ziff, 1960; Martin, 1969) by labeling words which belong to known semantic classes (e.g., colors, size denominators, etc.). We intend to explore deriving such labels from resources such as WordNet or OntoNotes.

We also plan to continue exploration of MSA training methods. We see considerable room for refinement in generative MSA models; our maximum likelihood training provides a strong starting point for EM optimization, conditional likelihood, or gradient descent methods. We are also considering applying maximum entropy approaches to improving the discriminative model.

Finally (and perhaps most importantly), we expect that our model would benefit from additional training data, and plan to train on a larger, automatically-parsed corpus.

Even in its current form, our approach improves the state-of-the-art, and we believe MSA techniques can be a useful tool for ordering prenominal modifiers in NLP tasks.

Good Question! Statistical Ranking for Question Generation

Abstract

We address the challenge of automatically generating questions from reading materials for educational practice and assessment. Our approach is to overgenerate questions, then rank them. We use manually written rules to perform a sequence of general purpose syntactic transformations (e.g., subject-auxiliary inversion) to turn declarative sentences into questions. These questions are then ranked by a logistic regression model trained on a small, tailored dataset consisting of labeled output from our system. Experimental results show that ranking nearly doubles the percentage of questions rated as acceptable by annotators, from 27% of all questions to 52% of the top ranked 20% of questions.

1 Introduction

In this paper, we focus on question generation (QG) for the creation of educational materials for reading practice and assessment. Our goal is to generate fact-based questions about the content of a given article. The top-ranked questions could be filtered and revised by educators, or given directly to students for practice. Here we restrict our investigation to questions about factual information in texts.

We begin with a motivating example. Consider the following sentence from the Wikipedia article on the history of Los Angeles:[1] *During the Gold Rush years in northern California, Los Angeles became known as the "Queen of the Cow Counties" for its role in supplying beef and other foodstuffs to hungry miners in the north.*

Consider generating the following question from that sentence: *What did Los Angeles become known as the "Queen of the Cow Counties" for?*

We observe that the QG process can be viewed as a two-step process that essentially "factors" the problem into simpler components.[2] Rather than simultaneously trying to remove extraneous information and transform a declarative sentence into an interrogative one, we first transform the input sentence into a simpler sentence such as *Los Angeles become known as the "Queen of the Cow Counties" for its role in supplying beef and other foodstuffs to hungry miners in the north*, which we then can then transform into a more succinct question.

Question transformation involves complex long distance dependencies. For example, in the question about Los Angeles, the word *what* at the beginning of the sentence is a semantic argument of the verb phrase *known as* … at the end of the question. The characteristics of such phenomena are (arguably) difficult to learn from corpora, but they have been studied extensively in linguistics (Ross, 1967; Chomsky, 1973). We take a rule-based approach in order to leverage this linguistic knowledge.

However, since many phenomena pertaining to question generation are not so easily encoded with rules, we include statistical ranking as an integral component. Thus, we employ an overgenerate-and-rank approach, which has been applied successfully in areas such as generation (Walker et al., 2001; Langkilde and Knight, 1998) and syntactic parsing (Collins, 2000). Since large datasets of the appropriate domain, style, and form of questions are not available to train our ranking model, we learn to rank from a relatively small, tailored dataset of human-labeled output from our rule-based system.

The remainder of the paper is organized as fol-

lows. §2 clarifies connections to prior work and enumerates our contributions. §3 discusses particular terms and conventions we will employ. §4 discusses rule-based question transformation. §5 describes the data used to learn and to evaluate our question ranking model, and §6 then follows with details on the ranking approach itself. We then present and discuss results from an evaluation of ranked question output in §7 and conclude in §8.

2 Connections with Prior Work

The generation of questions by humans has long motivated theoretical work in linguistics (e.g., Ross, 1967), particularly work that portrays questions as transformations of canonical declarative sentences (Chomsky, 1973).

Questions have also been a major topic of study in computational linguistics, but primarily with the goal of *answering* questions (Dang et al., 2008). While much of the question answering research has focused on retrieval or extraction (e.g., Ravichandran and Hovy, 2001; Hovy et al., 2001), models of the transformation from answers to questions have also been developed (Echihabi and Marcu, 2003) with the goal of finding correct answers *given* a question (e.g., in a source-channel framework). Also, Harabagiu et al. (2005) present a system that automatically generates questions from texts to predict which user-generated questions the text might answer. In such work on question answering, question generation models are typically not evaluated for their intrinsic quality, but rather with respect to their utility as an intermediate step in the question answering process.

QG is very different from many natural language generation problems because the input is natural language rather than a formal representation (cf. Reiter and Dale, 1997). It is also different from some other tasks related to generation: unlike machine translation (e.g., Brown et al., 1990), the input and output for QG are in the same language, and their length ratio is often far from one to one; and unlike sentence compression (e.g., Knight and Marcu, 2000), QG may involve substantial changes to words and their ordering, beyond simple removal of words.

Some previous research has directly approached the topic of generating questions for educational purposes (Mitkov and Ha, 2003; Kunichika et al., 2004; Gates, 2008; Rus and Graessar, 2009; Rus and Lester, 2009), but to our knowledge, none has involved statistical models for choosing among output candidates. Mitkov et al. (2006) demonstrated that automatic generation and manual correction of questions can be more time-efficient than manual authoring alone. Much of the prior QG research has evaluated systems in specific domains (e.g., introductory linguistics, English as a Second Language), and thus we do not attempt empirical comparisons. Existing QG systems model their transformations from source text to questions with many complex rules for specific question types (e.g., a rule for creating a question *Who did the* `Subject Verb`*?* from a sentence with SVO word order and an object referring to a person), rather than with sets of general rules.

This paper's contributions are as follows:

- We apply statistical ranking to the task of *generating* natural language questions. In doing so, we show that question rankings are improved by considering features beyond surface characteristics such as sentence lengths.
- We model QG as a two-step process of first simplifying declarative input sentences and then transforming them into questions, the latter step being achieved by a sequence of general rules.
- We incorporate linguistic knowledge to explicitly model well-studied phenomena related to long distance dependencies in WH questions, such as noun phrase island constraints.
- We develop a QG evaluation methodology, including the use of broad-domain corpora.

3 Definitions and Conventions

The term "source sentence" refers to a sentence taken directly from the input document, from which a question will be generated (e.g., *Kenya is located in Africa.*). The term "answer phrase" refers to phrases in declarative sentences which may serve as targets for WH-movement, and therefore as possible answers to generated questions (e.g., *in Africa*). The term "question phrase" refers to the phrase containing the WH word that replaces an answer phrase (e.g., *Where* in *Where is Kenya located?*).

To represent the syntactic structure of sentences, we use simplified Penn Treebank-style phrase structure trees, including POS and category labels, as produced by the Stanford Parser (Klein and Manning, 2003). Noun phrase heads are selected using Collins' rules (Collins, 1999).

To implement the rules for transforming source sentences into questions, we use `Tregex`, a tree query language, and `Tsurgeon`, a tree manipulation language built on top of `Tregex` (Levy and Andrew, 2006). The `Tregex` language includes various relational operators based on the primitive relations of immediate dominance (denoted "<") and immediate precedence (denoted "."). `Tsurgeon` adds the ability to *modify* trees by relabeling, deleting, moving, and inserting nodes.

4 Rule-based Overgeneration

Many useful questions can be viewed as lexical, syntactic, or semantic transformations of the declarative sentences in a text. We describe how to model this process in two steps, as proposed in §1.[3]

4.1 Sentence Simplification

In the first step for transforming sentences into questions, each of the sentences from the source text is expanded into a set of derived declarative sentences (which also includes the original sentence) by altering lexical items, syntactic structure, and semantics. Many existing NLP transformations could potentially be exploited in this step, including sentence compression, paraphrase generation, or lexical semantics for word substitution.

In our implementation, a set of transformations derive a simpler form of the source sentence by removing phrase types such as leading conjunctions, sentence-level modifying phrases, and appositives. `Tregex` expressions identify the constituents to move, alter, or delete. Similar transformations have been utilized in previous work on headline generation (Dorr and Zajic, 2003) and summarization (Toutanova et al., 2007).

To enable questions about syntactically embedded content, our implementation also extracts a set of declarative sentences from any finite clauses, relative clauses, appositives, and participial phrases that appear in the source sentence. For example, it transforms the sentence *Selling snowballed because of waves of automatic stop-loss orders, which are triggered by computer when prices fall to certain levels* into *Automatic stop-loss orders are triggered by computer when prices fall to certain levels*, from which the next step will produce *What are triggered by computer when prices fall to certain levels?*.

4.2 Question Transformation

In the second step, the declarative sentences derived in step 1 are transformed into sets of questions by a sequence of well-defined syntactic and lexical transformations (subject-auxiliary inversion, WH-movement, etc.). It identifies the answer phrases which may be targets for WH-movement and converts them into question phrases.[4]

In the current implementation, answer phrases can be noun phrases or prepositional phrases, which enables *who*, *what*, *where*, *when*, and *how much* questions. The system could be extended to transform other types of phrases into other types of questions (e.g., *how*, *why*, and *what kind of*). It should be noted that the transformation from answer to question is achieved by applying a series of general-purpose rules. This would allow, for example, the addition of a rule to generate *why* questions that builds off of the existing rules for subject-auxiliary inversion, verb decomposition, etc. In contrast, previous QG approaches have employed separate rules for specific sentence types (e.g., Mitkov and Ha, 2003; Gates, 2008).

For each sentence, many questions may be produced: there are often multiple possible answer phrases, and multiple question phrases for each answer phrase. Hence many candidates may result from the transformations.

These rules encode a substantial amount of linguistic knowledge about the long distance dependencies prevalent in questions, which would be challenging to learn from existing corpora of questions and answers consisting typically of only thousands of examples (e.g., Voorhees, 2003).

Specifically, the following sequence of transfor-

[3] See Heilman and Smith (2009) for details on the rule-based component.

[4] We leave the generation of correct answers and distractors to future work.

Figure 1: An illustration of the sequence of steps for generating questions. For clarity, trees are not shown for all steps. Also, while many questions may be generated from a single source sentence, only one path is shown.

mations is performed, as illustrated in Figure 1: mark phrases that cannot be answer phrases due to constraints on WH movement (§4.2.1, not in figure); select an answer phrase, remove it, and generate possible question phrases for it (§4.2.2); decompose the main verb; invert the subject and auxiliary verb; and insert one of the possible question phrases.

Some of these steps do not apply in all cases. For example, no answer phrases are removed when generating yes-no questions.

4.2.1 Marking Unmovable Phrases

In English, various constraints determine whether phrases can be involved in WH-movement and other phenomena involving long distance dependencies. In a seminal dissertation, Ross (1967) described many of these phenomena. Goldberg (2006) provides a concise summary of them.

For example, noun phrases are "islands" to movement, meaning that constituents dominated by a noun phrase typically cannot undergo WH-movement. Thus, from *John liked the book that I gave him*, we generate *What did John like?* but not **Who did John like the book that gave him?*.

We operationalize this linguistic knowledge to appropriately restrict the set of questions produced. Eight `Tregex` expressions mark phrases that cannot be answer phrases due to WH-movement constraints. For example, the following expression encodes the noun phrase island constraint described above, where `unmv` indicates unmovable noun phrases: `NP << NP=unmv`.

4.2.2 Generating Possible Question Phrases

After marking unmovable phrases, we iteratively remove each possible answer phrase and generate possible question phrases from it. The system annotates the source sentence with a set of entity types taken from the BBN Identifinder Text Suite (Bikel et al., 1999) and then uses these entity labels along with the syntactic structure of a given answer phrase to generate zero or more question phrases, each of which is used to generate a final question. (This step is skipped for yes-no questions.)

5 Rating Questions for Evaluation and Learning to Rank

Since different sentences from the input text, as well as different transformations of those sentences, may be more or less likely to lead to high-quality questions, each question is scored according to features of the source sentence, the input sentence, the question, and the transformations used in its generation. The scores are used to rank the questions. This is an example of an "overgenerate-and-rank" strategy (Walker et al., 2001; Langkilde and Knight, 1998).

This section describes the acquisition of a set of rated questions produced by the steps described above. Separate portions of these labeled data will be used to develop a discriminative question ranker (§6), and to evaluate ranked lists of questions (§7).

Fifteen native English-speaking university students rated a set of questions produced from steps 1 and 2, indicating whether each question exhibited any of the deficiencies listed in Table 1.[5] If a question exhibited no deficiencies, raters were asked to label it "acceptable." Annotators were asked to read the text of a newswire or encyclopedia article (§5.1 describes the corpora used), and then rate approximately 100 questions generated from that text. They were asked to consider each question independently, such that similar questions about the same information would receive similar ratings.

For a predefined training set, each question was rated by a single annotator (not the same for each question), leading to a large number of diverse examples. For the test set, each question was rated by three people (again, not the same for each question) to provide a more reliable gold standard. To assign final labels to the test data, a question was labeled as acceptable only if a majority of the three raters rated it as acceptable (i.e., without deficiencies).[6]

An inter-rater agreement of Fleiss's $\kappa = 0.42$ was computed from the test set's acceptability ratings. This value corresponds to "moderate agreement" (Landis and Koch, 1977) and is somewhat lower than for other rating schemes.[7]

5.1 Corpora

The training and test datasets consisted of 2,807 and 428 questions, respectively. The questions were generated from three corpora.

The first corpus was a random sample from the featured articles in the English Wikipedia[8] with between 250 and 2,000 word tokens. This English Wikipedia corpus provides expository texts written at an adult reading level from a variety of domains, which roughly approximates the prose that a secondary or post-secondary student would encounter. By choosing from the featured articles, we intended to select well-edited articles on topics of general interest. The training set included 1,328 questions about 12 articles, and the test set included 120 questions about 2 articles from this corpus.

The second corpus was a random sample from the articles in the Simple English Wikipedia of similar length. This corpus provides similar text but at a reading level corresponding to elementary education or intermediate second language learning.[9] The training set included 1,195 questions about 16 articles, and the test set included 118 questions about 2 articles from this corpus.

The third corpus was Section 23 of the *Wall Street Journal* data in the Penn Treebank (Marcus et al., 1993).[10] The training set included 284 questions about 8 articles, and the test set included 190 questions about 2 articles from this corpus.

6 Ranking

We use a discriminative ranker to rank questions, similar to the approach described by Collins (2000) for ranking syntactic parses. Questions are ranked by the predictions of a logistic regression model of question acceptability. Given the question q and source text t, the model defines a binomial distribution $p(R \mid q, t)$, with binary random variable R ranging over a ("acceptable") and u ("unacceptable").

We estimate the parameters by optimizing the regularized log-likelihood of the training data (cf. §5.1) with a variant of Newton's method (le Cessie and

[5] The ratings from one person were excluded due to an extremely high rate of accepting questions as error-free and other irregularities.

[6] The percentages in Table 1 do not add up to 100% for two reasons: first, questions are labeled acceptable in the test set only if the majority of raters labeled them as having no deficiencies, rather than the less strict criterion of requiring no deficiencies to be identified by a majority of raters; second, the categories are not mutually exclusive.

[7] E.g., Dolan and Brockett (2005) and Glickman et al. (2005) report κ values around 0.6 for paraphrase identification and textual entailment, respectively.

[8] The English and Simple English Wikipedia data were downloaded on December 16, 2008 from `http://en.wikipedia.org` and `http://simple.wikipedia.org`, respectively.

[9] The subject matter of the articles in the two Wikipedia corpora was not matched.

[10] In separate experiments with the Penn Treebank, gold-standard parses led to an absolute increase of 15% in the percentage of acceptable questions (Heilman and Smith, 2009).

Question Deficiency	Description	%
Ungrammatical	The question is not a valid English sentence. (e.g., *In what were nests excavated exposed to the sun?* from ... *eggs are usually laid ..., in nests excavated in pockets of earth exposed to the sun.*. This error results from the incorrect attachment by the parser of *exposed to the sun* to the verb phrase headed by *excavated*)	14.0
Does not make sense	The question is grammatical but indecipherable. (e.g., *Who was the investment?*)	20.6
Vague	The question is too vague to know exactly what it is asking about, even after reading the article (e.g., *What do modern cities also have?* from ..., *but modern cities also have many problems*).	19.6
Obvious answer	The correct answer would be obvious even to someone who has not read the article (e.g., a question where the answer is obviously the subject of the article).	0.9
Missing answer	The answer to the question is not in the article.	1.4
Wrong WH word	The question would be acceptable if the WH phrase were different (e.g., a *what* question with a person's name as the answer).	4.9
Formatting	There are minor formatting errors (e.g., with respect to capitalization, punctuation).	8.9
Other	The question was unacceptable for other reasons.	1.2
None	The question exhibits none of the above deficiencies and is thus acceptable.	27.3

Table 1: Deficiencies a question may exhibit, and the percentages of test set questions labeled with them.

van Houwelingen, 1997). In our experiments, the regularization constant was selected through cross-validation on the training data.

The features used by the ranker can be organized into several groups described in this section. This feature set was developed by an analysis of questions generated from the training set. The numbers of distinct features for each type are denoted in parentheses, with the second number, after the addition symbol, indicating the number of histogram features (explained below) for that type.

Length Features (3 + 24) The set includes integer features for the numbers of tokens in the question, the source sentence, and the answer phrase from which the WH phrase was generated. These numbers of tokens will also be used for computing the histogram features discussed below.

WH Words (9 + 0) The set includes boolean features for the presence of each possible WH word in the question.

Negation (1 + 0) This is a boolean feature for the presence of *not*, *never*, or *no* in the question.

N-Gram Language Model Features (6 + 0) The set includes real valued features for the log likelihoods and length-normalized log likelihoods of the question, the source sentence, and the answer phrase. Separate likelihood features are included for unigram and trigram language models. These language models were estimated from the written portion of the American National Corpus Second Release (Ide and Suderman, 2004), which consists of approximately 20 million tokens, using Kneser and Ney (1995) smoothing.

Grammatical Features (23 + 95) The set includes integer features for the numbers of proper nouns, pronouns, adjectives, adverbs, conjunctions, numbers, noun phrases, prepositional phrases, and subordinate clauses in the phrase structure parse trees for the question and answer phrase. It also includes one integer feature for the number of modifying phrases at the start of the question (e.g., as in *At the end of the Civil War, who led the Union Army?*); three boolean features for whether the main verb is in past, present, or future tense; and one boolean feature for whether the main verb is a form of *be*.

Transformations (8 + 0) The set includes binary features for the possible syntactic transformations (e.g., removal of appositives and parentheticals, choosing the subject of source sentence as the answer phrase).

Vagueness (3 + 15) The set includes integer features for the numbers of noun phrases in the question, source sentence, and answer phrase that are potentially vague. We define this set to include pronouns as well as common nouns that are not specified by a subordinate clause, prepositional phrase, or possessive. In the training data, we observed many vague questions resulting from such noun phrases (e.g., *What is the bridge named for?*).

Histograms In addition to the integer features for lengths, counts of grammatical types, and counts of vague noun phrases, the set includes binary "histogram" features for each length or count. These features indicate whether a count or length exceeds various thresholds: 0, 1, 2, 3, and 4 for counts; 0, 4, 8, 12, 16, 20, 24, and 28 for lengths. We aim to account for potentially non-linear relationships between question quality and these values (e.g., most good questions are neither very long nor very short).

7 Evaluation and Discussion

This section describes the results of experiments to evaluate the quality of generated questions before and after ranking. Results are aggregated across the 3 corpora (§5.1). The evaluation metric we employ is the percentage of test set questions labeled as acceptable. For rankings, our metric is the percentage of the top $N\%$ labeled as acceptable, for various N.

7.1 Results for Unranked Questions

First, we present results for the *unranked* questions produced by the rule-based overgenerator. As shown in Table 1, 27.3% of test set questions were labeled acceptable (i.e., having no deficiencies) by a majority of raters.[11]

The most frequent deficiencies were ungrammaticality (14.0%), vagueness (19.6%), and semantic errors labeled with the "Does not make sense" category (20.6%). Formatting errors (8.9%) were due to both straightforward issues with pre-processing and more challenging issues such as failing to identifying named entities (e.g., *Who was nixon's second vice president?*).

While Table 1 provides data on how often bad questions were generated, a measure of how often good questions were not generated would require knowing the number of *possible* valid questions. Instead, we provide a measure of *productivity*: the system produced an average of 6.0 acceptable questions per 250 words (i.e., the approximate average number of words on a single page in a printed book).

7.2 Configurations and Baselines

For ranking experiments, we present results for the following configurations of features:

All This configuration includes the entire set of features described in §6.

Surface Features This configuration includes only features that can be computed from the surface form of the question, source sentence, and answer phrase—that is, without hidden linguistic structures such as parts of speech or syntactic structures. Specifically, it includes features for lengths, length histograms, WH words, negation, and language model likelihoods.

Question Only This configuration includes all features of questions, but no features involving the source sentence or answer phrase (e.g., it does not include source sentence part of speech counts). It does not include transformation features.

We also present two baselines for comparison:

Random The expectation of the performance if questions were ranked randomly.

Oracle The expected performance if all questions that were labeled acceptable were ranked higher than all questions that were labeled unacceptable.

7.3 Ranking Results

Figure 2 shows that the percentage of questions rated as acceptable generally increases as the set of questions is restricted from the full 428 questions in the test set to only the top ranked questions. While 27.3% of all test set questions were acceptable, 52.3% of the top 20% of ranked questions were acceptable. Thus, the quality of the top fifth was nearly doubled by ranking with all the features.

Ranking with surface features also improved question quality, but to a lesser extent. Thus, unobserved linguistic features such as parts of speech and syntax appear to add value for ranking questions.[12]

The ranker seems to have focused on the "Does not make sense" and "Vague" categories. The percentage of nonsensical questions dropped from 20.6% to 4.7%, and vagueness dropped from 19.6%

[11] 12.1% of test set questions were unanimously acceptable.

[12] Ranking with all features was statistically significantly better ($p < .05$) in terms of the percentage of acceptable questions in the top ranked 20% than ranking with the "question only" or "surface" configurations, or the random baseline, as verified by computing 95% confidence intervals with the BC$_a$ Bootstrap (Efron and Tibshirani, 1993).

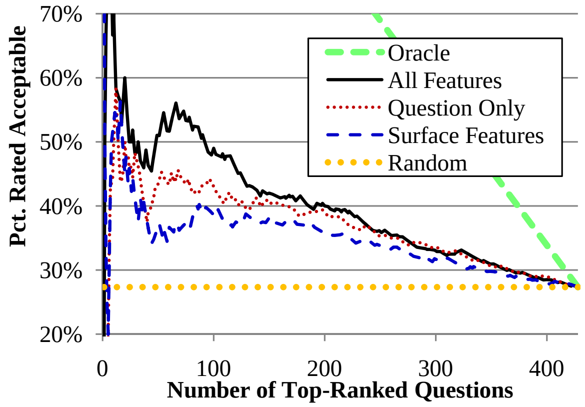

Figure 2: A graph of the percentage of acceptable questions in the top-N questions in the test set, using various rankings, for N varying from 0 to the size of the test set. The percentages become increasingly unstable when restricted to very few questions (e.g., < 50).

Features	#	Top 20%	Top 40%
All	187	52.3	40.8
All – Length	160	52.3	42.1
All – WH	178	50.6	39.8
All – Negation	186	51.7	39.3
All – Lang. Model	181	51.2	39.9
All – Grammatical	69	43.2	38.7
All – Transforms	179	46.5	39.0
All – Vagueness	169	48.3	41.5
All – Histograms	53	49.4	39.8
Surface	43	39.5	37.6
Question Only	91	41.9	39.5
Random	-	27.3	27.3
Oracle	-	100.0	87.3

Table 2: The total numbers of features (#) and the percentages of the top 20% and 40% of ranked test set questions labeled acceptable, for rankers built from variations of the complete set of features ("All"). E.g., "All – WH" is the set of all features *except* WH word features.

to 7.0%, while ungrammaticality dropped from 14.0% to 10.5%, and the other, less prevalent, categories changed very little.[13]

7.4 Ablation Study

Ablation experiments were also conducted to study the effects of removing each of the different types of features. Table 2 presents the percentages of acceptable test set questions in the top 20% and top 40% when they are scored by rankers trained with various feature sets that are defined by removing various feature types from the set of all possible features.

Grammatical features appear to be the most important: removing them from the feature set resulted in a 9.0% absolute drop in acceptability in the top 20% of questions, from 52.3% to 43.3%.

Some of the features did not appear to be particularly helpful, notably the N-gram language model features. We speculate that they might improve results when used with a larger, less noisy training set.

Performance did not drop precipitously upon the removal of any particular feature type, indicating a high amount of shared variance among the features. However, removing several types of features at once led to somewhat larger drops in performance. For example, using only surface features led to a 12.8% drop in acceptability in the top 20%, and using only features of questions led to a 10.4% drop.

8 Conclusion

By ranking the output of rule-based natural language generation system, existing knowledge about WH-movement from linguistics can be leveraged to model the complex transformations and long distance dependencies present in questions. Also, in this overgenerate-and-rank framework, a statistical ranker trained from a small set of annotated questions can capture trends related to question quality that are not easily encoded with rules. In our experiments, we found that ranking approximately doubled the acceptability of the top-ranked questions generated by our approach.

Acknowledgments

We acknowledge partial support from the Institute of Education Sciences, U.S. Department of Education, through Grant R305B040063 to Carnegie Mellon University; and from the National Science Foundation through a Graduate Research Fellowship for the first author and grant IIS-0915187 to the second author. We thank the anonymous reviewers for their comments.

[13] We speculate that improvements in syntactic parsing and entity recognition would reduce the proportion of ungrammatical questions and incorrect WH words, respectively.

Abstract

Open-class semantic lexicon induction is of great interest for current knowledge harvesting algorithms. We propose a general framework that uses patterns in bootstrapping fashion to learn open-class semantic lexicons for different kinds of relations. These patterns require seeds. To estimate the *goodness* (the potential yield) of new seeds, we introduce a regression model that considers the connectivity behavior of the seed during bootstrapping. The generalized regression model is evaluated on six different kinds of relations with over 10000 different seeds for English and Spanish patterns. Our approach reaches robust performance of 90% correlation coefficient with 15% error rate for any of the patterns when predicting the *goodness* of seeds.

1 Introduction: What is a Good Seed?

The automated construction of semantically typed lexicons (terms classified into their appropriate semantic class) from unstructured text is of great importance for various kinds of information extraction (Grishman and Sundheim, 1996), question answering (Moldovan et al., 1999), and ontology population (Suchanek et al., 2007). Maintaining large semantic lexicons is a time-consuming and tedious task, because open classes (such as: all singers, all types of insects) are hard to cover completely, and even closed classes (such as: all countries, all large software companies) change over time. Since it is practically impossible for a human to collect such knowledge adequately, many supervised, unsupervised, and semi-supervised techniques have been developed.

All these techniques employ some sort of context to specify the appearance in text of the desired information. This approach is based on the general intuition, dating back at least to the distributional similarity idea of (Harris, 1954), that certain contexts are specific enough to constrain terms or expressions within them to be specific classes or types. Often, the context is a string of words with an empty slot for the desired term(s); sometimes, it is a regular expression-like pattern that includes word classes (syntactic or semantic); sometimes, it is a more abstract set of features, including orthographic features like capitalization, words, syntactic relations, semantic types, and other characteristics, which is the more complete version of the distributional similarity approach.

In early information extraction work, these contexts were constructed manually, and resembled regular expressions (Appelt et al., 1995). More recently, researchers have focused on learning them automatically. Since unsupervised algorithms require large training data and may or may not produce the types and granularities of the semantic class desired by the user, and supervised algorithms may require a lot of manual oversight, semi-supervised algorithms have become more popular. They require only a couple of seeds (examples filling the desired semantic context) to enable the learning mechanism to learn patterns that extract from unlabeled texts additional instances of the same class (Riloff and Jones, 1999; Etzioni et al., 2005; Pasca, 2004).

Sometimes, the pattern(s) learned are satisfactory

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 618–626,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

enough to need no further elaboration. They are applied to harvest as many additional terms of the desired type as possible (for example, the instance-learning pattern ‘*<type> such as ?*’ introduced in (Hearst, 1992)). More often, the method is applied recursively: once some pattern(s) have been learned, they are used to find additional terms, which are then used as new seeds in the patterns to search for additional new patterns, etc., until no further patterns are found. At that point, the satisfactory patterns are selected and large-scale harvesting proceeds as usual. In an interesting variation of this method, (Kozareva et al., 2008) describe the ‘doubly-anchored pattern’ (DAP) that includes a seed term in conjunction with the open slot for the desired terms to be learned, making the pattern itself recursive by allowing learned terms to replace the initial seed terms directly: ‘*<type> such as <seed> and ?*’.

Context-based information harvesting is well understood and has been the focus of extensive research. The core unsolved problem is the selection of seeds. In current knowledge harvesting algorithms, seeds are chosen either at random (Davidov et al., 2007; Kozareva et al., 2008), by picking the top N most frequent terms of the desired class (Riloff and Jones, 1999; Igo and Riloff, 2009), or by asking experts (Pantel et al., 2009). None of these methods is quite satisfactory. (Etzioni et al., 2005) report on the impact of seed set noise on the final performance of semantic class learning, and Pantel et al. observe a tremendous variation in the entity set expansion depending on the initial seed set composition. These studies show that the selection of ‘good’ seeds is very important. Recently, (Vyas et al., 2009) proposed an automatic system for improving the seeds generated by editors (Pantel et al., 2009). The results show 34% improvement in final performance using the appropriate seed set. However, using editors to select seeds or to guide their seed selection process is expensive and therefore not always possible. Because of this, we address in this paper two questions: “*What is a good seed?*” and “*How can the goodness of seeds be automatically measured without human intervention?*”.

The contributions of this paper are as follows:

- First, we use recursive patterns to automatically learn seeds for open-class semantic lexicons.
- Second, we define what the ‘goodness’ of a seed term is. Then we introduce a regression model of seed quality measurement that, after a certain amount of training, automatically estimates the goodness of new seeds with above 90% accuracy for bootstrapping with the given relation.
- Next, importantly, we discover that training a regression model on certain relations enables one to predict the goodness of a seed even for other relations that have never been seen before, with an accuracy rate of over 80%.
- We conduct experiments with six kinds of relations and more than 10000 automatically harvested seed examples in both English and Spanish.

The rest of the paper is organized as follows. In the next section, we review related work. Section 3 describes the recursive pattern bootstrapping (Kozareva et al., 2008). Section 4 presents our seed quality measurement regression model. Section 5 discusses experiments and results. Finally, we conclude in Section 6.

2 Related Work

Seeds are used in automatic pattern extraction from text corpora (Riloff and Jones, 1999) and from the Web (Banko, 2009). Seeds are used to harvest instances (Pasca, 2004; Etzioni et al., 2005; Kozareva et al., 2008) or attributes of a given class (Paşca and Van Durme, 2008), or to learn concept-specific relations (Davidov et al., 2007), or to expand already existing entity sets (Pantel et al., 2009). As mentioned above, (Etzioni et al., 2005) report that seed set composition affects the correctness of the harvested instances, and (Pantel et al., 2009) observe an increment of 42% precision and 39% recall between the best and worst performing seed sets for the task of entity set expansion.

Because of the large diversity of the usage of seeds, there has been no general agreement regarding exactly how many seeds are necessary for a given task. According to (Pantel et al., 2009) 10 to 20 seeds are a sufficient starting set in a distributional similarity model to discover as many new correct instances as may ever be found. This observation differs from the claim of (Paşca and Van Durme, 2008) that 1 or 2 instances are sufficient to discover thousands of instance attributes. For some pattern-based algorithms one to two seeds are sufficient (Davidov et al., 2007; Kozareva et al., 2008), some require ten seeds (Riloff and Jones, 1999; Igo and Riloff, 2009), and others use a variation of 1, 5, 10 to 25 seeds (Talukdar et al., 2008).

As mentioned, seed selection is not yet well understood. Seeds may be chosen at random (Davidov et al., 2007; Kozareva et al., 2008), by picking the most frequent terms of the desired class (Riloff and Jones, 1999; Igo and Riloff, 2009), or by asking humans (Pantel et al., 2009). The intuitions for seed selection that experts develop over time seem to prefer instances that are neither ambiguous nor too frequent, but that at the same time are prolific and quickly lead to the discovery of a diverse set of instances. These criteria are vague and do not always lead to the discovery of good seeds. For some approaches, infrequent and ambiguous seeds are acceptable while for others they lead to deterioration in performance. For instance, the DAP (Kozareva et al., 2008) performance is not affected by the ambiguity of the seed, because the class and the seed in the pattern mutually disambiguate each other, while for the distributional similarity model of (Pantel et al., 2009), starting with an ambiguous seed leads to 'leakage' and the harvesting of non-true class instances. (Kozareva et al., 2008) show that for the closed class *country*, both high-frequency seeds like *USA* and low-frequency seeds like *Burkina Faso* can equally well yield all remaining instances. An open question to which no-one provides an answer is whether and which high/low frequency seeds can yield all instances of large, open classes like people or singers.

3 Bootstrapping Recursive Patterns

There are many algorithms for harvesting information from the Web. The main objective of our work is not the creation of a new algorithm, but rather determining the effect of seed selection on the general class of recursive bootstrapping harvesting algorithms for the acquisition of semantic lexicons for open class relations. For our experiments, since it is time-consuming and difficult for humans to provide large sets of seeds to start the bootstrapping process, we employ the recursive DAP mechanism introduced by (Kozareva et al., 2008) that produces seeds on its own.

The algorithm starts with a *seed* of type *class* which is fed into the doubly-anchored pattern '*<class> such as <seed> and* *' and learns in the * position new instances of type *class*. The newly learned instances are then systematically placed into the position of the *seed* in the DAP pattern, and the harvesting process is repeated until no new instances are found. The general framework is as follows:

1. Given:
   a language L={English, Spanish}
   a pattern P_i={e.g., [verb prep, noun, verb]}
   a seed $seed$ for P_i
2. Build a query in DAP-like fashion for P_i using template T_i of the type 'class such as $seed$ and *', '* and $seed$ verb prep', '* and $seed$ noun', '* and $seed$ verb'
3. submit T_i to Yahoo! or another search engine
4. extract instances occupying the * position
5. take instances from 4. and go to 2.
6. repeat steps 2–5 until no new instances are found

At the end of bootstrapping, the harvested instances can be considered to be seeds with which the bootstrapping procedure could have been initiated. We can now compare any of them to study their relative 'goodness' as bootstrapping seeds.

4 Seed Quality Measurement

4.1 Problem Formulation

We define our task as:

Task Definition: Given a seed and a pattern in a language (say English or Spanish), (1) use the bootstrapping procedure to learn instances from the Web; (2) build a predictive model to estimate the 'goodness' of seeds (whether generated by a human or learned) .

Given a desired semantic class, a recursive harvesting pattern expressing its context, and a seed term for use in this pattern, we define the 'goodness' of the seed as consisting of two measures:

- the *yield*: the total number of instances learned, not counting duplicates, until the bootstrapping procedure has run to exhaustion;
- the *distance*: the number of iterations required by the process to reach exhaustion.

Our approach is to build a model of the behavior of many seeds for the given pattern. Any new seed can then be compared against this model, once its basic characteristics have been determined, and its yield and distance estimates produced. In order to determine the characteristics of the new seed, it first has to be employed in the pattern for a small number of iterations. The next subsection describes the regression model we employ in our approach.

4.2 Regression Model

Given a seed s, we seek to predict the yield g of s as defined above. We do this via a parametrized function f:$\hat{g} = f(s; w)$, where $w \in R^d$ are the weights. Our approach is to learn w from a collection of N training examples $\{< s_i, g_i >\}_{i=1}^N$, where each s_i is a seed and each $g_i \in R$.

Support vector regression (Drucker et al., 1996) is a well-known method for training a regression model by solving the following optimization problem:

$$\min_{w \in R^s} \frac{1}{2}||w||^2 + \frac{C}{N}\sum_{i=1}^{N} \underbrace{\max(0, |g_i - f(s_i; w)| - \epsilon)}_{\epsilon\text{-insensitive loss function}}$$

where C is a regularization constant and ϵ controls the training error. The training algorithm finds weights w that define a function f minimizing the empirical risk.

Let h be a function from seeds into some vector-space representation $\subseteq R^d$, then the function f takes the form: $f(s; w) = h(s)^T w = \sum_{i=1}^N \alpha_i K(s, s_i)$, where f is re-parameterized in terms of a polynomial kernel function K with dual weights α_i. K measures the similarity between two seeds. Full details of the regression model and its implementation are beyond the scope of this paper; for more details see (Schölkopf and Smola, 2001; Smola et al., 2003). In our experimental study, we use the freely available implementation of SVM in Weka (Witten and Frank, 2005).

To evaluate the quality of our prediction model, we compare the actual yield of a seed with the predicted value obtained, and compute the correlation coefficient and the relative absolute error.

5 Experiments and Results

5.1 Data Collection

We conducted an exhaustive evaluation study with the open semantic classes *people* and *city*, initiated with the seeds *John* and *London*. For each class, we submitted the DAP patterns as web queries to Yahoo!Boss and retrieved the top 1000 web snippets for each query, keeping only unique instances. In total, we collected 1.5GB of snippets for people and 1.9GB of snippets for cities. The algorithm ran until complete exhaustion, requiring 19 iterations for people and 12 for cities. The total number of unique harvested instances was 3798 for people and 5090 for cities. We used all instances as seeds and instantiated for each seed the bootstrapping process from the very beginning. This resulted in 3798 and 5090 separate bootstrapping runs for people and cities respectively. For each seed, we recorded the total number of instances learned at the end of bootstrapping, the number of iterations, and the number of unique instances extracted on each iteration. After the harvesting part terminated, we analyzed the connectivity / bootstrapping behavior of the seeds, and produced the regression model.

5.2 Seed Characteristics

For many knowledge harvesting algorithms, the selection of a non-ambiguous seeds is of great importance. In the DAP bootstrapping framework, the ambiguity of the seed is eliminated as the *class* and the *seed* mutually disambiguate each other. Of great importance to the bootstrapping algorithm is the selection of a seed that can yield a large number of instances and can keep the bootstrapping process energized.

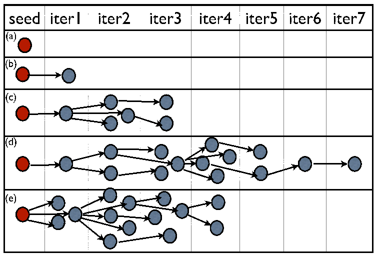

Figure 1: Seed Connectivity

Figure 1 shows the different kinds of seeds we found on analyzing the results of the bootstrapping process. Based on the yield learned on each iteration, we identify four major kinds of seeds: **hermit**, **one-step**, **mid**, and **high** connectors. In the figure, seed (a) is a hermit because it does not discover other instances. Seed (b) is a one-step connector as it discovers instances on the first iteration but then becomes inactive. Seeds (d) and (e) are high connectors because they find a rich population of instances. Seed (c) is a mid connector because it has lower yield than (d) and (e), but higher than (a) and (b).

Table 1 shows the results of classifying the 3798 people and 5090 city seeds into the four kinds of seed. The majority of the seeds for both patterns are hermits, from 23 to 41% are high connectors, and the rest are one-step and mid connectors. For each kind of seed, we also show three examples.

people such as X and *		examples
#hermit	2271 (60%)	Leila, Anne Boleyn, Sophocles
#one-step	329 (9%)	Helene, Frida Kahlo, Cornelius
#mid	315 (8%)	Brent, Ferdinand, Olivia
#high	883 (23%)	Diana, Donald Trump, Christopher

cities such as X and *		examples
#hermit	2393 (47%)	Belfast, Najafabad, El Mirador
#one-step	406 (8%)	Durnstein, Wexford, Al-Qaim
#mid	207 (4%)	Bialystok, Gori, New Albany
#high	2084 (41%)	Vienna, Chicago, Marrakesh

Table 1: Connectivity-based Seed Classification.

This study shows that humans are very likely to choose non-productive seeds for bootstrapping: it is difficult for a human to know a priori that a name like Diana will be more productive than Leila, Helene, or Olivia.

Another interesting characteristic of a seed is the speed of learning. Some seeds, such as (e), extract large quantity of instances from the very beginning, resulting in fewer bootstrapping iterations, while others, such as (d), spike much later, resulting in more. In our analysis, we found that some high connector seeds of the people pattern can learn the whole population in 12 iterations, while others require from 15 to 20 iterations. Figure 2 shows the speed of learning of ten high connector seeds for the *people* pattern. The y axis shows the number of unique instances harvested on each iteration. Intuitively, a good seed is the one that produces a large *yield* of instances in short *distance*. Thus the 'goodness' of seed (e) is better than that of seed (d).

As shown in Figure 2, for each seed, we observe a single hump that corresponds to the point in which a seed generates the maximum number of instances. The peak occurs on different iterations because it is dependent both on the yield learned with each iteration and the total distance, for each seed. The occurrence of a single hump reveals regularity in the connectivity behavior of seeds, and is discussed in the Conclusion. We model this behavior as features in our regression model and use it to measure the quality of new seeds. The next subsection explains the features of the regression model and the experimental results obtained.

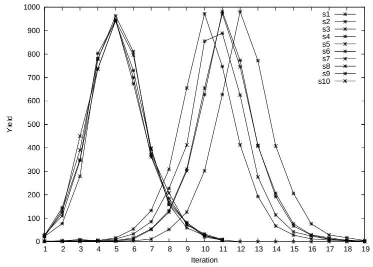

Figure 2: Seed Learning Speed

5.3 Predicting the Goodness of Seeds

Building a pattern specific model: For each pattern, we build N different regression models, where N corresponds to the total number of bootstrapping iterations of the pattern. For regression model R_i, we use the yield of a seed from iterations 1 to i as features. This information is used to model the activity of the seed in the bootstrapping process and later on to predict the extraction power of new seeds. For example, in Figure 1 on the first iteration seeds (b), (c), and (d) have the same low connectivity compared to seed (e). As bootstrapping progresses, seed (d) reaches productive neighbors that discover more instances, while seeds (b) and (c) become inactive. This example shows that the yield in the initial stage of bootstrapping is not sufficient to accurately predict the quality of the seeds. Since we do not know exactly how many iterations are necessary to accurately determine the 'goodness' of seeds, we model the yield learned on each iteration by each seed and subsequently include this information in the regression models.

The yield of a seed s_k at iteration i is computed as $yield(s_k)_i = \sum_{m=1}^{n}(s_m)$, where n is the total number of unique instances s_m harvested on iteration i. $Yield(s_k)_i$ is high when s_k discovers a large number of instances (new seeds), and small otherwise. For hermit seeds, $yield$=0 at any iteration, because the seeds are totally isolated and do not discover other instances (seeds). For example, when building the second regression model R_2 using seeds (d) and (e) from Figure 1, the feature values corresponding to each seed in R_2 are: $yield(s_d)_1$=1 and $yield(s_d)_2$=2 for seed (d), and $yield(s_e)_1$=3 and $yield(s_e)_2$=5 for seed (e).

Results: Figure 3 shows the correlation coefficients (cc) and the relative absolute errors of each regression model R_i for the *people* and *city* patterns. The results are computed over ten-fold cross validation of the 3798 people and 5090 city seeds. The x axis shows the regression model R_i,. The y axis in the two upper graphs shows the correlation coefficient of the predicted and the actual total yield of the seeds using R_i, and in the two lower graphs, the y axis shows the error rate of each R_i.

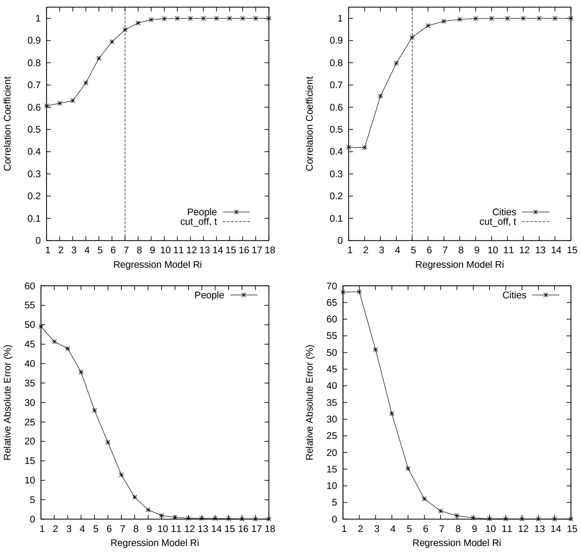

Figure 3: Regression for People and City.

We consider as a baseline model the regression R_1 which uses only the yield of the seeds on first iteration. The prediction of R_1 has cc=0.6 with 50% error for people and cc=0.4 with 70% error for cities. These results confirm our previous observation that the quality of the seeds cannot be accurately measured in the very beginning of bootstrapping. However, by the ninth iteration, the regression models for people and cities reach cc=1.0 with 5% error rate. To make such an accurate prediction, the model uses around one half of all bootstrapping iterations—generally, just past the hump in Figure 2, once the yield starts dropping.

Often in real applications or when under limited resources (e.g., a fixed amount of Web queries per day), running half the bootstrapping iterations is not feasible. This problem can be resolved by employing different stopping criteria, at the cost of lower cc and greater error. For example, one cut-off point can be the (averaged) iteration number of the hump for the given pattern. For people, the average hump occurs at the seventh iteration, and for the city at the fifth iteration. At this point, both patterns have a cc=0.9 with 15% error rate. An alternative stopping point can be the fourth iteration, where cc=0.7–0.8 with 35% error.

Overall, our study shows that it is possible to model the behavior of seeds and use it to accurately predict the 'goodness' of previously unseen seeds. The results obtained for both *people* and *city* patterns are very promising. However, a disadvantage of this regression is that it requires training over the whole extent of the given pattern. Also, each regression model is specific to the particular pattern it is trained over. Next, we propose a generalized regression model which surmounts the problem of training pattern-specific regression models.

5.4 Generalized Model for Goodness of Seeds

We built a generalized regression model (RG) combining evidence from the people and city patterns. We generated the features of each model as previously described in Section 5.3. From each pattern, we randomly picked 1000 examples which resulted in 30% of the people and 20% of the city seeds. We used these seed examples to train the RG_i models. In total, we built 15 RG_i, which is the maximum number of overlapping iterations between the two patterns. We tested our RG model with the remaining 2798 people and 4090 city seeds.

Figure 4 shows the results of the RG_i models for the people and city patterns. In the first two iterations, the predictions of the RG model are poorer compared to the pattern-specific regression. On the fourth iteration, both models have cc=0.7 and 0.8 for the people and city patterns respectively. The error rates of the generalized model are 41% and 35% for people and city, while for the pattern-specific model the errors are 37% and 32%. The early iterations show a difference of around 4% in the error rate of the two models, but around the ninth iteration both models have comparable results.

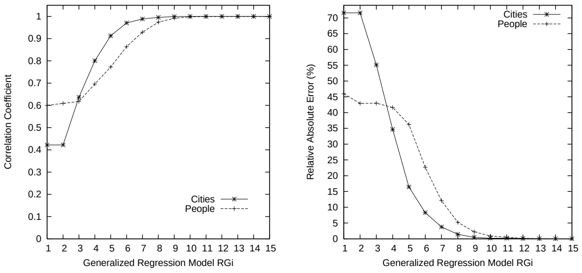

Figure 4: Generalized Regression for People and City.

This study shows that it is possible to combine evidence from two patterns harvesting different semantic information to predict accurately the behavior of unseen seed examples for either of the two patterns.

5.5 Evaluating the Generalized Model on Different Languages and Kinds of Patterns

So far, we have studied the performance of the generalized seed quality prediction method for specific patterns in English. However, the connectivity behavior of the seeds might change for other languages and kinds of patterns, making the generalized model impractical to use in such cases. To verify this, we evaluated the generalized model (RG) from Section 5.4 with the people and city patterns in Spanish (‘ *gente como X y **’ and ‘ *ciudades como X y **’), as well as with two new kinds of patterns (‘ ** and X fly to*’ and ‘ ** and X work for*’[1]). For each pattern, we ran the bootstrapping process from Section 3 until exhaustion and collected all seeds.

First, for each pattern we studied the connectivity behavior of the seeds. Table 2 shows the obtained results. The distribution is similar to the seed distribution for the English people and cities patterns. Although the total number of harvested instances (i.e., seeds) is different for each pattern, the proportion of hermits to other seeds remains larger. From 20% to 37% of the seeds are high connectors, and the rest are one-step and mid connectors. This analysis shows that the connectivity behavior of seeds across different languages and patterns is similar, at least for the examples studied. In addition to the seed analysis, we show in the table the total number of bootstrapping iterations for each pattern. The ‘*work for*’ and ‘*fly to*’ patterns run for a longer distance compared to the other patterns. While for the majority of the patterns the hump is observed on the fifth or seventh iteration, for these two patterns the average peak is observed on the fifteenth.

	gente como X y	ciudades como X y
#hermit	318 (56%)	1061 (51%)
#one-step	58 (10%)	150 (8%)
#mid	79 (14%)	79 (4%)
#high	117 (20%)	795 (38%)
tot#iter	20	16
	and X fly to	and X work for
#hermit	389 (45%)	1262 (48%)
#one-step	87 (9%)	238 (9%)
#mid	75 (8%)	214 (8%)
#high	322 (37%)	922 (35%)
tot#iter	26	33

Table 2: Seed Classification for Spanish and Verb-Prep Patterns.

Second, we test the RG_i models from Section 5.4, which were trained on people and cities, to predict the total yield of the seeds in the new patterns. Figure 5 shows the correlation coefficient and the relative absolute error results of each pattern for RG_i.

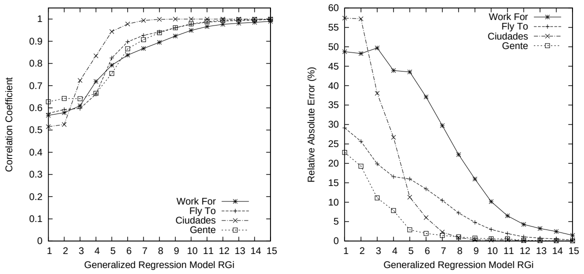

Figure 5: Generalized Regression for Different Languages and Patterns.

Interestingly, we found that our generalized method has consistent performance across the different languages and patterns. On the twelfth iteration, the model is able to predict the ‘goodness’ of seeds with cc=1.0 and from 0.4% to 8.0% error rate. Around the fifth and sixth iterations, all patterns reach cc=0.8 with error of 5% to 15%. The higher error bound is for patterns like ‘work for’ and ‘fly to’ which run for a longer distance. This experimental study confirms the robustness of our generalized model which is trained on the behavior of seeds from one kind of pattern and tested with seeds in different languages and on completely different kinds of patterns.

[1] The X indicates the position of the seed and (*) corresponds to the instances learned during bootstrapping.

6 Conclusions and Future Work

It would, a fortiori, seem impossible to estimate the goodness of a seed term used in a recursive bootstrapping pattern for harvesting information from the web. After all, its eventual total yield and distance depend on the cumulation of the terms produced in each iteration of the bootstrapping, and there are no external constraints or known web language structure to be exploited.

We have shown that it is possible to create, using regression, a model of the grown behavior of seeds for a given pattern, and fitting it with an indication of a new seed's growth (considering its grown behavior in a limited number of bootstrapping iterations) in order to obtain a quite reliable estimate of the new seed's eventual yield and distance.

Going further, we are delighted to observe that the regularity of the single-hump harvesting behavior makes it possible to learn a regression model that enables one to predict, with some accuracy, both the yield and the distance of a new seed, even when the pattern being considered is not yet seen. All that is required is the indication of the seed's growth behavior, obtained through a number of iterations using the pattern of interest.

Our ongoing analysis takes the following approach. Let T_i be the set of all new terms (terms not yet found) harvested during iteration i. Then $T_0 = \{t_{0,1}\}$, just the initial seed term. Let $NY(t_{i,j})$ be the novel yield of term $t_{i,j}$, that is, the number of as yet undiscovered terms produced by a single application of the pattern using the term $t_{i,j}$. Notice that bootstrapping ceases when for some $i = d$ (the distance), $\sum_j NY(t_{d,j}) = 0$. Since the total number of terms that can be learned, $\sum_{i=0}^{d} \sum_j NY(t_{i,j}) = N$, is finite and fixed, there are exactly three alternatives for the growth of the NY curve when it is shown summed over each iteration: (i) either $\sum_j NY(t_{i,j}) = \sum_j NY(t_{i+1,j})$ and there is no larger NY sum for any iteration; or (ii) $\sum_j NY(t_{i,j})$ grows to a maximal value for some iteration $i = m$ and then decreases again; or (iii) $\sum_j NY(t_{i,j})$ reaches more than one locally maximal value at different iterations. The first case, in which exactly the same number of new terms is harvested every iteration for several or all iterations, would require that each new term once learned yields precisely and only one subsequent new term, or that the number of hermits is exactly balanced by the NY of one or more of the other terms in that iteration. This situation is so unlikely as to be dismissed outright. Case (ii), in which there is a single hump, appears to be how text is written on the web, as shown in Figure 2. Case (iii), the multi-hump case, would require that the terms be linked in semi-disconnected 'islands', with a relatively much smaller inter-island connectivity than intra-island one. Given our studies, it appears that language on the web is not organized this way, at least not for the patterns we studied. However, it is not impossible: this two-hump case would have to have occurred in (Kozareva et al., 2008) when the ambiguous seed term *Georgia* was used in the DAP '*states such as Georgia and **', where initially the US states were harvested but, at some point, the learned term Georgia also initiated harvesting of the ex-USSR states. Such 'leakage' into a new semantic domain requires not only ambiguity of the seed but also parallel ambiguity of the class term, which is highly unlikely as well.

Accepting case (ii), therefore, we postulate that for any (or all regular) patterns there is some iteration m in which $\sum_j NY(t_{m,j})$ is maximal. The question is how rapidly the summed NY curve approaches it and then abates again. This depends on the out-degree connectivity of terms overall. In the population of N terms for a given semantic pattern, is the distribution of out-degrees Poisson (or Zipfian), or is it normal (Gaussian)? In the former case, there will be a few high-degree connector terms and a large number (the long tail) of one-step and hermit terms; in the latter, there will be a small but equal number of low-end and high-end connector terms, with the bulk of terms falling in the mid-connector range. One direction of our ongoing work is to determine this distribution, and to empirically derive its parameters. It might be possible to discover some interesting regularities about the (preferential) uses of terms within semantic domains, as reflected in term network connectivity.

Although not all seeds are equal, it appears to be possible to treat them with a single regression model, regardless of pattern, to predict their 'goodness'.

Abstract

Like most natural language disambiguation tasks, word sense disambiguation (WSD) requires world knowledge for accurate predictions. Several proxies for this knowledge have been investigated, including labeled corpora, user-contributed knowledge, and machine readable dictionaries, but each of these proxies requires significant manual effort to create, and they do not cover all of the ambiguous terms in a language. We investigate the task of automatically extracting world knowledge, in the form of glosses, from an unlabeled corpus. We demonstrate how to use these glosses to automatically label a training corpus to build a statistical WSD system that uses no manually-labeled data, with experimental results approaching that of a supervised SVM-based classifier.

1 Introduction

For many semantic natural language processing tasks, systems require world knowledge to disambiguate language utterances. Word sense disambiguation (WSD) is no exception — systems for WSD require world knowledge to figure out which aspects of a word's context indicate one sense over another. A fundamental problem for WSD is that the required knowledge is open-ended. That is, for every ambiguous term, new kinds of information about the world become important, and the knowledge that a system may have acquired for previously-studied ambiguous terms may have little or no impact on the next ambiguous term. Thus open-ended knowledge acquisition is a fundamental obstacle to strong performance for this disambiguation task.

Researchers have investigated a variety of techniques that address this knowledge acquisition bottleneck in different ways. Supervised WSD techniques, for instance, can learn to associate features in the context of a word with a particular sense of that word. Knowledge-based techniques rely on machine-readable dictionaries or lexical resources like WordNet (Fellbaum, 1998) to provide the necessary knowledge. And most recently, systems have used resources like Wikipedia, which contain user-contributed knowledge in the form of sense-disambiguated links, to acquire world knowledge for WSD. Yet each of these approaches is limited by the amount of manual effort that is needed to build the necessary resources, and as a result the techniques are limited to a subset of English words for which the manually-constructed resources are available.

In this work we investigate an alternative approach that attacks the problem of knowledge acquisition head-on. We use information extraction (IE) techniques to extract *glosses*, or short textual characterizations of the meaning of one sense of a word. In the ideal case, we would extract full logical forms to define word senses, but here we instead focus on a more feasible, but still very useful, sub-task: for a given word sense, extract a collection of terms that are highly correlated with that sense and no other sense of the ambiguous word. Our system requires as input only an unlabeled corpus of documents that each contain the ambiguous term of interest.

In experiments, we demonstrate that our gloss extraction system can often determine key aspects of a word's senses. In one experiment our system was able to extract glosses with 60% precision for 20 ambiguous biomedical terms, while discovering 7 senses of those terms that never appeared in a widely-used dictionary of biomedical terminology. In addition, we demonstrate that our extracted glosses are useful for real WSD problems: our sys-

tem outperforms a state-of-the-art unsupervised system, and it comes close to the performance of a supervised WSD system on a challenging dataset.

In the next section, we describe previous work. In Section 3, we formally define the gloss extraction task and refine it into a sub-task that is feasible for an IE approach, and Section 5 presents our technique for using extracted glosses in a WSD task. Section 6 discusses our experiments and results.

2 Previous Work

Many previous systems (Cui et al., 2007; Androutsopoulos and Galanis, 2005) have studied the related task of answering definitional questions on the Web, such as "What does cold mean?". Such systems are focused on information retrieval for human consumption, and especially on recall of definitional information (Velardi et al., 2008). They generally do not consider the problem of how to merge the large number of similar extracted definitions into a single item (Fujii and Ishikawa, 2000), so that the overall result contains one definition per sense of the word. A separate approach (Pasca, 2005) relies on the WordNet lexical database to supply the set of senses, and extracts alternate glosses for the senses that have already been defined. When glosses are to be used by computational methods, as in a WSD system in our case, it becomes critical that the system extract one coherent gloss per sense. As far as we are aware, no previous system has extracted glosses for word sense disambiguation.

Gloss extraction is related to the task of ontology extraction, in which systems extract hierarchies of word classes (Snow et al., 2006; Popescu et al., 2004). Gloss extraction differs from ontology extraction in that it extracts definitional information characterizing senses of a single word, rather than trying to place a word in a hierarchy of other words.

Most WSD systems have relied on hand-labeled training examples (Leroy and Rindflesch, 2004; Joshi et al., 2005; Mohammad and Pedersen, 2004) or on dictionary glosses (Lesk, 1986; Stevenson and Wilks, 2001) or the WordNet hierarchy (Boyd-Graber et al., 2007) to help make disambiguation choices. In recent coarse-grained evaluations, such systems have achieved accuracies of close to 90% (Pradhan et al., 2007; Agirre and Soroa, 2007; Schijvenaars et al., 2005). However, by some estimates, English contains over a million word types, and new words and new senses are added to the language every day. It is unreasonable to expect that any system will have access to hand-labeled training examples or useful dictionary glosses for each of them.

More recent techniques based on user-contributed knowledge (Mihalcea, 2007; Chklovski and Mihalcea, 2002; Milne and Witten, 2008), such as that found in Wikipedia, suffer from similar problems – Wikipedia contains many articles on well known entities, categories, and events, but very few articles that disambiguate verbs, adjectives, adverbs, and certain kinds of nouns which are poorly represented in an encyclopedia.

On the other hand, word usages in large corpora like the Web reflect nearly all of the word senses in use in English today, albeit without manually-supplied labels. Unsupervised approaches to WSD use clustering techniques to group instances of words into clusters that correspond to different senses (Pantel and Lin, 2002). While such systems are more general than supervised and dictionary-based approaches in that they can handle any word type and word sense, they have lagged behind other approaches in terms of accuracy thus far – for example, the best system in the recent word sense induction task of Semeval 2007 (Agirre and Soroa, 2007) achieved an F1 score of 78.7, slightly below the baseline (78.9) in which all instances of a word are part of a single cluster. Part of the problem is that the clustering techniques operate in a bag-of-words-like representation. This is an extremely high-dimensional space, and it is difficult in such a space to determine which dimensions are noise and which ones correlate with different senses. Our gloss extraction technique helps to address this curse of dimensionality by reducing the large vocabulary of a corpus to a much smaller set of terms that are highly relevant for WSD. Others (Kulkarni and Pedersen, 2005) have used feature selection techniques like mutual information to reduce dimensionality, but so far these techniques have only been able to find features that correlate with an ambiguous term. With gloss extraction, we are able to find features that correlate with individual senses of a term.

3 Overview: The Gloss Extraction Task

Given an input corpus $\mathcal{C}$ of documents where each document contains at least one instance of a *keyword* k, a Gloss Extraction system should produce a set of *glosses* $G = \{g_i\}$, where each g_i is a logical expression defining the meaning of a particular sense s_i of

Glosses:
1. cold(a) $\equiv$ isA(a, b) $\wedge$ disease(b) $\wedge$ symptom(a, c) $\wedge$ possibly-includes(c, d) $\wedge$ fever(d)
2. cold(a) $\equiv$ isA(a, b) $\wedge$ physical-entity(b) $\wedge$ temperature(a, c) $\wedge$ less-than(c, 25C)

Sense Indicators:
1. common cold, virus, symptom, fever
2. hot, ice cold, lukewarm, cold room, room temperature

Figure 1: **Example glosses and sense indicators for two senses of the word *cold*.**

k, to the exclusion of all other senses of k. Note that the system must discover the appropriate number of senses in addition to the gloss for each sense.

While extraction technology has made impressive advancements, it is not yet at a stage where it can produce full logical forms for sense glosses. As a first step towards this goal, we introduce the task of Sense Indicator Extraction, in which each gloss g_i consists of a set of features that, when present in the context of an instance of k, strongly indicate that the instance has sense s_i, and no other sense. Examples of both tasks are given in Figure 1. The Sense Indicator Extraction task represents a nontrivial extraction challenge, but it is much more feasible than full Gloss Extraction. And the task preserves key properties of Gloss Extraction: the results are quite useful for word sense disambiguation. The results are also readily interpreted upon inspection, making it easy to monitor a system's accuracy.

4 Extracting Word Sense Glosses

We present the GLOSSY system, an unsupervised information extraction system for Sense Indicator Extraction. GLOSSY proceeds in two phases: a *collocation detection* phase, in which the system detects components of the glosses, and an *arrangement* phase, in which the system decides how many distinct senses there are, and puts together the components of the glosses.

4.1 Collocation Detection

The first major challenge to a Gloss Extraction system is that the space of possible features is enormous, and almost all of them are irrelevant to the task at hand. Supervised techniques can use labeled examples to provide clues, but in an unsupervised setting the curse of dimensionality can be overwhelming. Indeed, unsupervised WSD techniques suffer from exactly this problem.

GLOSSY's answer to this problem is based on the following observation: pairs of potential features which rarely or never co-occur in the same document in a large corpus are likely to represent features for two distinct senses. The well-known observation that words rarely exhibit more than one sense per discourse (Yarowsky, 1995) implies that features closely associated with a particular sense have a low probability of appearing in the same document as features associated with another sense. Features that are independent of any particular sense of the keyword, on the other hand, have no such restriction, and are just as likely to appear in the context of one sense as any other. As a consequence, a low count for the co-occurrence of two potential features over a large corpus of documents for keyword k is a reliable indicator that the two features are part of the glosses of two distinct senses of k.

GLOSSY's collocation detector begins by indexing the corpus and counting the frequency of each vocabulary word. Using the index, the collocation detector determines all pairs of potential features such that each feature appears at least T times, and the pair of features never co-occurs in the same document. We call the pairs that this step finds the "non-overlapping" features. Finally, we rank the feature pairs according to the total number of documents they appear in, and choose the most frequent N pairs. This excludes non-overlapping pairs that have not been seen often enough to provide reliable evidence that they are features of different senses, and it cuts down on processing time for the next phase of the algorithm. The collocation detector outputs the set of features $F = \{f | \exists_{f'}(f, f')$ or (f', f) is one of the top N non-overlapping pairs$\}$. The GLOSSY system uses stems, words, and bigrams as potential features. We use $N = 100$ and $T = 50$ in our experiments. Figure 2 shows an example corpus and the set of features that the collocation detector would output.

Corpus of documents for term `cold`:
DOCUMENT 1: “Symptoms of the common cold may include fever, headache, sore throat, and coughing.”
DOCUMENT 2: “Hibernation is a common response to the cold winter weather of temperate climates.”

Non-overlapping feature pairs:
(symptoms,temperate) (headache, climate) (cold winter, common cold) (*response*, headache)

Detected collocations:
symptoms, temperate, headache, climate, cold winter, common cold, *response*

Arranged glosses:
`cold 1`: symptoms, common cold, headache
`cold 2`: temperate, climate, cold winter

Figure 2: **Example operation of the GLOSSY extraction system.** The collocation detector finds potential features using its non-overlapping pair heuristic. The arranger selects a subset of the potential features (in this example, it drops the feature *response*) and clusters them to produces glosses containing sense indicators.

4.2 Arranging Glosses

Given the corpus $\mathcal{C}$ for keyword k and the features F that GLOSSY’s collocation detector has discovered, the arrangement phase groups these features into coherent sense glosses. Figure 2 shows an example of how the features found during collocation detection may be arranged to form coherent glosses for two senses of the word “cold.”

GLOSSY’s Arranger component uses a combination of a small set of statistics to determine whether a particular arrangement of the features into glosses is warranted, based on the given corpus. Let $\mathcal{A} \subset 2^F$ be an arrangement of the features into clusters representing glosses. We require that clusters in $\mathcal{A}$ be disjoint, but we do not require every feature in F to be included in a cluster in $\mathcal{A}$ — in other words, $\mathcal{A}$ is a partition of a subset of F. We define a scoring function S that is a linear interpolation of several statistics of the arrangement $\mathcal{A}$ and the corpus $\mathcal{C}$:

$$S(\mathcal{A}|\mathcal{C}, \mathbf{w}) = \sum_i w_i f_i(\mathcal{A}, \mathcal{C}) \qquad (1)$$

After experimenting with a number of options, we settled on the following for our statistics f_i:

NUMCLUSTERS: the number of clusters in $\mathcal{A}$. We use a negative weight for this statistic to favor fewer senses and encourage clustering.

DOCSCOVERED: the total number of documents in $\mathcal{C}$ in which at least one feature from $\mathcal{A}$ appears. We use this statistic to encourage the Arranger to find an arrangement that explains the sense of as many examples of the keyword as possible.

BADOVERLAPS: the number of pairs of features that co-occur in at least one document in $\mathcal{C}$, and that belong to different clusters of $\mathcal{A}$. A negative weight for this statistic encourages overlapping feature pairs to be placed in the same cluster.

BADNONOVERLAPS: the number of pairs of features that never co-occur in $\mathcal{C}$, and that belong to the same cluster in $\mathcal{A}$. A negative weight for this statistic encourages non-overlapping feature pairs to be placed in different clusters.

Given such an optimization function, the Arranger attempts to maximize its value by searching for an optimal $\mathcal{A}$. Note that this is a structured prediction task in which the choice for some sub-component of $\mathcal{A}$ can greatly affect the choice of other clusters and features. GLOSSY addresses this optimization problem with a greedy hill-climbing search with random restarts. Each round of hill-climbing is initialized with a randomly chosen subset of features, which are then all assigned to a single cluster. Using a randomly chosen search operator from a pre-defined set, the search procedure attempts to move to a new arrangement $\mathcal{A}'$. It accepts the move to $\mathcal{A}'$ if the optimization function gives a higher value than at the previous state; otherwise, it continues from the previous state. Our set of search operators include a move that splits a cluster; a move that joins two clusters; a move that swaps a feature from one cluster to another; a move that removes a feature from the arrangement altogether; and a move that adds a feature from the pool of unused features. We used 100 rounds of hill-climbing, and found that each round converged in fewer than 1000 moves.

To estimate the weights w_i for each of the four features of the Arranger, we use a development corpus consisting of 185 documents each containing the same ambiguous term, and each labeled with sense information. Because of the small number of parameters, we performed a grid search on the development data for the optimal values of the weights.

5 A Bootstrapping WSD System

Yarowsky (1995) first recognized that it is possible to use a small number of features for different senses to bootstrap an unsupervised word sense disambiguation system. In Yarowsky's work, his system requires an initial, manually-supplied collocation as a feature for each sense of a keyword. In contrast, we can use GLOSSY's extracted glosses to supply starter features fully automatically, using only an unlabeled corpus. Thus GLOSSY complements the efforts of Yarowsky and other bootstrapping techniques for WSD (Diab, 2004; Mihalcea, 2002).

Building on their efforts, we design a bootstrapping WSD system using GLOSSY's extracted glosses as follows. Let $\mathcal{A}$ be the arranged features representing glosses for a keyword. We first retrieve all the documents from our unlabeled corpus which contain features in $\mathcal{A}$. We then label appearances of the target word according to the cluster of the features that appear in that document. If features for more than one cluster appear in the same document, we discard it. The result is an automatically labeled corpus containing examples of all the extracted senses.

We use this automatically labeled "bootstrap corpus" to perform supervised WSD. This allows our system a great deal of flexibility once the bootstrap corpus is created: we can use any features of the corpus, plus the labels, in our classifier. Importantly, this means we do not need to rely on just the features in the extracted glosses. We use a multi-class SVM classifier with a linear kernel and default parameter settings. We use LibSVM (Chang and Lin, 2001) for all of our experiments. We use standard features for supervised WSD (Liu et al., 2004): all stems, words, bigrams, and trigrams within a context window of 20 words surrounding the ambiguous term.

6 Experiments

We ran two types of experiments, one to measure the accuracy of our sense gloss extractor, and one to measure the usefulness of the extracted knowledge for word sense disambiguation.

6.1 Data

We use a dataset of biomedical literature abstracts from Duan *et al.*(2009). The data contains a set of documents for 21 ambiguous terms. We reserved one of these terms ("MCP") for setting parameters, and ran our algorithms on the remaining keywords. The ambiguous terms vary from acronyms (7 terms), which are common and important in biomedical literature, to ambiguous biomedical terminology (3 terms), to terms like "culture" and "mole" that have some biomedical senses and some senses that are part of the general lexicon (11 terms). There were on average 271 labeled documents per term; the smallest number of documents for a term is 125, and the largest is 503. For every ambiguous term, we added on average 9625 (minimum of 1544, maximum of 15711) unlabeled documents to our collection by searching for the term on PubMed Central and downloading additional PubMed abstracts.

6.2 Extracting Glosses

We measured the performance of GLOSSY's gloss extraction by comparing the extracted glosses with definitions contained in the Unified Medical Language System (UMLS) Metathesaurus. First, for each ambiguous term, we looked up the set of exact matches for that term in the Metathesaurus, and downloaded definitions for all of the different senses listed under that term. Wherever possible, we used the MeSH definition of a sense; when that was unavailable, we used the definition from the NCI Thesaurus; and when both were unavailable, we used the definition from the resource listed first. 34 senses (40%) had no available definitions at all, but in all cases, the Metathesaurus lists a short (usually 1-3 word) gloss of the sense, which we used instead.

We manually aligned extracted glosses with UMLS senses in a way that maximizes the number of matched senses for every ambiguous term. We consider an extracted gloss to match a UMLS sense when the extracted gloss unambiguously refers to a single sense of the ambiguous term, and that sense matches the definition in UMLS. Typically, this means that the extracted features in the gloss overlap content words in the UMLS definition (*e.g.*, the extracted feature "symptoms" for the "common cold" sense of the term "cold"). In some cases, however, there was no strict overlap in content words between the extracted gloss and the UMLS definition, but the sense of the extracted gloss still unambiguously matched a unique UMLS sense: *e.g.*, for the term "transport," the extracted gloss "intracellular transport" was matched with the UMLS sense of "Molecular Transport," which the NCI Thesaurus defines as, "Any subcellular or molecular process involved in translocation of a biological entity, such as a macromolecule, from one site or compartment to another." In the end, such matchings were determined by hand. Table 1 shows extracted glosses and UMLS definitions for the term "mole."

For each ambiguous term, we measure the number of extracted glosses, the number of UMLS senses, and the number of matches between the two. We report on the precision (number of matches / number of extracted glosses), recall (number of matches / number of UMLS senses), and F1 score (harmonic mean of precision and recall). Table 2 shows the average of the precision and recall numbers over all terms. Since these terms have different numbers of senses, we can compute this average in two different ways: a Macro average, in which each term has equal weight in the average; and a Micro average, in which each term's weight in the average is proportional to the number of senses (extracted senses for the precision, and UMLS senses for the recall). We report on both.

A strict matching between GLOSSY's glosses and UMLS senses is potentially unfair to GLOSSY in several ways: GLOSSY may discover valid senses that happen not to appear in UMLS; UMLS senses may overlap one another, and so multiple UMLS senses may match a single GLOSSY gloss; and the two sets of senses may differ in granularity. For the sake of repeatable experiments, in this evaluation we make no attempt to change existing UMLS senses.

However, to highlight one particular strength of the Gloss Extraction paradigm, we do consider a separate evaluation that allows for new senses that GLOSSY discovers, but do not appear in UMLS. For instance, "biliopancreatic diversion" and "bipolar disorder" are both valid senses for the acronym "BPD." GLOSSY discovers both, but UMLS does not contain entries for either, so in our original evaluation both senses would count against GLOSSY's precision. To correct for this, our second evaluation adds senses to the list of UMLS senses whenever GLOSSY discovers valid entries missing from the Metathesaurus. The last five columns of Table 2 show our results under these conditions.

Despite the difficulty of the task, GLOSSY is able to find glosses with 53% precision and 47% recall (Macro average, no discovered senses) using only unlabeled corpora as input, and it is extracting roughly the right number of senses for each ambiguous term. In addition, GLOSSY is able to identify 7 valid senses missing from UMLS for the 20 terms in our evaluation. Including these senses in the evaluation increases GLOSSY's F1 by 6.2 points Micro (4.7 Macro). We are quite encouraged by the results, especially because they hold promise for WSD. Note that in order to improve upon a WSD baseline which tags all instances of a word as the same sense, GLOSSY only needs to be able to separate one sense from the rest. GLOSSY is finding between 1.85 and 2.2 correct glosses per term, more than enough to help with WSD.

6.3 WSD with Extracted Glosses

While extracting glosses is an important application in its own right, we also aim to show that this extracted knowledge is useful for an established application: namely, word sense disambiguation. Our next experiment compares the performance of our WSD system with an established unsupervised algorithm, and with a supervised technique — support vector machines (SVMs).

Using the same dataset as above, we trained GLOSSY on the ambiguous term "MCP", and tested it on the remaining ones. For comparison, we also report the state-of-the-art results of Duan *et al.*'s (2009) SENSATIONAL system, and the results of a BASELINE system that lumps all documents into a single cluster. SENSATIONAL is a fast clustering system based on minimum spanning trees and a pruning mechanism that eliminates noisy points from consideration during clustering. Since SENSATIONAL uses both "MCP" and "white" to train a small set of parameters, we leave "white" out of our comparison as well. We measure accuracy by aligning each system's clusters with the gold standard clusters in such a way as to maximize the number of elements that belong to aligned clusters. We use an implementation of the MaxFlow algorithm to determine this alignment. We then compute accuracy

Micro Avg	N/A	N/A	N/A	42.5	43.5	43.0	N/A	N/A	50.6	47.8	49.2

Table 2: GLOSSY **can automatically discover glosses that match definitions in an online dictionary.** "Without Discovered Senses" counts only the senses that are listed in the UMLS Metathesaurus; "With Discovered Senses" enhances the Metathesaurus with 7 new senses that GLOSSY has automatically discovered.

as the percentage of elements that belong to aligned clusters. This metric is very similar to the so-called "supervised" evaluation of Agirre *et al.* (2006).

The first four columns of Table 3 show our results. Clearly, both SENSATIONAL and GLOSSY outperform the BASELINE significantly, and traditionally this is a difficult baseline for unsupervised WSD systems to beat. SENSATIONAL outperforms GLOSSY by approximately 6%. There appear to be two reasons for this. In other experiments, SENSATIONAL has been shown to be competitive with supervised systems, but only when the corpus consists mostly of two, fairly well-balanced senses, as is true for this particular dataset, where the two most common senses always covered at least 70% of the examples for every ambiguous term.

A more serious problem for GLOSSY is that the unlabeled corpus that it extracts glosses from may not match well with the labeled test data. If the relative frequency of senses in the unlabeled documents does not match the relative frequency of senses in the labeled test set, GLOSSY may not extract the right set of glosses. Manual inspection of the extracted glosses shows that this is indeed a problem: for example, the labeled data contains two senses of the word "mole": a discolored area of skin (78%), and a burrowing mammal (22%); our unlabeled data contains both of these senses, but the additional sense of "mole" as a unit of measurement is by far predominant. GLOSSY manages to extract glosses for "skin" and "unit of measurement," but misses out on "mammal" as a result of the skew in the data.

Note that this problem, though serious for our experiments, is largely artificial from the point of view of applications. In a typical usage of a WSD system, there is a supply of data that the system needs to disambiguate, and accuracy is measured on a labeled sample of this data. Here, we started from a sample of labeled data, constructed a larger corpus that does not necessarily match it, and then ran our algorithm.

To correct for the artificial bias in our experiment, we ran a second test in which we manually labeled a random sample of 100 documents for each ambiguous term from the larger unlabeled corpus. We used a subset of 14 of the 21 keywords in the original dataset. As before, we compared our system against SENSATIONAL and the most-frequent-sense BASELINE. We also compare against an SVM system using 3-fold cross-validation. We use a linear kernel SVM, with the same set of features that are available

	Duan *et al.*(2009) Data				Sampled Data

Table 3: GLOSSY**'s extracted glosses can be used to create an unsupervised WSD system that achieves an accuracy within 3% of a supervised system.** Our WSD system outperforms our BASELINE system, widely recognized as a difficult baseline for unsupervised WSD, by 16.9% and 3.3% on two different datasets.

to the SVM in the GLOSSY system. We run our unsupervised systems on all of the unlabeled data, and then intersect the resulting clusters with the document set that we randomly sampled.

The last four columns of Table 3 show our results. The sampled data set appears to be a significantly harder test, since even the supervised SVM achieves only a 6% gain over the BASELINE. The SENSATIONAL system does significantly worse on this data, where there is a wider variation in the distribution of senses. The GLOSSY system outperforms both the SENSATIONAL system and the BASELINE.

7 Conclusion and Future Work

Gloss Extraction is an important, and difficult task of extracting definitions of words from unlabeled text. The GLOSSY system succeeds at a more feasible refinement of this task, the Sense Indicator Extraction task. GLOSSY's extractions have proven useful as seed definitions in an unsupervised WSD task. There is a great deal of room for future work in expanding the ability of Gloss Extraction systems to extract sense glosses that more closely match the meanings of a word. An important first step in this direction is to extract relations, rather than ngrams, that make up the definition a word's senses.

Can Recognising Multiword Expressions Improve Shallow Parsing?

Ioannis Korkontzelos, Suresh Manandhar

Abstract

There is significant evidence in the literature that integrating knowledge about multiword expressions can improve shallow parsing accuracy. We present an experimental study to quantify this improvement, focusing on *compound nominals*, *proper names* and *adjective-noun constructions*. The evaluation set of multiword expressions is derived from *WordNet* and the textual data are downloaded from the web. We use a classification method to aid human annotation of output parses. This method allows us to conduct experiments on a large dataset of unannotated data. Experiments show that knowledge about multiword expressions leads to an increase of between 7.5% and 9.5% in accuracy of shallow parsing in sentences containing these multiword expressions.

1 Introduction

Multiword expressions are sequences of words that tend to co-occur more frequently than chance and are characterised by various levels of idiosyncracy (Baldwin et al., 2003; Baldwin, 2006). There is extended literature on various issues relevant to multiword expression; recognition, classification, lexicography, etc. (see Section 6). The vast majority of these publications identifies as motivation for multiword expression research its potential contribution to deep or shallow parsing. On the other side of this issue, the state-of-the-art parsing systems seem to ignore the fact that treating multiword expressions as syntactic units would potentially increase parser's accuracy.

In this paper, we present an experimental study attempting to estimate the contribution of integrating multiword expressions into shallow parsing. We focus on multiword expressions that consist of two successive tokens; in particular, *compound nominals proper names* and *adjective-noun constructions*. We also present a detailed classification method to aid human annotation during the procedure of deciding if a parse is correct or wrong. We present experimental results about the different classes of changes that occur in the parser output while unifying multiword expression components.

We conclude that treating known multiwords expressions as singletons leads to an increase of between 7.5% and 9.5% in accuracy of shallow parsing of sentences containing these multiword expressions. Increase percentages are higher for multiword expressions that consist of an adjective followed by a noun (12% to 15%); and even higher for non-compositional multiword expressions[1] that consist of an adjective and a noun (15.5% to 19.5%).

The rest of the paper is structured as follows: In Section 2 we present how multiword expressions can be annotated in text and used by a shallow parser. In Section 3 we present an overview of our experimental process. Section 4 explains how the set of target multiword expressions and textual corpora were created. In Section 5 we present and discuss the results of the experimental process. In Section 6 we present parts of the related literature. Section 7 concludes the paper and proposes some future work.

[1] Compositionality is defined as the degree to which the meaning of a multiword expression can be predicted by combining the meanings of its components (Nunberg et al., 1994).

2 Annotating Multiword expressions

In this paper, we present a study to inspect the extent to which knowledge of multiword expressions improves shallow parsing. Our approach focuses on English multiword expressions that appear as sequences in text. In particular, we focus on *compound nominals* (e.g. lemon tree), *proper names* (e.g. prince Albert) and *adjective-noun constructions* (e.g. red carpet).

Shallow or deep parsing should treat multiword expression as units that cannot be divided in any way. We replace the multiword expression tokens with a special made up token, i.e. the multiword expression constituents joined with an underscore. For example, we replace all occurrences of "lemon tree" with "lemon_tree".

We choose to replace the multiword expression words with a token that does not exist in the dictionary of the part of speech tagger. This is quite an important decision. Usually, a part of sheech tagger assigns to an unknown words the part of speech that best fits to it with respect to the parts of speech of the words around it and the training data. This is a desirable behaviour for our purposes.

The experimental results of our study quantify the difference between the shallow parser output of a big number of sentences after the replacement and the shallow parser output of the same sentences before the replacement. The comparison is done ignoring changes of parts of speech, assigned by the part of speech tagger.

3 Evaluation

The target of our experiment is to evaluate whether replacing the multiword expression tokens with a single token, unknown to the part of speech tagger, improves shallow parsing accuracy. The ideal way to perform this evaluation would be to use a corpus with manual annotation about parsing and multiword expressions. Given this corpus we would be able to measure the accuracy of a shallow (or deep) parser before and after replacing multiword expressions. However, to the best of our knowledge there is no corpus available to include this type of annotations in English.

Instead, there are two options: Firstly, we can use treebank data, where manual parsing annotation is readily available, and manually annotate multiword expressions. The advantage of this approach is that results are directly comparable with other results of the literature, due to the use of benchmark data. Manual annotation of multiword expressions is a very time- and effort-consuming process due to the large size of most treebanks. Alternatively, multiword expression annotation could be done using a method of recognition. Annotating the multiword expressions that appear in *WordNet* could be a safe decision, in terms of correctness, however, *WordNet* is reported to have limited coverage of multiword expressions (Baldwin, 2006; Laporte and Voyatzi, 2008). *WordNet* covers only 9.1 % and 16.1 % of the datasets of Nicholson and Baldwin (2008) (484 noun compounds) and Kim and Baldwin (2008) (2169 noun compounds), respectively.

Figure 1: Evaluation process

Secondly, we can use a set of multiword expressions as a starting point and then create corpora that contain instances of these multiword expressions. In succession, these sentences need to be manually annotated in terms of parsing, and this requires huge human effort. Alternatively, we can parse the corpora before and after replacing the multiword expression and then compare the parser output. This is the evaluation procedure that we chose to follow, and is shown in Figure 1.

The above procedure is only able to retrieve instances where the replacement of the multiword expression leads to a different parsing, a different allocation of tokens to phrases. It is not able to spot instances where the parser output remains unchanged after the replacement, no matter if they are correct. Since we are interested in measuring if replacing

Example A - Replacement causes no change	
Before:	*[NP they] [VP jumped] [PP over] [NP a bonfire] and [VP rolled] [NP a fire wheel] .*
After:	*[NP they] [VP jumped] [PP over] [NP a bonfire] and [VP rolled] [NP a fire_wheel] .*

Example B - Replacement corrects an error	
Before:	*[NP the blades] [VP ignited] and [NP he] [VP threw]* ***[NP the fire] wheel up*** *[PP into] [NP the air] .*
After:	*[NP the blades] [VP ignited] and [NP he] [VP threw]* ***[NP the fire_wheel] [PRT up]*** *[PP into] [NP the air] .*

Table 1: 2 shallow parsing examples. Multiword expression: *"fire wheel"*

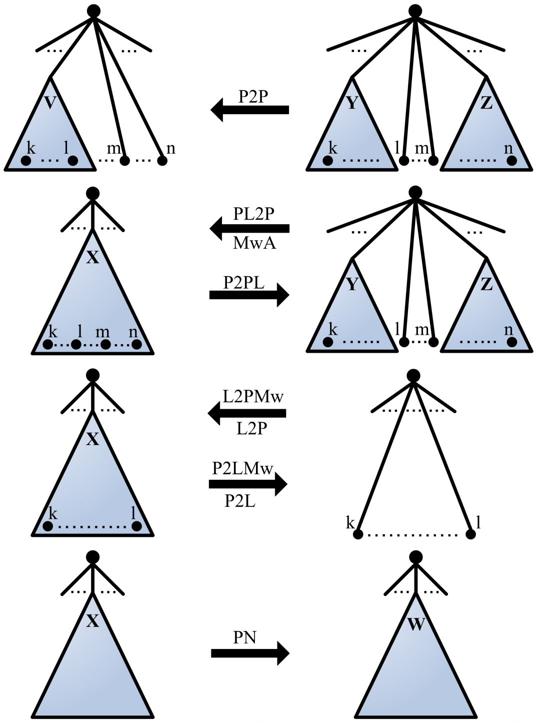

Figure 2: Change classes (following the notation of Bille (2005)). Triangles denote phrases and uppercase bold letters V...Z denote phrase labels. Lowercase letters k...n denote parsing leaves. For change classes *P2LMw* and *L2PMw*, X includes the multiword expression tokens. For change classes *P2L* and *L2P* it does not. For change class *MwA*, the multiword expression tokens are not assigned to the same phrase Y or Z.

multiword expressions with a single token improves parsing accuracy, we are not interested in instances that remain unchanged. We focus on instances that changed; either they were corrected or they were made wrong or they remain erroneous. For example, the shallow parser output for example A in Table 1 did not change after the replacement. Example B in Table 1 shows a sentence which was corrected after the replacement.

Instead of manually annotating the sentences whose parser output changed after the replacement as corrected or not, we identify a number of change classes under which we classify all these sentences. In the following section, we present the change classes. For each we thoroughly discuss whether its form guarantees that its sentences are wrongly parsed before the change and correctly parsed after the change. In this case, the sentences of the corresponding class should be counted as false positives. We also discuss the opposite; if the form of each change class guarantees that its sentences are correctly parsed before the change and wrongly parsed after the change. In this case, the sentences of the corresponding class should be counted as true negatives. For this discussion we hypothesize that among the possible output shallow parses for a given sentence the correct one has (a) the smallest number phrases, and (b) the smallest number of tokens not assigned to any phrase.

3.1 Shallow parsing change classes

In this section, we present a classification of cases where the shallow parser output of the sentence is different from the parser output of the same sentence after replacing the multiword expression with a single token. The secondary focus of this discussion is to estimate whether the specific form of each change class can lead to a safe conclusion about if the parser output of the sentence under discussion: (a) was wrong before the replacement and was then corrected, (b) was correct before the replacement and was then made wrong, or (c) was wrong before the replacement and remained wrong. For this discussion, we refer to words that are not assigned to any phase in the shallow parser output as "leaves".

Hypothesis: We base our analysis on the hypothesis that among the possible output shallow parses for a given sentence the correct one has (a) the smallest number phrases, and (b) the smallest number of leaves. The theoretical intuitions behind the hypothesis are: (a) parse trees with just leaves are partial parse trees and hence should not be preferred over complete parse trees. (b) when mistaken parse trees are generally larger (with more phrases). We checked the hypothesis by manually annotating 80 randomly chosen instances; 10 for each change class that is counted as correct or wrong (see Table 2). 74 instances validated the hypothesis (92.5%).

Table 2 shows one example for each change class. Figure 2 presents the classes as transformations between trees, following the notation of Bille (2005).

Change class *P2LMw* (***P***hrase to ***L***eaves including the ***M***ulti***w***ord expression) Before replacing the multiword expression sequence with a single token, the multiword expression is assigned to some phrase, possibly together with other words. After the replacement, the components of that phrase are not assigned to any phrase, but instead as leaves.

Change class *P2L* (***P***hrase to ***L***eaves excluding the multiword expression) Similarly to change class *P2LMw*, before the replacement, some successive tokens excluding the multiword expression itself are assigned to some phrase. After the replacement, the components of that phrase appear as leaves.

Change class *L2PMw* (***L***eaves to ***P***hrase including the ***M***ulti***w***ord expression) The changes covered by this class are the opposite changes of change class *P2LMw*. Before the replacing the multiword expression sequence with a single token, the multiword expression sequence is not assign to any phrase possibly among other words. After the replacement, the multiword expression is assigned to a phrase.

Change class *L2P* (***L***eaves to ***P***hrase excluding the multiword expression) Similarly to change class *L2PMw*, before the replacement, one or more successive tokens excluding the multiword expression itself appear as leaves. After the replacement, these tokens are assigned to a phrase.

Change class *PL2P* (***P***hrases or ***L***eaves to ***P***hrase) After the replacement, the tokens of more than one phrases or leaves are assigned to a single phrase.

Change class *P2PL* (***P***hrase to ***P***hrases or ***L***eaves) In contrast to change class *PL2P*, after the replacement, the tokens of one phrase either are assigned to more than one phrases or appear as leaves.

Change class *PN* (***P***hrase label ***N***ame) After replacing the multiword expression sequence with a single token, one phrase appears with a different phrase label, although it retains exactly the same component tokens.

Change class *PoS* (***P***art ***o***f ***S***peech) After replacing the multiword expression sequence with a single token, one or more tokens appears with a different part of speech. This class of changes comes from the part of speech tagger, and are out of the scope of this study. Thus, in the results section we show a size estimate of this class, and then we present results about change classes, ignoring change class *PoS*.

Change class P2P (***P***hrases to less ***P***hrases) After replacing the multiword expression sequence with a single token, the component tokens of more than one successive phrases α are assigned to a different set of successive phrases β. However, it is always the case that phrases α are less than phrases β ($|\alpha| < |\beta|$).

Change class MwA (***M***ulti***w***ord expression ***A***llocation) Before replacing the multiword expression sequence, the multiword expression constituents are assigned to different phrases.

The instances of change classes where the parser output after the replacement has more parsing leaves or phrases than before are counted towards sentences that were parsed wrongly after the replacement. For these classes, change classes *P2LMw*, *P2L* and *P2PL*, most probably the parser output after the replacement is wrong.

In contrast, the instances of change classes where a sequence of tokens is assigned to a phrase, or many phrases are merged are counted towards sentences that were parsed wrongly before the replacement and correctly after the replacement. These changes, that are described by classes *L2PMw*, *L2P*, *PL2P* and *P2P*, most probably describe improvements in shallow parsing. The instances of change class *MwA* are counted as correct after the replacement because by definition all tokens of a multiword expression are expected to be assigned to the same phrase.

The instances of change class *PN* can be either correct or wrong after the replacement. For this reason, we present our results as ranges (see Table 4). The minimum value is computed when the instances of class *PN* are counted as wrong after the replacement. In contrast, the maximum value is computed when the instances of this class are counted as correct after the replacement.

3.2 Shallow parsing complex change classes

During the inspection of instances where the shallow parser output before the replacement is dif-

	A	***[NP the(DT) campus(NN) affirmative(JJ) action_officer(NN)]*** *[VP serves(VBZ)]...*	

Table 2: Examples for change classes. Multiword expression: *"action officer"*. Parts of speech appear within parentheses. "B" stands for "before" and "A" for "after" (multiword expression replacement). ✓or ✗ denote change classes that count positively or negatively towards improving shallow parsing. *?* denotes classes that are treated specially.

ferent from the shallow parser output after the replacement, we came across a number of instances that were classified in more than one class of the previous subsection. In other words, two or more classes of change happened. For example, in a number of instances, before the replacement, the multiword expression constituents are assigned to different phrases (change class *MwA*). After the replacement, the tokens of more than one phrases are assigned to a single phrase (change class *PL2P*). These instances consist new complex change classes and are named as the sum of names of the participating classes. The instances of the example above consist the complex change class *PL2P+MwA*.

4 Target multiword expressions and corpora collection

We created our set of target multiword expressions using *WordNet 3.0* (Miller, 1995). Out of its $52,217$ multiword expressions we randomly chose 120. Keeping the ones that consist of two tokens resulted in the 118 expressions of Table 3. Manually inspecting these multiword expressions proved that they are all *compound nominals*, *proper names* or *adjective-noun constructions*. Each multiword expression was manually tagged as compositional or non-compositional, following the procedure described in Korkontzelos and Manandhar (2009). Table 3 shows the chosen multiword expressions together with information about their compositionality and the parts of speech of their components.

Compositional Multiword expressions (Noun - Noun sequences)				
action officer (3119)	bile duct (21649)	cartridge brass (479)	field mushroom (789)	fire wheel (480)
key word (3131)	king snake (2002)	labor camp (3275)	life form (5301)	oyster bed (1728)
pack rat (3443)	palm reading (4428)	paper chase (1115)	paper gold (1297)	paper tiger (1694)
picture palace (2231)	pill pusher (924)	pine knot (1026)	potato bean (265)	powder monkey (1438)
prison guard (4801)	rat race (2556)	road agent (1281)	sea lion (9113)	spin doctor (1267)
tea table (62)	telephone service (9771)	upland cotton (3235)	vegetable sponge (806)	winter sweet (460)

Non-Compositional Multiword expressions (Noun - Noun sequences)				
agony aunt (751)	air conditioner (24202)	band aid (773)	beach towel (1937)	car battery (3726)
checker board (1280)	corn whiskey (1862)	corner kick (2882)	cream sauce (1569)	fire brigade (5005)
fish finger (1423)	flight simulator (5955)	honey cake (843)	jazz band (6845)	jet plane (1466)
laser beam (16716)	lemon tree (3805)	lip service (3388)	love letter (3265)	luggage van (964)
memory device (4230)	monkey puzzle (1780)	motor pool (3184)	power cord (5553)	prince Albert (2019)
sausage pizza (598)	savoy cabbage (1320)	surface fire (2607)	torrey tree (10)	touch screen (9654)
water snake (2649)	water tank (5158)	wood aster (456)		

Compositional Multiword expressions (Adjective - Noun sequences)				
basic color (2453)	cardiac muscle (6472)	closed chain (1422)	common iguana (668)	cubic meter (4746)
eastern pipistrel (128)	graphic designer (8228)	hard candy (2357)	ill health (2055)	kinetic theory (2934)
male parent (1729)	medical report (3178)	musical harmony (1109)	mythical monster (770)	red fox (10587)
relational adjective (279)	parking brake (7199)	petit juror (991)	taxonomic category (1277)	thick skin (1338)
toxic waste (7220)	universal donor (1454)	parenthesis-free notation (113)		

Non-Compositional Multiword expressions (Adjective - Noun sequences)				
black maria (930)	dead end (5256)	dutch oven (4582)	golden trumpet (607)	green light (5960)
high jump (4455)	holding pattern (3622)	joint chiefs (2865)	living rock (985)	magnetic head (2457)
missing link (5314)	personal equation (873)	personal magnetism (2869)	petit four (1506)	pink lady (1707)
pink shower (351)	poor devil (1594)	public eye (3231)	quick time (2323)	red devil (2043)
red dwarf (6526)	red tape (2024)	round window (1380)	silent butler (332)	small beer (2302)
small voice (4313)	stocking stuffer (7486)	sweet bay (1367)	teddy boy (2413)	think tank (4586)

Table 3: 118 multiword expressions randomly chosen from *WordNet*. The size of the respective corpus in sentences appears within parentheses.

For each multiword expression we created a different corpus. Each consists of webtext snippets of length 15 to 200 tokens in which the multiword expression appears. Snippets were collected following Korkontzelos and Manandhar (2009). Given a multiword expression, a set of queries is created: All synonyms of the multiword expression extracted from WordNet are collected[2]. The multiword expression is paired with each synonym to create a set of queries. For each query, snippets are collected by parsing the web-pages returned by *Yahoo!*. The union of all snippets produces the multiword expression corpus.

In Table 3, the number of collected corpus sentences for each multiword expression are shown within parentheses. *GENIA* tagger (Tsuruoka et al., 2005) was used as part of speech tagger. *SNoW-based Shallow Parser* (Munoz et al., 1999) was used for shallow parsing.

5 Experimental results and discussion

The corpora collecting procedure of Section 4 resulted in a corpus of $376,007$ sentences, each one containing one or more multiword expressions. In $85,527$ sentences (22.75%), the shallow parser output before the replacement is different than the shallow parser output after the replacement. 7.20% of these change instances are due to one or more parts of speech changes, and are classified to change class *PoS*. In other words, in 7.20% of cases where there is a difference between the shallow parses before and after replacing the multiword expression tokens there is one or more tokens that were assigned a different part of speech. However, excluding parts of speech from the comparison, there is no other difference between the two parses.

The focus of this study is to quantify the effect of unifying multiword expressions in shallow parsing. Part of speech tagging is a component of our approach and parts of speech are not necessarily parts of the parser output. For this reason, we chose to ignore part of speech changes, the changes of class *PoS*. Below, we discuss results for all other classes.

[2] e.g. for “red carpet”, corpora are collected for “red carpet” and “carpet”. The synonyms of “red carpet” are “rug”, “carpet” and “carpeting”.

Multiword expressions			Shallow Parsing improvement	
class	*PS*	sentences	min.	max.
On average	-	376,007	7.47%	9.49%
Comp.	N N	93,166	5.54%	7.19%
Non-Comp.	N N	127,875	3.66%	4.44%
Comp.	J N	68,707	7.34%	9.21%
Non-Comp.	J N	86,259	15.32%	19.67%
-	N N	221,041	4.45%	5.60%
	J N	154,966	11.78%	15.03%
Comp.	-	161,873	6.30%	8.05%
Non-Comp.	-	214,134	8.36%	10.57%

Table 4: Summary of results. *PS*: parts of speech, Comp: compositional, N: noun, J: adjective, min.: minimum, max.: maximum.

Table 4 shows a summary of our results. The first two columns describe classes of multiword expression with respect to compositionality and the parts of speech of the component words. The first line accounts for the average of all multiword expressions, the second one for compositional multiword expressions made of nouns, etc. The third column shows the number of corpus sentences of each class.

For each one of the classes of Table 4, the fourth and fifth columns show the minimum and maximum improvement in shallow parsing, respectively, caused by unifying multiword expression tokens. Let $\|X\|$ be the function that returns the number of instances assigned to change class X. With respect to the discussion of Subsection 3.1 about how the instances of each class should be counted towards the final results, the minimum and maximum improvements in shallow parsing are:

$$\begin{aligned} min &= -\|\mathit{P2LMw}\| - \|\mathit{P2L}\| + \|\mathit{L2PMw}\| + \|\mathit{L2P}\| + \\ &+ \|\mathit{PL2P}\| - \|\mathit{P2PL}\| + \|\mathit{PL2P{+}MwA}\| + \\ &+ \|\mathit{P2P}\| + \|\mathit{P2P{+}MwA}\| - \|\mathit{PN}\| \qquad (1) \\ max &= -\|\mathit{P2LMw}\| - \|\mathit{P2L}\| + \|\mathit{L2PMw}\| + \|\mathit{L2P}\| + \\ &+ \|\mathit{PL2P}\| - \|\mathit{P2PL}\| + \|\mathit{PL2P{+}MwA}\| + \\ &+ \|\mathit{P2P}\| + \|\mathit{P2P{+}MwA}\| + \|\mathit{PN}\| \qquad (2) \end{aligned}$$

On average of all multiword expressions, unifying multiword expression tokens contributes from 7.47% to 9.49% in shallow parsing accuracy. It should be noted that this improvement is reported on sentences which contain at least one known multiword expression. To project this improvement on any general text, one needs to know the percentage of sentences that contain known multiword expressions. Then the projected improvement can be computed by multiplying these two percentages.

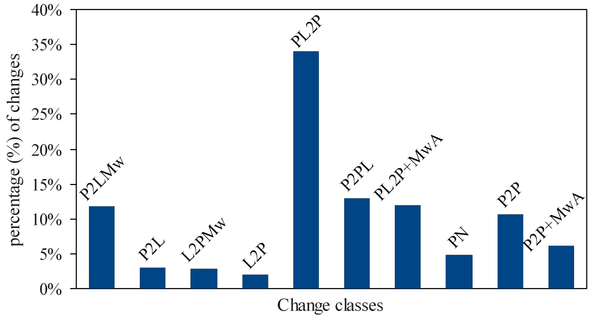

Figure 3: Average change percentages per change class.

Table 4 shows that the increase in shallow parsing accuracy is lower for expressions that consist of nouns than for those that consist of an adjective and a noun. Moreover, the improvement is higher for non-compositional expressions than compositional ones. This is expected, due to the idiosyncratic nature of non-compositional multiword expressions. The highest improvement, 15.32% to 19.67%, occurs for non-compositional multiword expressions that consist of an adjective followed by a noun.

Figure 3 shows the percentage of each class over the sum of sentences whose parse before unifying multiword expression tokens is different for the parse after the replacement. The most common change class is *PL2P*. It contains sentences in the shallow parser output of which many phrases or leaves were all assigned to a single phrase. 34.03% of the changes are classified in this class. The least common classes are change classes *P2L*, *L2PMw* and *L2P*. Each of these accounts for less than 3% of the overall changes.

6 Related Work

There have been proposed several ways to classify multiword expressions according to various properties such as compositionality and institutionalisation[3] (Moon, 1998; Sag et al., 2002; Baldwin, 2006). There is a large variety of methods in the literature that address recognising multiword expressions or some subcategory. McCarthy (2006) divides multiword expression detect-

[3] Institutionalisation is the degree that a multiword expression is accepted as lexical item through consistent use over time.

ing methods into statistical (e.g. pointwise mutual information (*PMI*)), translation-based, dictionary-based, substitution-based, and distributional. Statistical methods score multiword expression candidates based on co-occurrence counts (Manning and Schutze, 1999; Dunning, 1993; Lin, 1999; Frantzi et al., 2000). Translation-based methods usually take advantage of alignment to discover potential multiword expressions (Venkatapathy and Joshi, 2005).

Other methods use dictionaries to reveal semantic relationships between the components of potential multiword expressions and their context (Baldwin et al., 2003; Hashimoto et al., 2006). Substitution-based methods decide for multiword expressions by substituting their components with other similar words and measuring their frequency of occurrence (Lin, 1999; Fazly and Stevenson, 2006). These techniques can be enriched with selectional preference information (Van de Cruys and Moirón, 2007; Katz and Giesbrecht, 2006). Fazly and Stevenson (2007) propose measures for *institutionalisation*, *syntactic fixedness* and *compositionality* based on the selectional preferences of verbs. There are several studies relevant to detecting compositionality of noun-noun, verb-particle and light verb constructions and verb-noun pairs (e.g. Katz and Giesbrecht (2006)).

To the best of our knowledge there are no approaches integrating multiword expression knowledge in deep or shallow parsing. However, there are several attempts to integrate other forms of lexical semantics into parsing. Bikel (2000) merged the Brown portion of the Penn Treebank with SemCor, and used it to evaluate a generative bilexical model for joint word sense disambiguation and parsing. Similarly, Agirre et al. (Agirre et al., 2008) integrated semantic information in the form of semantic classes and observed significant improvement in parsing and PP attachment tasks. Xiong et al. (2005) integrated first-sense and hypernym features in a generative parse model applied to the Chinese Penn Treebank and achieved significant improvement over their baseline model. Fujita et al. (2007) extended this work by implementing a discriminative parse selection model, incorporating word sense information and achieved great improvements as well. Examples of integrating selectional preference information into parsing are Dowding et al. (1994) and Hektoen (1997).

7 Conlusion and future work

In this paper, we presented an experimental study attempting to estimate the contribution of unifying multiword expression components into shallow parsing. The evaluation is done based on 118 multiword expressions extracted from *WordNet 3.0*. They consist of two successive components and are in particular, *compound nominals*, *proper names* or *adjective-noun constructions*.

Instead of using pre-annotated text, we collected sentences that contain the above multiword expressions from the web. We applied shallow parsing before and after unifying multiword expression tokens and compared the outputs. We presented a detailed classification of changes in the shallow parser output to aid human annotation during the procedure of deciding if a parser output is correct or wrong.

We presented experimental results about change classes and about the overall improvement of unifying multiword expression tokens with respect to compositionality and the parts of speech of their components. We conclude that unifying the tokens of known multiwords expressions leads to an increase of between 7.5% and 9.5% in accuracy of shallow parsing of sentences that contain these multiword expressions. Increase percentages are higher on *adjective-noun constructions* (12% to 15%); and even higher on non-compositional *adjective-noun constructions* (15.5% to 19.5%).

Future work will focus in conducting similar experiments for multiword expressions longer than two words. One would expect that due to their size, a wrong interpretation of their structure would affect the shallow parser output more than it does for multiword expressions consisting of two words. Thus, unifying multiword expressions longer than two words would potentially contribute more to shallow parsing accuracy.

Furthermore, the evaluation results presented in this paper could be strengthened by adding manual multiword expression annotation to some treebank. This would provide a way to avoid the change class analysis presented in Subsection 3.1 and compute statistics more accurately. Finally, the results of this paper suggest that implementing a parser able to recognise multiword expressions would be very helpful towards high accuracy parsing.

Abstract

In a supertagging task, sequence labeling models are commonly used. But their limited ability to model long-distance information presents a bottleneck to make further improvements. In this paper, we modeled this long-distance information in dependency formalism and integrated it into the process of HPSG supertagging. The experiments showed that the dependency information is very informative for supertag disambiguation. We also evaluated the improved supertagger in the HPSG parser.

1 Introduction

Supertagging is a widely used speed-up technique for lexicalized grammar parsing. It was first proposed for lexicalized tree adjoining grammar (LTAG) (Bangalore and Joshi, 1999), then extended to combinatory categorial grammar (CCG) (Clark, 2002) and head-driven phrase structure grammar (HPSG) (Ninomiya et al., 2006). For deep parsing, supertagging is an important preprocessor: an accurate supertagger greatly reduces search space of a parser. Not limited to parsing, supertags can be used for NP chunking (Shen and Joshi, 2003), semantic role labeling (Chen and Rambow, 2003) and machine translation (Birch et al., 2007; Hassan et al., 2007) to explore rich syntactic information contained in them.

Generally speaking, supertags are lexical templates extracted from a grammar. These templates encode possible syntactic behavior of a word. Although the number of supertags is far larger than the 45 POS tags defined in Penn Treebank, sequence labeling techniques are still effective for supertagging. Previous research (Clark, 2002) showed that a POS sequence is very informative for supertagging, and some extent of local syntactic information can be captured by the context of surrounding words and POS tags. However, since the context window length is limited for the computational cost reasons, there are still long-range dependencies which are not easily captured in sequential models (Zhang et al., 2009). In practice, the multi-tagging technique proposed by Clark (2002) assigned more than one supertag to each word and let the ambiguous supertags be selected by the parser. As for other NLP applications which use supertags, resolving more supertag ambiguities in supertagging stage is preferred. With this consideration, we focus on supertagging and aim to make it as accurate as possible.

In this paper, we incorporated long-distance information into supertagging. First, we used dependency parser formalism to model long-distance relationships between the input words, which is hard to model in sequence labeling models. Then, we combined the dependency information with local context in a simple point-wise model. The experiments showed that dependency information is very informative for supertagging and we got a competitive 93.70% on supertagging accuracy (fed golden POS). In addition, we also evaluated the improved supertagger in the HPSG parser.

2 HPSG Supertagging and Dependency

2.1 HPSG Supertags

HPSG (Pollard and Sag, 1994) is a lexicalist grammar framework. In HPSG, a large number of lexical entries is used to describe word-specific syntactic characteristics, while only a small number of schemas is used to explain general construction rules. These lexical entries are called "HPSG supertags". For example, one possible supertag for the word "like" is written like "[NP.nom<V.bse>NP.acc]_lxm", which indicates

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 645–648,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

the head syntactic category of "like" is verb in base form. It has a NP subject and a NP complement. With such fine-grained grammatical type distinctions, the number of supertags is much larger than the number of tags used in other sequence labeling tasks. The HPSG grammar used in our experiment includes 2,308 supertags. This increases computational cost of sequence labeling models.

2.2 Why Use Dependency in Supertagging

By analyzing the internal structure of the supertags, we found that subject and complements are two important syntactic properties for each supertag. If we could predict subject and complements of the word well, supertagging would be an easier job to do. However, current widely used sequence labeling models have the limited ability to catch these long-distance syntactic relations. In supertagging stage, tree structures are still not constructed. Dependency formalism is an alternative way to describe these two syntactic properties. Based on this observation, we think dependency information could assist supertag prediction.

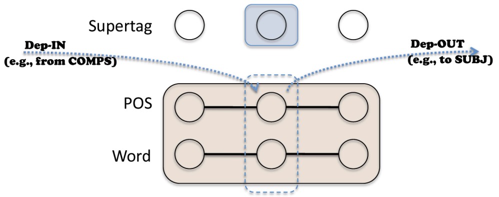

Figure 1: Model structure of incorporating dependency information into the supertagging stage. Dotted arrows describe the augmented long distance dependency information provided for supertag prediction.

3 Our Method

3.1 Modeling Dependency for Supertags

First of all, we need to characterize the dependency between words for supertagging. Since exact dependency locations are not encoded in supertags, to make use of state-of-the-art dependency parser, we recover HPSG supertag dependencies with the aid of HPSG treebanks. The dependencies are extracted from each branch in the HPSG trees by regarding the non-head daughter as the modifier of the head-daughter. HPSG schemas are expressed in dependency arcs.

To model the dependency, we follow mainstream dependency parsing formalism. Two representative methods for dependency parsing are transition-based model like MaltParser (Nivre, 2003) and graph-based model like MSTParser[1] (McDonald et al., 2005). Previous research (Nivre and McDonald, 2008) showed that MSTParser is more accurate than MaltParser for long dependencies. Since our motivation is to capture long-distance dependency as a complement for local supertagging models, we use the projective MSTParser formalism to model dependencies.

MOD-IN	$\{(p_i \Leftarrow p_j)\&s_j \mid (j,i) \in E\}$ $\{(p_i \Leftarrow w_j)\&s_j \mid (j,i) \in E\}$ $\{(w_i \Leftarrow p_j)\&s_j \mid (j,i) \in E\}$ $\{(w_i \Leftarrow w_j)\&s_j \mid (j,i) \in E\}$
MOD-OUT	$\{(p_i \Rightarrow p_j)\&s_i \mid (i,j) \in E\}$ $\{(p_i \Rightarrow w_j)\&s_i \mid (i,j) \in E\}$ $\{(w_i \Rightarrow p_j)\&s_i \mid (i,j) \in E\}$ $\{(w_i \Rightarrow w_j)\&s_i \mid (i,j) \in E\}$

Table 1: Non-local feature templates used for supertagging. Here, p, w and s represent POS, word and schema respectively. Direction (Left/Right) from MODIN/MODOUT word to the current word is also considered in the feature templates.

3.2 Integrating Dependency into Supertagging

There are several ways to combine long-distance dependency into supertagging. Integrating dependency information into training process would be more intuitive. Here, we use feature-based integration. The base model is a point-wise averaged perceptron (PW-AP) which has been shown very effective (Zhang et al., 2009). The improved model structure is described in Figure 1. The long-distance information is formalized as first-order dependency. For the word being predicted, we extract its modifiers (MODIN) and its head (MODOUT) (Table 1) based on first-order dependency arcs. Then MODIN and MODOUT relations are combined as features with local context for supertag prediction. To compare with previous work, the basic local context features are the same as in Matsuzaki et al. (2007).

[1] http://sourceforge.net/projects/mstparser/

4 Experiments

We evaluated dependency-informed supertagger (PW-DEP) both by supertag accuracy [2] and by a HPSG parser. The experiments were conducted on WSJ-HPSG treebank (Miyao, 2006). Sections 02-21 were used to train the dependency parser, the dependency-informed supertagger and the HPSG parser. Section 23 was used as the testing set. The evaluation metric for HPSG parser is the accuracy of predicate-argument relations in the parser's output, as in previous work (Sagae et al., 2007).

Model	Dep Acc%†	Acc%
PW-AP	/	91.14
PW-DEP	90.98	**92.18**
PW-AP (gold POS)	/	92.48
PW-DEP (gold POS)	92.05	**93.70**
	100	**97.43**

Table 2: Supertagging accuracy on section 23. (†) Dependencies are given by MSTParser evaluated with labeled accuracy. PW-AP is the baseline point-wise averaged perceptron model. PW-DEP is point-wise dependency-informed model. The automatically tagged POS tags were given by a maximum entropy tagger with 97.39% accuracy.

4.1 Results on Supertagging

We first evaluated the upper-bound of dependency-informed supertagging model, given gold standard first-order dependencies. As shown in Table 2, with such long-distance information supertagging accuracy can reach 97.43%. Comparing to point-wise model (PW-AP) which only used local context (92.48%), this absolute 4.95% gain indicated that dependency information is really informative for supertagging. When automatically predicted dependency relations were given, there still were absolute 1.04% (auto POS) and 1.22% (gold POS) improvements from baseline PW-AP model.

We also compared supertagging results with previous works (reported on section 22). Here we mainly compared the dependency-informed point-wise models with perceptron-based Bayes point machine (BPM) plus CFG-filter (Zhang et al., 2009). To the best of our knowledge, these are the state-of-the-art results on the same dataset with gold POS tags. CFG-filtering can be considered as an alternative way of incorporating long-distance constraints on supertagging results. Although our baseline system was slightly behind (PW-AP: 92.16% vs. BPM:92.53%), the final accuracies of grammatically constrained models were very close (PW-DEP: 93.53% vs. BPM-CFG: 93.60%); They were not statistically significantly different (P-value is 0.26). As the result of oracle PW-DEP indicated, supertagging accuracy can be further improved with better dependency modeling (e.g., with a semi-supervised dependency parser), which makes it more extensible and attractive than using CFG-filter after the supertagging process.

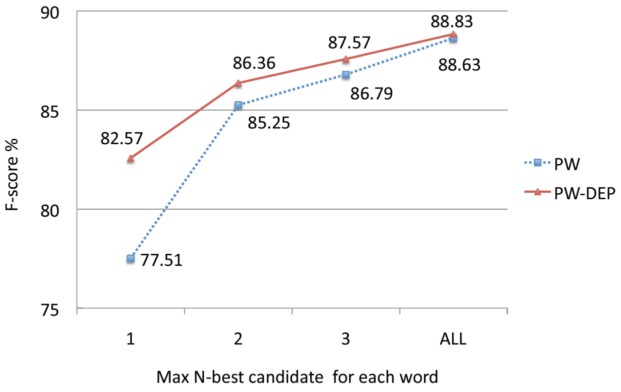

Figure 2: HPSG Parser F-score on section 23, given automatically tagged POS.

4.2 HPSG parsing results

We also evaluated the dependency-informed supertagger in a HPSG parser. Considering the efficiency, we use the HPSG parser[3] described by Matsuzaki et al. (2007).

In practice, several supertag candidates are reserved for each word to avoid parsing failure. To evaluate the quality of the two supertaggers, we restricted the number of each word's supertag candidates fed to the HPSG parser. As shown in Figure 2, for the case when only one supertag was predicted for each word, F-score of the HPSG parser using dependency-informed supertagger is 5.06% higher than the parser using the baseline supertagger module. As the candidate number increased, the gap narrowed: when all candidates were given, the gains gradually came down to 0.2%. This indicated that

[2] "UNK" supertags are ignored in evaluation as previous.

[3] Enju v2.3.1, http://www-tsujii.is.s.u-tokyo.ac.jp/enju.

improved supertagger can optimize the search space of the deep parser, which may contribute to more accurate and fast deep parsing. From another aspect, supertagging can be viewed as an interface to combine different types of parsers.

As for the overall parsing time, we didn't optimize for speed in current setting. The parsing time[4] saved by using the improved supertagger (around 6.0 ms/sen, 21.5% time reduction) can not compensate for the extra cost of MSTParser (around 73.8 ms/sen) now. But there is much room to improve the final speed (e.g., optimizing the dependency parser for speed or reusing acquired dependencies for effective pruning). In addition, small beam-size can be "safely" used with improved supertagger for speed.

Using shallow dependencies in deep HPSG parsing has been previously explored by Sagae et al. (2007), who used dependency constraints in schema application stage to guide HPSG tree construction (F-score was improved from 87.2% to 87.9% with a single shift-reduce dependency parser). Since the baseline parser is different, we didn't make a direct comparison here. However, it would be interesting to compare these two different ways of incorporating the dependency parser into HPSG parsing. We left it as further work.

5 Conclusions

In this paper, focusing on improving the accuracy of supertagging, we proposed a simple but effective way to incorporate long-distance dependency relations into supertagging. The experiments mainly showed that these long-distance dependencies, which are not easy to model in traditional sequence labeling models, are very informative for supertag predictions. Although these were preliminary results, the method shows its potential strength for related applications. Not limited to HPSG, it can be extended to other lexicalized grammar supertaggers.

Ensemble Models for Dependency Parsing: Cheap and Good?

Mihai Surdeanu and Christopher D. Manning
Computer Science Department

{mihais,manning}@stanford.edu

Abstract

Previous work on dependency parsing used various kinds of combination models but a systematic analysis and comparison of these approaches is lacking. In this paper we implemented such a study for English dependency parsing and find several non-obvious facts: (a) the diversity of base parsers is more important than complex models for learning (e.g., stacking, supervised meta-classification), (b) approximate, linear-time re-parsing algorithms guarantee well-formed dependency trees without significant performance loss, and (c) the simplest scoring model for re-parsing (unweighted voting) performs essentially as well as other more complex models. This study proves that fast and accurate ensemble parsers can be built with minimal effort.

1 Introduction

Several ensemble models have been proposed for the parsing of syntactic dependencies. These approaches can generally be classified in two categories: models that integrate base parsers at learning time, e.g., using stacking (Nivre and McDonald, 2008; Attardi and Dell'Orletta, 2009), and approaches that combine independently-trained models only at parsing time (Sagae and Lavie, 2006; Hall et al., 2007; Attardi and Dell'Orletta, 2009). In the latter case, the correctness of the final dependency tree is ensured by: (a) selecting entire trees proposed by the base parsers (Henderson and Brill, 1999); or (b) re-parsing the pool of dependencies proposed by the base models (Sagae and Lavie, 2006). The latter approach was shown to perform better for constituent parsing (Henderson and Brill, 1999).

While all these models achieved good performance, the previous work has left several questions unanswered. Here we answer the following questions, in the context of English dependency parsing:

1. When combining models at parsing time, what is the best scoring model for candidate dependencies during re-parsing? Can a meta classifier improve over unsupervised voting?
2. Are (potentially-expensive) re-parsing strategies justified for English? What percentage of trees are not well-formed if one switches to a light word-by-word voting scheme?
3. How important is the integration of base parsers at learning time?
4. How do ensemble models compare against state-of-the-art supervised parsers?

2 Setup

In our experiments we used the syntactic dependencies from the CoNLL 2008 shared task corpus (Surdeanu et al., 2008).

We used seven base parsing models in this paper: six are variants of the Malt parser[1] and the seventh is the projective version of MSTParser that uses only first-order features[2] (or MST for short). The six Malt

3 Experiments

3.1 On scoring models for parser combination

The most common approach for combining independently-trained models at parsing time is to assign each candidate dependency a score based on the number of votes it received from the base parsers. Considering that parsers specialize in different phenomena, these votes can be weighted by different criteria. To understand the importance of such weighting strategies we compare several voting approaches in Table 2: in the "unweighted" strategy all votes have the same weight; in all other strategies each vote is assigned a value equal to the accuracy of the given parser in the particular instance of the context considered, e.g., in the "weighted by POS of modifier" model we use the accuracies of the base models for each possible part-of-speech (POS) tag of a modifier token. In the table we show results as more base parsers are added to the ensemble (we add parsers in the order given by Table 1). The results in Table 2 indicate that weighting strategies do not have an important contribution to overall performance. The only approach that outperforms the LAS score of the unweighted voting model is the model that weighs parsers by their accuracy for a given modifier POS tag, but the improvement is marginal. On the other hand, the number of base parsers in the ensemble pool is crucial: performance generally continues to improve as more base parsers are considered. The best ensemble uses 6 out of the 7 base parsers.[3]

It is often argued that the best way to re-score candidate dependencies is not through voting but rather through a meta-classifier that selects candidate dependencies based on their likelihood of belonging to the correct tree. Unlike voting, a meta-classifier can combine evidence from multiple contexts (such as the ones listed in Table 2). However, in our experiments such a meta-classifier[4] did not offer any gains over the much simpler unweighted voting strategy. We explain these results as follows: the meta-classifier can potentially help only when it proposes dependencies that disagree with the majority vote. We call such dependencies *minority dependencies*.[5] For a given parser and context instance (e.g., a modifier POS), we define precision of minority dependencies as the ratio of minority dependencies in this group that are correct. Obviously, a

[3] We drew similar conclusions when we replaced voting with the re-parsing algorithms from the next sub-section.

[4] We implemented a L2-regularized logistic regression classifier using as features: identifiers of the base models, POS tags of head and modifier, labels of dependencies, length of dependencies, length of sentence, and combinations of the above.

[5] (Henderson and Brill, 1999) used a similar framework in the context of constituent parsing and only three base parsers.

group of minority dependencies provides beneficial signal only if its precision is larger than 50%. Table 3 lists the total number of minority dependencies in groups with precision larger than 50% for all our base parsers and the most representative features. The table shows that the number of minority dependencies with useful signal is extremely low. All in all, it accounts for less than 0.7% of all dependencies in the development corpus.

3.2 On re-parsing algorithms

To guarantee that the resulting dependency tree is well-formed, most previous work used the dynamic programming algorithm of Eisner (1996) for re-parsing (Sagae and Lavie, 2006; Hall et al., 2007).[6] However, it is not clear that this step is necessary. In other words, how many sentences are not well-formed if one uses a simple word-by-word voting scheme? To answer this, we analyzed the output of our best word-by-word voting scheme (six base parsers weighted by the POS of the modifier). The results for both in-domain and out-of-domain testing corpora are listed in Table 4. The table shows that the percentage of badly-formed trees is relatively large: almost 10% out of domain. This indicates that the focus on algorithms that guarantee well-formed trees is justified.

However, it is not clear how the Eisner algorithm, which has runtime complexity of $O(n^3)$ (n – number of tokens per sentence), compares against approximate re-parsing algorithms that have lower runtime complexity. One such algorithm was proposed by Attardi and Dell'Orletta (2009). The algorithm, which has a runtime complexity of $O(n)$, builds dependency trees using a greedy top-down strategy, i.e., it starts by selecting the highest-scoring root node, then the highest-scoring children, etc. We compare these algorithms against the word-by-word voting scheme in Table 5.[7] The results show that both algorithms pay a small penalty for guaranteeing well-formed trees. This performance drop is statistically significant out of domain. On the other hand, the difference between the Eisner and Attardi algorithms is not statistically significant out of domain.

	In domain	Out of domain
Zero roots	0.83%	0.70%
Multiple roots	3.37%	6.11%
Cycles	4.29%	4.23%
Total	7.46%	9.64%

Table 4: Percentage of badly-formed dependency trees when base parsers are combined using a word-by-word voting scheme. The different error classes do not sum up to the listed total because the errors are not mutually exclusive.

	In domain		Out of domain	
	LAS	UAS	LAS	UAS
Word by word	88.89	91.52	82.13*	87.51*
Eisner	88.83*	91.47*	81.99	87.32
Attardi	88.70	91.34	81.82	87.29

Table 5: Scores of different combination schemes. * indicates that a model is significantly different than the next lower ranked model.

This experiment proves that approximate re-parsing algorithms are a better choice for practical purposes, i.e., ensemble parsing in domains different from the training material of the base models.

3.3 On parser integration at learning time

Recent work has shown that the combination of base parsers at learning time, e.g., through stacking, yields considerable benefits (Nivre and McDonald, 2008; Attardi and Dell'Orletta, 2009). However, it is unclear how these approaches compare against the simpler ensemble models, which combine parsers only at runtime. To enable such a comparison, we reimplemented the best stacking model from (Nivre and McDonald, 2008) – MST$_{Malt}$ – which trains a variant of the MSTParser that uses additional features extracted from the output of a Malt parser.

In Table 6, we compare this stacking approach against four variants of our ensemble models. The superscript in the ensemble name indicates the runtime complexity of the model ($O(n^3)$ or $O(n)$). The cubic-time models use all base parsers from Table 1 and the Eisner algorithm for re-parsing. The linear-time models use only Malt-based parsers and the Attardi algorithm for re-parsing. The subscript in the model names indicates the percentage of available base parsers used, e.g., ensemble$^3_{50\%}$ uses only the first three parsers from Table 1. These results show that MST$_{Malt}$ is statistically equivalent to an ensemble that uses MST and two Malt variants, and both our ensemble$_{100\%}$ models are significantly better than MST$_{Malt}$. While this comparison is somewhat unfair (MST$_{Malt}$ uses two base models, whereas our ensemble models use at least three) it

[6] We focus on projective parsing algorithms because 99.6% of dependencies in our data are projective (Surdeanu et al., 2008).

[7] Statistical significance was performed using Dan Bikel randomized parsing evaluation comparator at 95% confidence.

	In domain		Out of domain	
	LAS	UAS	LAS	UAS
ensemble$^3_{100\%}$	88.83*	91.47*	81.99*	87.32*

ensemble$^1_{100\%}$	88.01	90.76	80.78	86.55

Table 7: Comparison with state of the art parsers.

does illustrate that the advantages gained from combining parsers at learning time can be easily surpassed by runtime combination models that have access to more base parsers. Considering that variants of shift-reduce parsers can be generated with minimal effort (e.g., by varying the parsing direction, learning algorithms, etc.) and combining models at runtime is simpler than combining them at learning time, we argue that runtime parser combination is a more attractive approach.

3.4 Comparison with the state of the art

In Table 7 we compare our best ensemble models against the top two systems of the CoNLL-2008 shared task evaluation. The table indicates that our best ensemble model ranks second, outperforming significantly 19 other systems. The only model performing better than our ensemble is a parser that uses higher-order features and has a higher runtime complexity ($O(n^4)$) (Johansson and Nugues, 2008). While this is certainly proof of the importance of higher-order features, it also highlights a pragmatic conclusion: in out-of-domain corpora, an ensemble of models that use only first-order features achieves performance that is within 1% LAS of much more complex models.

4 Conclusions

This study unearthed several non-intuitive yet important observations about ensemble models for dependency parsing. First, we showed that the diversity of base parsers is more important than complex learning models for parser combination, i.e., (a) ensemble models that combine several base parsers at runtime performs significantly better than a state-of-the-art model that combines two parsers at learning time, and (b) meta-classification does not outperform unsupervised voting schemes for the re-parsing of candidate dependencies when six base models are available. Second, we showed that well-formed dependency trees can be guaranteed without significant performance loss by linear-time approximate re-parsing algorithms. And lastly, our analysis indicates that unweighted voting performs as well as weighted voting for the re-parsing of candidate dependencies. Considering that different base models are easy to generate, this work proves that ensemble parsers that are both accurate and fast can be rapidly developed with minimal effort.

Abstract

Stochastic Inversion Transduction Grammars constitute a powerful formalism in Machine Translation for which an efficient Dynamic Programming parsing algorithm exists. In this work, we review this parsing algorithm and propose important modifications that enlarge the search space. These modifications allow the parsing algorithm to search for more and better solutions.

1 Introduction

Syntax Machine Translation has received great attention in the last few years, especially for pairs of languages that are sufficiently non-monotonic. Several works have explored the use of syntax for Machine Translation (Wu, 1997; Chiang, 2007). In (Wu, 1997), Stochastic Inverse Transduction Grammars (SITGs) were introduced for describing structurally correlated pairs of languages. SITGs can be used to simultaneously analyze two strings from different languages and to correlate them. An efficient Dynamic Programming parsing algorithm for SITGs was presented in (Wu, 1997). This algorithm is similar to the CKY algorithm for Probabilistic Context Free Grammars. The parsing algorithm does not allow the association of two items that have the empty string in one of their sides. This limitation restricts the search space and prevents the algorithm from exploring some valid parse trees.

In this paper, we review Wu's parsing algorithm for SITGs (referred to as the original algorithm) and propose some modifications to increase the search space in order to make it possible to find these valid parse trees.

2 SITG Parsing

SITGs (Wu, 1997) can be viewed as a restricted subset of Stochastic Syntax-Directed Transduction Grammars (Maryanski and Thomason, 1979). Formally, a SITG in Chomsky Normal Form can be defined as a set of lexical rules that are noted as $A \rightarrow x/\epsilon$, $A \rightarrow \epsilon/y$, $A \rightarrow x/y$; direct syntactic rules that are noted as $A \rightarrow [BC]$; and inverse syntactic rules that are noted as $A \rightarrow \langle BC \rangle$, where A, B, C are non-terminal symbols, x, y are terminal symbols, ϵ is the empty string, and each rule has a probability value p attached. The sum of the probabilities of the rules with the same non-terminal in the left side must be equal to 1. When a direct syntactic rule is used in parsing, both strings are parsed with the syntactic rule $A \rightarrow BC$. When an inverse rule is used in parsing, one string is parsed with the syntactic rule $A \rightarrow BC$, and the other string is parsed with the syntactic rule $A \rightarrow CB$.

An efficient Viterbi-like parsing algorithm that is based on a Dynamic Programming Scheme was proposed in (Wu, 1997). It allows us to obtain the most probable parse tree that simultaneously analyzes two strings, $X = x_1 ... x_{|X|}$ and $Y = y_1 ... x_{|Y|}$, i.e. the bilingual string X/Y. It has a time complexity of $O(|X|^3|Y|^3|R|)$, where $|R|$ is the number of rules of the grammar.

The parsing algorithm is based on the definition of:

$$\delta_{ijkl}(A) = \widehat{\Pr}(A \overset{*}{\Rightarrow} x_{i+1} \cdots x_j / y_{k+1} \cdots y_l)$$

as the maximum probability of any parsing tree that simultaneously generates the substrings $x_{i+1} \cdots x_j$ and $y_{k+1} \cdots y_l$ from the non-terminal symbol A .

In (Wu, 1997), the parsing algorithm was defined as follows:

\end{aligned}$$

2. Recursion

For all $A\in N$ and i,j,k,l such that $\begin{cases} 0\le i<j\le |X|,\\ 0\le k<l\le |Y|,\\ j-i+l-k>2,\end{cases}$ (1)

$$\delta_{ijkl}(A) = \max(\delta^{[]}_{ijkl}(A), \delta^{\langle\rangle}_{ijkl}(A))$$

where

$$\delta^{[]}_{ijkl}(A) = \max_{\substack{B,C\in N\\ i\le I\le j, k\le K\le l\\ (I-i)(j-I)+(K-k)(l-K)>0}} p(A\to[BC])\delta_{iIkK}(B)\delta_{IjKl}(C) \quad (2)$$

$$\delta^{\langle\rangle}_{ijkl}(A) = \max_{\substack{B,C\in N\\ i\le I\le j, k\le K\le l\\ (I-i)(j-I)+(K-k)(l-K)>0}} p(A\to\langle BC\rangle)\delta_{iIKl}(B)\delta_{IjkK}(C) \quad (3)$$

$$\begin{array}{rlllrlll}
p & S & \to [SS] & & p & S & \to \langle SS\rangle\\
q & S & \to \epsilon/b & & q & S & \to a/\epsilon\\
1-2p-2q & S & \to a/b & & & &
\end{array}$$

Figure 1: Example SITG.

This algorithm cannot provide the correct parsing tree in some situations. For example, consider the SITG shown in Fig. 1. If the input pair is a/b, this SITG provides the parse tree (a) that is shown in Fig. 2 with probability $1-2p-2q$. However, the parse tree (b) is more likely if $1-2p-2q<2pq$. The above parsing algorithm is not able to obtain this parse tree due to the restriction $j-i+l-k>2$ in (1). This restriction does not allow the algorithm to consider two subproblems in which each substring has length 1 which have not been previously considered in the initialization step. Changing this restriction to $j-i+l-k\ge 2$ is not enough to tackle this situation since the restriction $(I-i)(j-I)+(K-k)(l-K)\neq 0$ in expression (2) is not accomplished given that $I=i$ or $I=j$, and $K=k$ or $l=K$ (similarly in expression (3)).

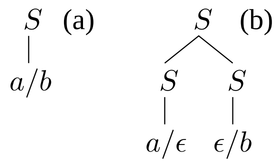

Figure 2: Parse tree (a) can be obtained with Wu's algorithm for a/b, but parse tree (b) cannot be obtained.

From now on, we will use the term *non-explored trees* to denote the set of trees that are possible when rules of the grammar are applied but cannot be explored with Wu's algorithm. In fact, this situation appears for other paired strings (see Fig. 3) in which a string in one side is associated with the empty string in the other side through rules that are not lexical rules. For example, in Fig. 3b, substring aa could be associated with ϵ. However,this parse tree cannot be obtained with the algorithm due to the search restrictions described above.

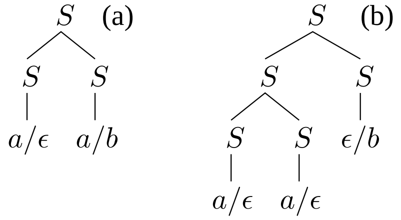

Figure 3: Parse tree (a) can be obtained with Wu's algorithm for aa/b, but parse tree (b) would be more probable if $pq^2>1-2p-2q$.

The changes needed in the algorithm to be able to find the sort of parsing trees described above are the following:

- Changing restriction $j-i+l-k>2$ in (1) to $j-i+l-k\ge 2$. Note that this new restriction is redundant and could be removed.
- Changing restriction $(I-i)(j-I)+(K-k)(l-K)\neq 0$ to $((j-I)+(l-K))*((I-i)+(K-k))\neq 0$ in (2) and to $((j-I)+(K-k))*((I-i)+(l-K))\neq 0$ in (3) in order to guarantee the algorithm's termination.

3 Search under SITG Constraints

The modifications that have been introduced in Section 2 enlarge the search space and allow the parsing algorithm to explore a greater number of possible solutions. We illustrate this situation with an example. Consider the SITG introduced in Figure 1. Fig. 4 shows the possible complete matched trees for the input pair a/b that are considered in the search process with the modifications introduced.

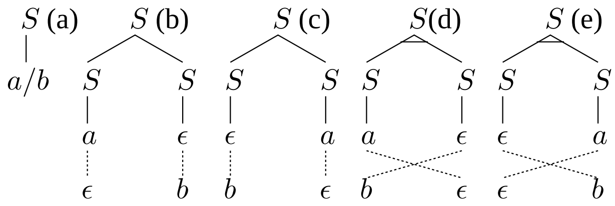

Figure 4: Parse trees for input pair a/b that are taken into account in the search process with the modifications.

Without these modifications, the parsing algorithm only takes into account tree (a) of Fig. 4. For this grammar, we have computed the growth in number of complete matched trees. Table 1 shows how the search space grows notably with the modifications introduced.

n	Wu's alg.	Modified alg.	ratio
1	1	5	0.200
2	34	290	0.117
3	1,928	34,088	0.057
4	131,880	5,152,040	0.026
5	10,071,264	890,510,432	0.011
6	827,969,856	167,399,588,160	0.005

Table 1: Growth in number of explored trees for the original and modified parsing algorithms (n is the length of the input pair strings and the last column represents the ratio between columns two and three).

As a preliminary experiment and in order to evaluate empirically the Wu's parsing algorithm versus the modified algorithm, we parsed first 100K sentence of German-English Europarl corpus. The lexical rules in the Bracketing SITG used for parsing were obtained from a probabilistic dictionary by aligning with IBM3 model (NULL aligments were also included). In this experiment, the modified algorithm obtained a more probable parse tree for 6% of the sentences. If we added brackets to the sentences separately with monolingual parsers, we could use a parsing algorithm similar to the algorithm that is described in (Sánchez and Benedí, 2006). The monolingual brackets restricted the parse tree to those that were compatible with the brackets. In that case the modified algorithm obtained a more probable parse tree for 14% of the sentences.

4 Inside Probability

The parsing algorithm described above computes the most likely parse tree for a given paired string X/Y. However, in some cases (Wu, 1995; Huang and Zhou, 2009), we need the inside probability ($\beta_{0,|X|,0,|Y|}(S)$), i.e., the probability that the grammar assigns to the whole set of parse trees that yield X/Y. If the maximizations are replaced by sums, the algorithm can be used to compute the inside probability. However, as stated above, the original algorithm cannot find the whole set of trees for a given paired string in some cases. These non-explored trees have a probability greater than 0.

As an example, we computed the amount of probability lost in the inside computation using the original algorithm with the grammar shown in Fig. 1. Let Γ be the amount of probability of the non-explored trees (the lost probability). It must be noted that since height 1 trees are all reachable, we must accumulate lost probability for trees of height 2 or more. Hence, let γ be the amount of lost probability for trees of height 2 or more. Note that all such trees must have initially used the production $S \to SS$ inversely or directly. Thus, $\Gamma = 2p \cdot \gamma$. Fig. 5 shows the kinds of non-explored trees. Then γ is:

$$\gamma = 4 \cdot q^2 + 2 \cdot 2p \cdot (1-2p) \cdot \gamma + (2p)^2 \cdot (2\gamma(1-\gamma)+\gamma^2)$$

The first addend is the probability of the non-explored trees of height 2 (Fig. 5a). The second addend is the probability that one of the subtrees uses a syntactic production, this new subtree produces a non-explored tree ($2p \cdot \gamma$) and the other subtree

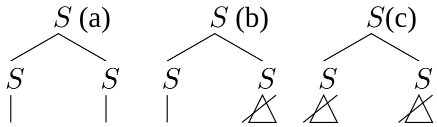

Figure 5: Partial representation of non-explored parse trees from the non-terminal string SS introduced after the first derivation step: (a) both non-terminals yield a terminal in one side and the empty string in the other; (b) one of the non-terminals uses a lexical production and the other non-terminal yields a non-explored tree; (c) both non-terminals use a syntactic production and one (or both) yields a non-explored tree.

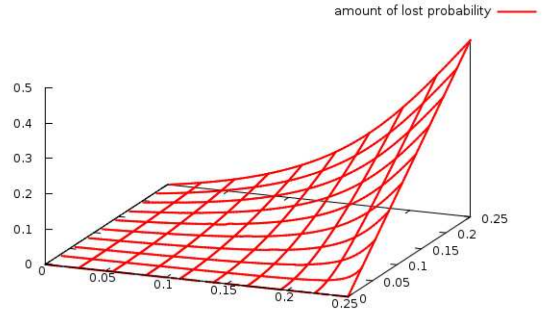

Figure 6: Amount of lost probability for values of p and q.

rewrites itself using a lexical production $(1 - 2p)$. Note that the non-explored tree can be yielded from either the left or the right non-terminal, (Fig. 5b). The third addend is the probability that both non-terminals use a syntactic production $(2p)^2$ and either one $(2(\gamma)(1-\gamma))$ or both (γ^2) subtrees are non-explored trees (Fig. 5c). If we isolate Γ, we get

$$\Gamma = 2p \cdot \frac{1 - 4p \pm \sqrt{16p^2 - 8p + 1 + 64p^2q^2}}{4p^2}$$

Since the solution with the positive square root takes values greater than 1, we can discard it.

Fig. 6 shows the probability accumulated in the non-explored trees for values of p and q between 0 and 0.25 (higher values of p produce inconsistent SITGs). That is the amount of probability lost in the inside parsing for the whole language generated by the grammar shown in Fig. 1.

In order to prove the loss of probability produced by the original algorithm, we use the grammar in Fig. 1 with $p = q = 0.2$. We parse all the paired strings X/Y such that $|X| + |Y| \leq l$, where l is a fixed maximum length. We repeat the same experiment using the modified algorithm. Fig. 7 shows the accumulated inside probabilities for both original and modified algorithms and the theoretical maximums ($1 - \Gamma$ for the original algorithm and 1 for the modified algorithm). Note that the computed results approach the theoretical maximums and the modified algorithm covers the whole search space.

5 Conclusions

SITGs have proven to be a powerful tool in Syntax Machine Translation. However, the algorithms have been proposed do not explore all the possible parse trees. This work proposes modifications of the algorithms to be able to explore the whole search space.

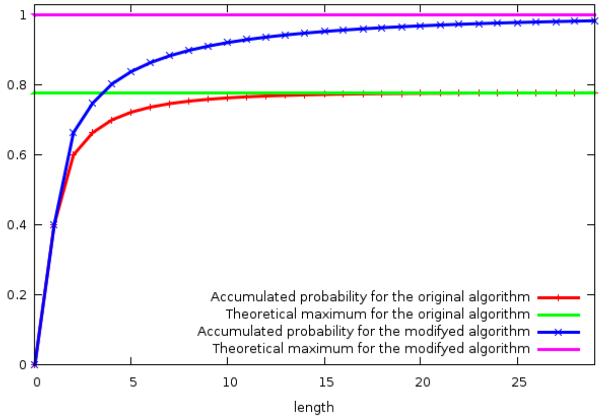

Figure 7: Accumulated inside probability for the original and modified algorithms.

Using an example, we have shown that the modifications allow a complete search. As future work, we plan to proove the correctness of the modified algorithm and to study the impact of these modifications on the use of SITGs for Machine Translation, and the estimation of SITGs.

Abstract

The paper describes a data driven dependency parsing approach which uses clausal information of a sentence to improve the parser performance. The clausal information is added automatically during the parsing process. We demonstrate the experiments on Hindi, a language with relatively rich case marking system and free-word-order. All the experiments are done using a modified version of MSTParser. We did all the experiments on the ICON 2009 parsing contest data. We achieved an improvement of 0.87% and 0.77% in unlabeled attachment and labeled attachment accuracies respectively over the baseline parsing accuracies.

1 Introduction

Linguistic analysis of morphologically rich free-word-order languages (MoRFWO) using dependency framework have been argued to be more effective (Shieber, 1985; Mel'čuk, 1988, Bharati et al., 1993). Not surprisingly, most parsers for such languages are dependency based (Nivre et al., 2007a; Bharati et al., 2008a; Hall et al., 2007). In spite of availability of annotated treebanks, state-of-the-art parsers for MoRFWO have not reached the performance obtained for English. Some of the reasons stated for the low performance are small treebank size, complex linguistic phenomenon, long-distance dependencies, and non-projective structures (Nivre et al., 2007a, 2007b; Bharati et al., 2008a).

Several approaches have been tried to handle these difficulties in such languages. For Hindi, Bharati et al. (2008a) and Ambati et al. (2009) used semantic features in parsing to reduce the negative impact of unavailable syntactic features and showed that use of minimal semantics can help in identifying certain core dependency labels. Various attempts have proved to simplify the structure by dividing the sentence into suitable linguistic units (Attardi and Dell'Orletta 2008; Bharati et al., 1993, 2008b, 2009; Husain et al., 2009). These approaches handle complex structures by breaking the parsing process into several steps. Attardi and Dell'Orletta (2008) used chunk information as a feature to MaltParser (Nivre et al., 2007a) for parsing English. Bharati et al., 1993 used the notion of local word groups, while Bharati et al., 2009 and Husain et al., 2009 used clauses.

In this paper, we describe a data driven dependency parsing approach which uses clausal information of a sentence to improve the parser performance. Previous attempts at data driven parsing for Hindi have failed to exploit this feature explicitly. The clausal information is added automatically during the parsing process. We demonstrate the experiments on Hindi[1]. All the experiments are done using a modified version of MSTParser (McDonald et al., 2005a and the references therein) (henceforth MST) on the ICON 2009 parsing contest[2] (Husain, 2009) data. We achieved an improvement of 0.87% and 0.77% in unlabeled attachment and labeled attachment accuracies respectively over the baseline parsing accuracies.

[1] Hindi is a verb final language with free word order and a rich case marking system. It is an official language of India and is spoken by ~800 million people.

2 Why Clausal Information?

Traditionally, a clause is defined as a group of words having a subject and a predicate. Clause boundary identification is the process of dividing the given sentence into a set of clauses. It can be seen as a partial parsing step after chunking, in which one tries to divide the sentence into meaningful units. It is evident that most of the dependents of words in a clause appear inside the same clause; in other words the dependencies of the words in a clause are mostly localized within the clause boundary.

In the dependency parsing task, a parser has to disambiguate between several words in the sentence to find the parent/child of a particular word. This work is to see whether the clause boundary information can help the parser to reduce the search space when it is trying to find the correct parent/child for a word. The search space of the parser can be reduced by a large extent if we solve a relatively small problem of identifying the clauses. Interestingly, it has been shown recently that most of the non-projective cases in Hindi are inter-clausal (Mannem et al., 2009). Identifying clausal boundaries, therefore, should prove to be helpful in parsing non-projective structures. The same holds true for many long-distance dependencies.

3 Experimental Setup

3.1 Dataset

The experiments reported in this paper have been done on Hindi; the data was released as part of the ICON 2009 parsing contest (Husain, 2009). The sentences used for this contest are subset of the Hyderabad Dependency Treebank (HyDT) developed for Hindi (Begum et al., 2008). The dependency relations in the treebank are syntactico-semantic. The dependency tagset in the annotation scheme has around 28 relations. The dependency trees in the treebank show relations between chunk heads. Note, therefore, that the experiments and results described in this paper are based on parse trees that have chunk head as nodes.

The data provided in the task contained morphological features along with the lemma, POS tag, and coarse POS tag, for each word. These are six morphological features namely category, gender, number, person, vibhakti[3] or TAM[4] markers of the node

3.2 Clause Boundary Identifier

We used the Stage1[5] parser of Husain et al. (2009), to provide the clause boundary information that is then incorporated as features during the actual parsing process. The Stage1 parser uses MST to identify just the intra-clausal relations. To achieve this, Husain et al., introduce a special dummy node named _ROOT_ which becomes the head of the sentence. All the clauses are connected to this dummy node with a dummy relation. In effect the Stage1 parser gives only intra-clausal relations. In the current work, we used MaltParser[6] (Nivre et al., 2007b) (henceforth Malt) to do this task. This is because Malt performs better than MST in case of intra-clausal relations, which are mostly short distance dependencies. We use the same algorithm and feature setting of Bharati et al., (2008a) to train the Stage1 parser.

Since the above tool parses clauses, therefore along with the clause boundary information we also know the root of the clausal sub-tree. Several experiments were done to identify the most optimal set of clausal features available from the partial parse. The best results are obtained when the clause boundary information, along with the head information i.e. head node of a clause, is given as a feature to each node.

We trained the Stage1 parser by converting the treebank data into the stage1 format, following the steps that were given in Husain et al. (2009). This conversion depends on the definition of the clause. We experimented with different definitions of clause in order to tune the tool to give the optimal clause boundary and head information required for parsing. For the results reported in this paper, a clause is a sequence of words, with a single verb, unless the verb is a child of another verb.

[3] Vibhakti is a generic term for preposition, post-position and suffix.

[4] TAM: Tense, Aspect and Modality.

[5] Stage1 handles intra-clausal dependency relations. These relations generally correspond to the argument structure of the verb, noun-noun genitive relation, infinitive-noun relation, adjective-noun, adverb-verb relations, etc.

[6] Malt version 1.2

	Precision	Recall
Clause Boundary	84.83%	91.23%
Head Information	92.42%	99.40%

Table 1. Accuracies of the features being used

Table 1 gives the accuracy of the clausal information being used as features in parsing. It is clear from Table1 that the tool being used doesn't have very high clause boundary identification performance; nevertheless, the performance is sufficient enough to make an improvement in parsing experiments. On the other hand, the head of the clause (or, the root head in the clausal sub-tree) is identified efficiently. All the above experiments for parameter tuning were done on the development data of the ICON 2009 parsing contest.

3.3 Parser

We used MSTParser[7] for the actual parsing step. MST uses Chu-Liu-Edmonds Maximum Spanning Tree Algorithm for non-projective parsing and Eisner's algorithm for projective parsing (Eisner, 1996). It uses online large margin learning as the learning algorithm (McDonald et al., 2005b).

We modified MST so that it uses the clause boundary. Unlike the normal features that MST uses, the clause boundary features span across many words.

.

4 Experiments and Results

We experimented with different combinations of the information provided in the data (as mentioned in 3.1). Vibhakti and TAM fields gave better results than others. This is consistent with the best previous settings for Hindi parsing (Bharati et al., 2008a, Ambati et al., 2009). We used the results obtained using this setting as our baseline (F1).

We first experimented by giving only the clause inclusion (boundary) information to each node (F2). This feature should help the parser reduce its search space during parsing decisions. Then, we provided only the head and non-head information (whether that node is the head of the clause or not) (F3). The head or non-head information helps in handling complex sentences that have more than one clause and each verb in the sentence has its own argument structure. We achieved the best performance by using both as features (F4) during the parsing process.

	LA (%)	UA (%)	L (%)
F1	73.62	91.00	76.04
F2	72.66	91.00	74.74
F3	73.88	91.35	75.78
F4	74.39	91.87	76.21

Table 2. Parsing accuracies with different features

Table 2 gives the results for all the settings. It is interesting to note that the boundary information (F1) alone does not cross the baseline; however this feature is reliable enough to give the best performance when combined with F3.

5 Observations

We see from the above results (F4 in Table 2) that there is a rise of 0.87% in UA (unlabeled attachment) and 0.77% in LA (labeled attachment) over previous best (F1). This shows the positive effect of using the clausal information during the parsing process.

We analyzed the performance of both the parsers in handling the long distance dependencies and non-projective dependencies. We found that the non-projective arcs handled by F4 have a precision and recall of 41.1% and 50% respectively for UA, compared to 30.5% and 39.2% for the same arcs during F1.

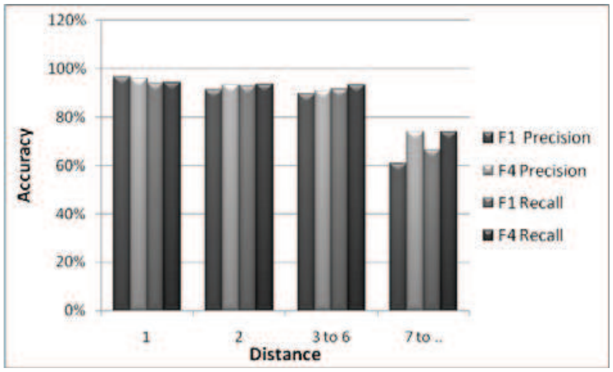

Figure 1. Distance stats

Figure 1 compares the accuracies of the dependencies at various distances. It is clear that the effect of clausal information become more

[7] MST version 0.4b

pronounced as the distance increases. This means F4 does help the parser in effectively handling long distance dependencies as well.

6 Conclusion and Future Work

The results show that there is a significant improvement in the parsing accuracy when the clausal information is being used.

The clausal information is presently being used only as attachment features in MST. Experiments can be done in future, to find out if there is a label bias to the clause boundary, which also helps in reducing the search space for specific labels. Improving the feature set for the labeled parse also improves the unlabeled attachment accuracy, as MST does attachments and labels in a single step, and the labels of processed nodes will also be taken in features.

We can see from Table1 that the precision of the clause boundary is 84.83%. Using a tool, targeted at getting just the clausal information, instead of using a parser can improve the accuracy of the clausal information, which helps improving parsing.

A Treebank Query System Based on an Extracted Tree Grammar

Seth Kulick and **Ann Bies**
Linguistic Data Consortium
University of Pennsylvania
3600 Market St., Suite 810
Philadelphia, PA 19104
{skulick,bies}@ldc.upenn.edu

Abstract

Recent work has proposed the use of an extracted tree grammar as the basis for treebank analysis and search queries, in which queries are stated over the elementary trees, which are small chunks of syntactic structure. However, this work was lacking in two crucial ways. First, it did not allow for including lexical properties of tokens in the search. Second, it did not allow for using the derivation tree in the search, describing how the elementary trees are connected together. In this work we describe an implementation that overcomes these problems.

1 Introduction

(Kulick and Bies, 2009) describe the need for treebank search that compares two sets of trees over the same tokens. Their motivation is the problem of comparing different annotations of the same data, such as with inter-annotator agreement evaluation during corpus construction. The typical need is to recognize which annotation decisions the annotators are disagreeing on. This is similar to the problem of determining where the gold trees and parser output differ, which can also be viewed as two annotations of the same data.

As they point out, for this purpose it would be useful to be able to state queries in a way that relates to the decisions that annotators actually make, or that a parser mimics. They provide examples suggesting that (parent, head, sister) relations as in e.g. (Collins, 2003) are not sufficient, and that what is needed is the ability to state queries in terms of small chunks of syntactic structure.

Their solution is to use an extracted tree grammar, inspired by Tree Adjoining Grammar (Joshi and Schabes, 1997). The "elementary trees" of the TAG-like grammar become the objects on which queries can be stated. They demonstrate how the "lexicalization" property of the grammar, in which each elementary tree is associated with one or more token, allows for the the queries to be carried out in parallel across the two sets of trees.

However, the work was lacking in two crucial ways. First, it did not allow for including lexical properties of a token, such as its Part-of-Speech tag, together with the elementary tree search. This made it impossible to formulate such queries as "find all ADVP elementary trees for which the head of the tree is a NOUN_NUM". Even more seriously, there was no way to search over the "derivation tree", which encodes how the extracted elementary trees combine together to create the original tree. This made it impossible to carry out searches such as "find all verb frames with a PP-LOC modifying it", and in general to search for the crucial question of where annotators disagree on attachment decisions.

In this paper we describe how we have solved these two problems.

2 Tree Extraction

Following (Kulick and Bies, 2009), we draw our examples from the Arabic Treebank[1] For our gram-

[1] Part 3, v3.1 - Linguistic Data Consortium LDC2008E22. Also, we use the Buckwalter Arabic transliteration scheme http://www.qamus.org/transliteration.htm.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 661–664,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

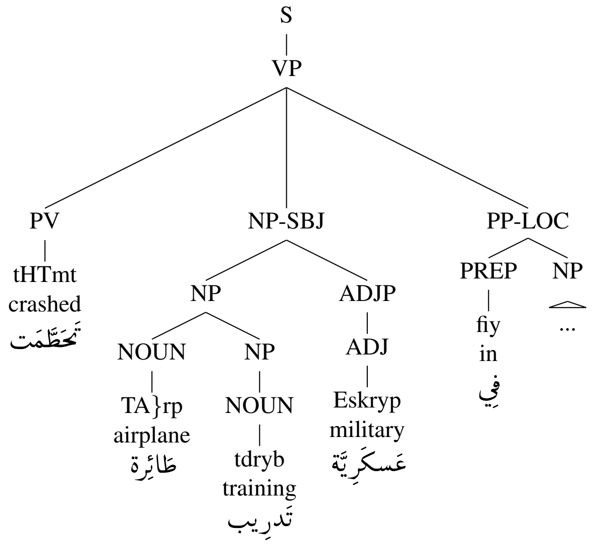

Figure 1: Sample tree

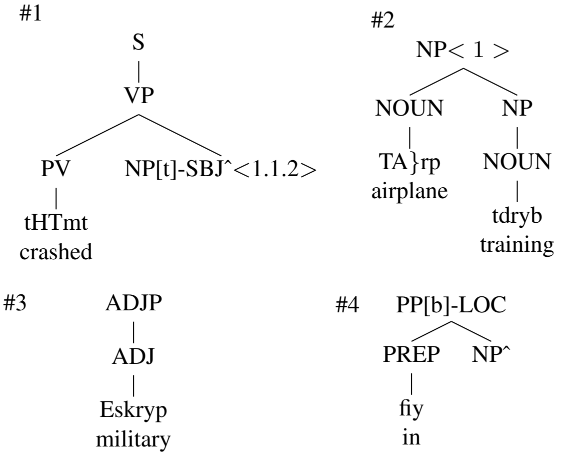

Figure 2: Extracted trees from Figure 1

mar we use a TAG variant with tree-substitution, sister-adjunction, and Chomsky-adjunction (Chiang, 2003), using head rules to decompose the full trees and extract the elementary trees. Sister adjunction attaches a tree (or single node) as a sister to another node, and Chomsky-adjunction forms a recursive structure as well, duplicating a node. As one example, the full tree is shown in Figure 1, and the extracted elementary trees[2] are shown in Figure 2. We briefly mention two unusual features of this extraction, and refer the reader to (Kulick and Bies, 2009) for detail and justification.

(1)The function tags are included in the tree extraction, with the syntactic tags such as SBJ treated as a top feature value, and semantic tags such as LOC treated as a bottom feature value, extending the traditional TAG feature system to handle function tags.

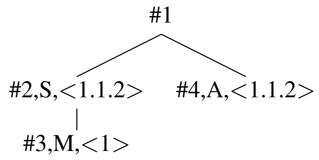

Figure 3: Derivation Tree for Figures 1 and 2

(2) Etree #2 consists of two anchors, rather than splitting up the tree decomposition further. This is because this is an instance of the "construct state" construction in Arabic, in which two or more words are grouped tightly together.

The nodes in the elementary trees are numbered with their Gorn address, and we make two such addresses explicit, in trees #1 and #2. These addresses appear in the derivation tree in Figure 3. Each node in the derivation tree refers to one etree in Figure 2, and each node (except the root) is labelled with the address in the parent etree to which it attaches, and the attachment type (M for Chomsky-adjunction, A for sister-adjunction, and S for substitution).[3] The ^ symbol at the node NP[t]-SBJ in tree #1 indicates that it is a substitution node. Etree #3 Chomsky-adjoins at the root of etree #2, thus forming a a new NP node. Etree #4 sister-adjoins at the NP[t]-SBJ node in etree #1, thus becoming a sister to that node.

It is often the case that the same elementary tree structure will be repeated in different elementary trees extracted from a corpus. We call each such structure an "etree template", and a particular instance of that template, together with the "anchors" (tokens) used in that instance of the template, is called an "etree instance".

The extracted tokens, etree templates, etree instances, and derivation trees are stored in a MySQL database for later search. The derivation tree is implemented with a simple "adjacency list" representation as is often done in database representations of hierarchical structure. The database schema is organized with appropriate indexing so that a full tree is represented by a derivation tree, with integers point-

[2] We will use "etree" as shorthand for "elementary tree".

[3] This derivation tree is slightly simplified, since with sister-adjunction it includes more information to indicate the direction and order of attachment.

```
LEX   : (L1) text="fiy"
ETREE: (E1) (S (VP A$
                    NP[t]-SBJ^{dta:1}))
       (E2) (PP A${lex:L1} NP^)
DTREE: (D1) E2
       (D2) (E1 E2{dta:1})
```

Figure 4: Examples of one lexical restriction, two etree queries, and two dtree queries

ing to the etree instances, which in turn use integers to represent the etree template in that etree instance and also point to the anchors of that etree instance.

The section of ATB we are working with has 402,246 tokens, resulting in 319,981 etree instances and only 2804 etree templates, which gives an indication of the huge amount of duplication of structure in a typical treebank representation. From the perspective of database organization, the representation of the etree templates can be perhaps be viewed as a type of database "normalization", in which duplicate information is placed in a separate table.

3 Query Processing

We now describe the algorithm used for searching on the database with the extracted tree grammar, focusing on how the algorithm now allows searching based on the derivation tree and lexical information.

Queries are specified as "etree queries" and "dtree queries". Sample queries are shown in Figure 4. The query processing is as follows:

Step 1:
The etree templates are searched to determine which match a given etree query.[4] This is a simple tree matching between each template and query, all of which are small small trees. It is within this tree matching that several of the typical relations can be specified, such as precedence and dominance. A table stores the information on which templates match which queries.

In addition, the Etree queries can now include two new properties. First, they can include a specification for a lexical restriction, such as lex:L1 in E2 in Figure 4. However, step 1 of the query processing does not actually check this, since it is simply going through each template, without examining any anchors, to determine which have the appropriate structure to match a query. Therefore, we store in another table the information that for a (template, query) to match it must be the case that an anchor at a particular address in that template satisfies a particular lexical restriction. It in effect produces specialized information for the given template as to what additional restrictions apply for that (template, query) pair to succeed as a match, in each etree instance that uses that etree template. For example, in this case the stored information specifies that an etree instance with template (PP A NP^) matches the query E2 if the instance has an anchor with the text fiy at address 1.1 (the anchor A).

Similarly, the etree query can include a specification dta (as in E1), for "derivation tree address", indicating that the corresponding address in each matching template needs to be stored for later reference in derivation tree searching. In this case, the template for etree instance #1 will match etree query E1, with the additional information stored that the address 1.1.2 will be used for later processing.

An important point here is that this additional information is not necessarily the same for the different templates that otherwise match a query. For example, the two templates

```
(1)       (S (VP A NP[t]-SBJ<1.1.2>)
(2) (SBAR (S (VP A NP[t]-SBJ<1.1.1.2>))
```

both match query E1, but for (1) the stored address dta:1 is 1.1.2, while for (2) the stored address is is 1.1.1.2. The same point holds for the address of the anchor with a lexical restriction.

Step 2:
For a given query, the matching etree instances are found. First it finds all etree instances such that the (template, query) is a match for the instance's etree template. It then filters this list by checking the lexical restriction, if any, for the anchor at the appropriate address in the etree instance, using the information stored from step 1. In the above example, this will select etree instance #4 as satisfying query E2, since the template for instance #4 was determined in step 1 to match E2, and the particular instance #4

[4] Each etree query has a "distinguished" anchor marked A$ that indicates the anchor (word) of an etree template that is associated with that query. The reason for that is that if an etree template has more than one anchor, we only want one to trigger that query, so that the etree is not counted twice.

also satisfies the lexical restriction in query E2.

Step 3:

The final results are reported using the dtree queries. Some dtree queries are singletons naming an etree query, such as D1, indicating that the dtree query is simply that etree query. In this example, any etree instance that satisfies the etree query E2 is reported as satisfying the dtree query D1.

The dtree query can also specify nodes in a derivation tree that must satisfy specified etree queries and also be in a certain relationship in the derivation tree. For example, dtree query D2 in Figure 4 specifies that the query is for two nodes in a parent-child relationship in the derivation tree, such that the parent node is for an etree instance that satisfies etree query E1, and the child is an instance that satisfies etree query E2. Furthermore, the address in the derivation tree is the same as the address dta:1 that was identified during Step 1. Note that the address is located on the parent tree during Step 1, but appears in the derivation tree on the child node.

Steps 1 and 2 identify etree instance #1 as satisfiying etree query E1, with dta:1 stored as address <1.1.2> for the template used by instance #1. These steps also identifed etree instance #4 as satisfying etree query E2. Step 3 now determines that etree instances #1 and #4 are in a derivation tree relationship that satisfies dtree query D2, by checking for a parent-child relationship between them with the address <1.1.2>.[5] So dtree query D1 is finding all PP etrees headed by ”fiy”, and dtree query D2 is finding all clauses with a subject after the verb, with a PP attaching next to the subject, where the PP is headed by ”fiy”.

We consider the distinguished anchor (see footnote 4) for a dtree query to be the distinguished anchor of the parent node. The earlier work on comparing two sets of trees (Kulick and Bies, 2009) can then use this to report such searches as ”the annotators agree on the same verbal structure, but one has a PP modification and the other does not”.

4 Conclusion and Future Work

Our immediate concern for future work is to work closely with the ATB team to ensure that the desired queries are possible and are integrated into the work on comparing two sets of trees. We expect that this will involve further specification of how queries select etree templates (Step 1), in interesting ways that can take advantage of the localized search space, such as searching for valency of verbs.

We are also working on an evaluation of the speed of this system, in comparison to systems such as (Ghodke and Bird, 2008) and Corpus Search[6]. The search algorithm described above for derivation tree searches can be made more efficient by only looking for relevant etree instances in the context of walking down the derivation tree. In general, while searching for etree instances is very efficient, even with lexical restrictions, complex searches over the derivation tree will be less so. However, our hope, and expectation, is that the vast majority of real-life dtree queries will be local (parent,child,sister) searches on the derivation tree, since each node of the derivation tree already encodes small chunks of structure.

Abstract

The Brown and the Berkeley parsers are two state-of-the-art generative parsers. Since both parsers produce n-best lists, it is possible to apply reranking techniques to the output of both of these parsers, and to their union. We note that the standard reranker feature set distributed with the Brown parser does not do well with the Berkeley parser, and propose an extended set that does better. An ablation experiment shows that different parsers benefit from different reranker features.

1 Introduction

Syntactic parsing is the task of identifying the phrases and clauses in natural language sentences. It has been intensively studied primarily because it is generally believed that identifying syntactic structure is a first step towards semantic interpretation. This paper focuses on parsing the Wall Street Journal (WSJ) section of the University of Pennsylvania treebank corpus (Marcus et al., 1993). There are a large number of different approaches to this task. For simplicity we focus on two popular generative statistical parsing models: Charniak's "Maximum Entropy Inspired" parser (Charniak and Johnson, 2005) and Petrov's "split-merge" parser (Petrov et al., 2006). We follow conventional informal usage and refer to these as the "Brown" and the "Berkeley" parsers respectively.

Briefly, the Berkeley parser is a smoothed PCFG whose non-terminals are refinements of the original treebank grammar obtained by an automatic split-merge procedure, while the Brown parser is effectively a smoothed PCFG whose non-terminals encode a wide variety of manually chosen conditioning information, such as heads, governors, etc. The Berkeley parser is usually viewed as unlexicalized (although the preterminals may be split so finely that they may be viewed as identifying lexical clusters), while essentially every distribution used in the Brown parser conditions on lexical information. Even from this cursory description it is clear that these parsers parsers extract generalizations from the training data in different ways.

This paper applies reranking (Collins and Koo, 2005) to the n-best output of both parsers individually, as well as to an n-best list consisting of the union of the outputs of both parsers. We are interested to see whether the same kinds of features improve the performance of both the Berkeley and the Brown parsers, or whether successful reranking requires features that are specially tuned to the parser it is applied to. Finally, we are interested in the performance of the reranker trained on the union n-best lists. Combining the output of multiple parsers in other more complex ways has been previously demonstrated to improve overall accuracy, so it is interesting to see if the relatively simple method used here improves parsing accuracy as well.

The approach of Zhang et al. (2009) is closest to the work described here. They combine n-best lists produced by the same parsers as we do, but use only a relatively small set of features (the log probabil-

Trees	Reranker features	
	standard	extended
Berkeley	91.6	91.7
Brown	**91.8**	91.6
Combined	**91.8**	**91.9**

Table 1: The f-scores on section 22 of rerankers trained on folds 1–18 by minimizing a regularized "MaxEnt" objective (negative log likelihood with a Gaussian regularizer) using L-BFGS. The weight of the regularizer was tuned to optimize f-score on folds 19–20.

ity of the parses plus a constituent overlap feature), while we investigate models with millions of features here. They report a higher f-score than we do when they replace the generative Brown parser with the the self-trained discriminatively-reranked parser of McClosky et al. (2006), but with inputs provided by the generative Berkeley and Brown n-best parsers they report an f-score of 91.43 on section 23, which is consistent with the results reported here.

2 Experimental setup

We ran both parsers in 50-best mode, and constructed 20-fold cross-validated training data as described in Collins and Koo (2005) and Charniak and Johnson (2005), i.e., the trees in sections 2–21 of the WSJ treebank were divided into 20 equal-sized folds, and the parses for each fold were generated by a parser trained on the trees in the other folds. Then sections 22, 23 and 24 were parsed using the standard "out-of-the-box" parser. Following the suggestion in Collins and Koo (2005), in order to avoid over-training on section 23 all reranking experiments reported here (except the final one) used folds 1–18 as training data, used folds 19–20 as development data and used section 22 as test data. (The averaged perceptron algorithm does not require development data, so the experiments using that algorithm report averages over folds 19–20 and section 22).

The Berkeley parser can be run in many modes; in order to produce the 20-fold training data we ran the Berkeley trainer with 6 splits, and ran the resulting parsers in "accurate" mode. It failed to produce any parses for 12 sentences in sections 2–21 and one sentence in section 24. The Brown parser was trained using the "out-of-the-box" settings, and produced parses for all sentences.

Using the reranker features distributed with the Brown reranker (Charniak and Johnson, 2005), which we call the "standard" set below, we obtained no overall improvement in f-score when either reranking the Berkeley parser n-best lists alone, or when the Berkeley parses were combined with the Brown parses.

However, it is possible that these results reflect the fact that the features used by the reranker were chosen because they improve the Brown parser, i.e., they are the result of feature selection based on reranking the Brown parser's n-best lists. In order to determine if this is the case, we developed an "extended" feature set that incorporates a wider set of features, specifically including features that capture global properties of the tree that might be harder for the Berkeley parser to learn.

Our extended feature set consists of 4,256,553 features, which are instances of 162 feature classes, which in turn are grouped into 20 feature "super-classes". By contrast, the standard feature set contains 1,333,950 features in 90 feature classes, grouped into 14 super-classes. A brief description of the extended feature set super-classes follows:

Parser: an indicator feature indicating which parsers generated this parse,

RelLogP: the log probability of this parse according to each parser,

InterpLogCondP: an indicator feature based on the binned log conditional probability according to each parser,

RightBranch: an indicator function of each node that lies on the right-most branch of the parse tree,

Heavy: an indicator function based on the size and location of each nonterminal (designed to identify the locations of "heavy" phrases),

LeftBranchLength: an indicator function of the binned length of each left-branching chain,

RightBranchLength: an indicator function of the binned length of each right-branching chain,

Rule: an indicator function of parent and children categories, optionally with head POS annotations,

NNGram: and indicator function of parent and n-gram sequences of children categories, optionally head

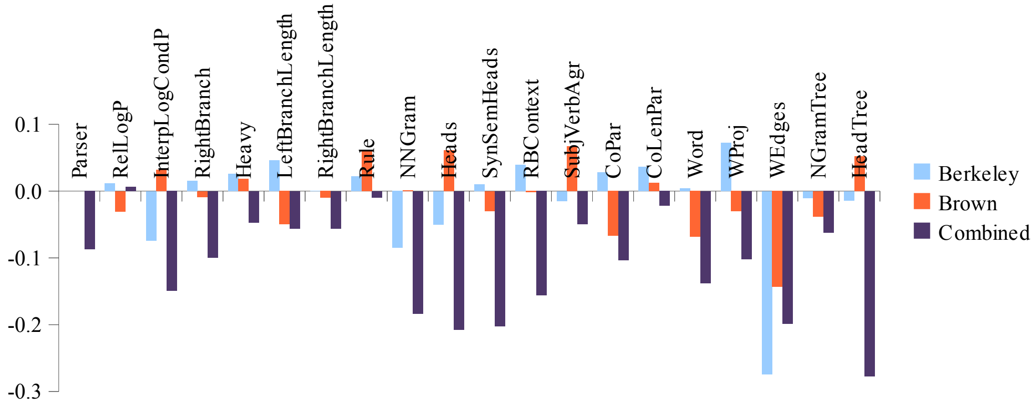

Figure 1: The average change in f-score on folds 19–20 and section 22 caused by removing a feature superclass from the extended feature set and retraining. Difference in scores less that 0.1% are probably not significant. In this experiment all rerankers were trained using the averaged perceptron algorithm. With the full extended feature set, rerankers trained with the averaged perceptron algorithm achieve f-scores of 91.2% on both the Berkeley and Brown parses, and 91.6% on the combined parses.

annotated, inspired by the n-gram rule features described in Collins and Koo (2005),

Heads: an indicator function of "head-to-head" dependencies,

SynSemHeads: an indicator function of the pair of syntactic (i.e., functional) and semantic (i.e., lexical) heads of each non-terminal,

RBContext: an indicator function of how much each subtree deviates from from right-branching,

SubjVerbAgr: an indicator function of whether subject-verb agreement is violated,

CoPar: an indicator function that fires when conjoined phrases in a coordinate structure have approximately parallel syntactic structure,

CoLenPar: an indicator function that fires when conjoined phrases in a coordinate structure have approximately the same length,

Word: an indicator function that identifies words and their preterminals,

WProj: an indicator function that identifies words and their phrasal projections up to their maximal projection,

WEdges: an indicator function that identifies the words and POS tags appearing at the edges of each nonterminal,

NGramTree: an indicator function of the subtree consisting of nodes connecting each pair of adjacent words in the parse tree, and

HeadTree: a tree fragment consisting of a head word and its projection up to its maximal projection, plus all of the siblings of each node in this sequence (this is like an auxiliary tree in a TAG).

The InterpLogCondP features were designed to capture non-linearities in the way that the Berkeley and Brown parsers assign probabilities to trees. We deliberately added features that incorporated linguistic notions such as head, governor and maximal projection, as the Berkeley parser does not explicitly condition on such information (in contrast to the Brown parser, which does).

In fact, as the reader can verify the differences in f-scores between rerankers containing the extended features and the standard features is minimal. In order to better study the importance of the various features we conducted an ablation study, in which we trained rerankers which were missing one feature superclass from the 20 superclasses of the extended feature set. In order to speed training time we used the averaged perceptron algorithm (Collins, 2002) (it converges an order of magnitude faster than the L-BFGS algorithm we used in the other experiments, but the f-score of the model estimated with the averaged perceptron is approximately 0.1% lower than when using L-BFGS). The results from this experiment are shown in Figure 1. The averaged perceptron algorithm does not rely on the development data (folds 19–20), so the results we report are average f-scores on the development data and on section 22 (we did this because the differences are small, so a larger evaluation set may be able to detect differences more reliably).

It is interesting that linguistically-informed features (such as Heads, SynSemHeads and HeadTree) seem to be much more important when reranking the combined n-best lists than when reranking the output of either parser alone. This suggests that the log probability scores from both parsers are internally consistent, but need to be recalibrated when the parses are combined. The log probability scores from the parsers themselves (in the form of the InterpLogCondP feature) are also supplying useful information that the reranker features on their own are not providing. Finally, the WEdges feature, which identifies the words and POS at the left and right boundaries of each nonterminal, also provides extremely useful information, especially for reranking the Berkeley parser.

3 Conclusion

Reranking is a straight-forward method for improving the accuracy of n-best parsers. While one might have hoped that reranking the n-best output of the Berkeley parser, or the union of the outputs of the Berkeley and Brown parsers, would dramatically improve overall f-score, this seems not to be the case. It's possible that the features of current rerankers have been implicitly designed to work well with parsers like the Brown parser, but a reranker with a dramatically enlarged feature set performs only marginally better. This result was confirmed by training a reranker with the extended features on the union of the output of the Berkeley and Brown parsers on sections 2–21 and testing on section 23 (i.e., the standard WSJ parsing evaluation), which achieved an f-score of 91.49%; approximately 0.1% higher than a reranker with the standard feature set trained on the output of the Brown parser alone.

Abstract

In a corpus of expert tutoring dialogue, conversation that is considered to be "off topic" (non-pedagogical) according to a previous coding scheme is explored for its value in tutoring dynamics. Using the Linguistic Inquiry and Word Count (LIWC) tool, phases of tutoring categorized as "off topic" were compared with interactive problem solving phases to explore how the two differ on the emotional, psychological, and topical dimensions analyzed by LIWC. The results suggest that conversation classified as "off topic" serves as motivation and broad pedagogy in tutoring. These findings can be used to orient future research on "off topic" conversation, and help to make sense of both previous coding schemes and noisy data sets.

1 Introduction

Methods of investigating a large and noisy data set are of paramount importance in computational linguistics. Quite often, qualitative coding schemes are used to capture snapshots of the data set, but these may gloss over finer details or miss the larger picture. Add to that the messy and unpredictable nature of naturalistic data, and analysis becomes even more complicated. Therefore, a multi-method approach to understanding pre-existing coding schemes and orienting future in-depth analyses of those schemes proves to be a useful means of exploring one's data.

Dialogue, particularly tutorial dialogue, is one area where large, noisy data sets are common. Computer and human tutoring data have been parsed, coded, and tested by a number of researchers, and much effort has been put into making sense of the variability in the task-oriented dialogue (e.g. Chi, Roy, and Hausmann, 2008; Graesser, Person, and Magliano, 1995; Person, Lehman, and Ozbun, 2007). This work has all been in pursuit of a deep understanding of the complex interaction between the human tutor and student, which, if understood, could be used to boost the efficacy of artificially intelligent computer tutors. Expert human tutoring has been found to increase learning gains by as much as 2 sigmas (Bloom, 1984), which makes understanding their methods and motives the goal of any tutor research.

The corpus under examination here was collected with the express purpose of understanding how truly expert tutors manage a tutoring session, with an emphasis on creating a corpus of naturalistic dialogue data. The corpus has been investigated at two different grain sizes, a dialogue move level and a sustained phases level. Our study investigates in detail an "other" category that these coding schemes, which emphasize the pedagogy of the tutors and the students reactions, classify as "off topic" conversation. Off topic conversation, by virtue of its name, does not address the tutoring task in which the tutor and student are engaged. However, given the prevalence of off topic conversation in the corpus, it is perhaps more likely that the function or utility of off topic conversation in expert tutoring is indirect rather than non-existent, suggesting that the noisiest part of the tutoring dialogue corpus, off topic conversation, should be further explored.

Because any topic not pertaining to the topic at hand may be broached in off topic conversation and because the dialogue itself is full of false

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 669–672,
Los Angeles, California, June 2010.

starts, interruptions, and fragmented sentences, it is reasonable to explore off topic conversation using a bag of words method that is applicable to a variety of formal and informal texts. One such method is the Linguistic Inquiry and Word Count (LIWC) tool developed by Pennebaker et al., (2001), which looks for words that fall into specific, predetermined categories such as COGNITIVE MECHANISMS and POSITIVE EMOTIONS, then reports the percent of words in the document that fall into that category. LIWC provides over 70 possible categories, and can help sketch a rough picture of the verbal dynamics of a text (Mairesse and Walker, 2006; Mihalcea and Strapparava, 2009). Using a readily available tool like LIWC allows an examination of the variability within off topic conversation based on predetermined LIWC features. We can also compare these results to a prominent pedagogical category, such as scaffolding, that a current coding scheme particularly emphasizes, and examine the differences between the two.

In this analysis, the task-orientation and utility of "off topic" conversation are investigated by comparing its outcome scores in certain dimensions of LIWC to a classic pedagogical and interactive phase of tutoring: scaffolding (Rogoff and Gardner, 1984). Scaffolding, previously identified in a tutorial dialogue coding scheme (Cade, Copeland, Person, and D'Mello, 2008), involves much of the conversational give-and-take expected in casual off topic conversation, but is considered to be a very focused, on task phase of tutoring. Knowing how off topic conversation differs from scaffolding may help further exploration of this forgotten phase of tutoring. Likewise, it would give us direction in how to structure future coding schemes that would help bring clarity to the data set.

2 Methods

In this study, pedagogical and non-pedagogical phases of expert tutoring sessions were compared on linguistic dimensions to get at the diverse nature of off topic conversation within a naturalistic expert tutoring session.

The corpus under examination was collected in a previous study on expert human tutors. Therefore, what follows is a brief synopsis of how this corpus was collected.

Ten expert math and science tutors (4 male and 6 female) were recruited through local tutoring agencies and schools. Tutors were considered "expert" when they met the following criteria: they had to be licensed to teach at the secondary level, have five or more years of tutoring experience, be employed by a professional tutoring agency, and come highly recommended by school personnel who specialize in providing support to students who are struggling academically. Student participants were in grades 7 to 12, except for one who was obtaining a GED. All of the students were in academic trouble and actively sought out tutoring.

All sessions were unobtrusively videotaped at the location decided upon by the tutor and student. The researcher turned on the camera and left the room when the session began. Each student participated in a maximum of two tutorial sessions, while each tutor participated in between two and eight tutoring sessions. These 50 1-hour tutoring sessions were then transcribed.

Two previously identified phases of tutoring (or "modes"), Off Topic and Scaffolding, were compared to investigate their psychological, emotional, and topical differences. To do this, instances of each mode were extracted from 30 sessions (all sessions that contained at least one Off Topic and one Scaffolding mode). If a session had multiple occurrences of a single mode, those modes were compiled into a single document. Documents were capped at 1000 words each to prevent differences in word count between the modes from affecting the outcomes. These documents were also separated by speaker (tutor or student); speakers may be differentially motivated to broach certain topics, and so separating out these effects leads to more specific identification of conversational dynamics.

Each session's Scaffolding and Off Topic document was then analyzed using LIWClite 7, which calculates the percentage of each document's words that fall into specific, predefined categories. Though this version of LIWC offers over 70 linguistic categories, only 15 were of interest in determining the nature of off topic conversation: SOCIAL PROCESSES (ex: *mate*, *talk*, *they*), FAMILY (*daughter*, *husband*, *aunt*), FRIENDS (*buddy*, *neighbor*), AFFECTIVE PROCESSES (*happy*, *cried*), POSITIVE EMOTION (*nice*, *sweet*), NEGATIVE EMOTIONN (*hurt*, *ugly*, *nasty*) ANXIETY (*worried*, *nervous*), TENTATIVENESS (*maybe*, *perhaps*), CERTAINTY (*always*, *never*), WORK (*majors*, *class*), ACHIEVEMENT (*earn*, *win*), LEISURE (*chat*, *movie*), HOME (*kitchen*, *family*), NONFLUENCIES (*umm*, *hm*), and FUTURE (*will*, *gonna*).

These categories are the most relevant in illustrating the emotional, topical, and psychological picture of conversation in tutoring when compared with the more on-task behavior of problem solving.

3 Discussion of Results

Table 1. LIWC Dimensions with Significant Results

Since a normal distribution of scores cannot be assumed in this analysis, comparisons between Off Topic conversation and Scaffolding dialogue were made by comparing the LIWC scores of the modes using both Wilcoxon's signed-rank test and a paired t-test, with similar outcomes. Effect sizes were also analyzed by calculating Cohen's *d*. Table 1 illustrates the significant results that emerged. In total, each category investigated occurs more in Off Topic than in Scaffolding, with the exception of a student's discussion of ACHIEVEMENT and FUTURE.

From this analysis, an interesting pattern of results emerges. The Off Topic mode had previously been characterized as a conversation that had nothing to do with the lesson at hand, which connoted that it is fairly irrelevant. However, Off Topic does not seem to be so wholly "off topic." Tutors and students in the Off Topic mode talk about work more often than they do in the Scaffolding mode, which is a mode where nothing but work is done. WORK words, according to the authors of LIWC, are mostly school-related. Off Topic may be a mode that allows the tutor to discuss test-taking skills, study strategies, and remind students what tasks need to be completed before the next tutoring session. For instance, one tutor divided up a study guide into manageable portions that needed to be completed every night so that the student would be prepared for an upcoming test. Previous to now, these conversations have only been qualitatively observed, but this supports a more in-depth analysis of what type of work tutors are talking about when they are supposedly discussing non-pedagogical topics.

This hypothesis is supported by the significant amount of conversation that takes place in Off Topic about the home; if FAMILY and FRIENDS (which may crop up in casual conversation about HOME-related topics) are not discussed significantly more in Off Topic, but HOME is, it may be that tutors are informing students of what sort of work needs to be done at home, and strategies to get work completed when on their own.

This may also explain why both students and tutors use more TENTATIVE words in Off Topic. Although it would seem that students should be more tentative and nonfluent when discussing difficult problem solving, they may be tentative in Off Topic when the tutor makes suggestions about studying and working. These suggestions of the tutor's may be framed using language like "maybe" and "perhaps" to make them more polite, and the student echoes this language in return. Thus, tentativeness may not come from uncertainty, but from suggestions couched in polite language.

It also appears that Off Topic conversation may not serve as a "pep talk" time; although it does contain more POSITIVE EMOTION words than Scaffolding, it does not expound upon the student's achievements. ACHIEVEMENT words are more common in Scaffolding, where students are receiving praise for their problem solving efforts. Off Topic conversation may seek to motivate the student in more subtle ways. By using more words that refer to SOCIAL PROCESSES (such as the third person plural and words like "talked"), the tutor and student may be building rapport with one another. This rapport may become important later on when the tutor gives the student blatantly negative feedback (Person et al., 2007), which can be motivationally damaging. Rapport may protect against flagging motivation in the student when the tutor uses "us" language and connects with the student in a more casual conversation.

4 Conclusions and Future Work

Our goal in this work was to use a simple linguistic analysis tool to uncover the hidden depths of an existing dialogue coding scheme. The use of such tools can paint a rich picture of the psychological, emotional, and topical content of a corpus, and can be used in two ways: first, it may help determine if a deeper inquiry into a hypothesis is warranted, and second, it can immediately orient future research towards key issues in a corpus without the less rigorous speculation and qualitative observations. The nature of broader coding schemes can come to be understood in a multifaceted manner using linguistic analysis, which may also inform future work.

Here, we have observed that off topic conversation in an expert tutoring dialogue corpus operates in a multidimensional way that is not irrelevant when studying the dynamics of an expert tutoring session. By using the LIWC tool developed by Pennebaker et al. (2001), themes concerning interpersonal rapport and global pedagogy emerge. The purpose of "off topic" conversation in tutoring may therefore be linked more to building a relationship between the tutor and the student, which is necessary for the trials of problem solving, and for the dispensation of "study strategies" that are more globally task-oriented, but are, nonetheless, important in understanding the pedagogical strategies of expert tutors. Off topic conversation was also hypothesized to function similarly in other tutorial work (Rosé, Kumar, Aleven, Robinson, and Wu, 2006).

One way of adding validity to these claims would be to investigate the topics broached in Off Topic through a topics model. In this way, recurring themes in off topic conversation can be revealed, and these themes can be aligned with the LIWC findings to see if a pattern emerges. From there, a new coding scheme may be devised to capture the multiple types of off topic conversation, which, for now, seem to be divided between interpersonal, rapport building and global pedagogy. This method of exploring a corpus has proven to be a useful approach when investigating possible avenues of improvement to coding schemes.

Abstract

In this paper we investigate how to identify initiation-response pairs in asynchronous, multi-threaded, multi-party conversations. We formulate the task of identifying initiation-response pairs as a pairwise ranking problem. A novel variant of Latent Semantic Analysis (LSA) is proposed to overcome a limitation of standard LSA models, namely that uncommon words, which are critical for signaling initiation-response links, tend to be deemphasized as it is the more frequent terms that end up closer to the latent factors selected through singular value decomposition. We present experimental results demonstrating significantly better performance of the novel variant of LSA over standard LSA.

1 Introduction

In recent years, research in the analysis of social media (e.g., weblogs, discussion boards, and messengers) has grown in popularity. Unlike expository text, the data produced through use of social media is often conversational, multi-threaded, and more complex because of the involvement of numerous participants who are distributed both across time and across space. Recovering the multi-threaded structure is an active area of research.

In this paper, we form the foundation for a broader study of this type of data by investigating the basic unit of interaction, referred to as an **initiation-response pair** (Schegloff, 2007). Initiation-response pairs are pairs of utterances that are typically contributed by different participants, and where the first pair part sets up an expectation for the second pair part. Types of common initiation-response pairs include question-answer, assessment-agreement, blame-denial, etc. Note that although sometimes discussion forum interfaces make the thread structure of the interaction explicit, these affordances are not always present. And even in forums that have these affordances, the apparent structure of the discourse as represented through the interface may not capture all of the contingencies between contributions in the unfolding conversation. Thus, the goal of this investigation is to investigate approaches for automatically identifying initiation-response pairs in conversations.

One of the challenges in identifying initiation-response pairs is that the related messages are not necessarily adjacent to each other in the stream of contributed messages, especially within the asynchronous environment of social media. Furthermore, individual differences related to writing style or creative expression of self may also complicate the identification of the intended connections between contributions. Identification of initiation-response pairs is an important step towards automatic processing of conversational data. One potential application of this work is conversation summarization. A summary should include both the initiation and response as a coherent unit or it may fail to capture the intended meaning.

We formulate the task of identifying initiation-response pairs as a pairwise ranking problem. The goal is to distinguish message pairs that constitute an initiation-response pair from those that do not. We believe a ranking approach, where the degree of relatedness between a message pair can be considered in light of the relatedness between each of them and the surrounding messages within the same thread, is a more suitable paradigm for this task than a discrete classification-based paradigm.

Previous work on recovering conversational structure has relied on simple lexical cohesion

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 673–676,
Los Angeles, California, June 2010.

measures (i.e., cosine similarity), temporal information (Lewis and Knowles, 1997; Wang et al., 2008), and meta-data (Minkov et al., 2006). However, relatively little work has investigated the importance of specifically **in-focus connections** between initiation-response pairs and utilized them as clues for the task. Consider, for example, the following excerpt discussing whether congress should pass a bill requiring the use of smaller cars to save the environment:

a) *Regressing to smaller* ***vehicles*** *would discourage business from producing more* ***pollution****.*

b) *If* ***CO2*** *emissions are lowered, wouldn't tax revenues be lowered as well? Are the democrats going to willingly give up Medicaid and social security?*

Although segment (b) is a reply to segment (a), the amount of word overlap is minimal. Nonetheless, we can determine that (b) is a response to (a) by recognizing the in-focus connections, such as "vehicles-CO2" and "pollution-CO2." To properly account for connections between initiations and responses, we introduce a novel variant of Latent Semantic Analysis (LSA) into our ranking model.

In section 2, we describe the Usenet data and how we extract a large corpus of initiation-response pairs from it. Section 3 explains our ranking model as well as the proposed novel LSA variation. The experimental results and discussion are detailed in Section 4 and Section 5, respectively.

2 Usenet and Generation of Data

The experiment for this paper was conducted using data crawled from the *alt.politics.usa Usenet* (User Network) discussion forum, including all posts from the period between June 2003 and June 2008. The resulting set contains 784,708 posts. The posts in this dataset also contain meta-data that makes parent-child relationships explicit (i.e., through the *References* field). Thus, we know 625,116 of the posts are explicit responses to others posts. The messages are organized into a total of 77,985 discussion threads, each of which has 2 or more posts.

In order to evaluate the quality of using the explicit reply structure as our gold standard for initiation-response links, we asked human judges to annotate the response structure of a random-selected medium-length discussion (19 posts) where we had removed the meta-data that indicated the initiation-reply structure. The result shows the accuracy of our gold standard is 0.89.

To set up the data as a pairwise ranking problem, we arranged the posts in the corpus into instances containing three messages each, one of which is a response message, one of which is the actual initiating message, and the other of which is a foil selected from the same thread. The idea is that the ranking model will be trained to prefer the actual initiating message in contrast to the foil.

The grain size of our examples is finer than whole messages. More specifically, positive examples are pairs of spans of text that have an initiation-reply relationship. We began the process with pairs of messages where the meta-data indicates that an initiation-reply relationship exits, but we didn't stop there. For our task it is important to narrow down to the specific spans of text that have the initiation-response relation. For this, we used the indication of quoted material within a message. We observed that when users explicitly quote a portion of a previously posted message, the portion of text immediately following the quoted material tends to have an explicit discourse connection with it. Consider the following example:

>> *Why is the quality of life of the child, mother,*
>> *and society at large, more important than the*
>> *sanctity of life?*
> *Because in the case of anencephaly at least,*
> *the life is ended before it begins.*
We disagree on this point. Why do you refuse to provide your very own positive definition of life? Do you believe life begins before birth? At birth? After birth? Never?

In this thread, the reply expresses an opinion against the first level quote, but not the second level quote. Thus, we used segments of text with single quotes as an initiation and the immediately following non-quoted text as the response. We extracted positive examples by scanning each post to locate the first level quote that is immediately followed by unquoted content. If such quoted material was found, the quoted material and the unquoted response were both extracted to form a positive example. Otherwise, the message was discarded.

For each post *P* where we extracted a positive example, we also extracted a negative example by picking a random post *R* from the same thread as *P*. We selected the negative example in such a way to make the task difficult in a realistic way. Choosing *R* from other threads would make the task too easy because the topics of *P* and *R* would most likely be different. We also stipulated that *R* cannot be the parent, grandparent, sibling, or child of *P*.

Together the non-quoted text of *P* and *R* forms a negative instance. Thus, the final dataset consists of pairs of message pairs ((p_i, p_j), (p_i, p_k)), where they have the same reply message p_i, and p_j is the correct quote message of p_i, but p_k is not. In other words, (p_i, p_j) is considered as a positive example; (p_i, p_k) is a negative example. We constructed a total of 100,028 instances for our dataset, 10,000 (~10%) of which were used for testing, and 90,028 (~90%) of which were the learning set used to construct the LSA space described in the next section.

3 Ranking Models for Identification of Initiation-Response Pairs

Our pairwise ranking model[1] takes as input an ordered pair of message pairs ((p_i, p_j), (p_i, p_k)) and computes their relatedness using a similarity function *sim*. Specifically,

$$(x_{ij}, x_{ik}) = (sim\ (p_i, p_j), sim\ (p_i, p_k))$$

where x_{ij} is the similarity value between post p_i and p_j; x_{ik} is the similarity value between post p_i and p_k. To determine which of the two message pairs ranks higher regarding initiation-response relatedness, we use the following scoring function to compare their corresponding similarity values:

$$score\ (x_{ij}, x_{ik}) = x_{ij} - x_{ik}$$

If the score is positive, the model ranks (p_i, p_j) higher than (p_i, p_k) and vice versa. A message pair ranked higher means it has more evidence of being an initiation-reply link, compared to the other pair.

3.1 Alternative Similarity Functions

We introduce and motivate 3 alternative similarity functions, where the first two are considered as baseline approaches and the third one is a novel variation of LSA. We argue that the proposed LSA variation is an appropriate semantic similarity measurement for identifying topic continuation and initiation-reply pairs in online discussions.

Cosine Similarity (*cossim*). We choose an approach that uses only lexical cohesion as our baseline. Previous work (Lewis and Knowles, 1997; Wang et al., 2008) has verified its usefulness for the thread identification task. In this case,

$$sim(p_i,p_j) = cossim(p_i,p_j)$$

where *cossim*(p_i,p_j) computes the cosine of the angle between two posts p_i and p_j while they are represented as term vectors.

LSA Average Similarity (*lsaavg*). LSA is a well-known method for grouping semantically related words (Landauer et al., 1998). It represents word meanings in a concept space with dimensionality *k*. Before we describe how to compute average similarity given an LSA space, we explain how the LSA space was constructed in our work. First, we construct a term-by-document matrix, where we use the 90,028 message learning set mentioned at the end of Section 2. Next, LSA applies singular value decomposition to the matrix, and reduces the dimensionality of the feature space to a *k* dimensional concept space. This generated LSA space is used by both *lsaavg* and *lsacart* later.

For *lsaavg*, we follow Foltz et al. (1998):

$$sim\left(p_i, p_j\right) = lsaavg\left(p_i, p_j\right) = \cos\left(\frac{\sum_{t_a \in p_i} \vec{t_a}}{\left|p_i\right|}, \frac{\sum_{t_b \in p_j} \vec{t_b}}{\left|p_j\right|} \right)$$

The meaning of each post is represented as a vector in the LSA space by averaging across the LSA representations for each of its words. The similarity between the two posts is then determined by computing the cosine value of their LSA vectors.

This is the typical method for using LSA in text similarity comparisons. However, note that not all words carry equal weight within the vector that results from this averaging process. Words that are closer to the "semantic prototypes" represented by each of the *k* dimensions of the reduced vector space will have vectors with longer lengths than words that are less prototypical. Thus, those words that are closer to those prototypes will have a larger effect on the direction of the resulting vector and therefore on the comparison with other texts. An important consideration is whether this is a desirable effect. It would lead to deemphasizing those unusual types of information that might be being discussed as part of a post. However, one might expect that those things that are unusual types of information might actually be more likely to be the in-focus information within an initiation that responses may be likely to refer to. In that case, for our purposes, we would not expect this typical method for applying LSA to work well.

LSA Cartesian Similarity (*lsacart*). To properly account for connections between initiations and

[1] We cast the problem as a pairwise ranking problem in order to focus specifically on the issue of characterizing how initiation-response links are encoded in language through lexical choice. Note that once trained, pairwise ranking models can be used to rank multiple instances.

responses that include unusual words, we introduce the following similarity function:

$$sim(p_i, p_j) = lsacart(p_i, p_j) = \frac{\sum_{(t_a, t_b) \in p_i \times p_j} \cos(\vec{t_a}, \vec{t_b})}{|p_i||p_j|}$$

where we take the mean of the cosine values for all the word pairs in the Cartesian product of posts p_i and p_j. Note that in this formulation, all words have an equal chance to affect the overall similarity between vectors since it is the angle represented by each word in a pair that comes to play when cosine distance is applied to a word pair. Length is no longer a factor. Moreover, the averaging is across cosine similarity scores rather than LSA vectors.

4 Experimental Results

The results are found in Table 1. For comparison, we also report the random baseline (0.50).

	Random Baseline	Cos-Similarity	LSA-Average	LSA-Cart
Accuracy	0.50	0.66	0.60	**0.71**

Table 1. Overview of results

Besides the random baseline, LSA-Average performs the worst (0.60), with simple Cosine similarity (0.66) in the middle, and LSA-Cart (0.71) the best, with each of the pairwise contrasts being statistically significant. We believe the reason why LSA-Average performs so poorly on this task is precisely because, as discussed in last section, it deemphasizes those words that contribute the most unusual content. LSA-Cart addresses this issue.

To further understand this effect, we conducted an error analysis. We divided the instances into 4 sets based on the lexical cohesion between the response and the true initiation and between the response and the foil, by taking the median split on the distributions of these two cohesion scores. Our finding is that model performances vary by subset. In particular, we find that it is only in cases where the positive example has low lexical cohesion (e.g. our "vehicles-CO2" and "pollution-CO2" example from the earlier section), that we see the benefit of the LSA-Cart approach. In other cases, where the cohesion between the reply and the true initiation is high, Cos-Similarity performs best.

5 Discussion and Conclusion

We have argued why the task of detecting initiation-response pairs in multi-party discussions is important and challenging. We proposed a method for acquiring a large corpus for use to identify initiation-response pairs. In our experiments, we have shown that the ranking model using a variant of LSA performs best, which affirms our hypothesis that unusual information and uncommon words tends to be the focus of ongoing discussions and therefore to be the key in identifying initiation-response links.

In future work, we plan to further investigate the connection between an initiation-response pairs from multiple dimensions, such as topical coherence, semantic relatedness, conversation acts, etc. One important current direction is to develop a richer operationalization of the interaction that accounts for the way posts sometimes respond to a user, a collection of users, or a user's posting history, rather than specific posts per se.

Abstract

Conversational Agents have been shown to be effective tutors in a wide range of educational domains. However, these agents are often ignored and abused in collaborative learning scenarios involving multiple students. In our work presented here, we design and evaluate interaction strategies motivated from prior research in small group communication. We will discuss how such strategies can be implemented in agents. As a first step towards evaluating agents that can interact socially, we report results showing that human tutors employing these strategies are able to cover more concepts with the students besides being rated as better integrated, likeable and friendlier.

1 Introduction

Conversational Agents (CAs) are autonomous interfaces that interact with users via spoken or written conversation. One of the applications of CAs is tutoring. Various research groups have developed tutoring agents in domains like reading, algebra, geometry, calculus, physics, computer literacy, programming, foreign languages, research methods and thermodynamics. Many of the evaluations show that CAs can be effective tutors (Arnott et. al., 2008; Kumar et. al., 2007; Graesser et. al., 2005).

Most systems that use CAs as tutors have been built for learning scenarios involving one student. Evaluation of learning technologies involving students working in groups with interactive agents has shown that learners are helped both by learning as a group and receiving tutorials from agents (Kumar et. al., 2007). However, some previous studies have reported that students learning in groups ignore the tutor's messages, unlike the case where students are individually tutored. Groups are more likely to abuse tutors than individual students.

We reason that the presence of other students in collaborative learning scenarios causes the agents to compete for the attention of the students. Since the agents are not adept at performing social interactive behavior, which makes up the bulk of formative communication in a group, they are quickly pushed to the periphery of the group.

Research on small group communication has identified twelve interaction categories that are commonly observed in small groups (Bales, 1950). These categories are broadly classified into task and social-emotional categories. Content presented by most current CAs mostly classifies under the task categories. In section 2, we will list the conversational strategies motivated from the three positive social-emotional interaction categories. Thereafter, the implementation and evaluation of a CA that interleaves these social interaction strategies while executing a task plan will be described.

2 Social Interaction Strategies

Balesian methodology (Bales, 1950) identifies three positive social-emotional interaction categories: showing solidarity, showing tension release and agreeing. Participants contribute turns of these categories to address the problems of re-integration, tension release and decision respectively. We have mapped these categories to practically implementable conversational strategies. This mapping is shown in table 1 ahead.

Each strategy is implemented as an instantiation of a conversational behavior. Most of the strategies listed in Table 1 are realized as prompts, triggered by rules based on agent plan, discourse and context features. For example, strategy 1e is triggered

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 677–680,
Los Angeles, California, June 2010.

when one or more students in the group are found to be inactive for over 5 minutes. In this event, the tutor chooses to raise the status of the inactive students by eliciting contributions from them through a prompt like: *Do you have any suggestions Mike?* More implementation details of these strategies and triggers are discussed in the following section.

1. Showing Solidarity *Raises other's status, gives help, reward*
1a. Do Introductions *Introduce and ask names of all participants*
1b. Be Protective & Nurturing *Discourage teasing*
1c. Give Re-assurance *When student is discontent, asking for help*
1d. Complement / Praise *To acknowledge student contributions*
1e. Encourage *When group or members are inactive*
1f. Conclude Socially
2. Showing Tension Release *Jokes, laughs, shows satisfaction*
2a. Expression of feeling better *After periods of tension, work pressure*
2b. Be cheerful
2c. Express enthusiasm, elation, satisfaction *On completing significant steps of the task*
3. Agreeing *Shows passive acceptance, understands, concurs, complies*
3a. Show attention *To student ideas as encouragement*
3b. Show comprehension / approval *To student opinions and orientations*

Table 1. Social Interaction Strategies for three social-emotional interaction categories

3 WrenchTalker: Implementation

WrenchTalker is a CA we have built to employ the social interaction strategies listed in section 2. It helps teams of engineering students learn and apply basic concepts of mechanical stress while they participate in a freshmen lab project to design an aluminum wrench. Students can interact with this agent using a text-based chat environment.

The agent is built using the Basilica architecture (Kumar and Rosé, 2009). Under this architecture, CAs are modeled as a network of behavioral components. There are three types of components: actors (actuators / performers), filters (perceptors / annotators / cordinators) and memories. Figure 1 below shows a simplified depiction of the WrenchTalker component network.

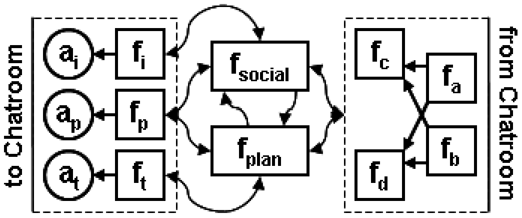

Figure 1. Component Network of WrenchTalker

Three of the actor and filter components correspond to three observable behaviors of the tutor, i.e., Introducing (a_i, f_i), Prompting (a_p, f_p) and Tutoring (a_t, f_t). Most of the other filter components form a sub-network that annotates turns with applicable semantic categories, accumulates them to identify inactive students and generates events that regulate the controllers.

The plan controller (f_{plan}) is responsible for executing the agent's interaction plan, which is comprised of 37 steps. The plan is executed largely sequentially; however the plan controller can choose to skip some steps in the interest of time. In the experiment described in section 5, the same plan controller is used in all three conditions. The social controller (f_{social}) implements the 12 strategies listed earlier. The strategies are triggered by rules based on combinations of three conditions: the last executed plan step, semantic categories associated with the most recent student turns and the ratio of tutor turns generated by f_{social} to f_{plan}. The first two conditions attempt to ensure that social behavior is suitable in the current conversational context and the third condition regulates the amount of social behavior by the CA.

The plan and social controllers are connected so that they regulate each other. For instance, when the plan controller is working, it blocks f_{social}. Upon completion of the blocking step, f_{social} is given control, which can then choose to perform a strategy by blocking f_{plan} before it progresses to the next step. Reflex strategies like 1b are not blocked.

Once the controllers determine a step or a strategy that is to be generated, the actors generate their turns. For example, strategy 1a is generated by actor a_i after it is triggered by the social controller.

We note that Basilica provides the flexibility to build complicated pipelines, as demonstrated in this case by the use of two controllers.

4 Related Work

To contextualize our research with other work on CAs, we classify agents with the social interaction strategies listed in Table 1 as *social interfaces* following the taxonomy proposed by Isbister (2002). Within this class of CAs, researchers have investigated the technical challenges and effects of conversational behavior that are similar in motivation to the ones we are exploring. Bickmore et. al. (2009) report that users found agents with autobiographies, i.e., back stories in first person more enjoyable and they completed more conversations with such agents. Dybala et. al. (2009) found that agents equipped with humor were evaluated as more human-like, funny and likeable. In a multi-party conversational scenario, Dohsaka et. al. (2009) found that an agent's use of emphatic expressions improved user satisfaction and user rating of the agent. We note that use of CAs as social interfaces has been found to have effects on both performance and perception metrics.

5 Experimental Design

In order to evaluate the effect of social interaction strategies listed in Table 1, we designed an experiment with three conditions. In the experimental condition (Social), students interacted with an agent that was equipped with our social interaction strategies, unlike the control condition (Task). In the third condition, a human tutor was allowed to intervene while the students interacted with a Task agent. In all three conditions, students go through the same task plan. However, the degree of social performance is varied from minimal (Task) to ideal (Human). We hypothesize that the human and social agents will be rated better than the Task agent.

We conducted a between subjects experiment during a freshmen computer aided engineering lab. 98 students participated in the experiment, which was held over six sessions spread evenly between two days. The two days of the experiment were separated by two weeks. Students were grouped into teams of three to four individuals. Students were grouped so that no two members of the same team sat next to each other during the lab, to ensure all communication was recorded. The teams were distributed between the three conditions.

Each session started with a follow-along tutorial of computer-aided analysis where the students analyzed a wrench they had designed earlier. The experimental manipulation happened during a collaborative design competition after the tutorial. Students were asked to work as a team to design a better wrench considering three aspects: ease of use, cost and safety. Students were instructed to make three new designs and calculate success measures of each of the three considerations. They were also told that a tutor will help them with two designs so that they are well-prepared to do the final design. No additional details about the tutor were given. The students communicated with each other and with the tutors using ConcertChat, an online environment that provides text-based instant messaging and workspace sharing facilities.

After spending 30-35 minutes on the design competition, each student filled out a questionnaire. It was comprised of eighteen questions on a seven point Likert-scale ranging from Strongly Disagree (1) to Strongly Agree (7). The questions were designed to elicit four types of ratings.

- Ratings about the tutor
- Ratings about the other team members
- Ratings about the design task
- Ratings about the team functioning

The questions in the first two classes elicited perceived liking and integration and checked whether the students noticed the tutor's display of the social interaction strategies. Task related questions asked about satisfaction, perceived legitimacy and discussion quality.

6 Results

Table 2 below shows the mean values for questionnaire categories apart from ratings about team members, since there were no significant effects related to those questions.

	D1	D2		T	S	H
Integration	3.85	3.94		3.03	*3.94*	**4.77**
Liking	3.68	3.63		2.78	3.53	**4.73**
Friendly	5.13	5.43		4.47	**5.56**	**5.83**
T.Releasing	4.49	4.63		3.84	4.61	**5.27**
Agreeing	4.30	4.45		3.97	4.44	4.73
Satisfaction	4.66	**5.77**		5.09	4.75	5.97

Table 2. Mean outcomes per condition ((T)ask,(S)ocial, (H)uman) and per day (Day1, and Day2)

The means are highlighted appropriately (**p<0.001**, **p<0.05**, *p<0.08*) to indicate significant differences from Day1 to Day2 and between the Task condition and each of the other two using a pairwise Tukey comparison.

First of all, we note that there is a significant difference in task satisfaction between the two days. We fine-tuned the timing parameters of the plan controller after day 1 so that the students had sufficient time to follow along with each of the steps. This was particularly useful for the task condition where the steps would be executed rapidly due to lack of regulation by the social controller.

On the right side of Table 2, we notice that the human tutors (H) were rated higher on being part of the team (Integration), being more liked, being friendlier and keeping the group more socially comfortable (T.Releasing). On the other hand, the social tutors (S) were rated to be friendlier and were only marginally better at being seen as part of the team.

	Strategy	**Social**	**Human**
Introducing	**1a**	2.67	3.80
Friendly	**1b-1e**	5.61	8.10
Concluding	**1f**	0.97	1.80
T.Releasing	**2a-2c**	5.81	1.77
Agreeing	**3a-3b**	1.78	4.90
Sum		16.83	22.17

Table 3. Mean counts of social turns by tutor

Note that human tutors were restricted to exhibit only social behaviors, which were displayed in addition to the same task related content given to students in the other two conditions. Clearly, the human tutors were better at employing the social interaction strategies. To further investigate this, we compare the number of turns corresponding to the broad categories of strategies in Table 3. Human tutors performed significantly more ($p<0.001$) social turns than the automated tutors in all strategies except showing tension release.

7 Conclusions

In order to make CAs that can participate in multiparty conversational scenarios, the agents must be able to employ Social Interaction Strategies. Here we have shown that the human tutors that use these strategies are better integrated into the group, and are considered more likeable and friendlier. These tutors also cover more steps and concepts and take less time to tutor the concepts, suggesting that the students are more engaged and responsive to them. On the other hand, automated tutors that employ these strategies in our current implementation do not show significant differences compared to task tutor.

We note a contrast between the performance of the human and the automated tutors with respect to the frequency with which they employ these strategies. Besides the frequent use of these strategies, we believe human tutors were better at identifying opportunities for employing these strategies, and they are able to customize the prompt to better suit the discourse context.

Abstract

We show how the Barzilay and Lapata entity-based coherence algorithm (2008) can be applied to a new, noisy data domain – *student essays*. We demonstrate that by combining Barzilay and Lapata's entity-based features with novel features related to grammar errors and word usage, one can greatly improve the performance of automated coherence prediction for student essays for different populations.

1 Introduction

There is a small body of work that has investigated using NLP for the problem of identifying coherence in student essays. For example, Foltz, Kintsch & Landauer (1998), and Higgins, Burstein, Marcu & Gentile (2004) have developed systems that examine coherence in student writing. Foltz, *et al.* (1998) systems measure lexical relatedness between text segments by using vector-based similarity between adjacent sentences; Higgins *et al*'s (2004) system computes similarity across text segments. Foltz *et al.*'s (1998) approach is in line with the earlier TextTiling method that identifies subtopic structure in text (Hearst, 1997). Miltsakaki and Kukich (2000) addressed essay coherence using Centering Theory (Grosz, Joshi & Weinstein, 1995). More recently, Barzilay and Lapata's (2008) approach (henceforth, BL08) used an entity-based representation to evaluate coherence. In BL08, *entities* (nouns and pronouns) are represented by their sentence roles in a text. The algorithm keeps track of the distribution of entity transitions between adjacent sentences, and computes a value for all transition types based on their proportion of occurrence in a text. BL08 apply their algorithm to three tasks, using well-formed newspaper corpora: text ordering, summary coherence evaluation, and readability assessment. For each task, their system outperforms a Latent Semantic Analysis baseline. In addition, best performance on each task is achieved using different system and feature configurations. Pitler & Nenkova (2008) applied BL08 to detect text coherence in well-formed texts.

Coherence quality is typically present in scoring criteria for evaluating a student's essay. This paper focuses on the development of models to predict *low*-and *high-coherence ratings* for essays. Student essay data, unlike newspaper text, is typically noisy, especially when students are non-native English speakers (NNES). Here, we evaluate how BL08 algorithm features can be used to model coherence in a new, noisy data domain -- *student essays*. We found that coherence can be best modeled by combining BL08 entity-based features with novel writing quality features. Further, our use of data sets from three different test-taker populations also shows that coherence models will differ across populations. Different populations might use language differently which could affect how coherence is presented. We expect to incorporate coherence ratings into e-rater®, ETS's automated essay scoring system (Attali & Burstein, 2006).

2 Corpus and Annotation

We collected approximately 800 essays (in total) across three data sets[1]: 1) adult, NNES test essays (TOEFL); 2) adult, native and NNES test essays; (GRE) 3) U.S. middle- and high-school native and NNES student essay submissions to *Criterion*®, ETS's instructional writing application.

Two annotators were trained to rate *coherence quality* based on how easily they could read an essay without stumbling on a *coherence barrier* (i.e., a confusing sentence(s)). Annotators rated

[1] TOEFL® is the Test of English as a Foreign Language, and GRE® is the Graduate Record Admissions Test.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 681–684,
Los Angeles, California, June 2010.

essays on a 3-point scale: 1) *low coherence*, 2) *somewhat coherent*, and 3) *high coherence*. They were instructed to ignore grammar and spelling errors, unless they affected essay comprehension.

During training, *Kappa* agreement statistics indicated that annotators had difficulty agreeing on the middle, *somewhat coherent* category. The annotation scale was therefore collapsed into a 2-point scale: *somewhat coherent* and *high coherence* categories were collapsed into the *high coherence* class (H), and *low-coherence* (L) remained unchanged. Two annotators labeled an overlapping set of about 100 essays to calculate inter-rater agreement; weighted Kappa was 0.677.

3 System

3.1 BL08 Algorithm

We implemented BL08's entity-based algorithm to build and evaluate coherence models for the essay data. In short, the algorithm generates a vector of *entity transition probabilities* for documents (essays, here). Vectors are used to build coherence models. The first step in the algorithm is to construct an entity grid in which all entities (*nouns and pronouns*) are represented by their roles (i.e., Subject **(S)**, Object **(O),** Other **(X)).** Entity roles are then used to generate *entity transitions* – the role transitions across adjacent sentences (e.g., Subject-to-Object, Object-to-Object). *Entity transition probabilities* are the proportions of different entity transition types within a text. The probability values are used then used as features to build a coherence model.

Entity roles can be represented in the following ways. In this study, consistent with BL08, different combinations are applied and reported (see Tables 2-4). Entities can be represented in grids with specified roles **(Syntax+)** (**S,O,X**). Alternatively, roles can be reduced to show *only* the presence and absence of an entity **(Syntax-)** (i.e., Entity Present **(P)** or Not **(N).** Co-referential entities can be resolved **(Coreference+)** or not **(Coreference-).** Finally, the **Salience** option reflects the frequency with which an entity appears in the discourse: if the entity is mentioned two or more times, it is salient **(Salient+),** otherwise, not **(Salient-)**.

Consistent with BL08, we systematically completed runs using various configurations of entity representations (see Section 4).

Given the combination, the entity transition probabilities were computed for all labeled essays in each data set. We used *n-fold* cross-validation for evaluation. Feature vectors were input to C5.0, a decision-tree machine learning application.

3.2 Additional Features

In BL08, augmenting the core coherence features with additional features improved the power of the algorithm. We extended the feature set with writing quality features (Table 1). **GUMS** features describe the technical quality of the essay. The motivation for type/token features **(*_TT)** is to measure word variety. For example, a high probability for a "Subject-to-Subject" transition indicates that the writer is repeating an entity in Subject position across adjacent sentences. However, this does not take into account whether the same word is repeated or a variety of words are used. The **{S,O,X,SOX}_TT** (type/token) features *uncover* the actual words collapsed into the entity transition probabilities. **Shell nouns** (Atkas & Cortes, 2008), common in essay writing, might also affect coherence.

NNES essays can contain many spelling errors. We evaluated the impact of a context-sensitive spell checker **(SPCR+),** as spelling variation will affect the transition probabilities in the entity grid.

Finally, we experimented with a *majority vote method* that combined the best performing feature combinations.

4 Evaluation

For all experiments, we used a series of *n-fold cross-validation* runs with C5.0 to evaluate performance for numerous feature configurations. In Tables 2, 3 and 4, we report: baselines, results on our data with BL08's best system configuration from the summary coherence evaluation task (closest to our task), and our best systems. In the Tables, "best systems" combined feature sets and outperformed baselines. Rows in **bold** indicate final independent best systems that contribute to best performance in the *majority vote* method. Agreement is reported as Weighted Kappa (**WK**), Precision (**P**), Recall (**R**) and F-measure (**F**).

Baselines. We implemented three non-trivial baseline systems. **E-rater** indicates use of the full feature set from e-rater. The **GUMS** (GUMS+) feature baseline, uses the Grammar (G+), Usage (U+), Mechanics (M+), and Style (ST+) flags (subset of e-rater features) to evaluate a coherence model. The third baseline represents the best run using **type/token features** ({S,O,X,SOX}_TT), and **{S,O,X}_TT_Shellnouns** feature sets (Table 1). The baseline majority voting system includes e-rater, GUMS, and the best performing type/token baseline (see Tables 2-4).

Feature Descriptor	**Feature Description**
GUMS	Grammar, usage, and mechanics errors, and style features from an AES system
S_TT **O_TT** **X_TT** **SOX_TT**[2] **P_TT**	Type/token ratios for actual words recovered from the entity grid, using the entity *roles*.
S_TT_Shellnouns **O_TT_Shellnouns** **X_TT_Shellnouns**	Type/token ratio of non-topic content, *shell nouns* (e.g., *approach, aspect, challenge*)

Table 1: New feature category description

Extended System. We combined our writing quality features with the core BL08 feature set. The combination improved performance over the three baselines, and over the best performing BL08 feature. Type/token features added to BL08 entity transitions probabilities improved performance of all single systems. This supports the need to *recover* actual word use. In Table 2, for TOEFL data, spell correction improved performance with the Mechanics error feature (where Spelling is evaluated). *This would suggest that annotators were trying to ignore spelling errors when labeling coherence.* In Table 3, for GRE data, spell correction improved performance with the Grammar error feature. *Spell correction did change grammar errors detected: annotators may have self-corrected for grammar.* Finally, the *majority vote* outperformed all systems. In Tables 3 and 4, Kappa was comparable to human agreement (K=0.677).

5 Conclusions and Future Work

We have evaluated how the BL08 algorithm features can be used to model coherence for student essays across three different populations. We found that the best coherence models for essays are built by combining BL08 entity-based features with writing quality features. BL08's outcomes showed that optimal performance was obtained by using different feature sets for different tasks. Our task was most similar to BL08's summary coherence task, but we used noisy essay data. The difference in the data types might also explain the need for our systems to include additional writing quality features.

Our *majority vote* method outperformed three baselines (and a baseline majority vote). For two of the populations, Weighted Kappa between system and human agreement was comparable. These results show promise toward development of an entity-based method that produces reliable coherence ratings for noisy essay data. We plan to evaluate this method on additional data sets, and in the context of automated essay scoring.

Abstract

In this paper, we focus on a recent Web trend called microblogging, and in particular a site called Twitter. The content of such a site is an extraordinarily large number of small textual messages, posted by millions of users, at random or in response to perceived events or situations. We have developed an algorithm that takes a trending phrase or any phrase specified by a user, collects a large number of posts containing the phrase, and provides an automatically created summary of the posts related to the term. We present examples of summaries we produce along with initial evaluation.

1 Introduction

Since Twitter's inception in 2006, it has grown at an unprecedented rate. In just four years, the service has grown to approximately 20 million unique visitors each month with users sending short 140-character messages (known as "tweets") approximately 40 million times a day. While the majority of these tweets are pointless babble or conversational, approximately 3.6% of these posts are topics of mainstream news (Pear Analytics, 2009). For example, Twitter has been cited as breaking many important events before traditional media, such as the attacks in Mumbai and the crash of the US Airways flight into the Hudson River.

In order to help users sort through the vast number of tweets that occur each day, Twitter.com has added a number of tools. For instance, Twitter's homepage displays important topics for three different ranges of time in order to see what topics are popular. For most topics, users are forced to read through related posts in order to try and understand why a topic is trending. In order to help users further, Twitter has partnered with the third-party website WhatTheTrend[1] in order to provide definitions of trending topics. WhatTheTrend allows users to manually enter descriptions of why a topic is trending. Unfortunately, WhatTheTrend suffers with spam and rants as well as lag time before a new trending topic is defined by a user.

While WhatTheTrend is a step in the right direction, a better approach is to automatically summarize important events as they occur in real time. We have developed such a method. Our method can automatically summarize a collection of microblogging posts that are all related to a topic into a short, one-line summary. Our results show that our automated summarizer produces summaries that are close to human-generated summaries for the same set of posts. For example, Table 1 below contains a sample of automatically produced summaries for some recently trending topics on Twitter.

2 Related Work

Some early work focused on summarizing results of database queries for presentation during natural language interactions (e.g., Kalita et al., 1986). Most summaries are generated for the purposes of providing a "gist" of a document or a set of documents to human readers (e.g., Luhn, 1958; Brandow et al., 1995). Summaries are sometimes also used as inputs to machine learning approaches, say for categorization. Kolcz et al. (2001) summarize textual documents in order to classify them, using the summaries as a feature to be input to a classifier. Most early studies used a news corpus like the Reuters dataset. As the Web started growing in size, the focus moved to Web pages.

Table 1. Example Summaries Produced by the Phrase Reinforcement Algorithm.

For example, Mahesh (1997) examines the effectiveness of Web document summarization by sentence extraction. Recently, there has been work on summarizing blogs (e.g. Zhou and Hovy, 2006; Hu et al., 2007). Most techniques focus on extraction: the selecting of salient pieces of documents in order to generate a summary. Applying extraction on microblogs at first appears irrelevant since a microblog post is already shorter than most summaries. However, extraction is possible when one considers extracting from multiple microblogs posts that are all related to a central theme.

3 Approach

3.1 Twitter API

Through an entirely HTTP-based API provided by Twitter, users can programmatically perform almost any task that can be performed via Twitter's web interface. For non-whitelisted users, Twitter restricts a user to 150 requests/hour. Furthermore, searches are limited to returning 1500 posts for a given request. Our summarizer has been shown to produce comparable automated summaries to human summaries with as few as 100 posts.

3.2 Phrase Reinforcement Algorithm

Given a trending topic, one can query Twitter.com for posts that contain the topic phrase. Presently, users would have to read these posts in order to comprehend and manually summarize their content. Instead, we automate this process using our Phrase Reinforcement Algorithm.

The central idea of the Phrase Reinforcement (PR) algorithm is to find the most commonly used phrase that encompasses the topic phrase. This phrase is then used as a summary. The algorithm was inspired from two simple observations: (1) users will often use the same word or sets of words adjacent to the topic phrase when describing a key idea and (2) users will often "re-tweet" (a Twitter form of quoting) the most relevant content for a trending topic. These two patterns create highly overlapping sequences of words when considering a large number of posts for a single topic. The PR algorithm capitalizes on these behaviors in order to generate a summary.

The Phrase Reinforcement algorithm begins with a starting phrase. This is typically a trending topic, but can be non-trending as well. Given the starting phrase, the PR algorithm submits a query to Twitter.com for a list of posts that each contains the phrase. Once the posts are retrieved, the algorithm filters the posts to remove any spam or other sources of irrelevant data (e.g. hyperlinks). Filtering is an important step in order to focus the algorithm on the most relevant content. We filter any spam by using a Naïve Bayes classifier which we trained using previously gathered spam content from Twitter.com. Next, non-English posts as well as duplicate posts are removed since we are concerned with English summaries only and want to prevent a single user from dominating a topic. Finally, given a set of relevant posts, we isolate the longest sentence from each post that contains the topic phrase. These sentences form the input into the PR algorithm.

Once we have the set of input sentences, the PR algorithm formally begins. The algorithm starts by building a graph representing the common sequences of words (i.e. phrases) that occur both before and after the topic phrase. The graph is generated such that it centers about a common root node representing the topic phrase. Adjacent to the root node are chains of common sequences of words found within the input sentences. In particular, each word is represented by a node and an associated count that indicates how many times the node's phrase occurs within the set of input sentences. The phrase of a node is simply the sequence of words generated by following the path from the node to the root node. To illustrate, consider the following set of input sentences for the topic "Ted Kennedy".

1. A tragedy: Ted Kennedy died today of cancer
2. Ted Kennedy died today
3. Ted Kennedy was a leader
4. Ted Kennedy died at age 77

Using these sentences, the PR algorithm would generate a graph similar to the one shown below in Figure 1.

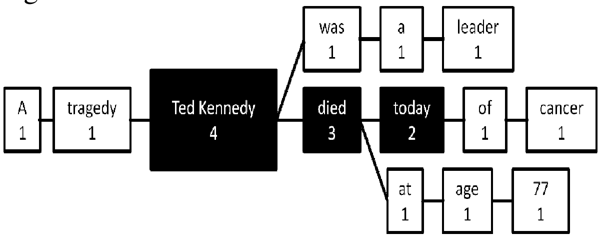

Figure 1. Example Phrase Reinforcement Graph.

In Figure 1, we see the node "today" has a count of two. This indicates that the phrase "Ted Kennedy died today" occurs exactly two times within the set of input sentences (in sentences 1 and 2). Likewise, the node "tradegy" has a count of one indicating the phrase "tragedy Ted Kennedy" only occurs one time (in sentence 1). In actuality, the PR algorithm would only add nodes to the graph with a count of at least two since it is looking for the most *common* phrase. These are shown as the black nodes in Figure 1. However, Figure 1 also includes unique nodes (shown in white) for helping illustrate the graph's structure.

After the graph is constructed, the PR algorithm assigns a weight to every node in order to prevent longer phrases from dominating the output. In particular, stop words are given a weight of zero while remaining words are given weights that are both proportional to their count and penalized the farther they are from the root node:

$$\begin{aligned} Weight(node) = Count(node) \\ - [RootDistance(node) \\ * \log_b Count(node)] \end{aligned}$$

In the above equation, the *RootDistance* of a node is simply the number of hops to get from the node to the root node and the logarithm base, b, is a parameter to the algorithm. Smaller values of b (e.g. 2) can be used for preferring shorter summaries over longer summaries.

Finally, once the graph is constructed and weighted, the PR algorithm is ready to generate a *partial summary*. To do so, the PR algorithm searches for the path with the most total weight by searching all paths that begin with the root node and end with a non-root node. This path is denoted as the best partial path since it only represents one half of the summary (i.e. the most common phrase occurring either before or after the topic phrase). In order to generate the remaining half of the summary, the PR algorithm is essentially repeated by initializing the root node with the partial summary and rebuilding the graph. The most heavily weighted path from this new graph is the final summary produced by the PR algorithm.

Using our example above and assuming that node weights are equal to their counts, the path with the most total weight is the path "Ted Kennedy died today of cancer" with a total weight of 11. This phrase would then be used as the root node of a new graph and the PR algorithm would be repeated. For this new graph, the only input sentence that contains this root phrase would be sentence 1. Therefore, the final summary for our example (assuming we allow unique phrases) would be sentence 1: "A tragedy: Ted Kennedy died today of cancer". However, if we only allow non-unique phrases in our graph (the black nodes), then our final summary would be "Ted Kennedy died today".

4 Results

In order to evaluate the PR algorithm, we gathered a set of testing data by collecting the top ten currently trending topics from Twitter's home page every day for five consecutive days. For each of the 50 trending topics, we retrieved the maximum number of posts from Twitter using its own API and then filtered the number of posts to 100 posts per topic. These posts were then given to two volunteers. The volunteers were instructed to simply generate the best summary possible using only the information contained within the posts and in 140 characters or less. Furthermore, automated summaries for each topic were also produced using the same 100 posts per topic. These summaries were then compared.

For comparing the manual and automated summaries, we adopted two of the metrics used by the Document Understanding Conference (DUC) of 2002 and 2004 (Lin and Hovy, 2003). First, we used their *Content* metric which asks a human judge to measure how completely an automated summary expresses the meaning of the manual summaries on a five point scale where 1 represents no meaning overlap and 5 represents complete meaning overlap. Next, we also used the automated evaluation metric ROUGE-1 developed by Lin (2004) which measures co-occurring unigram overlap between a set of manual and automated summaries. We restricted our automated evaluation to ROUGE-1 as opposed to the other ROUGE metrics since Lin indicates that this metric correlates highly with human judgments for very short summary tasks similar to the one we are performing (Lin, 2004).

For the 50 trending topics we used as our evaluation corpus, the PR algorithm produced an average Content score of 3.72 using $b = 100$ for our weighting measure. This result indicates our automated summaries express slightly less than most of the meaning of the manual summary content. To compare, we also used this same metric on our two sets of manual summaries which produced an average content score of 4.25. For the ROUGE-1 metric, the PR algorithm produced an average precision score of 0.31 and an average recall score of 0.30. Combining these scores using F_1-Measure, the PR algorithm produced a combined F_1 score of 0.30. Comparing the manual summaries against one another using ROUGE-1, they produced the same average precision, recall, and F_1 score of 0.34.

5 Future Work

Presently, we are working on extending our PR algorithm to providing real-time summaries within specific topics. We are experimenting with using a front-end classifier for producing trending topics within distinct categories and then summarizing around these topics in order to generate an automated real-time newspaper.

Automatic Generation of Personalized Annotation Tags for Twitter Users

Wei Wu, Bin Zhang, Mari Ostendorf
Electrical Engineering
University of Washington, Seattle, WA
{weiwu, binz, ostendor}@uw.edu

Abstract

This paper introduces a system designed for automatically generating personalized annotation tags to label Twitter user's interests and concerns. We applied TFIDF ranking and TextRank to extract keywords from Twitter messages to tag the user. The user tagging precision we obtained is comparable to the precision of keyword extraction from web pages for content-targeted advertising.

1 Introduction

Twitter is a communication platform which combines SMS, instant messages and social networks. It enables users to share information with their friends or the public by updating their Twitter messages. A large majority of the Twitter users are individual subscribers, who use Twitter to share information on "what am I doing" or "what's happening right now". Most of them update their Twitter messages very frequently, in which case the Twitter messages compose a detailed log of the user's everyday life. These Twitter messages contain rich information about an individual user, including what s/he is interested in and concerned about. Identifying an individual user's interests and concerns can help potential commercial applications. For instance, this information can be employed to produce "following" suggestions, either a person who shares similar interests (for expanding their social network) or a company providing products or services the user is interested in (for personalized advertisement).

In this work, we focus on automatically generating personalized annotation tags to label Twitter user's interests and concerns. We formulate this problem as a keyword extraction task, by selecting words from each individual user's Twitter messages as his/her tags. Due to the lack of human generated annotations, we employ an unsupervised strategy. Specifically, we apply TFIDF ranking and TextRank (Mihalcea and Tarau, 2004) keyword extraction on Twitter messages after a series of text preprocessing steps. Experiments on randomly selected users showed good results with TextRank, but high variability among users.

2 Related Work

Research work related to Twitter message analysis includes a user sentiment study (Jansen et al., 2009) and information retrieval indexing. To our knowledge, no previously published research has yet addressed problems on tagging user's personal interests from Twitter messages via keyword extraction, though several studies have looked at keyword extraction using other genres.

For supervised keyword extraction, (Turney, 2000; Turney, 2003; Hulth, 2003; Yih et al., 2006; Liu et al., 2008) employed TFIDF or its variants with Part-of-Speech (POS), capitalization, phrase and sentence length, etc., as features to train keyword extraction models, and discriminative training is usually adopted. Yih et al. (2006) use logistic regression to extract keywords from web pages for content-targeted advertising, which has the most similar application to our work. However, due to the lack of human annotation on Twitter messages, we have to adopt an unsupervised strategy.

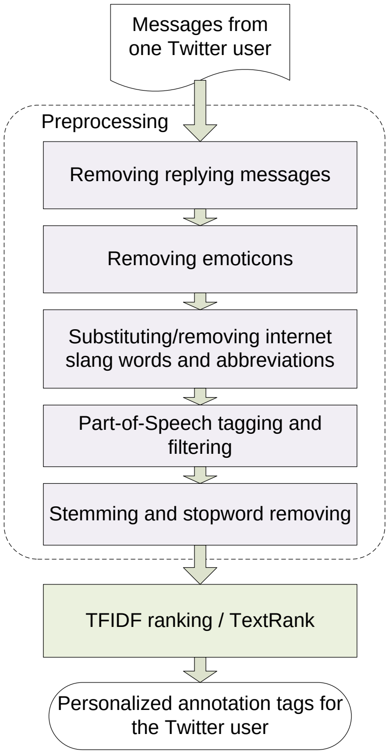
For unsupervised keyword extraction, TFIDF ranking is a popular method, and its effectiveness has been shown in (Hulth, 2003; Yih et al., 2006). TextRank and its variants (Mihalcea and Tarau, 2004; Wan et al., 2007; Liu et al., 2009) are graph-based text ranking models, which are derived from Google's PageRank algorithm (Brin and Page, 1998). It outperforms TFIDF ranking on traditional keyword extraction tasks. However, previous work on both TFIDF ranking and TextRank has been done mainly on academic papers, spoken documents or

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 689–692,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

web pages, whose language style is more formal (or, less "conversational") than that of Twitter messages. Twitter messages contain large amounts of "noise" like emoticons, internet slang words, abbreviations, and misspelled words. In addition, Twitter messages are a casual log of a user's everyday life, which often lacks of a coherent topic sequence compared to academic papers and most spoken documents. Hence, it remains to see whether TFIDF ranking and TextRank are effective for identifying user's interests from Twitter messages.

3 System Architecture

Figure 1 shows the framework of our system for tagging Twitter user's interests. A preprocessing pipeline is designed to deal with various types of "noise" in Twitter messages and produce candidate words for user tags. Then the TFIDF ranking or TextRank algorithm is applied to select user tags from the candidate words.



Messages from one Twitter user

Personalized annotation tags for the Twitter user

Figure 1: Framework of the personalized annotation tag generation system for Twitter users

3.1 Preprocessing

In addition to messages describing "What am I doing" or "what's happening right now", Twitter users also write replying messages to comment on other users' messages. This kind of message generally contains more information about the users they reply to than about themselves, and therefore they are removed in the preprocessing pipeline.

Emoticons frequently appear in Twitter messages. Although some of them help express user's sentiment on certain topics, they are not directly helpful for keyword analysis and may interfere with POS tagging in the preprocessing pipeline. Therefore, we designed a set of regular expressions to detect and remove them.

Internet slang words and abbreviations are widely used in Twitter messages. Most of them are out-of-vocabulary words in the POS tagging model used in the next step, and thus will deteriorate the POS tagging accuracy. Hence, we build a lookup table based on the list of abbreviations in the NoSlang online dictionary,[1] which we divide by hand into three sets for different processing. The first set includes 422 content words and phrases, such as "bff" (best friend forever) and "fone" (phone), with valid candidate words for user tags. The second set includes 67 abbreviations of function words that usually form grammatical parts in a sentence, such as "im" (i'm), "abt" (about). Simply removing them will affect the POS tagging. Thus, the abbreviations in both these sets are replaced with the corresponding complete words or phrases. The third set includes 4576 phrase abbreviations that are usually separable parts of a sentence that do not directly indicate discussion topics, such as "lol" (laugh out loud), "clm" (cool like me), which are removed in this step.

We apply the Stanford POS tagger (Toutanova and Manning, 2000) on Twitter messages, and only select nouns and adjectives as valid candidates for user tags. At the end of the preprocessing pipeline, the candidate words are processed with the rule-based Porter stemmer[2] and stopwords are filtered using a publicly available list.[3]

[3] armandbrahaj.blog.al/2009/04/14/list-of-english-stop-words/

3.2 User Tag Extraction

3.2.1 TFIDF ranking

In the TFIDF ranking algorithm, messages from user u are put together as one document. The TFIDF value of word i from this user's messages is computed as

$$tfidf_{i,u} = \frac{n_{i,u}}{\sum_j n_{j,u}} \log(\frac{U}{U_i})$$

where $n_{i,u}$ is the count of word i in user u's messages, U_i is the number of users whose messages contain word i, and U is the total number of users in the Twitter corpus. For each user, words with top *N* TFIDF values are selected as his/her tags.

3.2.2 TextRank

According to the TextRank algorithm (Mihalcea and Tarau, 2004), each candidate word is represented by a vertex in the graph; edges are added between two candidate words according to their co-occurrence. In the context of user tag extraction, we build a TextRank graph with undirected edges for each Twitter user. One edge is added between two candidate words if they co-exist within at least one message; the edge weight is set to be the total count of within-message co-occurrence of the two words throughout all messages of this user.

Starting with an arbitrarily assigned value (e.g. 1.0), the rank value $R(V_i)$ of the candidate word at vertex V_i is updated iteratively according to the following equation,

$$R(V_i) = (1-d) + d \sum_{V_j \in E(V_i)} \frac{w_{ji}}{\sum_{V_k \in E(V_j)} w_{jk}} R(V_j)$$

where w_{ji} is the weight of the edge that links V_j and V_i, $E(V_i)$ is the set of vertices which V_i is connected to, and d is a damping factor that is usually set to 0.85 (Brin and Page, 1998). The rank update iteration continues until convergence. The candidate words are then sorted according to their rank values. Words with top-*N* rank values are selected as tags for this user.

4 Experiment

4.1 Experimental Setup

We employed the Twitter API to download Twitter messages. A unigram English language model was used to filter out non-English users. We obtained messages from 11,376 Twitter users, each of them had 180 to 200 messages. The word IDF for TFIDF ranking was computed over these users.

Precision (%)	TFIDF	TextRank
top-1	59.6	67.3
top-3	61.5	66.0
top-5	61.2	63.0
top-10	59.0	58.3

Table 1: Tagging precision on all users in the test set

We adopted an evaluation measure similar to the one proposed in (Yih et al., 2006) for identifying advertising keywords on web pages, which emphasizes precision. We randomly selected 156 Twitter users to evaluate the top-*N* precision of TFIDF ranking and TextRank. After we obtained the top-*N* outputs from the system, three human evaluators were asked to judge whether the output tags from the two systems (unidentified) reflected the corresponding Twitter user's interests or concerns according to the full set of his/her messages.[4] We adopted a conservative standard in the evaluation: when a person's name is extracted as a user tag, which is frequent among Twitter users, we judge it as a correct tag only when it is a name of a famous person (pop star, football player, etc). The percentage of the correct tags among the top-*N* selected tags corresponds to the top-*N* precision of the system.

4.2 Experimental Results

Table 1 gives the top-*N* precision for TFIDF and TextRank for different values of *N*, showing that TextRank leads to higher precision for small *N*. Although Twitter messages are much "noisier" than regular web pages, the top-*N* precision we obtained for Twitter user tagging is comparable to the web page advertising keyword extraction result reported in (Yih et al., 2006).

Figure 2 shows an example of the candidate word ranking result of a Twitter user by TextRank (the font size is set to be proportional to each word's TextRank value). By examining the Twitter messages, we found that this user is an information tech-

[4] The pairwise Kappa value for inter-evaluator agreement ranged from 0.77-0.83, showing good agreement.

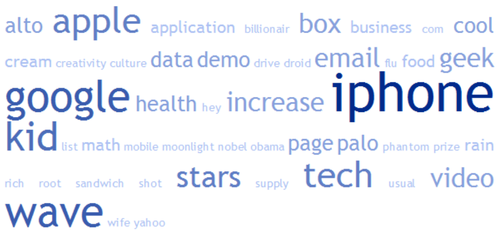

Figure 2: Example of a Twitter user's word ranks (the font size is proportional to each word's TextRank value)

	Precision (%)			
top-N	σ >0.6	σ ≤0.6	H>5.4	H≤5.4
top-1	71.6	60.7	78.5	50.8
top-3	71.9	56.8	74.2	54.0
top-5	69.3	53.1	69.2	53.7
top-10	65.1	47.7	63.8	50.2

Table 2: TextRank tagging precision on users with different Top-10 TextRank value standard deviation (σ) and user message text entropy (H).

nology “geek”, who is very interested in writing *Apple's iPhone applications*, and also a user of *Google Wave*. In this work, we use only isolated words as user tags, however, “google”, “wave”, and “palo”, “alto” extracted in this example indicate that phrase level tagging can bring us more information about the user, which is typical of many users.

Although most Twitter users express their interests to some extent in their messages, there are some users whose message content is not rich enough to extract reliable information. We investigated two measures for identifying such users: standard deviation of the top-10 TextRank values and the user's message text entropy. Table 2 shows a comparison of tagging precision where the users are divided into two groups with a threshold on each of the two measures. It is shown that users with larger TextRank value standard deviation or message text entropy tend to have higher tagging precision, and the message text entropy has better correlation with the top-10 tagging precision than TextRank value standard deviation (0.33 v.s. 0.20 absolute).

5 Summary

In this paper, we designed a system to automatically extract keywords from Twitter messages to tag user interests and concerns. We evaluated two tagging algorithms, finding that TextRank outperformed TFIDF ranking, but both gave a tagging precision that was comparable to that reported for web page advertizing keyword extraction. We noticed substantial variation in performance across users, with low entropy indicative of users with fewer keywords, and a need for extracting key phrases (in addition to words). Other follow-on work might consider temporal characteristics of messages in terms of the amount of data needed for reliable tags vs. their time-varying nature, as well as sentiment associated with the identified tags.

Language identification of names with SVMs

Aditya Bhargava and Grzegorz Kondrak
Department of Computing Science
University of Alberta
Edmonton, Alberta, Canada, T6G 2E8
{abhargava,kondrak}@cs.ualberta.ca

Abstract

The task of identifying the language of text or utterances has a number of applications in natural language processing. Language identification has traditionally been approached with character-level language models. However, the language model approach crucially depends on the length of the text in question. In this paper, we consider the problem of language identification of names. We show that an approach based on SVMs with n-gram counts as features performs much better than language models. We also experiment with applying the method to pre-process transliteration data for the training of separate models.

1 Introduction

The task of identifying the language of text or utterances has a number of applications in natural language processing. Font Llitjós and Black (2001) show that language identification can improve the accuracy of letter-to-phoneme conversion. Li et al. (2007) use language identification in a transliteration system to account for different semantic transliteration rules between languages when the target language is Chinese. Huang (2005) improves the accuracy of machine transliteration by clustering his training data according to the source language.

Language identification has traditionally been approached using character-level n-gram language models. In this paper, we propose the use of support vector machines (SVMs) for the language identification of very short texts such as proper nouns. We show that SVMs outperform language models on two different data sets consisting of personal names. Furthermore, we test the hypothesis that language identification can improve transliteration by pre-processing the source data and training separate models using a state-of-the-art transliteration system.

2 Previous work

N-gram approaches have proven very popular for language identification in general. Cavnar and Trenkle (1994) apply n-gram language models to general text categorization. They construct character-level language models using n-grams up to a certain maximum length from each class in their training corpora. To classify new text, they generate an n-gram frequency profile from the text and then assign it to the class having the most similar language model, which is determined by summing the differences in n-gram ranks. Given 14 languages, text of 300 characters or more, and retaining the 400 most common n-grams up to length 5, they achieve an overall accuracy of 99.8%. However, the accuracy of the n-gram approach strongly depends on the length of the texts. Kruengkrai et al. (2005) report that, on a language identification task of 17 languages with average text length 50 bytes, the accuracy drops to 90.2%. When SVMs were used for the same task, they achieved 99.7% accuracy.

Konstantopoulos (2007) looks particularly at the task of identifying the language of proper nouns. He focuses on a data set of soccer player names coming from 13 possible national languages. He finds that using general n-gram language models yields an average F_1 score of only 27%, but training the models specifically to these smaller data gives significantly better results: 50% average F_1 score for last names

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 693–696,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

only, and 60% for full names.

On the other hand, Li et al. (2007) report some good results for single-name language identification using n-gram language models. For the task of separating single Chinese, English, and Japanese names, they achieve an overall accuracy of 94.8%. One reason that they do better is because of the smaller number of classes. We can further see that the languages in question are very dissimilar, making the problem easier; for example, the character "x" appears only in the list of Chinese names, and the bigram "kl" appears only in the list of English names.

3 Language identification with SVMs

Rather than using language models to determine the language of a name, we propose to count character n-gram occurrences in the given name, for n up to some maximum length, and use these counts as the features in an SVM. We choose SVMs because they can take a large number of features and learn to weigh them appropriately. When counting n-grams, we include space characters at the beginning and end of each word, so that prefixes and suffixes are counted appropriately. In addition to n-gram counts, we also include word length as a feature.

In our initial experiments, we tested several different kernels. The kernels that performed the best were the linear, sigmoid, and radial basis function (RBF) kernels. We tested various maximum n-gram lengths; Figure 1 shows the accuracy of the linear kernel as a function of maximum n-gram length. Polynomial kernels, a substring match–count string kernel, and a string kernel based on the edit distance all performed poorly in comparison. We also experimented with other modifications such as normalizing the feature vectors, and decreasing the weights of frequent n-gram counts to avoid larger counts dominating smaller counts. Since the effects were negligible, we exclude these results from this paper.

In our experiments, we used the LIBLINEAR (Fan et al., 2008) package for the linear kernel and the LIBSVM (Chang and Lin, 2001) package for the RBF and sigmoid kernels. We discarded any periods and parentheses, but kept apostrophes and hyphens, and we converted all letters to lower case. We removed very short names of length less than two. For all data sets, we held out 10% of the data as the test set. We then found optimal parameters for each kernel type using 10-fold cross-validation on the remaining training set. This yielded optimum maximum n-gram lengths of four for single names and five for full names. Using the optimal parameters, we constructed models from the entire training data and then tested the models on the held-out test set.

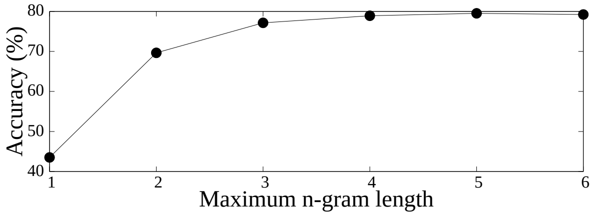

Figure 1: Cross-validation accuracy of the linear kernel on the Transfermarkt full names corpus.

4 Intrinsic evaluation

We used two corpora to test our SVM-based approach: the Transfermarkt corpus of soccer player names, and the Chinese-English-Japanese (CEJ) corpus of first names and surnames. These corpora are described in further detail below.

4.1 Transfermarkt corpus

The Transfermarkt corpus (Konstantopoulos, 2007) consists of European soccer player names annotated with one of 13 possible national languages, with separate lists provided for last names and full names. Diacritics were removed in order to avoid trivializing the task. There are 14914 full names, with average length 14.8, and 12051 last names, with average length 7.8. It should be noted that these data are noisy; the fact that a player plays for a certain nation's team does not necessarily indicate that his or her name is of that nation's language. For example, *Dario Dakovic* was born in Bosnia but plays for the Austrian national team; his name is therefore annotated as German.

Table 1 shows our results on the Transfermarkt corpus. Because Konstantopoulos (2007) provides only F_1 scores, we used his scripts to generate new results using language models and calculate the accuracy instead, which allows us to be consistent with our tests on other data sets. Our results show that us-

Method	Last names	Full names
Language models	44.7	54.2
Linear SVM	**56.4**	**79.9**
RBF SVM	55.7	78.9
Sigmoid SVM	56.2	78.7

Table 1: Language identification accuracy on the Transfermarkt corpus. Language models have $n = 5$.

ing SVMs clearly outperforms using language models on the Transfermarkt corpus; in fact, SVMs yield better accuracy on last names than language models on full names. Differences between kernels are not statistically significant.

4.2 CEJ corpus

The CEJ corpus (Li et al., 2007) provides a combined list of first names and surnames, each classified as Chinese, English, or Japanese. There are a total of 97115 names with an average length of 7.6 characters. This corpus was used for the semantic transliteration of personal names into Chinese.

We found that the RBF and sigmoid kernels were very slow—presumably due to the large size of the corpus—so we tested only the linear kernel. Table 2 shows our results in comparison to those of language models reported in (Li et al., 2007); we reduce the error rate by over 50%.

Method	Ch.	Eng.	Jap.	All
Lang. model	96.4	89.9	96.5	94.8
Linear SVM	**99.0**	**94.8**	**97.6**	**97.6**

Table 2: Language identification accuracy on the CEJ corpus. Language models have $n = 4$.

5 Application to machine transliteration

Machine transliteration is one of the primary potential applications of language identification because the language of a word often determines its pronunciation. We therefore tested language identification to see if results could indeed be improved by using language identification as a pre-processing step.

5.1 Data

The English-Hindi corpus of names (Li et al., 2009; MSRI, 2009) contains a test set of 1000 names represented in both the Latin and Devanagari scripts. We manually classified these names as being of either Indian or non-Indian origin, occasionally resorting to web searches to help disambiguate them.[1] We discarded those names that fell into both categories (e.g. "Maya") as well as those that we could not confidently classify. In total, we discarded 95 of these names, and randomly selected 95 names from the training set that we could confidently classify to complete our corpus of 1000 names. Of the 1000 names, 546 were classified as being of Indian origin and the remaining 454 were classified as being of non-Indian origin; the names have an average length of 7.0 characters.

We trained our language identification approach on 900 names, with the remaining 100 names serving as the test set. The resulting accuracy was **80%** with the linear kernel, **84%** with the RBF kernel, and **83%** with the sigmoid kernel. In this case, the performance of the RBF kernel was found to be significantly better than that of the linear kernel according to the McNemar test with $p < 0.05$.

5.2 Experimental setup

We tested a simple method of combining language identification with transliteration. We use a language identification model to split the training, development, and test sets into disjoint classes. We train a transliteration model on each separate class, and then combine the results.

Our transliteration system was DIRECTL (Jiampojamarn et al., 2009). We trained the language identification model over the entire set of 1000 tagged names using the parameters from above. Because these names comprised most of the test set and were now being used as the training set for the language identification model, we swapped various names between sets such that none of the words used for training the language identification model were in the final transliteration test set.

Using this language identification model, we split the data. After splitting, the "Indian" training, development, and testing sets had 5032, 575, and 483 words respectively while the "non-Indian" sets had 11081, 993, and 517 words respectively.

[1] Our tagged data are available online at `http://www.cs.ualberta.ca/~ab31/langid/`.

5.3 Results

Splitting the data and training two separate models yielded a combined top-1 accuracy of **46.0%**, as compared to **47.0%** achieved by a single transliteration model trained over the full data; this difference is not statistically significant. Somewhat counter-intuitively, using language identification as a pre-processing step for machine transliteration yields no improvement in performance for our particular data and transliteration system.

While it could be argued that our language identification accuracy of 84% is too low to be useful here, we believe that the principal reason for this performance decrease is the reduction in the amount of data available for the training of the separate models. We performed an experiment to confirm this hypothesis: we randomly split the full data into two sets, matching the sizes of the Indian and non-Indian sets. We then trained two separate models and combined the results; this yielded a top-1 accuracy of **41.5%**. The difference between this and the 46.0% result above is statistically significant with $p < 0.01$. From this we conclude that the reduction in data size was a significant factor in the previously described null result, and that language identification does provide useful information to the transliteration system. In addition, we believe that the transliteration system may implicitly leverage the language origin information. Whether a closer coupling of the two modules could produce an increase in accuracy remains an open question.

6 Conclusion

We have proposed a novel approach to the task of language identification of names. We have shown that applying SVMs with n-gram counts as features outperforms the predominant approach based on language models. We also tested language identification in one of its potential applications, machine transliteration, and found that a simple method of splitting the data by language yields no significant change in accuracy, although there is an improvement in comparison to a random split.

In the future, we plan to investigate other methods of incorporating language identification in machine transliteration. Options to explore include the use of language identification probabilities as features in the transliteration system (Li et al., 2007), as well as splitting the data into sets that are not necessarily disjoint, allowing separate transliteration models to learn from potentially useful common information.

Abstract

Phonetic string transduction problems, such as letter-to-phoneme conversion and name transliteration, have recently received much attention in the NLP community. In the past few years, two methods have come to dominate as solutions to supervised string transduction: generative joint n-gram models, and discriminative sequence models. Both approaches benefit from their ability to consider large, flexible spans of source context when making transduction decisions. However, they encode this context in different ways, providing their respective models with different information. To combine the strengths of these two systems, we include joint n-gram features inside a state-of-the-art discriminative sequence model. We evaluate our approach on several letter-to-phoneme and transliteration data sets. Our results indicate an improvement in overall performance with respect to both the joint n-gram approach and traditional feature sets for discriminative models.

1 Introduction

Phonetic string transduction transforms a source string into a target representation according to its pronunciation. Two important examples of this task are letter-to-phoneme conversion and name transliteration. In general, the problem is challenging because source orthography does not unambiguously specify the target representation. When considering letter-to-phoneme, ambiguities and exceptions in the pronunciation of orthography complicate conversion. Transliteration suffers from the same ambiguities, but the transformation is further complicated by restrictions in the target orthography that may not exist in the source.

Joint n-gram models (Bisani and Ney, 2002; Chen, 2003; Bisani and Ney, 2008) have been widely applied to string transduction problems (Li et al., 2004; Demberg et al., 2007; Jansche and Sproat, 2009). The power of the approach lies in building a language model over the operations used in the conversion from source to target. Crucially, this allows the inclusion of source context in the generative story. Smoothing techniques play an important role in joint n-gram models, greatly affecting their performance. Although joint n-gram models are capable of capturing context information in both source and target, they cannot selectively use only source or target information, nor can they consider arbitrary sequences within their context window, as they are limited by their back-off schedule.

Discriminative sequence models have also been shown to perform extremely well on string transduction problems. These begin with a Hidden Markov Model architecture, augmented with substring operations and discriminative training. The primary strength of these systems is their ability to include rich indicator features representing long sequences of source context. We will assume a specific instance of discriminative sequence modeling, DIRECTL (Jiampojamarn et al., 2009), which achieved the best results on several language pairs in the NEWS Machine Transliteration Shared Task (Li et al., 2009). The same system matches or exceeds the performance of the joint n-gram approach on letter-to-phoneme conversion (Jiampojamarn et al., 2008). Its features are optimized by an online, margin-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 697–700,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

based learning algorithm, specifically, the Margin Infused Relaxed Algorithm, MIRA (Crammer and Singer, 2003).

In this paper, we propose an approach that combines these two different paradigms by formulating the joint n-gram model as a new set of features in the discriminative model. This leverages an advantage of discriminative training, in that it can easily and effectively incorporate arbitrary features. We evaluate our approach on several letter-to-phoneme and transliteration data sets. Our results demonstrate an improvement in overall performance with respect to both the generative joint n-gram approach and the original DIRECTL system.

2 Background

String transduction transforms an input string $\mathbf{x}$ into the desired output string $\mathbf{y}$. The input and output are different representations of the same entity; for example, the spelling and the pronunciation of a word, or the orthographic forms of a word in two different writing scripts.

One approach to string transduction is to view it as a tagging problem where the input characters are tagged with the output characters. However, since sounds are often represented by multi-character units, the relationship between the input and output characters is often complex. This prevents the straightforward application of standard tagging techniques, but can be addressed by substring decoders or semi-Markov models.

Because the relationship between $\mathbf{x}$ and $\mathbf{y}$ is hidden, alignments between the input and output characters (or substrings) are often provided in a preprocessing step. These are usually generated in an unsupervised fashion using a variant of the EM algorithm. Our system employs the many-to-many alignment described in (Jiampojamarn et al., 2007). We trained our system on these aligned examples by using the online discriminative training of (Jiampojamarn et al., 2009). At each step, the parameter update is provided by MIRA.

3 Features

Jiampojamarn et al. (2009) describe a set of indicator feature templates that include (1) context features (2) transition features and (3) linear-chain features. Table 1 summarizes these features and introduces the new set of *joint n-gram features*.

context	$x_{i-c}\ y_i$ $\dots$ $x_{i+c}\ y_i$ $x_{i-c}x_{i-c+1}\ y_i$ $\dots$ $x_{i+c-1}x_{i+c}\ y_i$ $\dots\dots$ $x_{i-c}\dots x_{i+c}\ y_i$
transition	$y_{i-1}\ y_i$
linear-chain	$x_{i-c}\ y_{i-1}\ y_i$ $\dots$ $x_{i+c}\ y_{i-1}\ y_i$ $x_{i-c}x_{i-c+1}\ y_{i-1}\ y_i$ $\dots$ $x_{i+c-1}x_{i+c}\ y_{i-1}\ y_i$ $\dots\dots$ $x_{i-c}\dots x_{i+c},\ y_{i-1}\ y_i$
joint n-gram	$x_{i+1-n}y_{i+1-n}x_iy_i$ $\dots$ $x_{i-1}y_{i-1}x_iy_i$ $x_{i+1-n}y_{i+1-n}x_{i+2-n}y_{i+2-n}x_iy_i$ $\dots$ $x_{i-2}y_{i-2}x_{i-1}y_{i-1}x_iy_i$ $\dots\dots$ $x_{i+1-n}y_{i+1-n}\dots x_{i-1}y_{i-1}x_iy_i$

Table 1: Feature template

The context features represent the source side evidence that surrounds an input substring $\mathbf{x_i}$ as it generates the target output $\mathbf{y_i}$. These features include all possible n-grams that fit inside a source-side context windows of size $\mathbf{C}$, each conjoined with $\mathbf{y_i}$. The transition features enforce the cohesion of the generated output with target-side bigrams. The linear-chain features conjoin context and transition features.

The set of feature templates described above has been demonstrated to achieve excellent performance. The context features express rich information on the source side, but no feature template allows target context beyond $\mathbf{y_{i-1}}, \mathbf{y_i}$. Target and source context are considered jointly, but only in a very limited fashion, as provided by the linear chain features. Jiampojamarn et al. (2008) report that context features contribute the most to system performance. They also report that increasing the Markov order in the transition features from bigram to tri-

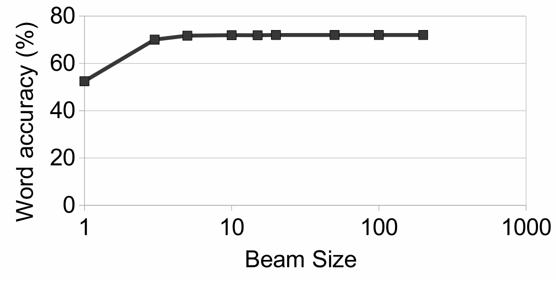

Figure 1: System accuracy as a function of the beam size

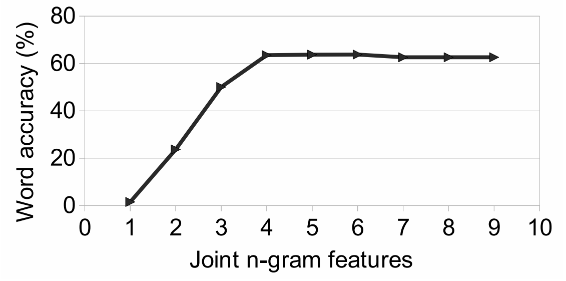

Figure 2: System accuracy as a function of n-gram size

gram results in no significant improvement. Intuitively, the joint information of both source and target sides is important in string transduction problems. By integrating the joint n-gram features into the online discriminative training framework, we enable the system to not only enjoy rich context features and long-range dependency linear-chain features, but we also take advantage of joint information between source and target substring pairs, as encoded by the joint n-gram template shown in the bottom of Table 1.

An alternative method to incorporate a joint n-gram feature would compute the generative joint n-gram scores, and supply them as a real-valued feature to the model. As all of the other features in the DIRECTL framework are indicators, the training algorithm may have trouble scaling an informative real-valued feature. Therefore, we represent these joint n-gram features as binary features that indicate whether the model has seen particular strings of joint evidence in the previous $\mathbf{n-1}$ operations when generating $\mathbf{y_i}$ from $\mathbf{x_i}$. In this case, the system learns a distinct weight for each substring of the joint n-gram.

In order to accommodate higher-order joint n-grams, we replace the exact search algorithm of Jiampojamarn et al. (2008) with a beam search. During our development experiments, we observed no significant decrease in accuracy after introducing this approximation. Figure 1 shows the system performance in terms of the word accuracy as a function of the beam size on a development set. The performance starts to converge quickly and shows no further improvement for values grater than 20. In the remaining experiments we set the beam size to 50.

We also performed development experiments with a version of the system that includes only joint n-gram indicators. Figure 2 shows the word accuracy with different values of n. The accuracy reaches its maximum for $n = 4$, and actually falls off for larger values of n. This anomaly is likely caused by the model using its expanded expressive power to memorize sequences of operations, overfitting to its training data. Such overfitting is less likely to happen in the generative joint n-gram model, which smooths high-order estimates very carefully.

4 Experiments and Results

We evaluate our new approach on two string transduction applications: (1) letter-to-phoneme conversion and (2) name transliteration. For the letter-to-phoneme conversion, we employ the English Celex, NETtalk, OALD, CMUdict, and the French Brulex data sets. In order to perform direct comparison with the joint n-gram approach, we follow exactly the same data splits as Bisani and Ney (2008). The training sizes range from 19K to 106K words. For the transliteration task, we use three data sets provided by the NEWS 2009 Machine Transliteration Shared Task (Li et al., 2009): English-Russian (EnRu), English-Chinese (EnCh), and English-Hindi (EnHi). The training sizes range from 10K to 30K words. We set $n = 6$ for the joint n-gram features; other parameters are set on the respective development sets.

Tables 2 and 3 show the performance of our new system in comparison with the joint n-gram approach and DIRECTL. The results in the rightmost column of Table 2 are taken directly from (Bisani and Ney, 2008), where they were evaluated on the same data splits. The results in the rightmost column of Table 3 are from (Jansche and Sproat, 2009), which was the best performing system based on joint

Data set	this work	DIRECTL	joint n-gram

Brulex	**95.21**	95.03	93.75

Table 2: Letter-to-phoneme conversion accuracy

Data set	this work	DIRECTL	joint n-gram
EnRu	**61.80**	61.30	59.70
EnCh	**74.17**	73.34	64.60
EnHi	**50.30**	49.80	41.50

Table 3: Name transliteration accuracy

n-grams at NEWS 2009. We report all results in terms of the word accuracy, which awards the system only for complete matches between system outputs and the references.

Our full system outperforms both DIRECTL and the joint n-gram approach in all data sets. This shows the utility of adding joint n-gram features to the DIRECTL system, and confirms an advantage of discriminative approaches: strong competitors can simply be folded into the model.

Comparing across tables, one can see that the gap between the generative joint n-gram and the DIRECTL methods is much larger for the transliteration tasks. This could be because joint n-grams are a poor fit for transliteration, or the gap could stem from differences between the joint n-gram implementations used for the two tasks. Looking at the improvements to DIRECTL from joint n-gram features, we see further evidence that joint n-grams are better suited to letter-to-phoneme than they are to transliteration: letter-to-phoneme improvements range from relative error reductions of 3.6 to 17.3, while in transliteration, the largest reduction is 3.1.

5 Conclusion

We have presented a new set of joint n-gram features for the DIRECTL discriminative sequence model. The resulting system combines two successful approaches for string transduction — DIRECTL and the joint n-gram model. Joint n-gram indicator features are efficiently trained using a large margin method. We have shown that the resulting system consistently outperforms both DIRECTL and strong joint n-gram implementations in letter-to-phoneme conversion and name transliteration, establishing a new state-of-the-art for these tasks.

A Hybrid Morphologically Decomposed Factored Language Models for Arabic LVCSR

Amr El-Desoky, Ralf Schlüter, Hermann Ney
Lehrstuhl für Informatik 6 – Computer Science Department
RWTH Aachen University, D-52056 Aachen, Germany
{desoky,schluter,ney}@cs.rwth-aachen.de

Abstract

In this work, we try a hybrid methodology for language modeling where both morphological decomposition and factored language modeling (FLM) are exploited to deal with the complex morphology of Arabic language. At the end, we are able to obtain from 3.5% to 7.0% relative reduction in word error rate (WER) with respect to a traditional full-words system, and from 1.0% to 2.0% relative WER reduction with respect to a non-factored decomposed system.

1 Introduction

Arabic language is characterized by a complex morphological structure where different kinds of prefixes and suffixes are appended to the word stems producing a very large number of inflectional forms. This leads to poor language model (LM) probability estimates, and thus high LM perplexities (PPLs) causing problems in large vocabulary continuous speech recognition (LVCSR). One successful approach to deal with this problem is to consider LMs including morphologically decomposed words. Another approach is to use the factored language models (FLMs) which are powerful models that combine multiple sources of information and efficiently integrate them via a complex backoff mechanism (Bilmes and Kirchhoff, 2003).

Morphological decomposition is successfully used for Arabic LMs in several previous works. Some are based on linguistic knowledge, and others are based on unsupervised methods. Some of the linguistic methods are based on the Buckwalter Arabic Morphological Analyzer (BAMA) like in (Lamel et al., 2008). Alternatively, in our previous work (El-Desoky et al., 2009), we use the Morphological Analyzer and Disambiguator for Arabic (MADA) (Habash and Rambow, 2007). On the other side, most of the unsupervised methods are based on the minimum description length principle (MDL) like in (Creutz et al., 2007).

Another type of models is the FLM, in which words are viewed as vectors of K factors, so that $w_t := \{f_t^{1:K}\}$. A factor could be any feature of the word such as morphological class, stem, root or even a semantic feature. An FLM is a model over factors, i.e., $p(f_t^{1:K}|f_{t-1}^{1:K}, f_{t-2}^{1:K}, ..., f_{t-n+1}^{1:K})$, which could be reformed as a product of probabilities of the form $p(f|f_1, f_2, ..., f_N)$. The main idea of the model is to backoff to other factors when some word n-gram is not observed in the training data, thus improving the probability estimates.

In this work we try to combine the strengths of morphological decomposition and factored language modeling. Therefore, language models with factored morphemes are used. For this purpose, the LM training data are processed such that full-words are decomposed into prefix-stem-suffix format with different added features. We compare our approach with the standard full-word, decomposed word, and factored full-word n-gram approaches.

2 Factorization and Decomposition

We use MADA 2.0 in order to perform morphological analysis and attach a complete set of morphological tags to Arabic words in context. From those tags

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 701–704,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

we derive three different features. Moreover, we derive a fourth feature based on the root of the word generated by "Sebawai" (Darwish, 2002). The list of features is:

- **"W"** (Word): word surface form.
- **"L"** (Lexeme): word lexeme.
- **"M"** (Morph): morphological description.
- **"P"** (Pattern): word after subtracting root.

The LM training corpora are processed so that words are replaced by the factored representation as required by SRILM-FLM extensions (Kirchhoff et al., 2008). Then, word decomposition is performed based on MADA as described in our previous publication (El-Desoky et al., 2009).

3 FLM topologies

In order to obtain a good performance via FLMs, we need to optimize the FLM parameters: the combination of the conditioning factors, backoff path, and smoothing options. For this purpose, we use a Genetic Algorithm based FLM optimization tool (GA-FLM) developed by Kirchhoff (2006) which seeks to minimize the PPL over some held-out text. Furthermore, we apply some manual optimization to fine tune the FLM parameters. For memory limitations, we only use factors up to 2 previous time slots (tri-gram like models). Finally, we come up with a set of competing FLMs with rather close PPLs. In Table 1, we record the PPLs measured for some held-out text. The first column gives the combination of the parent factors. So that, FLM_1 corresponds to the model $P(W_t|W_{t-1}, W_{t-2})$, which is the FLM equivalent of the standard tri-gram LM (our baseline model), while FLM_2 & FLM_3 correspond to the model $P(W_t|W_{t-1}, M_{t-1}, L_{t-1}, P_{t-1}, W_{t-2})$, however FLM_4 & FLM_5 correspond to the model $P(W_t|W_{t-1}, M_{t-1}, L_{t-1}, W_{t-2}, M_{t-2}, L_{t-2})$. The "gtmin" refers to the count threshold that is sufficient to have a language model hit at some node of the the backoff graph (for exact topologies, contact the first author). From Table 1, comparing PPLs (non-normalized) across factored and non-factored LMs, we see that using more factors other than the normal word could help decreasing the PPL. This is true for all the used types of vocabulary units.

	vocabulary		
FLM_x **parent factors**	**FW**	**PD**	**FD**
1: W1 W2 (baseline)	302.6	284.1	82.7
W1 M1 L1 P1 W2			
2: gtmin = 1	306.2	296.9	83.2
3: gtmin = 2-4	290.9	279.1	79.8
W1 M1 L1 W2 M2 L2			
4: gtmin = 1	300.2	291.1	83.6
5: gtmin = 2-4	294.5	283.7	81.1

4: gtmin = 1	**19.9**
5: gtmin = 2-4	20.3

Table 2: WERs using FLMs based on 70k full-words.

In order to select the best FLM topology, we run a simple one pass recognition for a small internal dev corpus derived from GALE data sets, consists of 40 minutes of audio data recorded during January to March 2007. The acoustic models are within-word tri-phone models trained using 1100h of audio material. The basic acoustic models are trained based on Maximum Likelihood (ML) method. Then, a discriminative training based on Minimum Phone Error (MPE) criterion is performed to enhance the models. A 70k full-words lexicon is used. The FLM training data consists of 206 Million running full-words. A standard bi-gram LM based on full-words is used to generate N-best lists, then N-best list rescoring is performed using the different FLM topologies shown in Table 1. We start by N = 1000-best down to 3-best sentences. Using N = 10 always gives the best results. The recognition WERs are recorded in Table 2. The least WER is obtained with FLM_4. We note that the best FLM does not correspond to the least PPL. This is because a higher "gtmin" value causes more backoff in cases of insufficient data leading to better estimates. Therefore, we select FLM_4 for the coming experiments.

4 Experimental Setup

Our recognition system is close to the one described in section 3. However, we use within and across-word models at different recognition passes. In addition, we use 70k or 256k lexicon of full-words or partially decomposed words. Alternatively, we evaluate the results on the GALE 2007 development and evaluation sets (dev07: 2.5h; eval07: 4h). Our recognizer works in 3 passes. In the first pass, within-word acoustic models are used with no adaptation, along with a standard bi-gram LM to generate lattices, followed by a standard tri-gram or 4-gram LM rescoring of lattices. The second pass does the same, but it uses across-word models with Constrained Maximum Likelihood Linear Regression (CMLLR) adaptation. Then, a third pass with additional Maximum Likelihood Linear Regression (MLLR) adaptation is performed, using a standard bi-gram LM to generate lattices or N-best lists. Then, one of the following is performed: **1)** lattice rescoring using standard tri-gram or 4-gram LM, **2)** N-best list rescoring using FLMs based on full-words, partially or fully decomposed words.

5 Experiments

In this section, we record our recognition results for: **1)** systems based on full-words, and **2)** systems based on decomposed words. Also, we introduce additional results for larger lexicon sizes.

5.1 Systems Based on Full-words

In this section, we present the WERs of our recognition systems based on full-words. Where, during the search, we use a lexicon of 70K full-words. In the first 2 passes, we use a standard bi-gram LM to generate lattices, followed by a standard tri-gram LM rescoring of lattices. However, in the third pass, we generate both lattices and N-best lists based on the same bi-gram LM. The final lattices and N-best lists are rescored using different LMs as shown in Table 3. In case we perform N-best list rescoring with a FLM, the N-best lists are processed to produce factored representation, followed by partial or full decomposition as previously described in section 2.

It is clear from Table 3 that the least WER is achieved when using N-best list rescoring using a full-words based FLM. This gives an absolute improvement of 0.8% (about 4.8% relative) compared to the standard tri-gram lattice rescoring. On the other hand, we have 0.6% absolute improvement (about 3.7% relative) compared to the standard 4-gram lattice rescoring. Decomposition does not help in this case. This is because the original N-best lists are generated in full-words format, whose decomposition might not lead to better LM scores. For this reason, we expect that it is better to start with a decomposed LM for lattice and N-best generation.

LM rescoring (3^{rd} **pass)**	**Dev07 [%]**
tri-gram lattice resc. (baseline)	16.5
4-gram lattice resc.	16.3
N-best FLM resc.:	
+ FW (original N-best)	**15.7**
+ PD (decomposed N-best)	15.8
+ FD (decomposed N-best)	16.0

Table 3: WERs for 70k full-words systems.

LM rescoring (3^{rd} **pass)**	**Dev07 [%]**
tri-gram lattice resc. (baseline)	14.7
4-gram lattice resc.	14.5
N-best FLM resc.:	
+ FW (re-joint N-best)	14.6
+ PD (original N-best)	**14.3**
+ FD (decomposed N-best)	14.4

Table 4: WERs for 70k partially decomposed systems (20k full-words + 50k morphemes).

5.2 Systems Based on Decomposed Words

This section introduces the WERs of our systems based on decomposed words. We use a similar setup as in section 5.1. However, we use a lexicon and a bi-gram LM based on a 70k partially decomposed words (20k full-words + 50k morphemes). Table 4 presents the results. As expected, we get the best WER when using N-best list rescoring with a FLM based on partially decomposed words. An absolute improvement of 0.4% (2.7% relative) is achieved compared to the new baseline. Compared to the old baseline of Table 3, we get an absolute improvement of 2.2% (13.3% relative).

5.3 Larger Lexicon Sizes

Now, we increase the size of our lexicon to 256k partially decomposed words (20k full-words + 236k

System	Dev07 [%]	Eval07 [%]
traditional full-words	14.9	16.5
partially decomposed		
+ 4-gram lat. resc. (baseline)	14.2	16.1
+ N-best FLM resc.:		
+ FW (re-joint N-best)	14.1	-
+ PD (original N-best)	**13.9**	**15.9**
+ FD (decomposed N-best)	14.0	-

Table 5: WERs for 256k full-words, and partially decomposed systems (20k full-words + 236k morphemes).

	70k vocabularies			256k vocabularies		
Corpus	**FW**	**PD**	**FD**	**FW**	**PD**	**FD**
Dev07	3.65	1.33	0.75	1.36	0.51	0.24
Eval07	4.82	1.94	1.13	1.85	0.64	0.41

Table 6: OOVs [%] of the used vocabularies.

morphemes). In addition, we use a standard 4-gram LM for rescoring the bi-gram lattices in the first 2 passes. To complete our comparisons, we record the WERs using traditional 256k full-words lexicon, standard bi-gram search, and standard 4-gram LM for lattice rescoring, with no decomposition or factorization. In Table 5, we see that the improvement persists for the larger lexicon. Compared to the new baseline, the 256k decomposed system achieves WER reductions of [dev07: 0.3% absolute (2.1% relative); eval07: 0.2% absolute (1.2% relative)] when using N-best list rescoring with a FLM based on partially decomposed words. Moreover, it improves over the traditional full-words by [dev07: 1.0% absolute (6.7% relative); eval07: 0.6% absolute (3.6% relative)]. The out-of-vocabulary rates (OOVs) are given in Table 6. It is worth noting that using fully decomposed lexicons as well as higher order LMs could not improve WERs, this we previously proved in (El-Desoky et al., 2009).

6 Conclusions

We have introduced a hybrid approach to Arabic language modeling. Our approach combines the strengths of both morphological decomposition and factored language modeling. Thus, we have used language models with factored morphemes. We have compared our approach to traditional approaches like: standard full-word n-grams, standard decomposed n-grams, and full-word based factored language models. Finally, we could achieve some improvements over all the traditional approaches. Nevertheless, we have only considered the use of factored language models in the rescoring phase.

Abstract

In this paper, we compare two novel methods for part of speech tagging of Arabic without the use of gold standard word segmentation but with the full POS tagset of the Penn Arabic Treebank. The first approach uses complex tags without any word segmentation, the second approach is segmention-based, using a machine learning segmenter. Surprisingly, word-based POS tagging yields the best results, with a word accuracy of 94.74%.

1 Introduction

Arabic is a morphologically rich language, in which a word carries not only inflections but also clitics, such as pronouns, conjunctions, and prepositions. This morphological complexity also has consequences for the part-of-speech (POS) annotation of Arabic: Since words can be complex, POS tags refer to segments rather than to whole words. Thus, the word wsyrfEwnhA (in Buckwalter transliteration; engl.: *and they will raise it*) is assigned the following POS tag: [CONJ+FUTURE_PARTICLE+IMPERFECT_VERB_PREFIX +IMPERFECT_VERB+IMPERFECT_VERB_SUFFIX_MASCULINE_PLURAL_3RD_PERSON+OBJECT_PRONOUN_FEMININE_SINGULAR] in the Penn Arabic Treebank (ATB) (Bies and Maamouri, 2003); the boundaries between segments are depicted by + signs. Automatic approaches to POS tagging either must assign such complex tags from a large tagset to complete words, or they must segment the word first and then assign POS tags to the segments. Previous approaches (Diab et al., 2004; Habash and Rambow, 2005; van den Bosch et al., 2007; AlGahtani et al., 2009) chose the segmentation approach but concentrated on POS tagging by using the segmentation provided by the ATB. Additionally, Diab et al. and Habash and Rambow used a reduced tagset. Diab et al. and Habash and Rambow used Support Vector Machines, the former with a standard windowing approach, the latter performing a full morphological analysis before POS tagging. Van den Bosch et al., whose approach is the most similar to ours, used memory-based learning with the full ATB tagset. They report a POS tagging accuracy of 91.5% (93.3% on known words, 66.4% on unknown words). However, they also evaluated on words as defined in the ATB, which differs from written Arabic in the treatment of affixes with syntactic functions (see section 2 for details). AlGahtani et al. used transformation-based learning combined with a morphological analysis for unknown words and words containing clitics. They reached a POS tagging accuracy of 96.9% on ATB1. Surprisingly, their results are lower for the experiment using the whole ATB (96.1%).

In this paper, we present two methods for Arabic POS tagging that do not require gold standard segmentation but can rather be used for naturally occurring Arabic. We investigate two different approaches: (1) Assigning complete POS tags to whole words, without any segmentation, and (2) a segmentation-based approach, for which we developed a machine learning based segmenter. In this approach, the words are first passed to the segmenter, then to the POS tagger. The first approach is surprisingly successful given the complex-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 705–708,
Los Angeles, California, June 2010.

ity of the task, reaching an accuracy on the word level of 94.74%, as compared to 93.47% for the segmentation-based approach. Thus, the result for the whole word approach is very close to the result obtained by using gold standard segmentation (94.91%). However, a more detailed analysis shows that this good performance of the word-based approach is due to its performance on known words while the few unknown words are more often misclassified: we reach an accuracy of 96.61% on known words but only 74.64% on unknown words.

2 Data, Methods, and Evaluation

Like the previous approaches, we base our experiments on the ATB, specifically on the after-treebank POS files, for extracting our training and test sets. More specifically, we use two sections of the ATB (P1V3 and P3V1) since those two sets do not contain duplicate sentences. This data set contains approximately 500,000 words. In order to be as representative of real-world Arabic, we use the non-vocalized version of the treebank. Since previous approaches, to our knowledge, used different data sets, our results are not directly comparable.

For both segmentation and POS tagging, we modified the ATB representation of words in order to obtain the text, as it would occur in newscasts. The ATB treats inflectional affixes, including the definite article `Al`, as part of a word but splits off those affixes that serve a syntactic function into separate words. In order to obtain text as it occurs in newscasts, we re-attached all conjunctions, prepositions, pronouns, and any elements that constitute parts of the word as an orthographic unit (with the exception of punctuation) to the word. The word `ltxbrh` (engl.: *in order to tell him*), for example, is represented as three words in the ATB, `l`, `txbr`, and `h`, but is treated as one single unit in our experiment. Our second modification concerns the null element in Arabic verbs. Since Arabic is pro-drop, the ATB annotation includes a null element in place of the omitted subject plus the POS tag it would receive. Since this information is not available in naturally occurring text, we delete the null element and its tag. For example, {`i$otaraY+(null)` and its tag PV+PVSUFF_SUBJ: 3MS would occur as {`i$otaraY` with the tag PV in our representation (we additionally remove the short vowels).

We perform 5-fold cross validation and use the same data split for all three types of experiments: (1) POS tagging using gold standard segmentation taken from the ATB, (2) POS tagging using a segmenter, and (3) POS tagging whole words with complex POS tags. The first experiment serves as the upper bound and as a comparison to previous approaches. The second experiment uses an automatic segmenter as a pre-processing component to the POS tagger. This means that the accuracy of the segmenter is also the upper limit of the POS tagger since errors in segmentation inevitably lead to errors in POS tagging. The last experiment uses full words and complex POS tags. The purpose of this experiment is to determine whether it is possible to tag complete words without segmentation.

The segmenter and the two POS taggers use memory-based learning. For segmentation, we use TiMBL (Daelemans and van den Bosch, 2005); for POS tagging MBT, a memory-based tagger (Daelemans et al., 1996). Memory-based learning is a lazy learning paradigm that does not abstract over the training data. During classification, the k nearest neighbors to a new example are retrieved from the training data, and the class that was assigned to the majority of the neighbors is assigned to the new example. MBT uses TiMBL as classifier; it offers the possibility to use words from both sides of the focus word as well as previous tagging decisions and ambitags as features. An ambitag is a combination of all POS tags of the ambiguity class of the word.

Word segmentation is defined as a per-letter classification task: If a character in the word constitutes the end of a segment, its class is '+', otherwise '-'. We use a sliding window approach with 5 characters before and 5 characters after the focus character, the previous decisions of the classifier, and the POS tag of the focus word assigned by the whole word tagger (cf. below) as features. The best results were obtained for all experiments with the IB1 algorithm with similarity computed as weighted overlap, relevance weights computed with gain ratio, and the number of k nearest neighbors equal to 1.

For POS tagging, we use the full tagset, with information about every segment in the word, rather than the reduced tagset (RTS) used by Diab et al. and Habash and Rambow, since the RTS assumes

Gold Standard Segmentation		Segmentation-Based Tagging		Whole Words
SAR	WAR	SAR	WAR	WAR
96.72%	94.91%	94.70%	93.47%	94.74%

Table 1: POS tagging results.

a segmentation of words in which syntactically relevant affixes are split from the stem. The word w+y+bHv+wn+hA, for example, in RTS is split into 3 separate tokens, w, ybHvwn, hA. Then, each of these tokens is assigned one POS tag, Conjunction for w, Imperfective Verb for ybHvwn, and Pronoun for hA. The split into tokens makes a preprocessing step necessary, and it also affects evaluation since a word-based evaluation is based on one word, the RTS evaluation on 3 tokens for the above example.

For all the POS tagging experiments, we use MBT. The best results were obtained with the Modified Value Difference Metric as a distance metric and with k = 25. For known words, we use the IGTree algorithm and 2 words to the left, their POS tags, the focus word and its ambitag, 1 right context word and its ambitag as features. For unknown words, we use IB1 as algorithm and the unknown word itself, its first 5 and last 3 characters, 1 left context word and its POS tag, and 1 right context word and its ambitag tag as features.

3 Experimental Results and Discussion

3.1 Word Segmentation

The memory-based word segmentation performs very reliably with a word accuracy of 98.23%. This also means that when the segmentation module is used as a pre-processing step for POS tagging, the accuracy of the tagger will have this accuracy as its upper bound. While there are cases where wrong segmentation results in the same number of segments, all of these words were assigned the wrong POS tags in our data. In an error analysis, we found that words of specific POS are more difficult to segment than others. Proper nouns constitute 33.87% of all segmentation errors, possibly due to the fact that many of these are either foreign names that resemble Arabic words (e.g. Knt, which is ambiguous between the English name *Kent*, and the Arabic verb *I was*), or they are ordinary nouns used as proper nouns but with a different segmentation (e.g. AlHyAp, engl.: *the life*). The POS tag with the second highest error rate was the noun class with 30.67%.

3.2 Part of Speech Tagging

Table 1 shows the results of the three POS tagging experiments described above. For the segmentation-based experiments, we report per-segment (SAR) and per-word (WAR) accuracy. As expected, POS tagging using gold standard segments gives the best results: 94.91% WAR. These results are approximately 3 percent points higher than those reported by van den Bosch et al. (2007). Although the results are not absolutely comparable because of the different data sets, this experiment shows that our approach is competitive. The next experiments investigate the two possibilities to perform POS tagging on naturally occurring Arabic, i.e. when gold segmentation is not available. The results of these experiments show that POS tagging based on whole words gives higher results (WAR: 94.74%) than tagging based on automatic segmentation (WAR: 93.47%). This result is surprising given that tagging whole words is more difficult than assigning tags to segments, as there are 993 complex tags (22.70% of which occur only once in the training set), versus 139 segment tags. A detailed error analysis of a previous but similar experiment can be found in Mohamed and Kübler (2010).

We assume that these results are an artifact of the ATB since it is based exclusively on newswire texts. This means that there is only a limited vocabulary, as shown by the very low rate of unknown words: across the five folds, we calculated an average of 8.55% unknown words. In order to test our hypothesis that unknown words are tagged more reliably with a segment-based approach, we performed an analysis on known and unknown words separately. The results of this analysis are shown in Table 2.

This analysis shows that for all experiments, the unknown words are tagged with a considerably

	Gold Standard Segmentation	Segmentation-Based Tagging	Whole Words
Known words	95.90%	95.57%	96.61%
Unknown words	84.25%	71.06%	74.64%

Table 2: POS results for known and unknown words.

lower accuracy. However, the loss of performance is more pronounced in the approaches without gold segmentation. It is also evident that tagging whole words reaches a higher accuracy than segment-based tagging for both known words and unknown words. From these results, we can conclude that while segmentation makes properties of the words available, it is not required for POS tagging. We also investigated the poor performance of the segmentation-based tagger. A closer look at the results for unknown words in segmentation-based tagging shows that 59.68% of the tagging errors are direct results from incorrect segmentation decisions. In comparison, for known words, only 6.24% of the incorrectly tagged words are also ill-segmented. This means that even though the quality of the segmenter is very high, the errors still harm the POS tagging step.

To make our results more comparable to those by Habash and Rambow (2005), we converted the test set with the POS tags from the whole word tagger to their tokenization and to a reduced tagset of 15 tags. In this setting, we reach a tokenization accuracy of 99.36% and a POS tagging accuracy of 96.41%. This is very close to the results by Habash and Rambow so that we conclude that high accuracy POS tagging for Arabic is possible without a full morphological analysis.

4 Conclusions and Future Work

We have presented a method for POS tagging for Arabic that does not assume gold segmentation, which would be unrealistic for naturally occurring Arabic. The approach we developed is competitive although it uses the full POS tagset, without any previous morphological analysis. The results of our experiments suggest that segmentation is not required for POS tagging. On the contrary, using whole words as basis for POS tagging yields higher accuracy, thus rendering a full morphological analysis or segmentation unnecessary. We reached the best results in tagging whole words both for known words and unknown words. These results were only marginally worse that the results obtained by the experiment based on gold segmentation.

The weakness of the segmentation-based approach is its low accuracy on unknown words. In the future, we will investigate knowledge-richer methods for segmentation. In particular, we will investigate whether an automatic vocalization step previous to segmentation will improve POS tagging accuracy for unknown words.

izitouni@us.ibm.com

Abstract

We investigate in this paper the adequate unit of analysis for Arabic Mention Detection. We experiment different segmentation schemes with various feature-sets. Results show that when limited resources are available, models built on morphologically segmented data outperform other models by up to 4F points. On the other hand, when more resources extracted from morphologically segmented data become available, models built with Arabic TreeBank style segmentation yield to better results. We also show additional improvement by combining different segmentation schemes.

1 Introduction

This paper addresses an important and basic task of information extraction: *Mention Detection* (MD)[1]: the identification and classification of textual references to objects/abstractions (i.e., *mentions*). These mentions can be either named (e.g. Mohammed, John), nominal (city, president) or pronominal (e.g. he, she). For instance, in the sentence "President *Obama* said he will visit ..." there are three mentions: *President, Obama* and *he*. This is similar to the Named Entity Recognition (NER) task with the additional twist of also identifying nominal and pronominal mentions. We formulate the mention detection problem as a classification problem, by assigning to each token in the text a label, indicating whether it starts a specific mention, is inside a specific mention, or is outside all mentions. The selection of the unit of analysis is an important step toward a better classification. When processing languages, such as English, using the word itself as the unit of analysis (after separating punctuations) leads to a good performance (Florian et al., 2004). For other languages, such as Chinese, character is considered as the adequate unit of analysis (Jing et al., 2003). In this paper, we investigate different segmentation schemes in order to define the best unit of analysis for Arabic MD. Arabic adopts a very complex morphology, i.e. each word is composed of zero or more *prefixes*, one *stem* and zero or more *suffixes*. Consequently, the Arabic data is sparser than other languages, such as English, and it is necessary to "segment" the words into several units of analysis in order to achieve a good performance.

(Zitouni et al., 2005) used Arabic morphologically segmented data and claimed to have very competitive results in ACE 2003 and ACE 2004 data. On the other hand, (Benajiba et al., 2008) report good results for Arabic NER on ACE 2003, 2004 and 2005 data using Arabic TreeBank (ATB) segmentation. In all published works, authors do not mention a specific motivation for the segmentation scheme they have adopted. Only for the Machine Translation task, (Habash and Sadat, 2006) report several results using different Arabic segmentation schemes. They report that the best results were obtained when the ATB-like segmentation was used. We explore here the four known and linguistically-motivated sorts of segmentation: punctuation separation, ATB, morphological and character-level segmentations. To our knowledge, this is the first paper which investigates different segmentation schemes to define the unit of analysis which best fits Arabic MD.

2 Arabic Segmentation Schemes

Character-level Segmentation: considers that each character is a separate token.

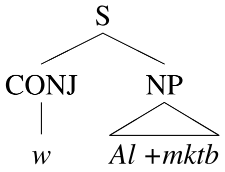
Morphological Segmentation : aims at segmenting

[1] We adopt here the ACE nomenclature: http://www.nist.gov/speech/tests/ace/index.html

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 709–712,
Los Angeles, California, June 2010.

all affixes of a word. The morphological segmentation for the word والمكتب (wAlmktb — and the office)[2] could be: “و +ال +مكتب” (w +Al +mktb).

Arabic TreeBank (ATB) segmentation : This segmentation considers splitting the word into affixes only if it projects an independent phrasal constituent in the parse tree. As an example, in the word shown above والمكتب, the phrasal independent constituents are: the conjunction و (*w* — and) and the noun المكتب (*Almktb* — the office). The morphological segmentation of this word would lead to the following parse tree:



Since the ال (*Al*, the definite article) is not an independent constituent, it is not considered for ATB segmentation. Hence, for والمكتب, the ATB segmentation would be و +المكتب (w +Almktb).

Punctuation separation : it consists of separating the punctuation marks from the word.

Both ATB and morphological segmentation systems are based on *weighted finite state transducers* (WFST). The decoder implements a general Bellman dynamic programming search for the best path on a lattice of segmentation hypotheses that match the input characters (Benajiba and Zitouni, 2009). ATB and morphological segmentation systems have a performance of 99.4 and 98.1 F-measure respectively on ATB data.

The unit of analysis when doing classification depends on the used segmentation. When using the punctuation separation or character-based segmentations, the unit of analysis is the word itself (without the punctuation marks attached) or the character, respectively. The ATB and morphological segmentations are language specific and are based on different linguistic viewpoint. When using one of these two segmentation schemes, the unit of analysis is the morph (i.e. prefix, stem or suffix). Our goal in this paper is to find the unit of analysis that fits best Arabic MD.

3 Mention Detection System

As explained earlier, we consider the MD task as a sequence classification problem where the class we predict for each unit of analysis (i.e., token) is the type of the entity which it refers to. We chose the maximum entropy (MaxEnt) classifier that can integrate arbitrary types of information and make a classification decision by aggregating all information available for a given classification. For more details about the system architecture, reader may refer to (Zitouni et al., 2009). The features used in our MD system can be divided into four categories:

Lexical Features: n-grams spanning the current token; both preceding and following it. A number of n equal to 3 turned out to be a good choice.

Stem n-gram Features: stem trigram spanning the current stem; both preceding and following it (Zitouni et al., 2005).

Syntactic Features: POS tags and shallow parsing information in a ± 2 window.

Features From Other Classifiers: outputs of MD and NER taggers trained on other data-sets different from the one we used here. They may identify types of mentions different from the mentions of interest in our task. For instance, such a tagger may identify dates or occupation references (not used in our task), among other types. Our hypothesis is that combining classifiers from diverse sources will boost performance by injecting complementary information into the mention detection models. We also use the two previously assigned classification tags as additional feature.

4 Data

Experiments are conducted on the Arabic ACE 2007 data. Since the evaluation tests set are not publicly available, we have split the publicly available *training* corpus into an 85%/15% data split. We use 323 documents ($80,000$ words, $17,634$ mentions) for training and 56 documents ($18,000$ words, $3,566$ mentions) as a test set. We are interested in 7 types of mentions: facility, Geo-Political Entity (GPE), location, organization, person, vehicle and weapon. We segmented the training and test set with four different styles building the following corpora:

Word$_s$: a corpus which is the result of running punctuation separation;

ATB$_s$: a corpus obtained by running punctuation separation and ATB segmentation;

Moph$_s$: a corpus where we conduct punctuation separation and morphological segmentation;

Char$_s$: a corpus where the original text is separated

[2] Throughout the paper, for each Arabic example we show between parenthesis its transliteration and English translation separated by “—”.

into a sequence of characters.

When building MD systems on $Word_s$, ATB_s, $Morph_s$ and $Char_s$, the unit of analysis is the word, the ATB token, the morph and the character, respectively.

5 Experiments

We show in this section the experimental results when using Arabic MD system with different segmentation schemes and different feature sets. We explore in this paper four categories of features (c.f. Section 3):
Lex$_f$: lexical features;
Stem$_f$: Lex_f + morphological features;
Synt$_f$: $Stem_f$ + syntactic features;
Sem$_f$: $Synt_f$ + output of other MD classifiers. Lex_f and $Stem_f$ features are directly extracted from the appropriate corpus based on the used segmentation style. This is different for Sem_f: we first run classifiers on the morphologically segmented data. Thereafter, we project those labels to other corpora. This is because, we use classifiers initially trained on morphologically segmented data such as ACE 2003, 2004 and 2005 data. In such data, two morphs belonging to the same word or ATB token may have 2 different mentions. During transfer, a token will have the label of the corresponding stem in the morphologically segmented data. One motivation to not re-train classifiers on each corpus separately is to be able to extract Sem_f features from classifiers with similar performance.

Table 1: Results in terms of F-measure per feature-set and segmentation scheme

	Lex_f	$Stem_f$	$Synt_f$	Sem_f
$Word_s$	66.4	66.6	69.0	77.1
ATB_s	70.1	69.8	72.1	**79.0**
$Morph_s$	**74.1**	**74.5**	**75.5**	78.3
$Char_s$	22.3	22.4	22.5	22.6

Results in Table 1 show that classifiers built on ATB_s and $Morph_s$ have shown to perform better than classifiers trained on data with other segmentation styles. When the system uses character as the unit of analysis, performance is poor. This is because the token itself becomes insignificant information to the classifier. On the other hand, when only punctuation separation is performed ($Word_s$), the data is significantly sparse and the obtained results achieves high F-measure (77.1) only when outputs of other classifiers are used. As mentioned earlier, classifiers used to extract those features are trained on $Morph_s$ (less sparse), which explains their remarkable positive impact since they resolve part of the data sparseness problem in $Word_s$. When using full morphological segmentation, the data is less sparse, which leads to less Out-Of-Vocabulary tokens (OOVs): the number of OOVs in the $Morph_s$ data is 1,518 whereas it is 2,464 in the ATB_s. As an example, the word الرهينة (Alrhynp — the hostage), which is person mention in the training data. This word is kept unchanged after ATB segmentation and is segmented to ”ال + رهين +ة” (Al+ rhyn +p) in $Morph_s$. In the development set the same word appears in its dual form without definite article, i.e. رهينتين. This word is unchanged in ATB_s and is segmented to ”رهين +ت +ين” (rhyn +p +yn) in $Morph_s$. For the model built on ATB_s, this word is an OOV, whereas for the model built on $Morph_s$ the stem has been seen as part of a person mention and consequently has a better chance to tag it correctly. These phenomena are frequent, which make the classifier trained on $Morph_s$ more robust for such cases. Also, we observed that models trained on ATB_s perform better on long span mentions. We think this is because a model trained on ATB_s has access to larger context. One may argue that a similar behavior of the model built on the $Morph_s$ might be obtained if we use a wider context window than the one used for ATB_s in order to have similar contextual information. In order to confirm this statement, we have carried out a set of experiments using all features over $Morph_s$ data for a context window up to $-5/+5$, the obtained results show no improvement. Similar behavior is observed when looking to results on identified named (Nam.), nominal (Nom.) and pronominal (Pro.) mentions on ATB_s and $Morph_s$ (c.f. Table 2); we remind the reader that NER is about recognizing named mentions. When limited resources are available (e.g. Lex_f, $Stem_f$ or $Synt_f$), we believe that it is more effective to morphologically segment the text ($Morph_s$) as a pre-processing step. The use of morph as a unit of analysis reduces the data sparseness issue and at the same time allows better context handling when compared to character. On the other hand, when a larger set of resources are available (e.g., Sem_f), the use of the ATB token as a unit of analysis combined with morph-based features leads to better performance (79.0 vs. 78.3 on $Morph_s$). This is because (1) classifiers trained on ATB_s handle better the context and (2) the use of morph-based features (output of classifiers trained on morphologically segmented data) removes some of the data sparseness from which classifiers trained on ATB_s suffer. The obtained improvement in performance is statistically significant when using the stratified bootstrap re-sampling significance test (Noreen, 1989). We consider results as statistically significant when $p < 0.02$, which is the case in this paper. For an accurate MD system, we think it is appropriate to benefit from ATB_s tokens and $Morph_s$. We investigate in the following the combination of these two segmentation styles.

Table 2: Performance in terms of F-measure per level on ATB_s and $Morph_s$

	$Seg.$	Lex_f	$Stem_f$	$Synt_f$	Sem_f
Nam.	ATB_s	68.2	69.0	72.8	79.1
	$Morph_s$	73.4	73.8	75.3	78.7
Nom.	ATB_s	65.6	64.6	66.9	75.8
	$Morph_s$	71.7	72.2	72.9	75.4
Pro.	ATB_s	60.7	60.1	59.9	66.3
	$Morph_s$	63.0	67.2	65.7	65.1

5.1 Combination of ATB and Morph

We trained a model on ATB_s that uses output of the model trained on $Morph_s$ as additional information ($M2A_f$ feature). We proceed similarly by training a model on $Morph_s$ using output of the model trained on ATB_s ($A2M_f$ feature). We have obtained the features by a 15-way round-robin. Table 3 shows the obtained results.

Table 3: Results in terms of F-measure of the combination experiments

	Lex_f	$Stem_f$	$Synt_f$	Sem_f
ATB_s	70.1	69.8	72.1	79.0
ATB_s+$M2A_f$	70.7	70.8	73.1	**79.1**
$Morph_s$	74.1	74.5	75.5	78.3
$Morph_s$+$A2M_f$	**74.9**	**75.2**	**75.4**	78.6

Results show a significant improvement for models that are trained on ATB_s using information from $Morph_s$ in addition to Lex_f, $Stem_f$ and $Synt_f$ features. This again confirms our claim that the use of features from morphologically segmented text reduces the data sparseness and consequently leads to better performance. For Sem_f features, only a 0.1 F-measure points have been gained. This is because we are *already* using output of classifiers trained on morphologically segmented data, which resolve some of the data sparseness issue. The $Morph_s$ side shows that the obtained performance when the ATB_s output is employed together with the $Stem_f$ (75.2) is only 0.3 points below the performance of the system using $Synt_f$ (75.5).

6 Conclusions

We have shown a comparative study aiming at defining the adequate unit of analysis for Arabic MD. We conducted our study using four segmentation schemes with four different feature-sets. Results show that when only limited resources are available, using morphological segmentation leads to the best results. On the other hand, model trained on ATB segmented data become more powerful and effective when data sparseness is reduced by the use of other classifier outputs trained on morphologically segmented data. More improvement is obtained when both segmentation styles are combined.

An MDL-based approach to extracting subword units for grapheme-to-phoneme conversion

Abstract

We address a key problem in grapheme-to-phoneme conversion: the ambiguity in mapping grapheme units to phonemes. Rather than using *single* letters and phonemes as units, we propose learning chunks, or *subwords*, to reduce ambiguity. This can be interpreted as learning a lexicon of subwords that has minimum description length. We implement an algorithm to build such a lexicon, as well as a simple decoder that uses these subwords.

1 Introduction

A system for converting written words to their pronunciations is an important component of speech-related applications, especially in large vocabulary tasks. This problem, commonly termed "grapheme-to-phoneme conversion", or g2p, is non-trivial for several written languages, including English, since a given letter (grapheme) may represent one of several possible phonemes, depending on the context. Because the length of the context varies throughout the dictionary, fixed-length contexts may overfit some words, or inaccurately model others.

We approach this problem by treating g2p as a function from *contiguous sequences* of graphemes, which we call 'grapheme subwords', to sequences of phonemes ('phoneme subwords'), so that there is *minimal ambiguity* in finding the phoneme subword that corresponds to a given grapheme subword. That is, we seek to minimize both these quantities:

1. The conditional entropy of the phoneme subwords given a grapheme subword. This directly tackles the problem of ambiguity – a perfectly unambiguous phoneme subword conditional distribution would have entropy = 0.
2. The entropy of the grapheme subwords. This prevents the model from getting arbitrarily complex.

As a toy example, consider the following word-pronunciation[1] pairs:

time	T AY M
sting	S T IH NG
negation	N AH G EY SH AH N

There are at least 5 graphemes whose corresponding phoneme distribution is ambiguous ('i', 'e', 't', 'n', 'g'). In the segmentation below, every grapheme subword corresponds to only one phoneme subword:

t + ime	T + AY M
s + t + ing	S + T + IH NG
neg + a + tion	N AH G + EY + SH AH N

2 Related Work

Many grapheme-to-phoneme algorithms rely on something resembling subwords; these are mainly used to account for sequences of letters representing a single phoneme ('ph' for F), or vice versa ('x' for K S). Some of the early works that create one-to-one alignments between a word and its pronunciation address these cases by allowing a letter to map to one phoneme, a null phoneme, or 2-3 phonemes.

Jiampojamarn and Kondrak (2009) use expectation-maximization (EM) to learn many-to-many alignments between words and pronunciations, effectively obtaining subwords.

[1] All phonemes are denoted by their Arpabet representations.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 713–716,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

Joint-sequence models divide a word-pronunciation pair into a sequence of disjoint *graphones* or *graphonemes* – tuples containing grapheme and phoneme subwords. Such segmentations may include only trivial graphones containing subwords of length at most 1 (Chen, 2003). Other such models use EM to learn the maximum likelihood segmentation into graphones (Deligne and Bimbot, 1995; Bisani and Ney, 2008; Vozilla et al., 2003).

Subwords – or phrases – are used widely in machine translation. There is a large body of work on phrase extraction starting from word alignments; see Koehn et al. (2003) for a review. Marcu and Wong (2002) learn phrases directly from sentence pairs using a joint probability model.

3 Subword Extraction

3.1 Motivation for using MDL

Consider a lexicon of grapheme subwords $\mathcal{G}$ and phoneme subwords $\mathcal{P}$ that is extracted from a dictionary of word-pronunciation pairs, along with a joint probability distribution over $\mathcal{G}$ and $\mathcal{P}$. As stated earlier, our objective is to minimize the entropy of phoneme subwords conditioned on a given grapheme subword, as well as the entropy of the grapheme subwords. That is, we would like to minimize $H(\mathcal{P}|\mathcal{G}) + H(\mathcal{G})$, which is

$$H(\mathcal{G},\mathcal{P}) = -\sum_{g\in\mathcal{G}}\sum_{p\in\mathcal{P}} pr(g,p)\log pr(g,p) \qquad (1)$$

This objective can be restated as minimizing the *expected description length* of the lexicon, which is given by its entropy. This is reflected in the MDL principle (Rissanen, 1978), which seeks to find a lexicon such that the description length of the lexicon (and the compression of the data under the lexicon) is minimized.

3.2 Lexicon Induction

We begin with an initial alignment between a word's graphemes and the phonemes in its pronunciation for all word-pronunciation pairs in the training dictionary. These alignments are derived using the standard string edit distance dynamic programming algorithm (Wagner and Fischer, 1974), giving a list of tuples $t = [(w_1, r_1), (w_2, r_2), \ldots]$ for each word-pronunciation pair.[2] The set of all tuple lists t composes the training dictionary $\mathcal{T}$.

The initial lexicon is composed of all singleton graphemes and phonemes (including null). The probability $pr(g,p)$ is taken to be the number of times the tuple (g,p) occurs in $\mathcal{T}$ divided by the total number of tuples over all alignments in $\mathcal{T}$.

Following a procedure similar the word-discovery algorithm of de Marcken (1996), the lexicon is iteratively updated as sketched in Table 1. At no point do we delete singleton graphemes or phonemes.

The subwords in the final updated lexicon are then used to decode the pronunciations of unseen words.

4 G2P Decoding

4.1 Joint segmentation and decoding

Finding the pronunciation of a word based on the induced subword lexicon involves segmenting the word into a sequence of grapheme subwords, and mapping it to a sequence of phoneme subwords.

One possibility is carry these steps out sequentially: first parse the word into grapheme subwords, and then use a sequence labeling algorithm to find the best corresponding sequence of phoneme subwords. However, it is likely that the true pronunciation of a word is *not* derived from its best parse into grapheme units. For example, the best parse of the word 'gnat' is 'g nat', which yields the pronunciation `G N AE T`, while the parse 'gn at' would give the correct pronunciation `N AE T`.

Therefore, we search for the best pronunciation over *all segmentations* of the word, adapting the monotone search algorithm proposed by Zens and Ney (2004) for phrase-based machine translation.[3]

4.2 Smoothing

A bigram model is used over both the grapheme and phoneme subwords. These bigrams need to be smoothed before the decoding step. Adding an equal probability mass to unseen bigrams would fail to reflect simple phonotactics (patterns that govern sound

[2] Phoneme insertions and deletions are represented by the null grapheme and null phoneme respectively.

[3] The key adaptation is in using a bigram model over both graphemes and phonemes, rather than only phonemes as in the original algorithm.

Table 1: Concatenative algorithm for building a subword lexicon that minimizes description length. The input is $\mathcal{T}$, the set of alignments, and a threshold integer k, which is tuned using a held-out development set.

1	Update $pr(g, p)$ by computing the *posterior probabilities* of the tuple (g, p) in $\mathcal{T}$, using the forward-backward algorithm. Repeat once more to get an intermediate lexicon.
2	Compute the Viterbi parse of each $t \in \mathcal{T}$ under the lexicon derived in step 1.
3	Let A, the set of candidate tuples for addition to the lexicon, contain all tuples $(w_i w_{i+1}, r_i r_{i+1})$ such that (w_i, r_i) and (w_{i+1}, r_{i+1}) are adjacent more than k times in the computed Viterbi parses. For each $(g, p) \in A$, estimate the change in description length of the lexicon if (g, p) is added. If description length decreases, remove any null symbols within g and p, and add (g, p) to the lexicon.
4	Repeat steps 1 and 2.
5	Delete all tuples that do not occur in any of the Viterbi parses.
6	Compare the description length of the new lexicon with the lexicon at the start of the iteration. If the difference is sufficiently small, return the new lexicon; else, repeat from step 1.

sequences) in several cases. For example, the bigram `L UW K + S` is much more likely than `L UW K + Z`, since `S` is more likely than `Z` to follow `K`.

To introduce a bias towards phonotacticaly likely bigrams, we define the smoothed bigram probability of the subword a following a subword b. Given that b is made up of a sequence of l phonemes $b_1 b_2 \ldots b_l$, the probability is defined as the interpolation[4]:

$$pr_{new}(a|b) = \lambda_1 pr(a|b_1 b_2 \ldots b_l) + \lambda_2 pr(a|b_1 b_2 \ldots b_{l-1}) + \lambda_3 pr(a|b_1 b_2 \ldots b_{l-2})$$

Both the grapheme and phoneme subword bigrams are smoothed as described.

5 Results

We test our algorithm on the CMU Pronouncing Dictionary[5]. The dictionary is divided randomly into a training (90% of the data) and a test set. Performance is evaluated by measuring the *phoneme error rate* (PER) and the *word error rate* (WER).

The subword extraction algorithm converges in 3 iterations.We run the g2p decoder using the lexicon after 3 iterations, as well as after $0, 1$ and 2 iterations. The results are shown in Table 2.

Table 2: Results after each iteration of subword extraction. While the maximum subword length after iteration 3 is 8, the vast majority of subwords have length 6 or less.

	# subwords	Max subword length	WER	PER
0	$\lvert\mathcal{G}\rvert$: 27, $\lvert\mathcal{P}\rvert$: 40	1	73.16	24.20
1	$\lvert\mathcal{G}\rvert$: 819, $\lvert\mathcal{P}\rvert$: 1254	2	48.39	12.43
2	$\lvert\mathcal{G}\rvert$: 5430, $\lvert\mathcal{P}\rvert$: 4954	4	28.32	7.16
3	$\lvert\mathcal{G}\rvert$: 6417, $\lvert\mathcal{P}\rvert$: 5358	6	26.31	6.29

Figure 1 compares the results of our method (denoted by **'MDL-Sub'**) to two baselines, at different values of *maximum subword length*. To evaluate the quality of our subwords, we substitute another extraction algorithm to create the lexicon – the grow-diag-final phrase extraction method (Koehn et al., 2005), denoted by 'GD' in the figure. We also run the implementation of Bisani and Ney (2008) – denoted by 'BN' – on the same data. BN is an example of a joint-sequence n-gram model, which uses a joint distribution $pr(\mathcal{G}, \mathcal{P})$ of graphemes and phonemes ('graphones'), conditioned on the preceding n-1 graphones for context information. Since this algorithm outperforms most of the existing g2p algorithms, it serves as a good point of comparison to the state of the art in g2p. The results of BN using an n-gram model are compared to MDL-Sub with an n-1 maximum subword length[6].

The MDL-Sub lexicon does significantly better than the phrases extracted by GD. While BN starts off doing better than MDL-Sub, the latter outperforms BN at longer subword lengths. Most of the additional errors in BN at that stage involve grapheme-to-phoneme ambiguity – phonemes like `AE`, `AA`, and `AH` being confused for one another when mapping

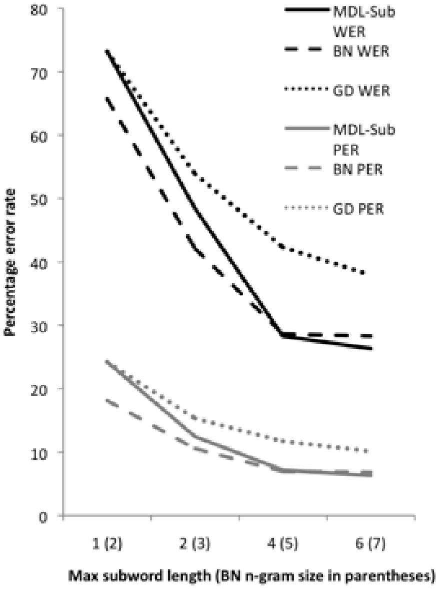
[4] In our experiments, we set $\lambda_1 = 0.5$, $\lambda_2 = 0.3$, $\lambda_3 = 0.2$.

[5] The CMU Pronouncing Dictionary. Available online at http://www.speech.cs.cmu.edu/cgi-bin/cmudict

[6] The contextual information of (n-1)-length subwords with bigrams is assumed to be roughly comparable to that of very short subwords over n-grams.

the grapheme ‘a’, and so on. Far fewer of these errors are produced by our algorithm. However, some of the longer subwords in MDL-Sub do introduce additional errors, mainly because the extraction algorithm merges smaller subwords from previous iterations. For example, one of the items in the extracted lexicon is ‘icati’ – a product of merging ‘ic’ and ‘ati’ – corresponding to `IH K EY SH`, thus generating incorrect pronunciations for words containing the string ‘icating’.

Figure 1: Comparison of error rates.



6 Conclusion

This paper deals with translational ambiguity, which is a major issue in grapheme-to-phoneme conversion. The core of our system consists of extracting subwords of graphemes and phonemes from the training data, so that the ambiguity of deriving a phoneme subword from a grapheme subword is minimized. This is achieved by formalizing ambiguity in terms of the minimum description length principle, and using an algorithm that reduces the description length of the subword lexicon at each iteration.

In addition, we also introduce a smoothing mechanism which retains some of the phonotactic dependencies that may be lost when using subwords rather than singleton letters and phonemes.

While retaining the basic approach to minimizing ambiguity, there are some avenues for improvement. The algorithm that builds the lexicon creates a more or less hierarchical structure – subwords tend to be composed from those extracted at the previous iteration. This appears to be the cause of many of the errors produced by our method. A subword extraction algorithm that does not use a strictly bottom-up process may create a more robust lexicon.

Our method of subword extraction could also be applied to phrase extraction for machine translation, or in finding subwords for related problems like transliteration. It may also be useful in deriving subword units for speech recognition.

Extracting Phrase Patterns with Minimum Redundancy for Unsupervised Speaker Role Classification

Bin Zhang, Brian Hutchinson, Wei Wu and Mari Ostendorf[*]
University of Washington, Seattle, WA 98125

Abstract

This paper addresses the problem of learning phrase patterns for unsupervised speaker role classification. Phrase patterns are automatically extracted from large corpora, and redundant patterns are removed via a graph pruning algorithm. In experiments on English and Mandarin talk shows, the use of phrase patterns results in an increase of role classification accuracy over n-gram lexical features, and more compact phrase pattern lists are obtained due to the redundancy removal.

1 Introduction

The identification of speaker roles is fundamental to the analysis of social content and information reliability in conversational speech. Previous work has primarily used supervised learning in automatic role classification. Barzilay et al. (2000) described a speaker role classification system for English broadcast news (BN), where the speakers were categorized into three types: anchor, journalist, and guest. The authors used supervised learning to discover n-gram signature phrases for speaker introduction and structural features such as duration, achieving an accuracy of 80% on ASR derived transcripts. Liu et al. (2006) studied speaker role classification on TDT-4 Mandarin BN data. Hidden Markov and maximum entropy models were used to label the sequence of speaker turns with the roles anchor, reporter, and other, based on n-gram features, which yielded 80% classification accuracy on human transcripts.

Hutchinson et al. (2010) extend previous work to the case of unsupervised learning, with the goal of portability across languages. That work explored speaker role classification using structural and n-gram features on talk show (or broadcast conversation (BC)) data. In this paper, we address a limitation of n-grams as features by proposing a method for learning phrases with gaps, which is particularly important for conversational speech, since there are more disfluencies that can cause failure of n-gram matching. In addition, we want to avoid topic words (e.g., proper nouns) in order to model speaker roles rather than topics. For example, for identifying the host, the phrase pattern "*We'll be back with * in a minute*" is more general than the n-grams "*We'll be back with John Smith in a minute*." To prevent these problems with n-grams, one must limit the length of learned n-grams, making them less discriminative.

Phrase patterns have been used in other NLP applications such as (Sun et al., 2007). To remove the redundancies in the automatically extracted phrase patterns, we propose a redundancy removal algorithm based on graph pruning that does not require role-labeled data. The resulting set of patterns is then used to extract lists of signature and conversational phrases, from which features are derived that are used to distinguish between the different roles. Using the phrase pattern-based lexical features in clustering, we obtain 82-89% speaker role classification accuracy on human transcripts of BC shows.

2 Method

Phrase patterns are generalizations of n-grams. A phrase pattern p of length n is an ordered list of words $(w_1, w_2, \ldots, w_n)$. It is matched by a word sequence of length $m \geq n$ if the sequence contains the words in the order defined by the pattern. Because the words in a phrase pattern need not appear contiguously in the sequence, phrase matching is less sensitive to disfluencies and topic words.

2.1 Phrase Pattern Extraction

Phrase patterns can be extracted by the sequential pattern mining algorithm PrefixSpan (Pei et al.,

2001). This algorithm efficiently extracts frequent phrase patterns in a corpus (i.e., relative frequency greater than a given threshold). Prior to the extraction, we perform text preprocessing including splitting the text into lines based on commas and periods to limit the pattern span, followed by case and punctuation removal. The extracted phrase patterns have variable length. As a result, longer patterns may contain shorter patterns. Phrase patterns with the same length may also be overlapped. These redundancies should be removed; otherwise, the same phrase may match several patterns, resulting in biased counts.

2.2 Phrase Pattern Redundancy Removal

Define a phrase pattern p as contained in another phrase pattern q if q contains all the words in p in the same order. p is called a parent pattern and q is the corresponding child pattern. Instead of constructing a tree as in (Siu et al., 2000) for variable length n-grams, we create a graph of phrase patterns based on containment, because a pattern can contain and be contained by multiple patterns. Our redundancy removal algorithm involves pruning this graph. With the nodes being the phrase patterns, the edges of the phrase pattern graph are constructed by connecting length-n phrase pattern p to length-$(n+1)$ phrase pattern q for all n, if p is contained in q. We connect only phrase patterns that differ by one word in length for computational efficiency, and this results in a multi-layer structure: the phrase patterns in each layer have the same length. For the convenience of pruning, a virtual node T is created as the "zeroth"-layer, and it is directly connected to all the nodes in the layer with the shortest pattern length.

Once a phrase pattern graph has been created, we prune the graph in order to remove the redundant nodes. First, we remove edges based on the ratio of counts $c(q)/c(p)$ between child node q and parent node p. A large ratio implies that the child appears in most of the cases where the parent appears. Hence, we keep the edge to indicate that the child can be used as a preferred substitute for the parent. On the other hand, the edge is removed if the ratio is small (less than a threshold t, see Fig. 1).

After this procedure is performed on all the edges in the graph, we determine whether a node is pruned based on its connectivity to parents and children. We define two levels of pruning, which differ in whether a node can be preserved even if its connections to parents are removed:

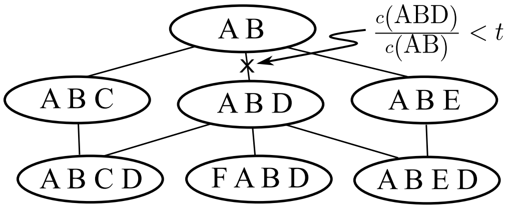

Figure 1: A fragment of an example phrase pattern graph. The letters represent words. The edge between "AB" and "ABD" is removed because the ratio of counts is less than the threshold.

Conservative pruning A node is pruned if it has at least one child.

Aggressive pruning A node is pruned if it has at least one child or is not on a path connected to T.

Both methods were investigated, in case some useful phrase patterns ended up being pruned with the more aggressive approach.

2.3 Features Based on Phase Patterns

Although (Hutchinson et al., 2010) uses both lexical and structural features, here we use only lexical features to better assess impact. Once the graph pruning has provided a list of phrase patterns (eliminating phrases of length one because of low reliability), two subsets are extracted to represent signature phrases as might be used by a host and conversational phrases as might occur more frequently in live interviews. The signature statistic

$$\theta_1 \quad = \quad \frac{DF}{SF} + \alpha \log(f_{\text{BC}}). \tag{1}$$

is based on the speaker frequency (SF, # speakers whose utterances match p), document frequency (DF, # shows that match p), and genre-dependent frequency f_{BC} (# occurrences of p in BC), all computed on the training data. The ratio $\frac{DF}{SF}$ favors phrases that occur in many documents but few speakers, e.g. one per show, as for a host. The log BC frequency term is a penalty to eliminate infrequent patterns. The conversation statistic

$$\theta_2 \quad = \quad \frac{f_{\text{BC}}}{f_{\text{BN}}+1}\mathbf{1}_{SF>\beta}. \tag{2}$$

uses frequency f_{BN} (# occurrences of p in BN), to look for phrases that are more frequent in BC data than BN, ideally live discussion phenomena. The indicator function $\mathbf{1}_{SF>\beta}$ eliminates phrases used by a small number of speakers to avoid topic-related phrases. Hyper-parameters α and β are tuned by inspecting the top phrase patterns after ranking. We use $\alpha = 10^{-3}, \beta = 500$ for English and $\alpha = 10^{-4}, \beta = 1000$ for Mandarin. Phrase patterns are ranked by the two statistics to generate lists of *signature* and *conversational* patterns, respectively.

During speaker-level feature extraction in role detection, each phrase pattern in the lists is matched against a speaker's utterances. The lexical features have two dimensions: the count of matches using the signature and conversational patterns, each normalized by the total number of patterns matched in the show to account for differences between shows.

3 Experiments

3.1 Task and Data

In the absence of speaker-role-labeled conversational speech training data, we perform unsupervised speaker role classification with three classes: host, expert guest, and soundbite. We evaluate on two human-labeled evaluation sets (English and Mandarin). The English eval set contains nine BC shows (150 speakers), while the Mandarin eval set contains 14 shows (140 speakers). There is an additional labeled Mandarin development set composed of ten shows (71 speakers). There are on average 7.6k words and 7.5k characters per show for English and Mandarin, respectively. The phrase patterns are learned from much larger corpora with speaker labels but without speaker role labels, including web transcripts for 310 English shows and quick rich transcripts for 4395 Mandarin shows. Because of the larger amount of Mandarin data, we use a lower threshold (5×10^{-5}) for phrase pattern extraction than for English (10^{-4}).

3.2 Classification

Spectral clustering (Shi and Malik, 2000) is used in this work, since we found it to outperform other clustering approaches such as k-means and Gaussian mixture models. Given a two-dimensional feature vector for each speaker in a show, we construct a speaker graph with edge weights defined by Gaussian similarity $\exp\left(-\frac{\|x_i - x_j\|^2}{2\sigma^2}\right)$. The spectral clustering is non-deterministic, because it uses k-means as its final step ($k = 3$), which is initialized by randomly choosing k samples as initial centroids. We vary σ as an integer from 1 to 100 in combination with different random initializations to generate multiple clustering alternatives, and then use a partition selection algorithm to pick the most common clustering among the candidates. We use domain knowledge to map speaker clusters into speaker roles: the cluster whose members have the largest average number of speaker turns is the host cluster, that with the smallest average number of turns is the soundbite cluster, and the remaining cluster contains the expert guests.

3.3 Results

The phase pattern pruning threshold t was tuned on the Mandarin dev set. We varied t from 0.1 to 0.9, and measured the classification accuracy. $t = 0.8$ was found to be optimal (Fig. 2).

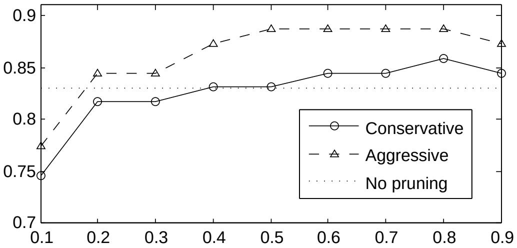

Figure 2: Accuracy on Man dev vs. pruning threshold t

The list of classification results on all the data sets is shown in Tab. 1. Aggressive pruning yields the best classification performance on all the data sets. It is also better than using n-gram matching for feature extraction (the last row of the table).

	Man dev	Man eval	Eng eval
No pruning	0.83	0.86	0.81
Cons. pruning	0.86	0.83	0.81
Aggr. pruning	**0.89**	**0.89**	**0.82**
N-gram	0.86	0.86	0.77

Table 1: Classification results

The size of phrase pattern lists is given in Tab. 2, and the number of redundant phrase patterns (the patterns that are contained in other patterns) is in Tab. 3 for different pruning levels. Using aggressive pruning, the list size and number of redundant phrase patterns are greatly reduced. However, the classification accuracy does not decrease. This demonstrates that the redundant phrase patterns are not helpful and can be harmful for this task.

Pruning level	Signature ptn.		Conv. ptn.	
	Eng	Man	Eng	Man
No pruning	2000	2000	1000	1000
Cons. pruning	1605	946	928	998
Aggr. pruning	244	370	465	835

Table 2: Phrase pattern list size

Pruning level	Signature ptn.		Conv. ptn.	
	Eng	Man	Eng	Man
No pruning	396	1331	337	142
Cons. pruning	35	307	334	142
Aggr. pruning	6	59	8	0

Table 3: Number of redundant phrase patterns in the list

The unsupervised speaker role classification system in (Hutchinson et al., 2010) uses both n-gram and structural features, giving classification accuracy on English and Mandarin eval sets of 0.86 and 0.84, respectively. Adding structural features to phrase-pattern-based lexical features improves the performance on English but not Mandarin, perhaps because soundbites in English tend to be much shorter than those in Mandarin.

3.4 Discussion

The experiments reflect differences between the two languages. We observe that the main gain in Mandarin comes from improved classification of hosts, due to the signature phrase patterns. In English, the improvement is attributed to improved classification of expert guests and soundbites, suggesting an improved conversational dimension of the lexical features. The performance difference of the two languages seems more related to the languages themselves, rather than the size of data sets on which phrase patterns are learned, because we were able to obtain similar performance on Mandarin even when the training set size is reduced.

Anecdotal inspection of the phrase patterns learned for the signature phrases suggests that the combination of redundancy pruning and the heuristic signature statistic is quite effective. For example, we observed English signature patterns such as "*back with after this*" and "*let's take a look at*." The former pattern can be matched by phrases with names or topics inserted, and the latter can be matched by "*let's just take a look at*" or "*let's take a brief look at*." In the Mandarin signature patterns, we also found patterns such as "今天 请到 演播室 的 嘉宾 是 * 的 * 教授" (*today the guest invited to the studio is Professor from*) and "谢谢 来自 * 的 报道" (*thanks to the report from*). These patterns can be considered to be templates for hosts, where the named-entities are skipped.

4 Conclusions

We have presented a method for extracting phrase patterns with minimum redundancy for speaker role classification. The proposed algorithm removes most of the redundancies in the phrase patterns, leading to more compact pattern lists and improved classification accuracy over n-gram lexical features. We can apply the algorithm to other applications such as text classification, where phrase patterns can be used in place of n-grams. One way to extend this work is to use the automatically extracted phrase patterns as initial features, and then employ supervised or semi-supervised learning techniques to learn a more discriminative feature set.

Classification of Prosodic Events using Quantized Contour Modeling

Andrew Rosenberg
Department of Computer Science
Queens College CUNY, New York, USA
andrew@cs.qc.cuny.edu

Abstract

We present Quantized Contour Modeling (QCM), a Bayesian approach to the classification of acoustic contours. We evaluate the performance of this technique in the classification of prosodic events. We find that, on BURNC, this technique can successfully classify pitch accents with 63.99% accuracy (.4481 CER), and phrase ending tones with 72.91% accuracy.

1 Introduction

Intonation can significantly vary the intended meaning of a spoken utterance. In Standard American English, contrast is frequently indicated with an accent that has a steeper pitch rise – "I went to the **store** (not the library)" – than an accent that is used to indicate focus or introduce new information – "I went to the **store** (before going home)" . At phrase boundaries, rising pitch can indicate uncertainty or that the speaker is asking a question – "John likes Mary?" vs. "John likes Mary". Automatically detecting prosodic events and classifying their type allows natural language understanding systems access to intonational information that would unavailable if processing transcribed text alone.

The ToBI standard of intonation (Silverman et al., 1992) describes intonational contours as a sequence of High and Low tones associated with two types of prosodic events – pitch accents and phrase boundaries. The tones describe an inventory of *types* of prosodic events. In this work, we present Quantized Contour Modeling, a novel approach to the automatic classification of prosodic event types.

In Section 2, we describe related work on this task. We describe Quantized Contour Modeling in Section 3. Our materials are described in Section 4. Experimental results are presented and discussed in Section 5. We conclude and describe future directions for this work in Section 6.

2 Related Work

Five types of pitch accents – pitch movements that correspond to perceived prominence of an associated word – are defined in the ToBI standard(Silverman et al., 1992): H*, L*, L+H*, L*+H, H+!H*. In addition to these five, high tones (H) can be produced in a compressed pitch range indicated by (!H). For the purposes of the experiments described in this paper, we collapse high (H) and downstepped High (!H) tones into a single class leaving five accent types. The ToBI standard describes two levels of phrasing, intermediate phrases and intonational phrases which are comprised of one or more intermediate phrases. Each intermediate phrase has an associated phrase accent describing the pitch movement between the ultimate pitch accent and the phrase boundary. Phrase accents can have High (H-), downstepped High (!H-) or low (L-) tones. Intonational phrase boundaries have an additional boundary tone, to describe a final pitch movement. These can be high (H%) or low (L%). Intonational phrases have five possible phrase ending tone combinations, L-L%, L-H%, H-L%, !H-L% and H-H%. In section 5.3, we describe experiments classifying these phrase ending tones.

The *detection* of pitch accents and phrase boundaries has received significantly more research attention than the *classification* of accent types and phrase ending behavior. However, one technique that has been used in a number of research efforts is to simultaneously detect and classify pitch accent. This is done by representing pitch accent detection and classfication as a four-way classification task, where a token may be classified as UNACCENTED, HIGH, LOW, or DOWNSTEPPED. Both Ross and Ostendorf (1996) and Sun (2002) used this approach, reporting 72.4% and 77.0% accuracy respectively when evaluated on a single speakers. Levow also used this four-way classification for pitch accent detection and classification under supervised (2005), and unsupervised and semi-supervised learning approaches (2006). Using

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 721–724,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

SVMs with only acoustic features, 81.3% accuracy at the syllable level is achieved. Using unsupervised spectral clustering, 78.4% accuracy is reported, while using the semi-supervised technique, Laplacian SVMs, 81.5% accuracy is achieved. Since these approaches simultaneously evaluate the detection *and* classification of pitch accents, direct comparison with this work is impossible.

Ananthakrishnan and Narayanan (2008) used RFC (Taylor, 1994) and Tilt (Taylor, 2000) parameters along with word and part of speech language modeling to classify pitch accents as H*, !H*, L+H* or L*. When evaluated on six BURNC speakers using leave-one-speaker-out cross-validation, accuracy of 56.4% was obtained. In the same work, the authors were able to classify L-L% from L-H% phrase-final tones in the BURNC with 67.7% accuracy. This performance was obtained using RFC F0 parameterization and a language model trained over categorical prosodic events.

3 Quantized Contour Modeling

In this section, we present a modeling technique, Quantized Contour Modeling. This technique quantizes the f0 contour of a word in the time and pitch domains, generating a low-dimensional representation of the contour. The pitch of the contour is linearly normalized to the range between the minimum and maximum pitch in the contour, and quantized into N equally sized bins. The time domain is normalized to the range [0,1] and quantized into M equally sized bins. An example of such a quantization is presented in Figure 1 where $N = 3$ and $M = 4$. Using this quantized representation of a pitch contour, we train a multinomial mixture model for each pitch accent type. Let the quantized contour be an M dimensional vector C where $C = (C_1, C_2, \ldots, C_M)$, where $C_i \in \{0 \ldots N-1\}$. We indicate pitch (f0) contours by C^{f0} and intensity contours by C^I. We train a multinomial model $p(type|C_i, i)$ for each time bin $i \in \{0 \ldots N-1\}$ with Laplace (add-one) smoothing. When using multinomial models, we quantize the mean of the pitch values assigned to a time bin. We use these pitch accent type models to classify a contour using the Bayesian classification function found in Equation 1. This formulation assumes that the values at each time are conditionally independent given the contour type. Also, we can modify the model incorporating a Markov hypothesis to include a sequential component by explicitly modeling the current and previous quantized values, as in Equation 2. We extend each of these models to model the energy contour shape simultaneously with the pitch contour. The classification technique allows for the number of pitch and energy value quantization bins to be distinct. However, in these experiments, we tie these, constraining them to be equal. The form of the classification functions using the energy contours are found in Figure 2.

4 Materials and Methods

We use two corpora that have been manually annotated with ToBI labels to evaluate the use of QCM in the classification of prosodic events. These two corpora are the Boston University Radio News Corpus (BURNC) (Ostendorf et al., 1995) and the Boston Directions Corpus (BDC) (Nakatani et al., 1995). The BURNC is a corpus of professionally read radio news data. A 2.35 hour, 29,578 word, subset from six speakers (three female and three male) has been prosodically annotated. The BDC is made up of elicited monologues spoken by four non-professional speakers, three male and one female. The BDC is divided into two subcorpora comprised of spontaneous and read speech. The 50 minutes of read speech contain 10,831 words. There are 60 minutes of annotated spontaneous material containing 11,627 words. Both are spoken by the same four speakers. In these experiments we evaluate these subcorpora separately, and refer to them as BDC-spon and BDC-read, respectively. The distribution of pitch accents and phrase-ending tones for these three corpora can be found in Figure 3.

Corpus	H*	L+H*	L*	L*+H	H+!H*
BDC-read	78.24%	13.72%	5.97%	1.36%	0.71%
BDC-spon	84.57%	6.32%	7.70%	0.68%	0.73%
BURNC	69.99%	21.64%	3.67%	0.34%	4.37%

Corpus	L-L%	L-H%	H-L%	!H-L%	H-H%
BDC-read	49.00%	35.62%	9.66%	4.29%	1.43%
BDC-spon	29.45%	32.57%	30.96%	4.40%	2.61%
BURNC	56.16%	38.38%	3.57%	0.68%	1.20%

Figure 3: *Distribution of prosodic event types in BURNC, BDC-read and BDC-spon corpora.*

In order to use QCM classification, we must first identify the region of an acoustic contour to quantify. Though there is evidence that acoustic evidence of prominence crosses the syllable boundary (Rosenberg and Hirschberg, 2009), it is largely held that the acoustic excursion corresponding to intonational prominence is centered around a syllable. To identify the region of analysis for QCM, we identify the accent-bearing syllable from the manual prosodic annotation, and quantize the contour extracted from the syllable boundaries. For the BURNC material, forced alignment syllable boundaries are available. However, no forced-alignment phone information is available for the BDC data. Therefore we apply Villing et al.'s (2004) envelope based pseudosyllabification routine to identify candidate syllabic regions. We use the pseudosyllable containing the accent annotation as the region of analysis for the BDC material. For classification of phrase ending intonation, we use the final syllable (or pseudosyllable) in the phrase as the region of analysis. To be clear, the accent and phrase boundary locations are derived from manual annotations; the intonational tones associated with these events are classified using QCM.

5 Prosodic Event Classification Results

In this section we present results applying QCM to the classification of pitch accents and phrase ending intonation. The work described in this section assumes the *presence* of prosodic events is known *a priori*. The approaches described can be seen as operating on output of an automatic prosodic event *detection* system.

5.1 Combined Error Rate

Automatic pitch accent classification poses an interesting problem. Pitrelli, et al. (Pitrelli et al., 1994) report human agreement of only 64.1% on accent classification in the ToBI framework. If downstepped variants of accents are collapsed with their non-downstapped forms this agreement improves to 76.1%. Second, pitch accents are overwhelmingly H* in most labeled corpus, including the BDC and BURNC material used in this paper. This skewed class distribution leads to a very high baseline, at or above the rate of human agreement. Because of this, we find accuracy an unreliable measure for evaluating the performance of this task. Multiple solutions can have similar accuracy, but radically different classification performance on minority classes. We therefore propose to use a different measure for the evaluation of pitch accent type classification. We define the Combined Error Rate (CER) as the mean of the weighted rates of Type I and Type II errors. The combination of these measures results in an increased penalty for errors of the majority class while being more sensitive to minority class performance than accuracy. Throughout this chapter, we will continue to report accuracy for comparison to other work, but consider CER to provide a more informative evaluation. To avoid confusion, accuracy will be reported as a percentage (%) while CER will be reported as a decimal.

$$CER = \frac{p(FP) + p(FN)}{2} \tag{5}$$

The Type I error rate measures the false positive rate for a given class (cf. Equation 6).

$$p(FP) = \sum_i p(C_i)p(FP_i) \tag{6}$$

We combine this measure with the Weighted Type II Error Rate (cf. Equation 7). The Type II error rate measures the false negative rate for a given class

$$p(FN) = \sum_i p(C_i)p(FN_i) \tag{7}$$

5.2 Pitch Accent Classification

The first step in applying Quantized Contour Modeling is to fix the desired quantization parameters. We do this by identifying a stratified 10% held out tuning set from the training data. We evaluate quantization sizes ranging between 2 and 7 for both the time and value parameters, leading to 36 candidates. Once we identify the best parameterization on this tuning data, we run ten-fold cross validation on the remaining data to evaluate the performance of each modeling technique (cf. Figure 2).

The classification accuracy and CER for each model is reported in Table 1 along with the number of time and value bins that were used. We first observe that modeling intensity information with f0 data does not improve classification performance. The alignment between pitch and intensity peaks have been shown to distinguish pitch accent types (Rosenberg, 2009); this relationship is not successfully captured by QCM. Moreover, we find that sequential modeling only leads to improvements in CER on BDC-read. On all corpora, the classification accuracy is improved, with statistically insignificant (p $>$ 0.05) reductions in CER. This leads us to consider sequential modeling of pitch to be the best performing approach to the classification of pitch accent using QCM.

Method	BDC-read	BDC-spon	BURNC
f0	46.51/.3860(5,3)	**55.41/.4103(3,4)**	**47.56/.4444(4,4)**
Seq. f0	**73.17/.3667(6,7)**	81.20/.4156 (7,5)	63.99/.4481(7,7)
f0+I	37.53/.4094(3,3)	47.96/.4222(4,2)	48.36/.4472(2,2)
Seq. f0+I	74.08/.4032(7,3)	80.60/.4361(5,4)	66.97/.4530(6,5)
Baseline	78.22/.0000	84.57/.0000	70.23/.0000

Table 1: *Accuracy (%), CER, time and value bins from QCM pitch accent type classification experiments.*

5.3 Phrase-ending Tone Classification

As in Section 5.2, we identify the best performing quantization parameters on a stratified 10% tuning set, then run 10-fold cross validation on the remaining data. Results from QCM classification experiments classifying intonational phrase ending tone combinations – phrase accent and boundary tone – can be found in Table 2. We find that the simultaneous modeling of f0 and intensity consistently yields the best performance in the classification of phrase ending tones. These results all represent significant improvement over the majority class baseline. The interaction between pitch and intensity contours in the classification of phrase-ending intonation has not been thoroughly investigated and remains an open area for future research.

Method	BDC-read	BDC-spon	BURNC
f0	48.21(3,6)	40.26(2,2)	70.36 (5,2)
Seq. f0	53.86(2,2)	43.80(4,4)	71.77 (6,2)

6 Conclusion and Future Work

In this paper we present a novel technique for the classification of two dimensional contour data, Quantized Contour Modeling (QCM). QCM operates by quantizing acoustic data into a pre-determined, fixed number of time and value bins. From this quantized data, a model of the value information is constructed for each time bin. The likelihood of new data fitting these models is then performed using a Bayesian inference.

We have applied QCM to the tasks of classifying pitch accent types, and phrase-ending intonation. The best performing parameterizations of QCM are able to classify pitch accent types on BURNC with 63.99% accuracy and $.4481$ Combined Error Rate (CER). QCM classifies phrase ending tones on this corpus with 72.91% accuracy.

These results do not represent the best performing approaches to these tasks. The best reported classification of pitch accent types on BURNC is 59.95% accuracy and .422 CER, for phrase ending intonation 75.09% (Rosenberg, 2009). However, the classification of phrase ending intonation is accomplished by including QCM posteriors in an SVM feature vector with other acoustic features.

This technique may be applicable to classifying other phenomena. Here we have used ToBI tone classifications as an intermediate representation of intonational phenomena. QCM could be used to directly classify turn-taking behavior, or dialog acts. Also, previous work has looked at using the same techniques to classify prosodic events and lexical tones in tonal languages such as Mandarin Chinese. QCM could be directly applied to lexical tone modeling; the only modification required would be a different segmentation routine.

Abstract

We suggest improvements to a previously proposed framework for integrating Conditional Random Fields and Hidden Markov Models, dubbed a Crandem system (2009). The previous authors' work suggested that local label posteriors derived from the CRF were too low-entropy for use in word-level automatic speech recognition. As an alternative to the log posterior representation used in their system, we explore frame-level representations derived from the CRF feature functions. We also describe a weight normalization transformation that leads to increased entropy of the CRF posteriors. We report significant gains over the previous Crandem system on the Wall Street Journal word recognition task.

1 Introduction

Conditional Random Fields (CRFs) (Lafferty et al., 2001) have recently emerged as a promising new paradigm in the domain of Automatic Speech Recognition (ASR). Unlike Hidden Markov Models (HMMs), CRFs are direct discriminative models: they predict the probability of a label sequence conditioned on the input. As a result, CRFs can capture long-range dependencies in the data and avoid the need for restrictive independence assumptions. Variants of CRFs have been successfully used in phone recognition tasks (Gunawardana et al., 2005; Morris and Fosler-Lussier, 2008; Hifny and Renals, 2009).

While the improvements in the phone recognition task are encouraging, recent efforts have been directed towards extending the CRF paradigm to the word recognition level (Zweig and Nguyen, 2009; Morris and Fosler-Lussier, 2009). The Crandem system (Morris and Fosler-Lussier, 2009) is one of the promising approaches in this regard. The Crandem system is directly inspired by the techniques of the Tandem system (Hermansky et al., 2000), where phone-label posterior estimates produced by a Multi-Layer Perceptron (MLP) are transformed into a suitable acoustic representation for a standard HMM. In both systems, the frame-based log posterior vector of $P(\text{phone}|\text{acoustics})$ over all phones is decorrelated using the Karhunen-Loeve (KL) transform; unlike MLPs, CRFs take into account the entire label sequence when computing local posteriors. However, posterior estimates from the CRF tend to be overconfident compared to MLP posteriors (Morris and Fosler-Lussier, 2009).

In this paper, we analyze the interplay between the various steps involved in the Crandem process. Is the local posterior representation from the CRF the best representation? Given that the CRF posterior estimates can be overconfident, what transformations to the posteriors are appropriate?

In Section 2 we briefly describe CRFs and the Crandem framework. We suggest techniques for improving Crandem word recognition performance in Section 3. Details of experiments and our results are discussed in Sections 4 and 5 respectively. We conclude with a discussion of future work in Section 6.

2 CRFs and the Crandem System

Conditional random fields (Lafferty et al., 2001) express the probability of a label sequence Q conditioned on the input data X as a log-linear sum of

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 725–728,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

weighted feature functions,

$$p(Q|X) = \frac{\exp \sum_t \sum_j \lambda_j s_j(q_t, X) + \sum_j \mu_j f_j(q_{t-1}, q_t, X)}{Z(X)} \quad (1)$$

where $s_j(\cdot)$ and $f_j(\cdot)$ are known as state feature functions and transition feature functions respectively, and λ_j and μ_j are the associated weights. $Z(X)$ is a normalization term that ensures a valid probability distribution. Given a set of labeled examples, the CRF is trained to maximize the conditional log-likelihood of the training set. The log-likelihood is concave over the entire parameter space, and can be maximized using standard convex optimization techniques (Lafferty et al., 2001; Sha and Pereira, 2003). The local posterior probability of a particular label can be computed via a forward-backward style algorithm. Mathematically,

$$p(q_t = q|X) = \frac{\alpha_t(q|X)\beta_t(q|X)}{Z(X)} \quad (2)$$

where $\alpha_t(q|X)$ and $\beta_t(q|X)$ accumulate contributions associated with possible assignments of labels before and after the current time-step t. The Crandem system utilizes these local posterior values from the CRF analogously to the way in which MLP-posteriors are treated in the Tandem framework (Hermansky et al., 2000), by applying a log transformation to the posteriors. These transformed outputs are then decorrelated using a KL-transform and then dimensionality-reduced to be used as a replacement for MFCCs in a HMM system. While the MLP is usually reduced to 39 dimensions, the standard CRF benefits from a higher dimensionality reduction (to 19 dimensions). The decorrelated outputs are then used as an input representation for a conventional HMM system.

3 Improving Crandem Recognition Results

Morris and Fosler-Lussier (2009) indicate that the local posterior outputs from the CRF model produces features that are more heavily skewed to the dominant phone class than the MLP system, leading to an increase in word recognition errors. In order to correct for this, we perform a non-linear transformation on the local CRF posterior representation before applying a KL-transform and subsequent stages. Specifically, we normalize all of the weights λ_j and μ_j in Equation 1 by a fixed positive constant n to obtain normalized weights λ'_j and μ'_j. We note that the probability of a label sequence computed using the transformed weights, $p'(Q|X)$, is equivalent to taking the nth-root of the CRF probability computed using the unnormalized weights, with a new normalization term $Z'(X)$

$$p'(Q|X) = \frac{p(Q|X)^{1/n}}{Z'(X)} \quad (3)$$

where, $p(Q|X)$ is as defined in Equation 1. Also observe that the monotonicity of the nth-root function ensures that if $p(Q_1|X) > p(Q_2|X)$ then $p'(Q_1|X) > p'(Q_2|X)$. In other words, the rank order of the n-best phone recognition results are not impacted by this change. The transformation does, however, increase the entropy between the dominant class from the CRF and its competitors, since $p'(Q|X) < p(Q|X)$. As we shall discuss in Section 5, this transformation helps improve word recognition performance in the Crandem framework.

Our second set of experiments are based on the following observation regarding the CRF posteriors. As can be seen from Equation 2, the CRF posteriors involve a global normalization over the entire utterance as opposed to the local normalization of the MLP posteriors in the output softmax layer. This motivates the use of representations derived from the CRF that are 'local' in some sense. We therefore propose two alternative representations that are modeled along the lines of the linear outputs from an MLP. The first uses the sum of the state feature functions, to obtain a vector $f^{\text{state}}(X, t)$ for each time step t and input utterance X of length $|\mathcal{Q}|$ dimensions, where $\mathcal{Q}$ is the set of possible phone labels

$$f^{\text{state}}(X, t) = \left[\sum_j \lambda_j s_j(q, X) \right]^T \qquad \forall q \in \mathcal{Q} \quad (4)$$

where q is a particular phone label. Note that the lack of an exponential term in this representation ensures that the representation is less 'spiky' than the CRF posteriors. Additionally, the decoupling of the representation from the transition feature functions could potentially allow the system to represent relative ambiguity between multiple phones hypothesized for a given frame.

The second 'local' representation that we experimented with incorporates the CRF transition feature functions as follows. For each utterance X we perform a Viterbi decoding of the most likely state sequence $Q^{\text{best}} = \text{argmax}_Q\{p(Q|X)\}$ hypothesized for the utterance X. We then augmented the state feature representation with the sum of the transition features corresponding to the phone label hypothesized for the previous frame (q_{t-1}^{best}) to obtain a vector $f^{\text{trans}}(X, t)$ of length $|\mathcal{Q}|$,

$$f^{\text{trans}}(X,t) = \left[\sum_j \lambda_j s_j(q,X) + \sum_j \mu_j f_j(q_{t-1}^{\text{best}}, q, X)\right]^T \tag{5}$$

As a final note, following (Morris and Fosler-Lussier, 2009), our CRF systems are trained using the linear outputs of MLPs as its state feature functions and transition biases as the transition feature functions. Hence, f^{state} is a linear transformation of the MLP linear outputs down to $|\mathcal{Q}|$ dimensions.[1] Both f^{state} and f^{trans} can thus be viewed as an implicit mapping performed by the CRF of the input feature function dimensions down to $|\mathcal{Q}|$ dimensions. Note that the CRF implicitly uses information concerning the underlying phone labels unlike dimensionality reduction using KL-transform.

4 Experimental Setup

To evaluate our proposed techniques, we carried out word recognition experiments on the speaker-independent portion of the Wall Street Journal 5K closed vocabulary task (WSJ0). Since the corpus is not phonetically transcribed, we first trained a standard HMM recognition system using PLP features and produced phonetic transcriptions by force aligning the training data. These were used to train an MLP phone classifier with a softmax output layer, using a 9-frame window of PLPs with 4000 hidden layer units to predict one of the 41 phone labels (including silence and short pause). The linear outputs of the MLP were used to train a baseline Tandem system. We then trained a CRF using the MLP linear outputs as its state feature functions. We extract local posteriors as well as the two 'local' representations described in Section 3. These input representations were then normalized at the utterance level, before applying a KL-transformation to decorrelate them and reduce dimensionality to 39 dimensions. Finally, each of these representations was used to train a HMM system with intra-word triphones and 16 Gaussians per mixture using the Hidden Markov Model Toolkit (Young et al., 2002).

System	Accuracy (%)
Crandem-baseline	89.4%
Tandem-baseline	91.8%
Crandem-NormMax	91.4%
Crandem-Norm5	92.1%
Crandem-state	91.7%
Crandem-trans	91.0%

Table 1: Word recognition results on the WSJ0 task

5 Results

Results for each of the experiments described in Section 4 are reported in Table 1 on the 330-sentence standard 5K non-verbalized test set. The Crandem-baseline represents the system of (Morris and Fosler-Lussier, 2009). Normalizing the CRF weights of the system by either the weight with largest absolute value (CRF-NormMax) or by 5 (tuned on the development set) leads to significant improvements ($p \leq 0.005$) over the Crandem baseline. Similarly, using either the state feature sum (Crandem-state) or the representation augmented with the transition features (Crandem-trans) leads to significant improvements ($p \leq 0.005$) over the Crandem baseline. Note that the performance of these systems is comparable to the Tandem baseline.

To further analyze the results obtained using the state feature sum representations and the Tandem baseline, we compute the mean distance for each phone HMM from every other phone HMM obtained at the end of the GMM-HMM training phase. The distance between two HMMs is computed as a uniformly weighted sum of the average distances between the GMMs of a one-to-one alignment of states corresponding to the two HMMs. GMM distances are computed using a 0.5-weighted sum of inter-dispersions normalized by self-dispersions (Wang et

[1] We note that our system uses an additional state bias feature that has a fixed value of 1. However, since this is a constant term, it has no role to play in the derived representation.

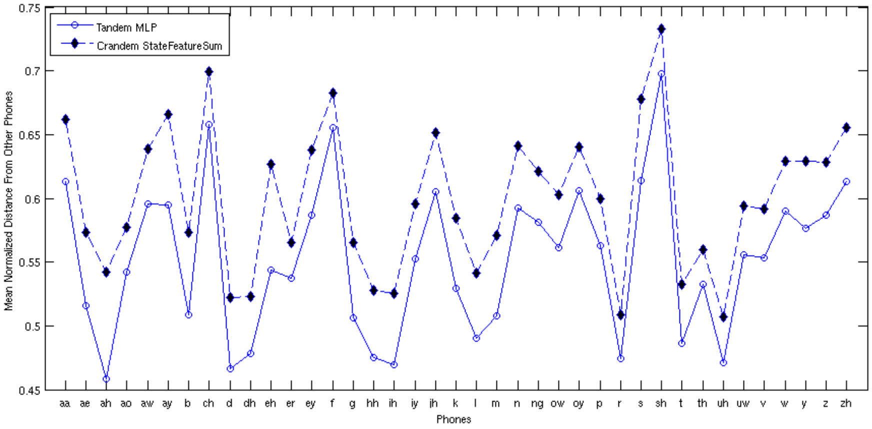

Figure 1: Normalized mean distances for each of the phone models from every other phone model trained using the Tandem MLP baseline and the state feature sum representation.

al., 2004). Distances between monomodal Gaussian distributions were computed using the Bhattacharyya distance measure. The phone HMM distances are normalized using the maximum phone distance for each system. As can be seen in Figure 1, the mean distances obtained from the state feature sum representation are consistently greater than the corresponding distances in the Tandem-MLP system, indicating larger separability of the phones in the feature space. Similar trends were seen with the transition feature sum representation.

6 Conclusions and Future Work

In this paper, we report significant improvements over the Crandem baseline. The weight normalization experiments confirmed the hypothesis that increasing the entropy of the CRF posteriors leads to better word-level recognition. Our experiments with directly extracting frame-level representations from the CRF reinforce this conclusion. Although our experiments with the systems using the state feature sum and transition feature augmented representation did not lead to improvements over the Tandem baseline, the increased separability of the phone models trained using these representations is encouraging. In the future, we intend to examine techniques by which these representations could be used to further improve word recognition results.

Abstract

Most learning algorithms for undirected graphical models require complete inference over at least one instance before parameter updates can be made. SampleRank is a rank-based learning framework that alleviates this problem by updating the parameters during inference. Most semi-supervised learning algorithms also perform full inference on at least one instance before each parameter update. We extend SampleRank to semi-supervised learning in order to circumvent this computational bottleneck. Different approaches to incorporate unlabeled data and prior knowledge into this framework are explored. When evaluated on a standard information extraction dataset, our method significantly outperforms the supervised method, and matches results of a competing state-of-the-art semi-supervised learning approach.

1 Introduction

Most supervised learning algorithms for undirected graphical models require full inference over the dataset (e.g., gradient descent), small subsets of the dataset (e.g., stochastic gradient descent), or at least a single instance (e.g., perceptron, Collins (2002)) before parameter updates are made. Often this is the main computational bottleneck during training.

SampleRank (Wick et al., 2009) is a rank-based learning framework that alleviates this problem by performing parameter updates *within* inference. Every pair of samples generated during inference is ranked according to the model and the ground truth, and the parameters are updated when the rankings disagree. SampleRank has enabled efficient learning for massive information extraction tasks (Culotta et al., 2007; Singh et al., 2009).

The problem of requiring a complete inference iteration before parameters are updated also exists in the semi-supervised learning scenario. Here the situation is often considerably worse since inference has to be applied to potentially very large unlabeled datasets. Most semi-supervised learning algorithms rely on marginals (GE, Mann and McCallum, 2008) or MAP assignments (CODL, Chang et al., 2007). Calculating these is computationally inexpensive for many simple tasks (such as classification and regression). However, marginal and MAP inference tends to be expensive for complex structured prediction models (such as the joint information extraction models of Singh et al. (2009)), making semi-supervised learning intractable.

In this work we employ a fast rank-based learning algorithm for semi-supervised learning to circumvent the inference bottleneck. The ranking function is extended to capture both the preference expressed by the labeled data, and the preference of the domain expert when the labels are not available. This allows us to perform SampleRank as is, without sacrificing its scalability, which is crucial for future large scale applications of semi-supervised learning.

We applied our method to a standard information extraction dataset used for semi-supervised learning. Empirically we demonstrate improvements over the supervised model, and closely match the results of a competing state-of-the-art semi-supervised learner.

2 Background

Conditional random fields (Lafferty et al., 2001) are undirected graphical models represented as factor

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 729–732,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

graphs. A factor graph $G = \{\Psi_i\}$ defines a probability distribution over assignments $\mathbf{y}$ to a set of output variables, conditioned on an observation $\mathbf{x}$. A factor Ψ_i computes the inner product between the vector of sufficient statistics $\mathbf{f}(\mathbf{x}_i, \mathbf{y}_i)$ and parameters Θ. Let $Z(\mathbf{x})$ be the data-dependent partition function used for normalization. The probability distribution defined by the graph is:

$$p(\mathbf{y}|\mathbf{x}, \Theta) = \frac{1}{Z(\mathbf{x})} \prod_{\Psi_i \in G} e^{\Theta \cdot \mathbf{f}(\mathbf{x}_i, \mathbf{y}_i)}$$

2.1 Rank-Based Learning

SampleRank (Wick et al., 2009) is a rank-based learning framework for that performs parameter updates *within* MCMC inference. Every pair of consecutive samples in the MCMC chain is ranked according to the model and the ground truth, and the parameters are updated when the rankings disagree. This allows the learner to acquire more supervision per sample, and has led to efficient training of models for which inference is very expensive (Singh et al., 2009).

SampleRank considers two ranking functions: (1) the unnormalized conditional probability (model ranking), and (2) a *truth function* $\mathcal{F}(\mathbf{y})$ (objective ranking) which is defined as $-\mathcal{L}(\mathbf{y}, \mathbf{y}_L)$, the negative loss between the possible assignment $\mathbf{y}$ and the true assignment $\mathbf{y}_L$. The truth function can take different forms, such as tokenwise accuracy or F1-measure with respect to some labeled data.

In order to learn the parameters for which model rankings are consistent with objective rankings, SampleRank performs the following update for each consecutive pair of samples $\mathbf{y}^a$ and $\mathbf{y}^b$ of the MCMC chain. Let α be the learning rate, and $\Delta = \mathbf{f}(\mathbf{x}_i, \mathbf{y}_i^a) - \mathbf{f}(\mathbf{x}_i, \mathbf{y}_i^b)$, then Θ is updated as follows:

$$\Theta \overset{+}{\leftarrow} \begin{cases} \alpha\Delta & \text{if } \frac{p(\mathbf{y}^a|\mathbf{x})}{p(\mathbf{y}^b|\mathbf{x})} < 1 \wedge \mathcal{F}(\mathbf{y}^a) > \mathcal{F}(\mathbf{y}^b) \\ -\alpha\Delta & \text{if } \frac{p(\mathbf{y}^a|\mathbf{x})}{p(\mathbf{y}^b|\mathbf{x})} > 1 \wedge \mathcal{F}(\mathbf{y}^a) < \mathcal{F}(\mathbf{y}^b) \\ 0 & \text{otherwise.} \end{cases}$$

This update is usually fast: in order to calculate the required model ratio, only factors that touch changed variables have to be taken into account.

SampleRank has been incorporated into the FACTORIE toolkit for probabilistic programming with imperatively-defined factor graphs (McCallum et al., 2009).

3 Semi-Supervised Rank-Based Learning

To apply SampleRank to the semi-supervised setting, we need to specify the truth function $\mathcal{F}$ over both labeled and unlabeled data. For labeled data $\mathcal{Y}_L$, we can use the true labels. These are not available for unlabeled data $\mathcal{Y}_U$, and we present alternative ways of defining a truth function $\mathcal{F}_U : \mathcal{Y}_U \rightarrow \Re$ for this case.

3.1 Self-Training

Self-training, which uses predictions as truth, fits directly into our SampleRank framework. After performing SampleRank on training data (using $\mathcal{F}_L$), MAP inference is performed on the unlabeled data. The prediction $\hat{\mathbf{y}}_U$ is used as the ground truth for the unlabeled data. Thus the self-training objective function $\mathcal{F}_s$ over the unlabeled data can be defined as $\mathcal{F}_s(\mathbf{y}) = -\mathcal{L}(\mathbf{y}, \hat{\mathbf{y}}_U)$.

3.2 Encoding Constraints

Constraint-driven semi-supervised learning uses constraints to incorporate external domain knowledge when labels are missing (Chang et al., 2007; Mann and McCallum, 2008; Bellare et al., 2009). Constraints prefer certain label configurations over others. For example, one constraint may be that occurrences of the word “California” are preferred to have the label “location”.

We can encode constraints directly into the objective function $\mathcal{F}_U$. Let a constraint i be specified as $\langle p_i, c_i \rangle$, where $c_i(\mathbf{y})$ denotes whether assignment $\mathbf{y}$ satisfies the constraint i (+1), violates it (−1), or the constraint does not apply (0), and p_i is the constraint strength. Then the objective function is:

$$\mathcal{F}_c(\mathbf{y}) = \sum_i p_i c_i(\mathbf{y})$$

3.3 Incorporating Model Predictions

When the objective function $\mathcal{F}_c$ is used, every prediction on unlabeled data is ranked only according to the constraints, and thus the model is trained to satisfy all the constraints. This is a problem when the constraints prefer a wrong solution while the model favors the correct solution, resulting in SampleRank updating the model away from the true solution. To avoid this, the ranking function needs to balance preferences of the constraints and the current model.

One option is to incorporate the self-training objective function $\mathcal{F}_s$. A new objective function that combines self-training with constraints can be defined as:

$$\begin{aligned}\mathcal{F}_{sc}(\mathbf{y}) &= \mathcal{F}_s(\mathbf{y}) + \lambda_s \mathcal{F}_c(\mathbf{y}) \\ &= -\mathcal{L}(\mathbf{y}, \hat{\mathbf{y}}_U) + \lambda_s \sum_i p_i c_i(\mathbf{y})\end{aligned}$$

This objective function has at least two limitations. First, self-training involves a complete inference step to obtain $\hat{\mathbf{y}}_U$. Second, the model might have low confidence in its prediction (this is the case when the underlying marginals are almost uniform), but the self-training objective des not take this into account. Hence, we also propose an objective function that incorporates the model score directly, i.e.

$$\begin{aligned}\mathcal{F}_{mc}(\mathbf{y}) &= \log p(\mathbf{y}|\mathbf{x}, \Theta) + \log Z(x) + \lambda_m \mathcal{F}_c(\mathbf{y}) \\ &= \sum_{\Psi_i} \Theta \cdot \mathbf{f}(\mathbf{x}_i, \mathbf{y}_i) + \lambda_m \sum_i p_i c_i(\mathbf{y})\end{aligned}$$

This objective does not require inference, and also takes into account model confidence.

In both objective functions $\mathcal{F}_{sc}$ and $\mathcal{F}_{mc}$, λ controls the relative contribution of the constraint preferences to the objective function. With higher λ, SampleRank will make updates that never try to violate constraints, while with low λ, SampleRank trusts the model more. λ corresponds to constraint satisfaction weights ρ used in (Chang et al., 2007).

4 Related Work

Chang et al. propose constraint-driven learning (CODL, Chang et al., 2007) which can be interpreted as a variation of self-training: Instances are selected for supervision based not only on the model's prediction, but also on their consistency with a set of user-defined constraints. By directly incorporating the model score and the constraints (as in $\mathcal{F}_{mc}$ in Section 3.3) we follow the same approach, but avoid the expensive "Top-K" inference step.

Generalized expectation criterion (GE, Mann and McCallum, 2008) and Alternating Projections (AP, Bellare et al., 2009) encode preferences by specifying constraints on feature expectations, which require expensive inference. Although AP can use online training, it still involves full inference over each instance. Furthermore, these methods only support constraints that factorize according to the model.

Li (2009) incorporates prior knowledge into conditional random fields as variables. They require full inference during learning, restricting the application to simple models. Furthermore, higher-order constraints are specified using large cliques in the graph, which slow down inference. Our approach directly incorporates these constraints into the ranking function, with no impact on inference time.

5 Experiments

We carried out experiments on the Cora citation dataset. The task is to segment each citation into different fields, such as "author" and "title". We use 300 instances as training data, 100 instances as development data, and 100 instances as test data. Some instances from the training data are selected as labeled instances, and the remaining data (including development) as unlabeled. We use the same token-label constraints as Chang et al. (2007).

We use the objective functions defined in Section 3, specifically self-training (Self:$\mathcal{F}_s$), direct constraints (Cons:$\mathcal{F}_c$), the combination of the two (Self+Cons:$\mathcal{F}_{sc}$), and combination of the model score and the constraints (Model+Cons:$\mathcal{F}_{mc}$). We set $p_i = 1.0$, $\alpha = 1.0$, $\lambda_s = 10$, and $\lambda_m = 0.0001$.

Average token accuracy for 5 runs is reported and compared with CODL[1] in Table 1. We also report supervised results from (Chang et al., 2007) and SampleRank. All of our methods show vast improvement over the supervised method for smaller training sizes, but this difference decreases as the training size increases. When the complete training data is used, additional unlabeled data hurts our performance. This is not observed in CODL since they use more unlabeled data, which may also explain their slightly higher accuracy. Note that Self+Cons performs better than Self or Cons individually.

Model+Cons also performs competitively, and may potentially outperform other methods if a better λ_m is chosen. Note, however, that λ_m is much harder to tune than λ_s since λ_m weighs the contribution of the unnormalized model score, the range

[1] We report *inference without constraints* results from CODL. Their results that incorporated constraints were higher, but we do not implement this alternative due to the difficulty in balancing the model score and constraint weights.

Table 1: **Tokenwise Accuracy:** for different methods as we vary the size of the labeled data

of which depends on many different factors such as properties of the data, the learning rate, number of samples, proposal function, etc. For self+cons (λ_s), the ranges of the predictions and constraint penalties are fixed and known, making the task simpler.

Self training takes 90 minutes to run on average, while Self+Cons and Model+Cons need 100 minutes. Since the Cons method skips the inference step over unlabeled data, it takes only 30 minutes to run. As the size of the model and unlabeled data set grows, this saving will become more significant. Running time of CODL was not reported.

6 Conclusion

This work extends the rank-based learning framework to semi-supervised learning. By integrating the two paradigms, we retain the computational efficiency provided by parameter updates *within inference*, while utilizing unlabeled data and prior knowledge. We demonstrate accuracy improvements on a real-word information extraction dataset.

We believe that the method will be of greater benefit to learning in complex factor graphs such as joint models over multiple extraction tasks. In future work we will investigate our approach in such settings. Additionally, various sensitivity, convergence, and robustness properties of the method need to be analyzed.

Softmax-Margin CRFs: Training Log-Linear Models with Cost Functions

Kevin Gimpel   Noah A. Smith

Pittsburgh, PA 15213, USA
{kgimpel,nasmith}@cs.cmu.edu

Abstract

We describe a method of incorporating task-specific cost functions into standard conditional log-likelihood (CLL) training of linear structured prediction models. Recently introduced in the speech recognition community, we describe the method generally for structured models, highlight connections to CLL and max-margin learning for structured prediction (Taskar et al., 2003), and show that the method optimizes a bound on risk. The approach is simple, efficient, and easy to implement, requiring very little change to an existing CLL implementation. We present experimental results comparing with several commonly-used methods for training structured predictors for named-entity recognition.

1 Introduction

Conditional random fields (CRFs; Lafferty et al, 2001) and other conditional log-linear models (Berger et al., 1996) achieve strong performance for many NLP problems, but the conditional log-likelihood (CLL) criterion optimized when training these models cannot take a task-specific cost function into account.

In this paper, we describe a simple approach for training conditional log-linear models with cost functions. We show how the method relates to other methods and how it provides a bound on risk. We apply the method to train a discriminative model for named-entity recognition, showing a statistically significant improvement over CLL.

2 Structured Log-Linear Models

Let $\mathcal{X}$ denote a structured input space and, for a particular $x \in \mathcal{X}$, let $\mathcal{Y}(x)$ denote a structured output space for x. The size of $\mathcal{Y}(x)$ is often exponential in x, which differentiates structured prediction from multiclass classification. For named-entity recognition, for example, x might be a sentence and $\mathcal{Y}(x)$ the set of all possible named-entity labelings for the sentence. Given an $x \in \mathcal{X}$ and a $y \in \mathcal{Y}(x)$, we use a conditional log-linear model for $p_{\boldsymbol{\theta}}(y|x)$:

$$p_{\boldsymbol{\theta}}(y|x) = \frac{\exp\{\boldsymbol{\theta}^\top \boldsymbol{f}(x,y)\}}{\sum_{y' \in \mathcal{Y}(x)} \exp\{\boldsymbol{\theta}^\top \boldsymbol{f}(x,y')\}} \quad (1)$$

where $\boldsymbol{f}(x,y)$ is a feature vector representation of x and y and $\boldsymbol{\theta}$ is a parameter vector containing one component for each feature.

2.1 Training Criteria

Many criteria exist for training the weights $\boldsymbol{\theta}$. We next review three choices in detail. For the following, we assume a training set consisting of n examples $\{\langle x^{(i)}, y^{(i)}\rangle\}_{i=1}^{n}$. Some criteria will make use of a task-specific cost function that measures the extent to which a structure y differs from the true structure $y^{(i)}$, denoted by $\mathrm{cost}(y^{(i)}, y)$.

2.1.1 Conditional Log-Likelihood

The learning problem for maximizing conditional log-likelihood is shown in Eq. 3 in Fig. 1 (we transform it into a minimization problem for easier comparison). This criterion is commonly used when a probabilistic interpretation of the model is desired.

2.1.2 Max-Margin

An alternative approach to training structured linear classifiers is based on maximum-margin Markov networks (Taskar et al., 2003). The basic idea is to choose weights such that the linear score of each $\langle x^{(i)}, y^{(i)}\rangle$ is better than $\langle x^{(i)}, y\rangle$ for all alternatives $y \in \mathcal{Y}(x^{(i)}) \setminus \{y^{(i)}\}$, with a larger margin for those y with higher cost. The "margin rescaling" form of this training criterion is shown in Eq. 4. Note that the cost function is incorporated into the criterion.

2.1.3 Risk

Risk is defined as the expected value of the cost with respect to the conditional distribution $p_{\boldsymbol{\theta}}(y|x)$;

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 733–736,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

on training data:

$$\sum_{i=1}^{n} \sum_{y \in \mathcal{Y}(x^{(i)})} p_{\boldsymbol{\theta}}(y|x^{(i)}) \mathrm{cost}(y^{(i)}, y) \quad (2)$$

With a log-linear model, learning then requires solving the problem shown in Eq. 5. Unlike the previous two criteria, risk is typically non-convex.

Risk minimization first appeared in the speech recognition community (Kaiser et al., 2000; Povey and Woodland, 2002). In NLP, Smith and Eisner (2006) minimized risk using k-best lists to define the distribution over output structures. Li and Eisner (2009) introduced a novel semiring for minimizing risk using dynamic programming; Xiong et al. (2009) minimized risk in a CRF.

2.1.4 Other Criteria

Many other criteria have been proposed to attempt to tailor training conditions to match task-specific evaluation metrics. These include the average per-label marginal likelihood for sequence labeling (Kakade et al., 2002), minimum error-rate training for machine translation (Och, 2003), F_1 for logistic regression classifiers (Jansche, 2005), and a wide range of possible metrics for sequence labeling and segmentation tasks (Suzuki et al., 2006).

3 Softmax-Margin

The softmax-margin objective is shown as Eq. 6 and is a generalization of that used by Povey et al. (2008) and similar to that used by Sha and Saul (2006). The simple intuition is the same as the intuition in max-margin learning: high-cost outputs for $x^{(i)}$ should be penalized more heavily. Another view says that we replace the probabilistic score inside the $\exp$ function of CLL with the "cost-augmented" score from max-margin. A third view says that we replace the "hard" maximum of max-margin with the "softmax" ($\log \sum \exp$) from CLL; hence we use the name "softmax-margin." Like CLL and max-margin, the objective is convex; a proof is provided in Gimpel and Smith (2010).

3.1 Relation to Other Objectives

We next show how the softmax-margin criterion (Eq. 6) bounds the risk criterion (Eq. 5). We first define some additional notation:

$$\mathbb{E}_{(i)}[F] \;=\; \sum_{y \in \mathcal{Y}(x^{(i)})} p_{\boldsymbol{\theta}}(y \mid x^{(i)}) F(y)$$

for some function $F : \mathcal{Y}(x^{(i)}) \rightarrow \mathbb{R}$. First note that the softmax-margin objective (Eq. 6) is equal to:

$$(\text{Eq. 3}) + \sum_{i=1}^{n} \log \mathbb{E}_{(i)}[\exp \mathrm{cost}(y^{(i)}, \cdot)] \quad (7)$$

The first term must be nonnegative. Taking each part of the second term, and using Jensen's inequality,

$$\begin{aligned} \log \mathbb{E}_{(i)}[e^{\mathrm{cost}(y^{(i)},\cdot)}] \;&\geq\; \mathbb{E}_{(i)}[\log e^{\mathrm{cost}(y^{(i)},\cdot)}] \\ &=\; \mathbb{E}_{(i)}[\mathrm{cost}(y^{(i)}, \cdot)] \end{aligned}$$

which is exactly Eq. 5. Softmax-margin is also an upper bound on the CLL criterion because, assuming cost is nonnegative, $\log \mathbb{E}[\exp \mathrm{cost}] \geq 0$. Furthermore, softmax-margin is a differentiable upper bound on max-margin, because the softmax function is a differentiable upper bound on the max function.

We note that it may also be interesting to consider minimizing the function $\sum_{i=1}^{n} \log \mathbb{E}_{(i)}[\exp \mathrm{cost}(y^{(i)}, \cdot)]$, since it is an upper bound on risk but requires less computation for computing the gradient.[1] We call this objective the **Jensen risk bound** and include it in our experimental comparison below.

3.2 Implementation

Most methods for training structured models with cost functions require the cost function to decompose across the pieces of the structure in the same way as the features, such as the standard methods for maximizing margin and minimizing risk (Taskar et al., 2003; Li and Eisner, 2009). If the same conditions hold, softmax-margin training can be implemented atop standard CRF training simply by adding additional "features" to encode the local cost components, *only* when computing the partition function during training.[2] The weights of these "cost features" are not learned.

4 Experiments

We consider the problem of named-entity recognition (NER) and use the English data from the CoNLL 2003 shared task (Tjong Kim Sang and De Meulder, 2003). The data consist of news articles

[1] Space does not permit a full discussion; see Gimpel and Smith (2010) for details.

[2] Since $\mathrm{cost}(y^{(i)}, y^{(i)}) = 0$ by definition, these "features" will never fire for the numerator and can be ignored.

$$\text{CLL:} \quad \min_{\boldsymbol{\theta}} \quad \sum_{i=1}^{n} -\boldsymbol{\theta}^\top \boldsymbol{f}(x^{(i)}, y^{(i)}) + \log \sum_{y \in \mathcal{Y}(x^{(i)})} \exp\{\boldsymbol{\theta}^\top \boldsymbol{f}(x^{(i)}, y)\} \tag{3}$$

$$\text{Max-Margin:} \quad \min_{\boldsymbol{\theta}} \quad \sum_{i=1}^{n} -\boldsymbol{\theta}^\top \boldsymbol{f}(x^{(i)}, y^{(i)}) + \max_{y \in \mathcal{Y}(x^{(i)})} \left(\boldsymbol{\theta}^\top \boldsymbol{f}(x^{(i)}, y) + \text{cost}(y^{(i)}, y)\right) \tag{4}$$

$$\text{Risk:} \quad \min_{\boldsymbol{\theta}} \quad \sum_{i=1}^{n} \sum_{y \in \mathcal{Y}(x^{(i)})} \text{cost}(y^{(i)}, y) \frac{\exp\{\boldsymbol{\theta}^\top \boldsymbol{f}(x^{(i)}, y)\}}{\sum_{y' \in \mathcal{Y}(x^{(i)})} \exp\{\boldsymbol{\theta}^\top \boldsymbol{f}(x^{(i)}, y')\}} \tag{5}$$

$$\text{Softmax-Margin:} \quad \min_{\boldsymbol{\theta}} \quad \sum_{i=1}^{n} -\boldsymbol{\theta}^\top \boldsymbol{f}(x^{(i)}, y^{(i)}) + \log \sum_{y \in \mathcal{Y}(x^{(i)})} \exp\{\boldsymbol{\theta}^\top \boldsymbol{f}(x^{(i)}, y) + \text{cost}(y^{(i)}, y)\} \tag{6}$$

Figure 1: Objective functions for training linear models. Regularization terms (e.g., $C \sum_{j=1}^{d} \theta_j^2$) are not shown here.

annotated with four entity types: person, location, organization, and miscellaneous. Our experiments focus on comparing training objectives for structured sequential models for this task. For all objectives, we use the same standard set of feature templates, following Kazama and Torisawa (2007) with additional token shape like those in Collins (2002b) and simple gazetteer features. A feature was included if it occurred at least once in training data (total 1,312,255 features).

The task is evaluated using the F_1 score, which is the harmonic mean of precision and recall (computed at the level of entire entities). Since this metric is computed from corpus-level precision and recall, it is not easily decomposable into features used in standard chain CRFs. For simplicity, we only consider Hamming cost in this paper; experiments with other cost functions more targeted to NER are presented in Gimpel and Smith (2010).

4.1 Baselines

We compared softmax-margin to several baselines: the structured perceptron (Collins, 2002a), 1-best MIRA with cost-augmented inference (Crammer et al., 2006), CLL, max-margin, risk, and our Jensen risk bound (JRB) introduced above.

We used L_2 regularization, experimenting with several coefficients for each method. For CLL, softmax-margin, max-margin, and MIRA, we used regularization coefficients $C \in \{0.01, 0.1, 1\}$. Risk has not always been used with regularization, as regularization does not have as clear a probabilistic interpretation with risk as it does with CLL; so, for risk and JRB we only used $C \in \{0.0, 0.01\}$. In addition, since these two objectives are non-convex, we initialized with the output of the best-performing CLL model on dev data (which was the CLL model with $C = 0.01$).[3] All methods except CLL and the perceptron make use of a cost function, for which we used Hamming cost. We experimented with different fixed multipliers m for the cost function, for $m \in \{1, 5, 10, 20\}$.

The hyperparameters C and m were tuned on the development data and the best-performing combination was used to label the test data. We also tuned the decision to average parameters across all training iterations; this has generally been found to help the perceptron and MIRA, but in our experiments had mixed results for the other methods.

We ran 100 iterations through the training data for each method. For CLL, softmax-margin, risk, and JRB, we used stochastic gradient ascent with a fixed step size of 0.01. For max-margin, we used stochastic subgradient ascent (Ratliff et al., 2006) also with a fixed step size of 0.01.[4] For the perceptron and MIRA, we used their built-in step size formulas.

4.2 Results

Table 1 shows our results. On test data, softmax-margin is statistically indistinguishable from MIRA, risk, and JRB, but performs significantly better than CLL, max-margin, and the perceptron ($p < 0.03$, paired bootstrap with 10,000 samples; Koehn,

[3] When using initialization of all ones for risk and JRB, results were several points below the results here, and with all zeroes, learning failed, resulting in 0.0 F-measure on dev data. Thus, risk and JRB appear sensitive to model initialization.

[4] In preliminary experiments, we tried other fixed and decreasing step sizes for (sub)gradient ascent and found that a fixed step of 0.01 consistently performed well across training objectives, so we used it for all settings for simplicity.

Method	Dev.	Test	(C, m, avg.?)
Perceptron	90.48	83.98	(Y)
MIRA	91.13	85.72	(0.01, 20, Y)
CLL	90.79	85.46	(0.01, N)
Max-Margin	91.17	85.28	(0.01, 1, Y)
Risk	91.14	85.59	(0.01, 10, N)
JRB	91.05	85.65	(0.01, 1, N)
Softmax-Margin	91.30	85.84	(0.01, 5, N)

Table 1: Results on development and test sets, along with hyperparameter values chosen using development set.

2004). It may be surprising that an improvement of 0.38 in F_1 could be significant, but this indicates that the improvements are not limited to certain categories of phenomena in a small number of sentences but rather appear throughout the majority of the test set. The Jensen risk bound performs comparably to risk, and takes roughly half as long to train.

5 Discussion

The softmax-margin approach offers (1) a convex objective, (2) the ability to incorporate task-specific cost functions, and (3) a probabilistic interpretation (which supports, e.g., hidden-variable learning and computation of posteriors). In contrast, max-margin training and MIRA do not provide (3); risk and JRB do not provide (1); and CLL does not support (2). Furthermore, softmax-margin training improves over standard CLL training of CRFs, is straightforward to implement, and requires the same amount of computation as CLL.

We have also presented the Jensen risk bound, which is easier to implement and faster to train than risk, yet gives comparable performance. The primary limitation of all these approaches, including softmax-margin, is that they only support cost functions that factor in the same way as the features of the model. Future work might exploit approximate inference for more expressive cost functions.

Bitext-Based Resolution of German Subject-Object Ambiguities

Florian Schwarck **Alexander Fraser** **Hinrich Schütze**
Institute for Natural Language Processing
University of Stuttgart
{koehlefn,fraser}@ims.uni-stuttgart.de

Abstract

We present a method for disambiguating syntactic subjects from syntactic objects (a frequent ambiguity) in German sentences taken from an English-German bitext. We exploit the fact that subject and object are usually easily determined in English. We show that a simple method disambiguates some subject-object ambiguities in German, while making few errors. We view this procedure as the first step in automatically acquiring (mostly) correct labeled data. We also evaluate using it to improve a state of the art statistical parser.

1 Introduction

Ambiguity of grammatical role is a problem when parsing a number of natural languages. In German, subject-object ambiguities are frequent. The sentence “Die Maus jagt die Katze” “the – mouse – chases – the – cat” exhibits such an ambiguity. Because word order is freer in German than in English, the sentence has two possible meanings: (i) The cat is chasing the mouse and (ii) the mouse is chasing the cat. We exploit the fact that such ambiguities are much less frequent in languages that possess a less flexible syntax than German. In English, the translation of the sentence “Die Maus jagt die Katze” is not ambiguous. If we have access to this translation, we can use this information to disambiguate the German sentence. The English translation is viewed as a surrogate for both contextual knowledge from the text and for world knowledge.

We present a method for disambiguating the subject and object roles in German sentences. We use an English-German *bitext* and exploit the fact that subject and object roles are rarely ambiguous in English. Using a new gold standard we created we show that our method disambiguates a significant proportion of subject-object ambiguities in German with high precision. We view this procedure as the first step in automatically acquiring (mostly) correct labeled data for training a statistical disambiguator that can be used on German text (even when no translation is available). In addition to measuring algorithm performance directly, we present experiments on improving the disambiguation of BitPar, a state of the art statistical parser.

2 Algorithm

Data and Word Alignment. We use the aligned English and German sentences in Europarl (Koehn, 2005) for our experiments. The corpus contains long and complex sentences. To establish translational correspondence between parallel sentences we use GIZA++ (Och and Ney, 2003). Its input is a tokenized parallel corpus. We lemmatized the text prior to aligning it.

Procedure. Figure 1 shows the architecture of our system. The boxes signify data sets, while the lines are processes applied to the data sets. The paper presents two applications. The first is the creation of a set of disambiguated German sentences (which involves word alignments in the upper right corner, and the use of parsers in the middle of the graphic). We also present a reranking of the N-best parses produced by BitPar (Schmid, 2004), a state of the art statistical parser (bottom of the graphic).

For processing of German we chose FSPar

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 737–740,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

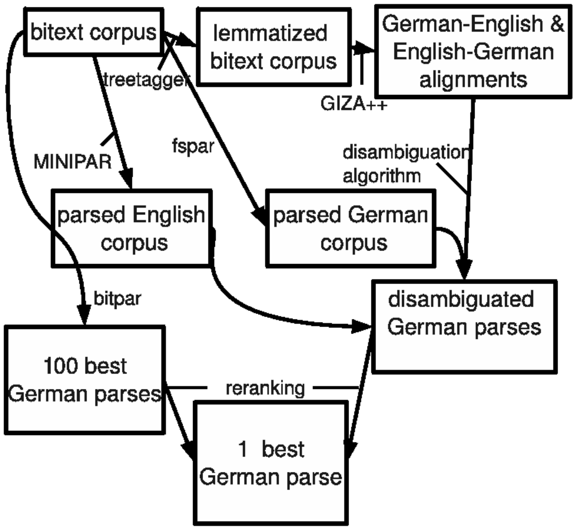

Figure 1: System Architecture

(Schiehlen, 2003), a fast shallow dependency parser. FSPar has extensive lexical knowledge which helps it to find subject-object ambiguities with high accuracy, but it does not try to resolve such ambiguities.

The key to our approach is to project syntactic roles from English text. For English parsing we used MINIPAR (Lin, 1998).

Based on FSPar's analysis, all German sentences with a subject-object ambiguity (about a third) were selected from EuroParl. The parallel English sentences were parsed with MINIPAR.

Words marked as ambiguous by FSPar were then processed using our algorithm. If an ambiguous German word was aligned to an English word that MINIPAR had (unambiguously) assigned the grammatical role of subject or object, then the syntactic role of the German word was defined by this information, see Figure 2.

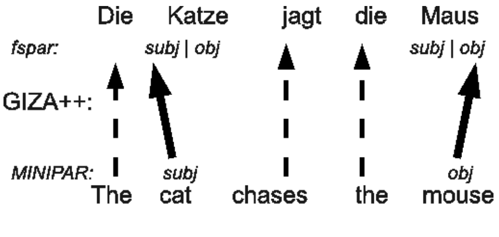

Figure 2: Disambiguation Algorithm

We used standard heuristics for improving word alignment (Och and Ney, 2003; Koehn et al., 2003), but there were many misalignments of ambiguous German words. In order for the procedure to work, we require that the German word to be disambiguated be aligned to the English subject or object. For this reason, we implemented *second guessing* based on a dictionary that lists for every German word the 10 most frequently aligned English words (found using the word alignment of all of Europarl). If an ambiguous German word was either unaligned or not aligned to the English subject or object, it was checked whether a dictionary translation was part of the parallel sentence and marked as subject or object by MINIPAR. If so, this dictionary word was used for disambiguation.

3 Evaluation

Gold Standard. We had access to a small set of gold standard parses (Padó and Lapata, 2009), but decided to create a larger corpus. We found that FSPar had acceptable performance for finding subject-object ambiguities[1]. The syntactic roles of words marked as ambiguous by FSPar were annotated. Four annotators annotated the syntactic roles in 4000 sentences using a graphical user interface (GUI). The GUI showed the ambiguous words in context and gave the annotator four different subject-object labels to choose from for each ambiguous word: *subject*, *object*, *expletive es* and *none*. Because the syntactic expletive "es" (English gloss: 'it') is frequent in German, as in "es scheint zu regnen" 'it appears to be raining,' we created a separate label for expletive "es", which is not treated as a subject.[2] The statistics are shown in table 1.

1000 sentences were annotated by all four annotators. Inter-annotator agreement was sufficient ($\kappa = 0.77$ on average (Carletta, 1996)).

Evaluation Measures. The output of our algorithm labels each word that FSPar classified as ambiguous with one of the three possible labels *subject*,

[1] FSPar has a very high precision in detecting subject-object ambiguities, as can be seen in Table 1 (approximately 0.955, the sum of two left columns divided by sum of all cells). We tried to get an idea of recall using the smaller gold standard. We made conservative assumptions about recall errors which we manually checked on a small sample, details are omitted. Using these assumptions led to an estimate for recall of 0.733, but true recall is likely higher.

[2] German "es" is also frequently used as a non-expletive, where it can take a syntactic role.

object and *no decision*[3]. We use the standard evaluation metrics **Precision** (P, the percentage of subject and object labelings in our hypothesis that are correct), **Recall** (R, the percentage of subject and object labelings in the gold standard that are correctly labeled in the hypothesis), and balanced **F** (F_1).

4 Experiments

Algorithm Performance. Table 2 shows the performance of our algorithm when evaluated against the manual annotation[4]. The lines *nosg*, *sg*, *filter-nosg* and *filter-sg* denote different configurations of the algorithm: Second guessing (section 2) was ("sg") or was not ("nosg") applied and filtering was ("filter") or was not applied. The filter increases precision by only keeping labels of subjects and objects that occur in the default order (e.g., the subject is to the left of the object in the main clause). As an aid to the user, FSPar presents such a determination of default order depending on its classification of clause type[5]. The columns indicate the heuristic postprocessing we applied to GIZA++'s alignment. *DE2EN* is the 1-to-N alignment calculated using German as the source language and English as the target language (i.e., each English word is linked to exactly zero or one German words).

As we see in table 2, with the most strict setup, *filter-nosg*, the algorithm resolves subject-object ambiguities with a precision of more than 92% but the best recall is only 39.4%, obtained using *DE2EN*. Second guessing increases recall but leads to losses in precision. The best precision result without the filter is 85.5%.

Improving BitPar's Subject-Object Decisions. For improving BitPar (which always tries to disambiguate subject-object), our baseline is the accuracy of the most probable parse shown in table 3, row 1.

Using the most probable parse from BitPar, we relabel a word "subject" or "object" if our system indicates to do so. With the algorithm alone we are able to improve recall (table 3, row 2). When we add the filter both precision and recall are improved (row 3). This experiment measures the improvement possible if our syntactic role information were directly integrated as a hard constraint into a parser (see section 5).

We now perform a simple reranking experiment, using BitPar's 100-best parses. For each sentence we choose the parse which agrees with as many of the subject/object decisions of the algorithm as possible (once again ignoring words where the algorithm chooses no decision). In case of ties in the number of agreements, we take the most probable parse. The results are in rows 4–5. Reranking increases F_1 by about 0.8%.

5 Related Work

Syntactic projection has been used to bootstrap treebanks in resource poor languages (Yarowsky and

[3] If *expletive es* or *none* was annotated, the system is correct if it does not make a decision.

[4] Because of problems with BitPar caused by preprocessing for FSPar, we use 11,279 sentences of the 13,000 annotated.

[5] Using this determination alone results in P 0.7728 R 0.8206 F 0.7960, very high recall but low precision.

Ngai, 2001; Hwa et al., 2005). In contrast with such work, we are addressing subject-object ambiguity in German. German parsers have no access to the contextual and world knowledge necessary to resolve this ambiguity.

Work on *projecting semantic roles* (Padó and Lapata, 2009; Fung et al., 2007) requires both syntactic parsing and semantic role labeling and is concerned with filling in the complete information in a semantic frame. Our approach is simpler and concerned only with syntactic disambiguation, not semantic projection. We focus only on difficult cases of subject-object ambiguity and although we do not always make a prediction, we obtain levels of precision that projection approaches making no use of knowledge of German syntax cannot achieve.

In *bitext parsing*, Burkett and Klein (2008) and Fraser et al. (2009) used feature functions defined on triples of (parse tree in language 1, parse tree in language 2, word alignment), combined in a log-linear model trained to maximize parse accuracy, requiring translated treebanks. We focus only on subject-object disambiguation in German, and annotated a new gold standard. We work on sentences that a partial parser has determined to be ambiguous. Fossum and Knight (2008) and Huang et al. (2009) improve English prepositional phrase attachment using features from an unparsed Chinese sentence. The latter work integrated the PP-attachment constraint (detected from the Chinese translation) directly into an English shift-reduce parser. As we have shown in the labeling experiment, integrating our subject-object disambiguation into BitPar could result in further increases beyond 100-best reranking.

6 Conclusion

We demonstrated the utility of bitext-based disambiguation of grammatical roles. We automatically created a large corpus of 164,874 disambiguated subject-object decisions with a precision of over 92%. This corpus will be of use in future research on syntactic role preferences and for the training of monolingual subject-object disambiguators. We presented a prototype application of subject-object disambiguation through a simple reranking of the 100-best list output by BitPar, and showed a possible further improvement if integrated in the parser. The new gold standard, which is publicly available, will hopefully be useful for work on both monolingual and bitext-based disambiguation.

Music, Language, and Computational Modeling: Lessons from the Key-Finding Problem

David Temperley
Eastman School of Music, University of Rochester
26 Gibbs St.
Rochester, NY 14604
dtemperley@esm.rochester.edu

Abstract

Recent research in computational music research, including my own, has been greatly influenced by methods in computational linguistics. But I believe the influence could also go the other way: Music may offer some interesting lessons for language research, particularly with regard to the modeling of cognition.

In this talk I will focus on an important problem in music cognition: the problem of key identification. I will argue that this problem is in some ways analogous to the problem of syntactic parsing in language. I will present a simple Bayesian model that performs well at the key-finding task. I will then consider some implications of the model for other issues. The model represents moment-to-moment changes in key over time and captures "reanalysis" effects in key perception. The model can be used to estimate the tonal ambiguity of a musical passage, and can also be used to estimate the probability of note patterns (just as a probabilistic grammar can be used to estimate the probability of word strings). An interesting question here concerns expectation: In forming expectations for the next surface element (note or word), do we consider all possible structures (syntactic structures or keys) or just the most probable one? Finally, the model sheds light on the concept of "information flow." It has been suggested that language reflects a tendency towards uniform density of information, in that less probable elements are spread out or elongated; I will suggest that the same may be true in music.

Slides for the talk will be available at my website, <www.theory.esm.rochester.edu/temperley>.

An Efficient Algorithm for Easy-First Non-Directional Dependency Parsing

Yoav Goldberg[*] and **Michael Elhadad**

Department of Computer Science
POB 653 Be'er Sheva, 84105, Israel
{yoavg|elhadad}@cs.bgu.ac.il

Abstract

We present a novel deterministic dependency parsing algorithm that attempts to create the easiest arcs in the dependency structure first in a non-directional manner. Traditional deterministic parsing algorithms are based on a shift-reduce framework: they traverse the sentence from left-to-right and, at each step, perform one of a possible set of actions, until a complete tree is built. A drawback of this approach is that it is extremely local: while decisions can be based on complex structures on the left, they can look only at a few words to the right. In contrast, our algorithm builds a dependency tree by iteratively selecting the best pair of neighbours to connect at each parsing step. This allows incorporation of features from already built structures both to the left and to the right of the attachment point. The parser learns both the attachment preferences and the order in which they should be performed. The result is a deterministic, best-first, $O(nlogn)$ parser, which is significantly more accurate than best-first transition based parsers, and nears the performance of globally optimized parsing models.

1 Introduction

Dependency parsing has been a topic of active research in natural language processing in the last several years. An important part of this research effort are the CoNLL 2006 and 2007 shared tasks (Buchholz and Marsi, 2006; Nivre et al., 2007), which allowed for a comparison of many algorithms and approaches for this task on many languages.

Current dependency parsers can be categorized into three families: local-and-greedy transition-based parsers (*e.g.*, MALTPARSER (Nivre et al., 2006)), globally optimized graph-based parsers (*e.g.*, MSTPARSER (McDonald et al., 2005)), and hybrid systems (*e.g.*, (Sagae and Lavie, 2006b; Nivre and McDonald, 2008)), which combine the output of various parsers into a new and improved parse, and which are orthogonal to our approach.

Transition-based parsers scan the input from left to right, are fast ($O(n)$), and can make use of rich feature sets, which are based on all the previously derived structures. However, all of their decisions are very local, and the strict left-to-right order implies that, while the feature set can use rich structural information from the left of the current attachment point, it is also very restricted in information to the right of the attachment point: traditionally, only the next two or three input tokens are available to the parser. This limited look-ahead window leads to error propagation and worse performance on root and long distant dependencies relative to graph-based parsers (McDonald and Nivre, 2007).

Graph-based parsers, on the other hand, are globally optimized. They perform an exhaustive search over all possible parse trees for a sentence, and find the highest scoring tree. In order to make the search tractable, the feature set needs to be restricted to features over single edges (first-order models) or edges pairs (higher-order models, e.g. (McDonald and Pereira, 2006; Carreras, 2007)). There are several attempts at incorporating arbitrary tree-based features but these involve either solving an ILP problem (Riedel and Clarke, 2006) or using computa-

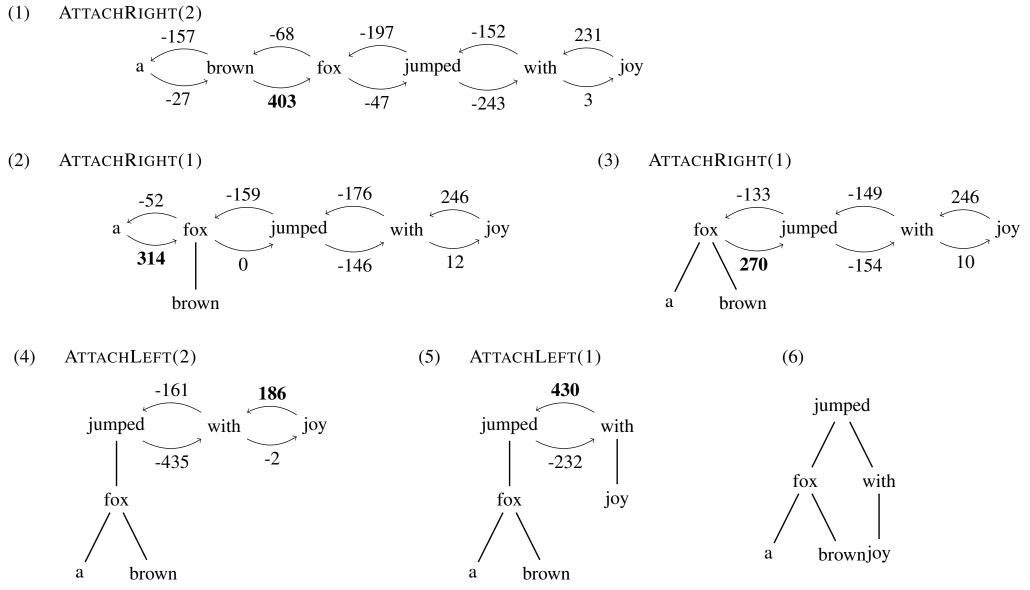

Figure 1: Parsing the sentence "a brown fox jumped with joy". Rounded arcs represent possible actions.

tionally intensive sampling-based methods (Nakagawa, 2007). As a result, these models, while accurate, are slow ($O(n^3)$ for projective, first-order models, higher polynomials for higher-order models, and worse for richer tree-feature models).

We propose a new category of dependency parsing algorithms, inspired by (Shen et al., 2007): non-directional easy-first parsing. This is a greedy, deterministic parsing approach, which relaxes the left-to-right processing order of transition-based parsing algorithms. By doing so, we allow the explicit incorporation of rich structural features derived from both sides of the attachment point, and implicitly take into account the entire previously derived structure of the whole sentence. This extension allows the incorporation of much richer features than those available to transition- and especially to graph-based parsers, and greatly reduces the locality of transition-based algorithm decisions. On the other hand, it is still a greedy, best-first algorithm leading to an efficient implementation.

We present a concrete $O(nlogn)$ parsing algorithm, which significantly outperforms state-of-the-art transition-based parsers, while closing the gap to graph-based parsers.

2 Easy-first parsing

When humans comprehend a natural language sentence, they arguably do it in an incremental, left-to-right manner. However, when humans consciously annotate a sentence with syntactic structure, they hardly ever work in fixed left-to-right order. Rather, they start by building several isolated constituents by making easy and local attachment decisions and only then combine these constituents into bigger constituents, jumping back-and-forth over the sentence and proceeding from easy to harder phenomena to analyze. When getting to the harder decisions a lot of structure is already in place, and this structure can be used in deciding a correct attachment.

Our parser follows a similar kind of annotation process: starting from easy attachment decisions, and proceeding to harder and harder ones. When making later decisions, the parser has access to the entire structure built in earlier stages. During the training process, the parser learns its own notion of easy and hard, and learns to defer specific kinds of decisions until more structure is available.

3 Parsing algorithm

Our (projective) parsing algorithm builds the parse tree bottom up, using two kinds of actions: **ATTACHLEFT(*i*)** and **ATTACHRIGHT(*i*)** . These actions are applied to a list of partial structures $p_1, \ldots, p_k$, called $pending$, which is initialized with the n words of the sentence $w_1, \ldots, w_n$. Each action connects the heads of two neighbouring structures, making one of them the parent of the other, and removing the daughter from the list of partial structures. **ATTACHLEFT(*i*)** adds a dependency edge (p_i, p_{i+1}) and removes p_{i+1} from the list. **ATTACHRIGHT(*i*)** adds a dependency edge (p_{i+1}, p_i) and removes p_i from the list. Each action shortens the list of partial structures by 1, and after $n-1$ such actions, the list contains the root of a connected projective tree over the sentence.

Figure 1 shows an example of parsing the sentence "a brown fox jumped with joy". The pseudocode of the algorithm is given in Algorithm 1.

```
Algorithm 1: Non-directional Parsing
    Input: a sentence= $w_1 \dots w_n$
    Output: a set of dependency arcs over the
            sentence ($Arcs$)
1   $Acts = \{$ATTACHLEFT, ATTACHRIGHT$\}$
2   $Arcs \leftarrow \{\}$
3   $pending = p_1 \dots p_n \leftarrow w_1 \dots w_n$
4   while $length(pending) > 1$ do
5       $best \leftarrow \operatorname{arg\,max}_{act \in Acts,\ 1 \le i \le len(pending)} score(act(i))$
6       $(parent, child) \leftarrow$ edgeFor($best$)
7       $Arcs$.add( $(parent, child)$ )
8       $pending$.remove($child$)
9   end
10  return $Arcs$

    edgeFor(act(i)) = $\begin{cases} (p_i, p_{i+1}) & \text{ATTACHLEFT}(i) \\ (p_{i+1}, p_i) & \text{ATTACHRIGHT}(i) \end{cases}$
```

At each step the algorithm chooses a specific action/location pair using a function $score($**ACTION(*i*)**$)$, which assign scores to action/location pairs based on the partially built structures headed by p_i and p_{i+1}, as well as neighbouring structures. The $score()$ function is learned from data. This scoring function reflects not only the correctness of an attachment, but also *the order* in which attachments should be made. For example, consider the attachments (brown,fox) and (joy,with) in Figure (1.1). While both are correct, the scoring function prefers the (adjective,noun) attachment over the (prep,noun) attachment. Moreover, the attachment (jumped,with), while correct, receives a negative score for the bare preposition "with" (Fig. (1.1) - (1.4)), and a high score once the verb has its subject and the PP "with joy" is built (Fig. (1.5)). Ideally, we would like to score easy and reliable attachments *higher than* harder less likely attachments, thus performing attachments in order of confidence. This strategy allows us both to limit the extent of error propagation, and to make use of richer contextual information in the later, harder attachments. Unfortunately, this kind of ordering information is not directly encoded in the data. We must, therefore, learn how to order the decisions.

We first describe the learning algorithm (Section 4) and a feature representation (Section 5) which enables us to learn an effective scoring function.

4 Learning Algorithm

We use a linear model $score(x) = \vec{w} \cdot \phi(x)$, where $\phi(x)$ is a feature representation and $\vec{w}$ is a weight vector. We write $\phi_{act(i)}$ to denote the feature representation extracted for action act at location i. The model is trained using a variant of the structured perceptron (Collins, 2002), similar to the algorithm of (Shen et al., 2007; Shen and Joshi, 2008). As usual, we use parameter averaging to prevent the perceptron from overfitting.

The training algorithm is initialized with a zero parameter vector $\vec{w}$. The algorithm makes several passes over the data. At each pass, we apply the training procedure given in Algorithm 2 to every sentence in the training set.

At training time, each sentence is parsed using the parsing algorithm and the current $\vec{w}$. Whenever an invalid action is chosen by the parsing algorithm, it is not performed (line 6). Instead, we update the parameter vector $\vec{w}$ by decreasing the weights of the features associated with the *invalid* action, and increasing the weights for the currently highest scoring *valid* action.[1] We then proceed to parse the sentence with the updated values. The process repeats until a valid action is chosen.

Note that each single update does not guarantee that the next chosen action is valid, or even different than the previously selected action. Yet, this is still an aggressive update procedure: we do not leave a sentence until our parameters vector parses it cor-

[1] We considered 3 variants of this scheme: (1) using the highest scoring valid action, (2) using the leftmost valid action, and (3) using a random valid action. The 3 variants achieved nearly identical accuracy, while (1) converged somewhat faster than the other two.

rectly, and we do not proceed from one partial parse to the next until $\vec{w}$ predicts a correct location/action pair. However, as the best ordering, and hence the best attachment point is not known to us, we do not perform a single aggressive update step. Instead, our aggressive update is performed incrementally in a series of smaller steps, each pushing $\vec{w}$ away from invalid attachments and toward valid ones. This way we integrate the search of confident attachments into the learning process.

Algorithm 2: Structured perceptron training for direction-less parser, over one sentence.

```
     Input: sentence,gold arcs,current $\vec{w}$,feature
            representation $\phi$
     Output: weight vector $\vec{w}$

 1   $Arcs \leftarrow \{\}$
 2   $pending \leftarrow sent$
 3   while $length(pending) > 1$ do
 4       $allowed \leftarrow \{act(i) | isValid(act(i), Gold, Arcs)\}$
 5       $choice \leftarrow \underset{\substack{act \in Acts \\ 1 \leq i \leq len(pending)}}{\arg\max} \vec{w} \cdot \phi_{act(i)}$
 6       if $choice \in allowed$ then
 7           $(parent, child) \leftarrow$ edgeFor($choice$)
 8           $Arcs$.add( $(parent, child)$ )
 9           $pending$.remove($child$)
10       else
11           $good \leftarrow \underset{act(j) \in allowed}{\arg\max} \vec{w} \cdot \phi_{act(j)}$
12           $\vec{w} \leftarrow \vec{w} + \phi_{good} - \phi_{choice}$
13   end
14   return $\vec{w}$
```

Function `isValid`(*action,Gold,Arcs*)

```
$(p, c) \leftarrow$ edgeFor($action$)
if $(\exists c' : (c, c') \in Gold \wedge (c, c') \notin Arcs)$
$\vee (p, c) \notin Gold$ then
    return false
return true
```

The function $isValid(act(i), gold, arcs)$ (line 4) is used to decide if the chosen action/location pair is valid. It returns True if two conditions apply: (a) (p_i, p_j) is present in $gold$, (b) all edges $(\square, p_j)$ in $gold$ are also in $arcs$. In words, the function verifies that the proposed edge is indeed present in the gold parse and that the suggested daughter already found all its own daughters.[2]

5 Feature Representation

The feature representation for an action can take into account the original sentence, as well as the entire parse history: $\phi_{act(i)}$ above is actually $\phi(act(i), sentence, Arcs, pending)$.

We use binary valued features, and each feature is conjoined with the type of action.

When designing the feature representation, we keep in mind that our features should not only direct the parser toward desired actions and away from undesired actions, but also provide the parser with means of choosing between several desired actions. We want the parser to be able to defer some desired actions until more structure is available and a more informed prediction can be made. This desire is reflected in our choice of features: some of our features are designed to signal to the parser the presence of possibly "incomplete" structures, such as an incomplete phrase, a coordinator without conjuncts, and so on.

When considering an action ACTION(i), we limit ourselves to features of partial structures around the attachment point: $p_{i-2}, p_{i-1}, p_i, p_{i+1}, p_{i+2}, p_{i+3}$, that is the two structures which are to be attached by the action (p_i and p_{i+1}), and the two neighbouring structures on each side[3].

While these features encode local context, it is local in terms of syntactic structure, and not purely in terms of sentence surface form. This let us capture some, though not all, long-distance relations.

For a partial structure p, we use w_p to refer to the head word form, t_p to the head word POS tag, and lc_p and rc_p to the POS tags of the left-most and right-most child of p respectively.

All our prepositions (IN) and coordinators (CC) are lexicalized: for them, t_p is in fact $w_p t_p$.

We define *structural*, *unigram*, *bigram* and *pp-attachment* features.

The *structural* features are: the length of the structures (len_p), whether the structure is a word (contains no children: nc_p), and the surface distance between structure heads ($\Delta_{p_i p_j}$). The *unigram* and *bigram* features are adapted from the feature set for left-to-right Arc-Standard dependency parsing de-

[2] This is in line with the Arc-Standard parsing strategy of shift-reduce dependency parsers (Nivre, 2004). We are currently experimenting also with an Arc-Eager variant of the non-directional algorithm.

[3] Our sentences are padded from each side with sentence delimiter tokens.

Structural	
for p in $p_{i-2}, p_{i-1}, p_i, p_{i+1}, p_{i+2}, p_{i+3}$	len_p , nc_p
for p,q in (p_{i-2}, p_{i-1}),(p_{i-1}, p_i),(p_i, p_{i+1}),$(p_{i+1}, pi+2)$,(p_{i+2}, p_{i+3})	Δ_{qp} , $\Delta_{qp} t_p t_q$

Bigram	
for p,q in (p_i, p_{i+1}),(p_i, p_{i+2}),(p_{i-1}, p_i),(p_{i-1}, p_{i+2}),(p_{i+1}, p_{i+2})	$t_p t_q$, $w_p w_q$, $t_p w_q$, $w_p t_q$ $t_p t_q lc_p lc_q$, $t_p t_q rc_p lc_q$ $t_p t_q lc_p rc_q$, $t_p t_q rc_p rc_q$
PP-Attachment	
if p_i is a preposition	$w_{p_{i-1}} w_{p_i} rc_{p_i}$, $t_{p_{i-1}} w_{p_i} rcw_{p_i}$
if p_{i+1} is a preposition	$w_{p_{i-1}} w_{p_{i+1}} rc_{p_{i+1}}$, $t_{p_{i-1}} w_{p_{i+1}} rcw_{p_{i+1}}$ $w_{p_i} w_{p_{i+1}} rc_{p_{i+1}}$, $t_{p_i} w_{p_{i+1}} rcw_{p_{i+1}}$
if p_{i+2} is a preposition	$w_{p_{i+1}} w_{p_{i+2}} rc_{p_{i+2}}$, $t_{p_{i+1}} w_{p_{i+2}} rcw_{p_{i+2}}$ $w_{p_i} w_{p_{i+2}} rc_{p_{i+2}}$, $t_{p_i} w_{p_{i+2}} rcw_{p_{i+2}}$

Figure 2: Feature Templates

scribed in (Huang et al., 2009). We extended that feature set to include the structure on both sides of the proposed attachment point.

In the case of unigram features, we added features that specify the POS of a word and its left-most and right-most children. These features provide the non-directional model with means to prefer some attachment points over others based on the types of structures already built. In English, the left- and right-most POS-tags are good indicators of constituency.

The *pp-attachment* features are similar to the bigram features, but fire only when one of the structures is headed by a preposition (IN). These features are more lexicalized than the regular bigram features, and include also the word-form of the right-most child of the PP (rcw_p). This should help the model learn lexicalized attachment preferences such as (hit, with-bat).

Figure 2 enumerate the feature templates we use.

6 Computational Complexity and Efficient Implementation

The parsing algorithm (Algorithm 1) begins with $n+1$ disjoint structures (the words of the sentence + ROOT symbol), and terminates with one connected structure. Each iteration of the main loop connects two structures and removes one of them, and so the loop repeats for exactly n times.

The argmax in line 5 selects the maximal scoring action/location pair. At iteration i, there are $n-i$ locations to choose from, and a naive computation of the argmax is $O(n)$, resulting in an $O(n^2)$ algorithm.

Each performed action changes the partial structures and with it the extracted features and the computed scores. However, these changes are limited to a fixed local context around the attachment point of the action. Thus, we observe that the feature extraction and score calculation can be performed once for each action/location pair in a given sentence, and reused throughout all the iterations. After each iteration we need to update the extracted features and calculated scores for only k locations, where k is a fixed number depending on the window size used in the feature extraction, and usually $k \ll n$.

Using this technique, we perform only $(k+1)n$ feature extractions and score calculations for each sentence, that is $O(n)$ feature-extraction operations per sentence.

Given the scores for each location, the argmax can then be computed in $O(logn)$ time using a heap, resulting in an $O(nlogn)$ algorithm: n iterations, where the first iteration involves n feature extraction operations and n heap insertions, and each subsequent iteration involves k feature extractions and heap updates.

We note that the dominating factor in polynomial-time discriminative parsers, is by far the feature-extraction and score calculation. It makes sense to compare parser complexity in terms of these operations only.[4] Table 1 compares the complexity of our

[4] Indeed, in our implementation we do not use a heap, and opt instead to find the argmax using a simple $O(n)$ *max* operation. This $O(n^2)$ algorithm is faster in practice than the heap based one, as both are dominated by the $O(n)$ feature extraction, while the cost of the $O(n)$ *max* calculationis negligible compared to the constants involved in heap maintenance.

parser to other dependency parsing frameworks.

Parser	Runtime	Features / Scoring
MALT	$O(n)$	$O(n)$
MST	$O(n^3)$	$O(n^2)$
MST2	$O(n^3)$	$O(n^3)$
BEAM	$O(n * beam)$	$O(n * beam)$
NONDIR (This Work)	$O(nlogn)$	$O(n)$

Table 1: Complexity of different parsing frameworks. MST: first order MST parser, MST2: second order MST parser, MALT: shift-reduce left-to-right parsing. BEAM: beam search parser, as in (Zhang and Clark, 2008)

In terms of feature extraction and score calculation operations, our algorithm has the same cost as traditional shift-reduce (MALT) parsers, and is an order of magnitude more efficient than graph-based (MST) parsers. Beam-search decoding for left-to-right parsers (Zhang and Clark, 2008) is also linear, but has an additional linear dependence on the beam-size. The reported results in (Zhang and Clark, 2008) use a beam size of 64, compared to our constant of $k = 6$.

Our Python-based implementation[5] (the perceptron is implemented in a C extension module) parses about 40 tagged sentences per second on an Intel based MacBook laptop.

7 Experiments and Results

We evaluate the parser using the WSJ Treebank. The trees were converted to dependency structures with the Penn2Malt conversion program,[6] using the head-finding rules from (Yamada and Matsumoto, 2003).[7]

We use Sections 2-21 for training, Section 22 for development, and Section 23 as the final test set. The text is automatically POS tagged using a trigram HMM based POS tagger prior to training and parsing. Each section is tagged after training the tagger on all other sections. The tagging accuracy of the tagger is 96.5 for the training set and 96.8 for the test set. While better taggers exist, we believe that the simpler HMM tagger overfits less, and is more representative of the tagging performance on non-WSJ corpus texts.

Parsers We evaluate our parser against the transition-based MALT parser and the graph-based MST parser. We use version 1.2 of MALT parser[8], with the settings used for parsing English in the CoNLL 2007 shared task. For the MST parser[9], we use the default first-order, projective parser settings, which provide state-of-the-art results for English. All parsers are trained and tested on the same data. Our parser is trained for 20 iterations.

Evaluation Measures We evaluate the parsers using three common measures:

(unlabeled) Accuracy: percentage of tokens which got assigned their correct parent.

Root: The percentage of sentences in which the ROOT attachment is correct.

Complete: the percentage of sentences in which all tokens were assigned their correct parent.

Unlike most previous work on English dependency parsing, we *do not* exclude punctuation marks from the evaluation.

Results are presented in Table 2. Our non-directional easy-first parser significantly outperforms the left-to-right greedy MALT parser in terms of accuracy and root prediction, and significantly outperforms both parsers in terms of exact match. The globally optimized MST parser is better in root-prediction, and slightly better in terms of accuracy.

We evaluated the parsers also on the English dataset from the CoNLL 2007 shared task. While this dataset is also derived from the WSJ Treebank, it differs from the previous dataset in two important aspects: it is much smaller in size, and it is created using a different conversion procedure, which is more linguistically adequate. For these experiments, we use the dataset POS tags, and the same parameters as in the previous set of experiments: we train the non-directional parser for 20 iterations, with the same feature set. The CoNLL dataset contains some non-projective constructions. MALT and MST deal with non-projectivity. For the non-directional parser, we projectivize the training set prior to training using the procedure described in (Carreras, 2007).

Results are presented in Table 3.

NonDir+Mst+Malt	92.70	38.31

Table 4: Parser combination with Oracle, choosing the highest scoring parse for each sentence of the test-set.

While all models suffer from the move to the smaller dataset and the more challenging annotation scheme, the overall story remains the same: the non-directional parser is better than Malt but not as good as Mst in terms of parent-accuracy and root prediction, and is better than both Malt and Mst in terms of producing complete correct parses.

That the non-directional parser has lower accuracy but more exact matches than the Mst parser can be explained by it being a deterministic parser, and hence still vulnerable to error propagation: once it erred once, it is likely to do so again, resulting in low accuracies for some sentences. However, due to the easy-first policy, it manages to parse many sentences without a single error, which lead to higher exact-match scores. The non-directional parser avoids error propagation by not making the initial error. On average, the non-directional parser manages to assign correct heads to over 60% of the tokens before making its first error.

The Mst parser would have ranked 5^{th} in the shared task, and NonDir would have ranked 7^{th}. The better ranking systems in the shared task are either higher-order global models, beam-search based systems, or ensemble-based systems, all of which are more complex and less efficient than the NonDir parser.

Parse Diversity The parses produced by the non-directional parser are different than the parses produced by the graph-based and left-to-right parsers. To demonstrate this difference, we performed an Oracle experiment, in which we combine the output of several parsers by choosing, for each sentence, the parse with the highest score. Results are presented in Table 4.

A non-oracle blending of Malt+Mst+NonDir using Sagae and Lavie's (2006) simplest combination method assigning each component the same weight, yield an accuracy of 90.8 on the CoNLL 2007 English dataset, making it the highest scoring system among the participants.

7.1 Error Analysis / Limitations

When we investigate the POS category of mistaken instances, we see that for all parsers, nodes with structures of depth 2 and more which are assigned an incorrect head are predominantly PPs (headed by 'IN'), followed by NPs (headed by 'NN'). All parsers have a hard time dealing with PP attachment, but Mst parser is better at it than NonDir, and both are better than Malt.

Looking further at the mistaken instances, we notice a tendency of the PP mistakes of the NonDir parser to involve, before the PP, an NP embedded in a relative clause. This reveals a limitation of our parser: recall that for an edge to be built, the child must first acquire all its own children. This means that in case of relative clauses such as "I saw the boy [who ate the pizza] with my eyes", the parser must decide if the PP "with my eyes" should be attached to "the pizza" or not *before* it is allowed to build parts of the outer NP ("the boy who..."). In this case, the verb "saw" and the noun "boy" are both outside of the sight of the parser when deciding on the PP attachment, and it is forced to make a decision in ignorance, which, in many cases, leads to mistakes. The globally optimized Mst does not suffer as much from such cases. We plan to address this deficiency in future work.

8 Related Work

Deterministic shift-reduce parsers are restricted by a strict left-to-right processing order. Such parsers can rely on rich syntactic information on the left, but not on the right, of the decision point. They are forced to commit early, and suffer from error propagation. Our non-directional parser addresses these deficiencies by discarding the strict left-to-right processing order, and attempting to make easier decisions before harder ones. Other methods of dealing with these deficiencies were proposed over the years:

Several Passes Yamada and Matsumoto's (2003) pioneering work introduces a shift-reduce parser which makes several left-to-right passes over a sentence. Each pass adds structure, which can then be used in subsequent passes. Sagae and Lavie (2006b) extend this model to alternate between left-to-right and right-to-left passes. This model is similar to ours, in that it attempts to defer harder decisions to later passes over the sentence, and allows late decisions to make use of rich syntactic information (built in earlier passes) on both sides of the decision point. However, the model is not explicitly trained to optimize attachment ordering, has an $O(n^2)$ runtime complexity, and produces results which are inferior to current single-pass shift-reduce parsers.

Beam Search Several researchers dealt with the early-commitment and error propagation of deterministic parsers by extending the greedy decisions with various flavors of beam-search (Sagae and Lavie, 2006a; Zhang and Clark, 2008; Titov and Henderson, 2007). This approach works well and produces highly competitive results. Beam search can be incorporated into our parser as well. We leave this investigation to future work.

Strict left-to-right ordering is also prevalent in sequence tagging. Indeed, one major influence on our work is Shen *et.al.*'s bi-directional POS-tagging algorithm (Shen et al., 2007), which combines a perceptron learning procedure similar to our own with beam search to produce a state-of-the-art POS-tagger, which does not rely on left-to-right processing. Shen and Joshi (2008) extends the bidirectional tagging algorithm to LTAG parsing, with good results. We build on top of that work and present a concrete and efficient greedy non-directional dependency parsing algorithm.

Structure Restrictions Eisner and Smith (2005) propose to improve the efficiency of a globally optimized parser by posing hard constraints on the lengths of arcs it can produce. Such constraints pose an explicit upper bound on parser accuracy.[10] Our parsing model does not pose such restrictions. Shorter edges are arguably easier to predict, and our parses builds them early in time. However, it is also capable of producing long dependencies at later stages in the parsing process. Indeed, the distribution of arc lengths produced by our parser is similar to those produced by the MALT and MST parsers.

9 Discussion

We presented a *non-directional* deterministic dependency parsing algorithm, which is not restricted by the left-to-right parsing order of other deterministic parsers. Instead, it works in an *easy-first* order. This strategy allows using more context at each decision. The parser learns both *what* and *when* to connect. We show that this parsing algorithm significantly outperforms a left-to-right deterministic algorithm. While it still lags behind globally optimized parsing algorithms in terms of accuracy and root prediction, it is much better in terms of exact match, and much faster. As our parsing framework can easily and efficiently utilize more structural information than globally optimized parsers, we believe that with some enhancements and better features, it can outperform globally optimized algorithms, especially when more structural information is needed, such as for morphologically rich languages.

Moreover, we show that our parser produces different structures than those produced by both left-to-right and globally optimized parsers, making it a good candidate for inclusion in an ensemble system. Indeed, a simple combination scheme of graph-based, left-to-right and non-directional parsers yields state-of-the-art results on English dependency parsing on the CoNLL 2007 dataset.

We hope that further work on this non-directional parsing framework will pave the way to better understanding of an interesting cognitive question: which kinds of parsing decisions are hard to make, and which linguistic constructs are hard to analyze?

[10] In (Dreyer et al., 2006), constraints are chosen "to be the minimum value that will allow recovery of 90% of the left (right) dependencies in the training corpus".

Abstract

We present three approaches for unsupervised grammar induction that are sensitive to data complexity and apply them to Klein and Manning’s Dependency Model with Valence. The first, *Baby Steps*, bootstraps itself via iterated learning of increasingly longer sentences and requires no initialization. This method substantially exceeds Klein and Manning’s published scores and achieves 39.4% accuracy on Section 23 (all sentences) of the Wall Street Journal corpus. The second, *Less is More*, uses a low-complexity subset of the available data: sentences up to length 15. Focusing on fewer but simpler examples trades off quantity against ambiguity; it attains 44.1% accuracy, using the standard linguistically-informed prior and batch training, beating state-of-the-art. *Leapfrog*, our third heuristic, combines *Less is More* with *Baby Steps* by mixing their models of shorter sentences, then rapidly ramping up exposure to the full training set, driving up accuracy to 45.0%. These trends generalize to the Brown corpus; awareness of data complexity may improve other parsing models and unsupervised algorithms.

1 Introduction

Unsupervised learning of hierarchical syntactic structure from free-form natural language text is a hard problem whose eventual solution promises to benefit applications ranging from question answering to speech recognition and machine translation. A restricted version that targets dependencies and assumes partial annotation, e.g., sentence boundaries, tokenization and typically even part-of-speech (POS) tagging, has received much attention, eliciting a diverse array of techniques (Smith and Eisner, 2005; Seginer, 2007; Cohen et al., 2008). Klein and Manning’s (2004) Dependency Model with Valence (DMV) was the first to beat a simple parsing heuristic — the right-branching baseline. Today’s state-of-the-art systems (Headden et al., 2009; Cohen and Smith, 2009) are still rooted in the DMV.

Despite recent advances, unsupervised parsers lag far behind their supervised counterparts. Although large amounts of unlabeled data are known to improve semi-supervised parsing (Suzuki et al., 2009), the best unsupervised systems use less data than is available for supervised training, relying on complex models instead: Headden et al.’s (2009) Extended Valence Grammar (EVG) combats data sparsity with smoothing alone, training on the same small subset of the tree-bank as the classic implementation of the DMV; Cohen and Smith (2009) use more complicated algorithms (variational EM and MBR decoding) and stronger linguistic hints (tying related parts of speech and syntactically similar bilingual data).

We explore what can be achieved through judicious use of data and simple, scalable techniques. Our first approach iterates over a series of training sets that gradually increase in size and complexity, forming an initialization-independent scaffolding for learning a grammar. It works with Klein and Manning’s simple model (the original DMV) and training algorithm (classic EM) but eliminates their crucial dependence on manually-tuned priors. The second technique is consistent with the intuition that learning is most successful within a band of the size-complexity spectrum. Both could be applied to more

intricate models and advanced learning algorithms. We combine them in a third, efficient hybrid method.

2 Intuition

Focusing on simple examples helps guide unsupervised learning,[1] as blindly added confusing data can easily mislead training. We suggest that unless it is increased gradually, unbridled, complexity can overwhelm a system. How to grade an example's difficulty? The cardinality of its solution space presents a natural proxy. In the case of parsing, the number of possible syntactic trees grows exponentially with sentence length. For longer sentences, the unsupervised optimization problem becomes severely under-constrained, whereas for shorter sentences, learning is tightly reined in by data. In the extreme case of a single-word sentence, there is no choice but to parse it correctly. At two words, a raw 50% chance of telling the head from its dependent is still high, but as length increases, the accuracy of even educated guessing rapidly plummets. In model re-estimation, long sentences amplify ambiguity and pollute fractional counts with noise. At times, batch systems are better off using less data.

Baby Steps: Global non-convex optimization is hard. We propose a meta-heuristic that takes the guesswork out of initializing local search. Beginning with an easy (convex) case, it slowly extends it to the fully complex target task by taking tiny steps in the problem space, trying not to stray far from the relevant neighborhoods of the solution space. A series of nested subsets of increasingly longer sentences that culminates in the complete data set offers a natural progression. Its base case — sentences of length one — has a trivial solution that requires neither initialization nor search yet reveals something of sentence heads. The next step — sentences of length one and two — refines initial impressions of heads, introduces dependents, and exposes their identities and relative positions. Although not representative of the full grammar, short sentences capture enough information to paint most of the picture needed by slightly longer sentences. They set up an easier, incremental subsequent learning task. Step $k + 1$ augments training input to include lengths $1, 2, \ldots, k, k + 1$ of the full data set and executes local search starting from the (smoothed) model estimated by step k. This truly is grammar induction.

Less is More: For standard batch training, just using simple, short sentences is not enough. They are rare and do not reveal the full grammar. We find a "sweet spot" — sentence lengths that are neither too long (excluding the truly daunting examples) nor too few (supplying enough accessible information), using Baby Steps' learning curve as a guide. We train where it flattens out, since remaining sentences contribute little (incremental) educational value.[2]

Leapfrog: As an alternative to discarding data, a better use of resources is to combine the results of batch and iterative training up to the sweet spot data gradation, then iterate with a large step size.

3 Related Work

Two types of scaffolding for guiding language learning debuted in Elman's (1993) experiments with "starting small": data complexity (restricting input) and model complexity (restricting memory). In both cases, gradually increasing complexity allowed artificial neural networks to master a pseudo-natural grammar they otherwise failed to learn. Initially-limited capacity resembled maturational changes in working memory and attention span that occur over time in children (Kail, 1984), in line with the "less is more" proposal (Newport, 1988; 1990). Although Rohde and Plaut (1999) failed to replicate this[3] result with simple recurrent networks, other machine learning techniques reliably benefit from scaffolded model complexity on a variety of language tasks. In word-alignment, Brown et al. (1993) used IBM Models 1-4 as "stepping stones" to training Model 5. Other prominent examples include "coarse-to-fine"

[1] It mirrors the effect that boosting hard examples has for supervised training (Freund and Schapire, 1997).

[2] This is akin to McClosky et al.'s (2006) "Goldilocks effect."

[3] Worse, they found that limiting input *hindered* language acquisition. And making the grammar more English-like (by introducing and strengthening semantic constraints), *increased* the already significant advantage for "starting large!" With iterative training invoking the optimizer multiple times, creating extra opportunities to converge, Rohde and Plaut (1999) suspected that Elman's (1993) simulations simply did not allow networks exposed exclusively to complex inputs sufficient training time. Our extremely generous, low termination threshold for EM (see §5.1) addresses this concern. However, given the DMV's purely syntactic POS tag-based approach (see §5), it would be prudent to re-test Baby Steps with a lexicalized model.

approaches to parsing, translation and speech recognition (Charniak and Johnson, 2005; Charniak et al., 2006; Petrov et al., 2008; Petrov, 2009), and recently unsupervised POS tagging (Ravi and Knight, 2009). Initial models tend to be particularly simple,[4] and each refinement towards a full model introduces only limited complexity, supporting incrementality.

Filtering complex data, the focus of our work, is unconventional in natural language processing. Such scaffolding qualifies as *shaping* — a method of instruction (routinely exploited in animal training) in which the teacher decomposes a complete task into sub-components, providing an easier path to learning. When Skinner (1938) coined the term, he described it as a "method of successive approximations." Ideas that gradually make a task more difficult have been explored in robotics (typically, for navigation), with reinforcement learning (Singh, 1992; Sanger, 1994; Saksida et al., 1997; Dorigo and Colombetti, 1998; Savage, 1998; Savage, 2001). Recently, Krueger and Dayan (2009) showed that shaping speeds up language acquisition and leads to better generalization in abstract neural networks. Bengio et al. (2009) confirmed this for deep deterministic and stochastic networks, using simple multi-stage *curriculum* strategies. They conjectured that a well-chosen sequence of training criteria — different sets of weights on the examples — could act as a continuation method (Allgower and Georg, 1990), helping find better local optima for non-convex objectives. Elman's learners constrained the peaky solution space by focusing on just the right data (simple sentences that introduced basic representational categories) at just the right time (early on, when their plasticity was greatest). Self-shaping, they simplified tasks through deliberate omission (or misunderstanding). Analogously, Baby Steps induces an early structural locality bias (Smith and Eisner, 2006), then relaxes it, as if annealing (Smith and Eisner, 2004). Its curriculum of binary weights initially discards complex examples responsible for "high-frequency noise," with earlier, "smoothed" objectives revealing more of the global picture.

There are important differences between our results and prior work. In contrast to Elman, we use a large data set (WSJ) of real English. Unlike Bengio et al. and Krueger and Dayan, we shape a parser, not a language model. Baby Steps is similar, in spirit, to Smith and Eisner's methods. Deterministic annealing (DA) shares nice properties with Baby Steps, but performs worse than EM for (constituent) parsing; Baby Steps handedly defeats standard training. Structural annealing works well, but requires a hand-tuned annealing schedule and direct manipulation of the objective function; Baby Steps works "out of the box," its locality biases a natural consequence of a complexity/data-guided tour of optimization problems. Skewed DA incorporates a good initializer by interpolating between two probability distributions, whereas our hybrid, Leapfrog, admits multiple initializers by mixing structures instead. "Less is More" is novel and confirms the tacit consensus implicit in training on small data sets (e.g., WSJ10).

4 Data Sets and Metrics

Klein and Manning (2004) both trained and tested the DMV on the same customized subset (WSJ10) of Penn English Treebank's Wall Street Journal portion (Marcus et al., 1993). Its 49,208 annotated parse trees were pruned[5] down to 7,422 sentences of at most 10 terminals, spanning 35 unique POS tags. Following standard practice, automatic "head-percolation" rules (Collins, 1999) were used to convert the remaining trees into dependencies. Forced to produce a single "best" parse, their algorithm was judged on accuracy: its *directed score* was the fraction of correct dependencies; a more flattering[6] *undirected score* was also used. We employ the same metrics, emphasizing directed scores, and generalize WSJk to be the subset of pre-processed sentences with at most k terminals. Our experiments focus on $k \in \{1, \ldots, 45\}$, but we also test on WSJ100 and Section 23 of WSJ$^\infty$ (the entire WSJ), as well as the held-out Brown100 (similarly derived from the Brown corpus (Francis and Kucera, 1979)). See Figure 1 for these corpora's sentence and token counts.

[4] Brown et al.'s (1993) Model 1 (and, similarly, the first baby step) has a global optimum that can be computed exactly, so that no initial or subsequent parameters depend on initialization.

[5] Stripped of all empty sub-trees, punctuation, and terminals (tagged # and $) not pronounced where they appear, those sentences still containing more than ten tokens were thrown out.

[6] Ignoring polarity of parent-child relations partially obscured effects of alternate analyses (systematic choices between modals and main verbs for heads of sentences, determiners for noun phrases, etc.) and facilitated comparison with prior work.

Corpus	*Sentences*	*POS Tokens*	*Corpus*	*Sentences*	*POS Tokens*

\end{aligned}$$

Figure 2: A simple dependency structure for a short sentence and its probability, as factored by the DMV.

5 New Algorithms for the Classic Model

The DMV (Klein and Manning, 2004) is a single-state head automata model (Alshawi, 1996) over lexical word classes $\{c_w\}$ — POS tags. Its generative story for a sub-tree rooted at a head (of class c_h) rests on three types of independent decisions: (i) initial direction $dir \in \{\mathtt{L}, \mathtt{R}\}$ in which to attach children, via probability $\mathbb{P}_{\text{ORDER}}(c_h)$; (ii) whether to seal dir, stopping with probability $\mathbb{P}_{\text{STOP}}(c_h, dir, adj)$, conditioned on $adj \in \{\mathtt{T}, \mathtt{F}\}$ (true iff considering dir's first, i.e., *adjacent*, child); and (iii) attachments (of class c_a), according to $\mathbb{P}_{\text{ATTACH}}(c_h, dir, c_a)$. This produces only projective trees.[7] A root token ◇ generates the head of a sentence as its left (and only) child. Figure 2 displays an example that ignores (sums out) $\mathbb{P}_{\text{ORDER}}$.

The DMV lends itself to unsupervised learning via inside-outside re-estimation (Baker, 1979). Klein and Manning did not use smoothing and started with an "ad-hoc harmonic" completion: aiming for balanced trees, non-root heads attached dependents in inverse proportion to (a constant plus) their distance; ◇ generated heads uniformly at random. This non-distributional heuristic created favorable initial conditions that nudged EM towards typical linguistic dependency structures.

5.1 Algorithm #0: Ad-Hoc* — A Variation on Original Ad-Hoc Initialization

Since some of the important implementation details are not available in the literature (Klein and Manning, 2004; Klein, 2005), we had to improvise initialization and terminating conditions. We suspect that our choices throughout this section do not match Klein and Manning's actual training of the DMV.

We use the following ad-hoc harmonic scores (for all tokens other than ◇): $\tilde{\mathbb{P}}_{\text{ORDER}} \equiv 1/2$;

$$\tilde{\mathbb{P}}_{\text{STOP}} \equiv (d_s + \delta_s)^{-1} = (d_s + 3)^{-1},\ d_s \geq 0;$$
$$\tilde{\mathbb{P}}_{\text{ATTACH}} \equiv (d_a + \delta_a)^{-1} = (d_a + 2)^{-1},\ d_a \geq 1.$$

Integers $d_{\{s,a\}}$ are distances from heads to stopping boundaries and dependents.[8] We initialize training by producing best-scoring parses of all input sentences and converting them into proper probability distributions $\mathbb{P}_{\text{STOP}}$ and $\mathbb{P}_{\text{ATTACH}}$ via maximum-likelihood estimation (a single step of Viterbi training (Brown et al., 1993)). Since left and right children are independent, we drop $\mathbb{P}_{\text{ORDER}}$ altogether, mak-

[7] Unlike spanning tree algorithms (McDonald et al., 2005), DMV's chart-based method disallows crossing dependencies.

[8] Constants $\delta_{\{s,a\}}$ come from personal communication. Note that δ_s is one higher than is strictly necessary to avoid both division by zero and determinism; δ_a could have been safely zeroed out, since we never compute $1 - \mathbb{P}_{\text{ATTACH}}$ (see Figure 2).

ing "headedness" deterministic. Our parser carefully randomizes tie-breaking, so that all parse trees having the same score get an equal shot at being selected (both during initialization and evaluation). We terminate EM when a successive change in overall per-token cross-entropy drops below 2^{-20} bits.

5.2 Algorithm #1: Baby Steps — An Initialization-Independent Scaffolding

We eliminate the need for initialization by first training on a trivial subset of the data — WSJ1; this works, since there is only one (the correct) way to parse a single-token sentence. We plug the resulting model into training on WSJ2 (sentences of up to two tokens), and so forth, building up to WSJ45.[9] This algorithm is otherwise identical to Ad-Hoc*, with the exception that it re-estimates each model using Laplace smoothing, so that earlier solutions could be passed to next levels, which sometimes contain previously unseen dependent and head POS tags.

5.3 Algorithm #2: Less is More — Ad-Hoc* where Baby Steps Flatlines

We jettison long, complex sentences and deploy Ad-Hoc*'s initializer and batch training at WSJ$\hat{k}^*$ — an estimate of the sweet spot data gradation. To find it, we track Baby Steps' successive models' cross-entropies on the complete data set, WSJ45. An initial segment of rapid improvement is separated from the final region of convergence by a *knee* — points of maximum curvature (see Figure 3). We use an improved[10] L method (Salvador and Chan, 2004) to automatically locate this area of diminishing returns. Specifically, we determine its end-points $[k_0, k^*]$ by minimizing squared error, estimating $\hat{k}_0 = 7$ and $\hat{k}^* = 15$. Training at WSJ15 just misses the plateau.

5.4 Algorithm #3: Leapfrog — A Practical and Efficient Hybrid Mixture

Cherry-picking the best features of "Less is More" and Baby Steps, we begin by combining their models at WSJ$\hat{k}^*$. Using one best parse from each, for every sentence in WSJ$\hat{k}^*$, the base case re-estimates a new model from a *mixture* of twice the normal number of trees; inductive steps leap over $\hat{k}^*$ lengths, conveniently ending at WSJ45, and estimate their initial models by applying a previous solution to a new input set. Both follow up the single step of Viterbi training with at most five iterations of EM.

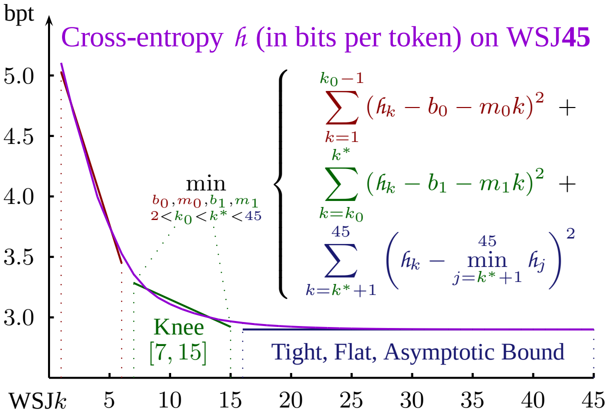

Figure 3: Cross-entropy on WSJ45 after each baby step, a piece-wise linear fit, and an estimated region for the knee.

Our hybrid makes use of two good (conditionally) independent initialization strategies and executes many iterations of EM where that is cheap — at shorter sentences (WSJ15 and below). It then increases the step size, training just three more times (at WSJ$\{15, 30, 45\}$) and allowing only a few (more expensive) iterations of EM. Early termination improves efficiency and regularizes these final models.

5.5 Reference Algorithms — Baselines, a Skyline and Published Art

We carve out the problem space using two extreme initialization strategies: (i) the uninformed uniform prior, which serves as a fair "zero-knowledge" baseline for comparing uninitialized models; and (ii) the maximum-likelihood "oracle" prior, computed from reference parses, which yields a *skyline* (a reverse baseline) — how well any algorithm that stumbled on the true solution would fare at EM's convergence.

In addition to citing Klein and Manning's (2004) results, we compare our accuracies on Section 23 of WSJ$^\infty$ to two state-of-the-art systems and past baselines (see Table 2). Headden et al.'s (2009) lexicalized EVG is the best on short sentences, but

[9] Its 48,418 sentences (see Figure 1) cover 94.4% of all sentences in WSJ; the longest of the missing 790 has length 171.

[10] Instead of iteratively fitting a two-segment form and adaptively discarding its tail, we use *three* line segments, applying ordinary least squares to the first two, but requiring the third to be horizontal and tangent to a minimum. The result is a *batch* optimization routine that returns an *interval* for the knee, rather than a point estimate (see Figure 3 for details).

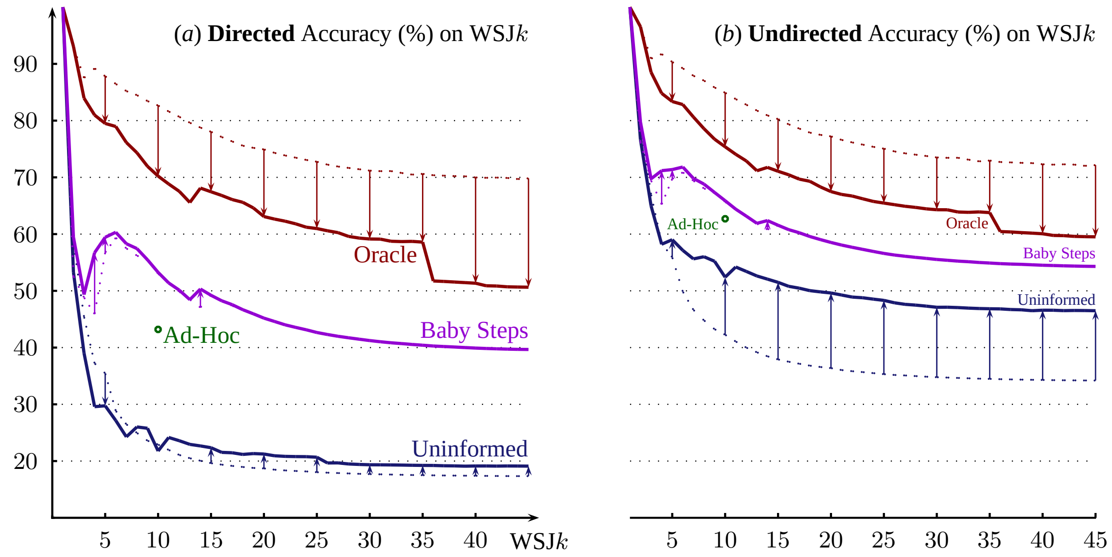

Figure 4: Directed and undirected accuracy scores attained by the DMV, when trained and tested on the same gradation of WSJ, for several different initialization strategies. Green circles mark Klein and Manning's (2004) published scores; red, violet and blue curves represent the supervised (maximum-likelihood oracle) initialization, Baby Steps, and the uninformed uniform prior. Dotted curves reflect starting performance, solid curves register performance at EM's convergence, and the arrows connecting them emphasize the impact of learning.

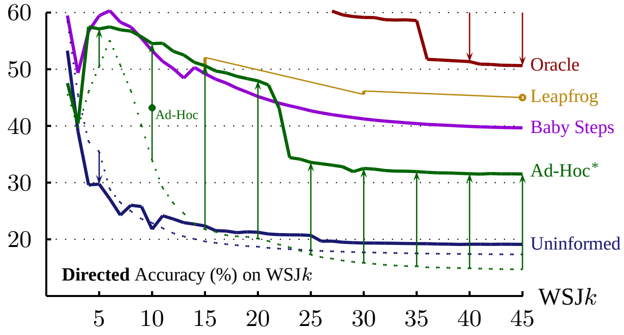

Figure 5: Directed accuracies for Ad-Hoc* (shown in green) and Leapfrog (in gold); all else as in Figure 4(*a*).

its performance is unreported for longer sentences, for which Cohen and Smith's (2009) seem to be the highest published scores; we include their intermediate results that preceded parameter-tying — Bayesian models with Dirichlet and log-normal priors, coupled with both Viterbi and minimum Bayes-risk (MBR) decoding (Cohen et al., 2008).

6 Experimental Results

We packed thousands of empirical outcomes into the space of several graphs (Figures 4, 5 and 6). The colors (also in Tables 1 and 2) correspond to different initialization strategies — to a first approximation, the learning algorithm was held constant (see §5).

Figures 4 and 5 tell one part of our story. As data sets increase in size, training algorithms gain access to more information; however, since in this unsupervised setting training and test sets are the same, additional longer sentences make for substantially more challenging evaluation. To control for these dynamics, we applied Laplace smoothing to all (otherwise unsmoothed) models and re-plotted their performance, holding several test sets fixed, in Figure 6.

We report undirected accuracies parenthetically.

6.1 Result #1: Baby Steps

Figure 4 traces out performance on the training set. Klein and Manning's (2004) published scores appear as dots (Ad-Hoc) at WSJ10: 43.2% (63.7%). Baby Steps achieves 53.0% (65.7%) by WSJ10; trained and tested on WSJ45, it gets 39.7% (54.3%). Uninformed, classic EM learns little about directed dependencies: it improves only slightly, e.g., from 17.3% (34.2%) to 19.1% (46.5%) on WSJ45 (learning some of the structure, as evidenced by its undirected scores), but degrades with shorter sentences, where its initial guessing rate is high. In the case of oracle training, we expected EM to walk away from supervised solutions (Elworthy, 1994; Meri-

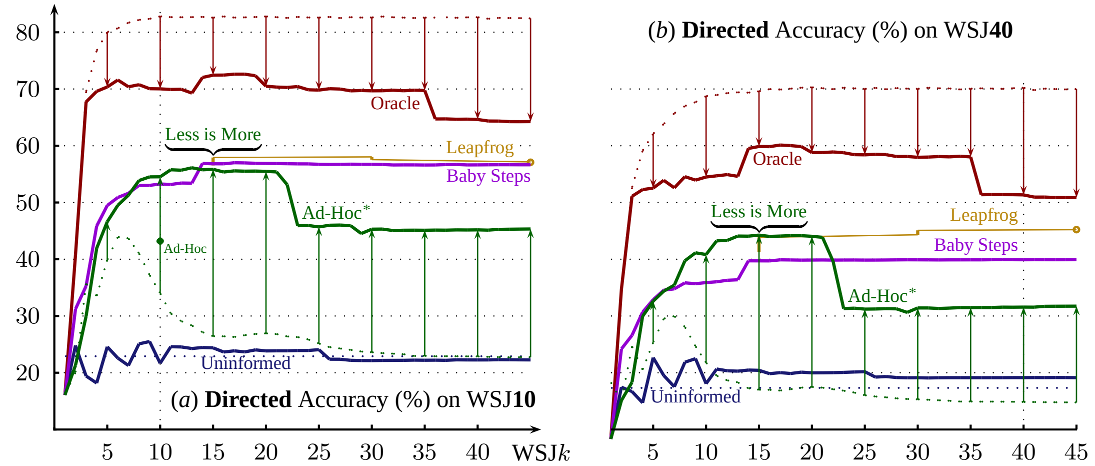

Figure 6: Directed accuracies attained by the DMV, when trained at various gradations of WSJ, smoothed, then tested against fixed evaluation sets — WSJ$\{10, 40\}$; graphs for WSJ$\{20, 30\}$, not shown, are qualitatively similar to WSJ40.

aldo, 1994; Liang and Klein, 2008), but the extent of its drops is alarming, e.g., from the supervised 69.8% (72.2%) to the skyline's 50.6% (59.5%) on WSJ45. In contrast, Baby Steps' scores usually do not change much from one step to the next, and where its impact of learning is big (at WSJ$\{4, 5, 14\}$), it is invariably positive.

6.2 Result #2: Less is More

Ad-Hoc*'s curve (see Figure 5) suggests how Klein and Manning's Ad-Hoc initializer may have scaled with different gradations of WSJ. Strangely, our implementation performs significantly above their reported numbers at WSJ10: 54.5% (68.3%) is even slightly higher than Baby Steps; nevertheless, given enough data (from WSJ22 onwards), Baby Steps overtakes Ad-Hoc*, whose ability to learn takes a serious dive once the inputs become sufficiently complex (at WSJ23), and never recovers. Note that Ad-Hoc*'s biased prior peaks early (at WSJ6), eventually falls below the guessing rate (by WSJ24), yet still remains well-positioned to climb, outperforming uninformed learning.

Figure 6 shows that Baby Steps scales better with more (complex) data — its curves do not trend downwards. However, a good initializer induces a sweet spot at WSJ15, where the DMV is learned best using Ad-Hoc*. This mode *is* "Less is More," scoring 44.1% (58.9%) on WSJ45. Curiously, even oracle training exhibits a bump at WSJ15: once sentences get long enough (at WSJ36), its performance degrades below that of oracle training with virtually no supervision (at the hardly representative WSJ3).

6.3 Result #3: Leapfrog

Mixing Ad-Hoc* with Baby Steps at WSJ15 yields a model whose performance initially falls between its two parents but surpasses both with a little training (see Figure 5). Leaping to WSJ45, via WSJ30, results in our strongest model: its 45.0% (58.4%) accuracy bridges half of the gap between Baby Steps and the skyline, and at a tiny fraction of the cost.

6.4 Result #4: Generalization

Our models carry over to the larger WSJ100, Section 23 of WSJ$^\infty$, and the independent Brown100 (see Table 1). Baby Steps improves out of domain, confirming that shaping generalizes well (Krueger and Dayan, 2009; Bengio et al., 2009). Leapfrog does best across the board but dips on Brown100, despite its safe-guards against over-fitting.

Section 23 (see Table 2) reveals, unexpectedly, that Baby Steps would have been state-of-the-art in 2008, whereas "Less is More" outperforms all prior work on longer sentences. Baby Steps is competitive with log-normal families (Cohen et al., 2008), scoring slightly better on longer sentences against Viterbi decoding, though worse against MBR. "Less is More" beats state-of-the-art on longer sentences by close to 2%; Leapfrog gains another 1%.

7 Conclusion

We explored three simple ideas for unsupervised dependency parsing. Pace Halevy et al. (2009), we find "Less is More" — the paradoxical result that better performance can be attained by training with less data, even when removing samples from the true (test) distribution. Our small tweaks to Klein and Manning's approach of 2004 break through the 2009 state-of-the-art on longer sentences, when trained at WSJ15 (the auto-detected sweet spot gradation).

The second, Baby Steps, is an elegant metaheuristic for optimizing non-convex training criteria. It eliminates the need for linguistically-biased manually-tuned initializers, particularly if the location of the sweet spot is not known. This technique scales gracefully with more (complex) data and should easily carry over to more powerful parsing models and learning algorithms.

Finally, Leapfrog forgoes the elegance and meticulousness of Baby Steps in favor of pragmatism. Employing both good initialization strategies at its disposal, and spending CPU cycles wisely, it achieves better performance than both "Less is More" and Baby Steps.

Future work could explore unifying these techniques with other state-of-the-art approaches. It may be useful to scaffold on both data and model complexity, e.g., by increasing head automata's number of states (Alshawi and Douglas, 2000). We see many opportunities for improvement, considering the poor performance of oracle training relative to the supervised state-of-the-art, and in turn the poor performance of unsupervised state-of-the-art relative to the oracle models.[11] To this end, it would be instructive to understand both the linguistic and statistical nature of the sweet spot, and to test its universality.

Relaxed Marginal Inference and its Application to Dependency Parsing

Sebastian Riedel   David A. Smith
Department of Computer Science

Abstract

Recently, relaxation approaches have been successfully used for MAP inference on NLP problems. In this work we show how to extend the relaxation approach to marginal inference used in conditional likelihood training, posterior decoding, confidence estimation, and other tasks. We evaluate our approach for the case of second-order dependency parsing and observe a tenfold increase in parsing speed, with no loss in accuracy, by performing inference over a small subset of the full factor graph. We also contribute a bound on the error of the marginal probabilities by a sub-graph with respect to the full graph. Finally, while only evaluated with BP in this paper, our approach is general enough to be applied with any marginal inference method in the inner loop.

1 Introduction

In statistical natural language processing (NLP) we are often concerned with finding the marginal probabilities of events in our models or the expectations of features. When training to optimize conditional likelihood, feature expectations are needed to calculate the gradient. Marginalization also allows a statistical NLP component to give confidence values for its predictions or to marginalize out latent variables. Finally, given the marginal probabilities of variables, we can pick the values that maximize these marginal probabilities (perhaps subject to hard constraints) in order to predict a good variable assignment.[1]

Traditionally, marginal inference in NLP has been performed via dynamic programming (DP); however, because this requires the model to factor in a way that lends itself to DP algorithms, we have to restrict the class of probabilistic models we consider. For example, since we cannot derive a dynamic program for marginal inference in second order non-projective dependency parsing (McDonald and Satta, 2007), we have non-projective languages such as Dutch using second order projective models if we want to apply DP. Some previous work has circumvented this problem for MAP inference by starting with a second-order projective solution and then greedily flipping edges to find a better non-projective solution (McDonald and Pereira, 2006).

In order to explore richer model structures, the NLP community has recently started to investigate the use of other, well-known machine learning techniques for marginal inference. One such technique is Markov chain Monte Carlo, and in particular Gibbs sampling (Finkel et al., 2005), another is (loopy) sum-product belief propagation (Smith and Eisner, 2008). In both cases we usually work in the framework of graphical models—in our case, with factor graphs that describe our distributions through variables, factors, and factor potentials. In theory, methods such as belief propagation can take any graph and perform marginal inference. This means that we gain a great amount of flexibility to represent more global and joint distributions for NLP tasks.

The graphical models of interest, however, are often too large and densely connected for efficient inference in them. For example, in second order

[1] With a loss function that decomposes on the variables, this amounts to Minimum Bayes Risk (MBR) decoding, which is often very effective.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 760–768,
Los Angeles, California, June 2010.

dependency parsing models, we have $O(n^2)$ variables and $O(n^3)$ factors, each of which may have to be inspected several times. While belief propagation is still tractable here (assuming we follow the approach of Smith and Eisner (2008) to enforce tree constraints), it is still much slower than simpler greedy parsing methods, and the advantage second order models give in accuracy is often not significant enough to offset the lack of speed in practice. Moreover, if we extend such parsing models to, say, penalizing all pairs of crossing edges or scoring syntax-based alignments, we will need to inspect at least $O\left(n^4\right)$ factors, increasing our efficiency concerns.

When looking at the related task of finding the most likely assignment in large graphical models (i.e., MAP inference), we notice that several recent approaches have significantly sped up computation through *relaxation* methods (Tromble and Eisner, 2006; Riedel and Clarke, 2006). Here we start with a small subset of the full graph, and run inference for this simpler problem. Then we search for factors that are "violated" in the solution, and add them to the graph. This is repeated until no more new factors can be added. Empirically this approach has shown impressive success. It often dramatically reduces the effective network size, with no loss in accuracy.

How can we extend or generalize MAP relaxation algorithms to the case of marginal inference? Roughly speaking, we answer it by introducing a notion of *factor gain* that is defined as the KL divergence between the current distribution with and without the given factor. This quantity is then used in an algorithm that starts with a sub-model, runs marginal inference in it and then determines the gains of the not-yet-added factors. In turn, all factors for which the gain exceeds some threshold are added to the current model. This process is repeated until no more new factors can be found or a maximum number of iterations is reached.

We evaluate this form of *relaxed marginal inference* for the case of second-order dependency parsing. We follow Smith and Eisner's tree-aware belief propagation procedure for inference in the inner loop of our algorithm. This leads to a tenfold increase in parsing speed with no loss in accuracy.

We also contribute a bound on the error on marginal probabilities the sub-graph defines with respect to the full graph. This bound can be used both for terminating (although not done here) and understanding the dynamics of inference. Finally, while only evaluated with BP so far, it is general enough to be applied with any marginal inference method in the inner loop.

In the following, we first give a sketch of the graphical model we apply. Then we briefly discuss marginal inference. In turn we describe our relaxation algorithm for marginal inference and some of its theoretic guarantees. Then we present empirical support for the effectiveness of our approach, and conclude.

2 Graphical Models of Dependency Trees

We give a brief overview of the graphical model we apply in our experiments. We chose the grandparents and siblings model, together with language specific multiroot and projectivity options as taken from Smith and Eisner (2008). All our models are defined over a set of binary variables L_{ij} that indicate a dependency between token i and j of the input sentence W.

2.1 Markov Random Fields

Following Smith and Eisner (2008), we define a probability distribution over all dependency trees as a collection of edges $\mathbf{y}$ for a fixed input sentence W. This distribution is represented by an undirected graphical model, or Markov random field (MRF):

$$p_{\mathcal{F}}(\mathbf{y}) \overset{\text{def}}{=} \frac{1}{Z} \prod_{i \in \mathcal{F}} \Psi_i(\mathbf{y}) \tag{1}$$

specified by an index set $\mathcal{F}$ and a corresponding family $(\Psi_i)_{\mathcal{F}}$ of **factors** $\Psi_i : \mathcal{Y} \mapsto \Re^+$. Here Z is the partition function $Z_{\mathcal{F}} = \sum_{\mathbf{y}} \prod_i \Psi_i(\mathbf{y})$.

We will restrict our attention to binary factors that can be represented as $\Psi_i(\mathbf{y}) = e^{\theta_i \phi_i(\mathbf{y})}$ with binary functions $\phi_i(\mathbf{y}) \in \{0,1\}$ and weights $\theta_i \in \Re$.[2] This

[2] These ϕ_i are also called *sufficient statistics* or *feature functions*, not to be confused with the features whose weighted sum forms the weight θ_i. The restriction to binary functions is without loss of generality since we can combine constraints on particular variable assignments into potential tables with several dimensions.

leads to

$$p_{\mathcal{F}}(\mathbf{y}) \overset{\text{def}}{=} \frac{1}{Z} \exp\left(\sum_{i \in \mathcal{F}} \theta_i \phi_i(\mathbf{y})\right)$$

as an alternative representation for $p_{\mathcal{F}}$. Note that when $\phi_i(\mathbf{y}) = 1$ we will say that Ψ_i **fires** for $\mathbf{y}$.

Note that a factor function $\Psi_i(\mathbf{y})$ can depend on any part of the observed input sentence W; however, for brevity we will suppress this extra argument to Ψ_i.

2.2 Hard and Soft Constraints on Trees

A particular model specifies its preference for set of dependency edges over another by a set of hard and soft constraints. We use hard constraints to rule out *a priori* illegal structures, such as trees where a word has two parents, and soft constraints to raise or lower the score of trees that contain particular good or bad substructures.

A **hard** factor (or constraint) Ψ_i evaluates an assignment $\mathbf{y}$ with respect to some specified condition and fires only if this condition is *violated*; in this case it evaluates to 0. It is therefore ruling out all configurations in which the condition does not hold. Note that a hard constraint Ψ_i corresponds to $\theta_i = -\infty$ in our loglinear representation.

For dependency parsing, we consider two particular hard constraints, each of which touches all edge variables in $\mathbf{y}$: the constraint **Tree** requires that all edges form a directed spanning tree rooted at the root node 0; the constraint **PTree** enforces the more stringent condition that all edges form a *projective* directed tree. As in (Smith and Eisner, 2008), we used algorithms from edge-factored parsing to compute BP messages for these factors. In our experiments, we enforced one or the other constraint depending on the projectivity of given treebank data.

A **soft** factor Ψ_i acts as a soft constraint that prefers some assignments to others. This is equivalent to saying that its weight θ_i is finite. Note that the weight of a soft factor is usually itself composed as a sum of (sub-)weights w_j for feature functions that have the same input-output behavior as $\phi_i(\mathbf{y})$ when conditioned on the current sentence. It is these w_j which are adjusted at training time.

We use three kinds of soft factors from Smith and Eisner (2008). In the full model, there are: $O(n^2)$ $\text{LINK}_{i,j}$ factors that judge dependency edges in isolation; $O(n^3)$ $\text{GRAND}_{i,j,k}$ factors that judge pairs of dependency edges in a grandparent-parent-child chain; and $O(n^3)$ $\text{SIB}_{i,j,k}$ factors that judge pairs of dependency edges that share the same parent.

3 Marginal Inference

Formally, given our set of factors $\mathcal{F}$ and an observed sentence W, marginal inference amounts to calculating the probability $\mu_i^{\mathcal{F}}$ that our binary features ϕ_i are active. That is, for each factor Ψ_i

$$\mu_i^{\mathcal{F}} \overset{\text{def}}{=} \sum_{\phi_i(\mathbf{y})=1} p_{\mathcal{F}}(\mathbf{y}) = E_{\mathcal{F}}[\phi_i] \qquad (2)$$

For compactness, we follow the convention of Wainwright and Jordan (2008) and represent the belief for a variable using the marginal probability of its corresponding unary factor. Hence, if we want to calculate $p_{\mathcal{F}}(L_{ij})$ we use $\mu_{\text{LINK}_{ij}}^{\mathcal{F}}$ in place. Moreover we will use $\mu_{\neg i}^{\mathcal{F}} \overset{\text{def}}{=} 1 - \mu_i^{\mathcal{F}}$ when we need the probability of the event $\phi_i(\mathbf{y}) = 0$.

The two most prominent approaches to marginal inference in general graphical models are Markov Chain Monte Carlo (MCMC) and variational methods. In a nutshell, MCMC iteratively generates a Markov chain that yields $p_{\mathcal{F}}$ as its stationary distribution. Any expectation $\mu_i^{\mathcal{F}}$ can then be calculated simply by counting the corresponding statistics in the generated chain.

Generally speaking, variational methods frame marginal inference as an optimization problem. Either in the sense of minimizing the KL divergence of a much simpler distribution to the actual distribution $p_{\mathcal{F}}$, as in mean field methods. Or in the sense of maximizing a variational representation of the log-partition function over the set $\mathcal{M}$ of *valid* mean vectors (Wainwright and Jordan, 2008). Note that the variational representation of the log partition function involves an entropy term that is intractable to calculate in general and therefore usually approximated. Likewise, the set of constraints that guarantee vectors μ to be valid mean vectors is intractably large and is often simplified.

Because we use belief propagation (BP) as baseline to compare to, and as a subroutine in our proposed algorithm, a brief characterization of it is in order. BP can be seen as a variational method that uses the Bethe Free Energy as approximation to the entropy, and the set $\mathcal{M}_L$ of locally consistent mean vectors as an outer bound on $\mathcal{M}$. A mean vector is locally consistent if its beliefs on factors are consistent with the beliefs of the factor neighbors.

BP solves the variational problem by iteratively updating the beliefs of factors and variables based on the current beliefs of their neighbors. When applied to acyclic graphical models BP yields the exact marginals at convergence. For general graphs, BP is not guaranteed to converge, and the beliefs it calculates are generally not the true marginals; however, in practice BP often does converge and lead to accurate marginals.

4 Relaxed Incremental Marginal Inference

Generally the runtime and accuracy of a marginal inference method depends on size, density, tree-width and interaction strength (i.e. the magnitude of its weights) of the Graphical Model. For example, in Belief Propagation the number of messages we have to send in each iteration scales with the number of factors (and their degrees). This means that when we add a large number of extra factors to our model, such as the $O(n^3)$ grandparent and sibling factors for dependency parsing, we have to pay a price in terms of speed, sometimes even accuracy.

However, on close inspection often many of the additional factors we use to model some higher order interactions are somewhat unnecessary or *redundant*. To illustrate this, let us look at a second order parsing model with grandparent factors. Surely determiners are not heads of other determiners, and this should be easy to encourage using LINK features only. Hence, a grandparent factor that discourages a determiner-determiner-determiner chain seems unnecessary.

This raises two questions: (a) can we get away without most of these factors, and (b) can we efficiently tell which factors should be discarded. We will see in section 5 that question (a) can be answered affirmatively: with a only fraction of all second order factors we can calculate marginals that are very close to the BP marginals, and when used in MBR decoding, lead to the same trees.

Question (b) can be approached by looking at how a similar problem has been tackled in combinatorial optimization and MAP inference. Riedel and Clarke (2006) tackled the MAP problem for dependency parsing by an incremental approach that starts with a relaxation of the problem, solves it, and adds additional constraints only if they are violated. If constraints were added, the process is repeated, otherwise we terminate.

4.1 Evaluating Candidate Factors

To develop such an incremental relaxation approach to marginal inference, we generalize the notion of a violated constraint. What does it mean for a factor to be violated with respect to the solution of a marginal inference problem?

One answer is to interpret the violation of a constraint as "adding this constraint will impact our current belief". To assess the impact of adding factor Ψ_i to a sub-graph $\mathcal{F}' \subseteq \mathcal{F}$ we can then use the following intuition: if the distribution $\mathcal{F}' \cup \{i\}$ is very similar to the distribution corresponding to $\mathcal{F}'$, it is probably safe to say that the marginals we get from both are close, too. If we use the KL divergence between the (distributions of) $\mathcal{F}' \cup \{i\}$ and $\mathcal{F}'$ for our interpretation of the above mentioned closeness, we can define a potential *gain* for adding Ψ_i as follows:

$$g_{\mathcal{F}'}(\Psi_i) \overset{\text{def}}{=} D_{KL}\left(p_{\mathcal{F}'} || p_{\mathcal{F}' \cup \{i\}}\right).$$

Together with a threshold ϵ on this gain we can now adapt the relaxation approach to marginal inference by simply replacing the question, "Is Ψ_i violated?" with the question, "Is $g_{\mathcal{F}'}(i) > \epsilon$?" We can see the latter question as a generalization of the former if we interpret MAP inference as the zero-temperature limit of marginal inference (Wainwright and Jordan, 2008).

The form of the gain function is chosen to be easily evaluated using the beliefs we have already available for the current sub-graph $\mathcal{F}'$. It is easy to show (see Appendix) that the following holds:

Proposition 1. *The gain of a factor Ψ_i with respect to the sub-graph $\mathcal{F}' \subseteq \mathcal{F}$ is*

$$g_{\mathcal{F}'}(\Psi_i) = \log\left(\mu_{\neg i}^{\mathcal{F}'} + \mu_i^{\mathcal{F}'} e^{\theta_i}\right) - \mu_i^{\mathcal{F}'} \theta_i \qquad (3)$$

That is, the gain of a factor Ψ_i depends on two properties of Ψ_i. First, the expectation $\mu_i^{\mathcal{F}'}$ that Ψ_i fires under the current model $\mathcal{F}'$, and second, its loglinear weight θ_i. To get an intuition for this gain, consider the limit $\lim_{\mu_i^{\mathcal{F}'}\to 1} g_{\mathcal{F}'}(\Psi_i)$ of a factor with positive weight that is expected to be active under $\mathcal{F}'$. In this case the gain becomes zero, meaning that the more likely Ψ_i fires under the current model, the less useful will it be to add according to our gain. For $\lim_{\mu_i^{\mathcal{F}'}\to 0} g_{\mathcal{F}'}(\Psi_i)$ the gain also disappears. Here the confidence of the current model in ϕ_i being inactive is so high that any single factor which indicates the opposite cannot make a difference.

Fortunately, the marginal probability $\mu_i^{\mathcal{F}'}$ is usually available after inference, or can be approximated. This allows us to maintain the same basic algorithm as in the MAP case: in each "inspection step" we can use the results of the last run of inference in order to evaluate whether a factor has to be added or not.

4.2 Algorithm

Algorithm 1 shows our proposed algorithm, *Relaxed Marginal Inference*. We are given an initial factor graph (for example, the first order dependency parsing model), a threshold ϵ on the minimal gain a factor needs to have in order to be added, and a solver S for marginal inference in the partial graphs we generate along the way.

We start by finding the marginals μ for the initial graph. These marginals are then used in step 4 to find the factors that would, when added in isolation, change the distribution substantially (i.e., by more than ϵ in terms of KL divergence). We will refer to this step as *separation*, in line with cutting plane terminology. The factors are added to the current graph, and we start from the top unless there were no new factors added. In this case we return the last marginals μ.

Clearly, this algorithm is guaranteed to converge: either we add at least one factor per iteration until we reach the full graph $\mathcal{F}$, or we converge before. However, it is difficult to make any general statements about the number of iterations it takes until convergence. Nevertheless, in our experiments we find that algorithm 1 converges to a much smaller graph after a small number of iterations, and hence we are always faster than inference on the full graph.

Finally, note that calculating the gain for all factors in $\mathcal{F} \setminus \mathcal{F}'$ in step 4 (separation) takes time proportional to $|\mathcal{F} \setminus \mathcal{F}'|$.

Algorithm 1 Relaxed Marginal Inference.

```
1: require:
       $\mathcal{F}'$:init. graph, $\epsilon$: threshold, $S$:solver, $R$: max. it
2: repeat
       Find current marginals using solver S
3:     $\mu \leftarrow$ marginals$(\mathcal{F}', S)$
       Find factors with high gain not yet added
4:     $\Delta\mathcal{F} \leftarrow \{i \in \mathcal{F} \setminus \mathcal{F}' | g_{\mathcal{F}'}(\Psi_i) > \epsilon\}$
       Add factors to current graph
5:     $\mathcal{F}' \leftarrow \mathcal{F}' \cup \Delta\mathcal{F}$
     Check: no more new factors were added or R reached
6: until $\Delta\mathcal{F} = \emptyset$ or iteration$>R$
     return the marginals for the last graph $\mathcal{F}'$
7: return $\mu$
```

4.3 Accuracy

We have seen how to evaluate the potential gain when adding a single factor. However, this does not tell us how good the current sub-model is with respect to the complete graph. After all, while all remaining factors individually might not contribute much, in concert they may. We therefore present a (calculable) bound on the KL divergence of the partial graph from the full graph that can give us confidence in the solutions we return at convergence.

Note that for this bound we still only need feature expectations from the current model. Moreover, we assume all weights θ_i are positive—without loss of generality since we can always replace ϕ_i with its negation $1 - \phi_i$ and then change the sign of θ_i (Richardson and Domingos, 2006).

Proposition 2. *Assume non-negative weights, let $\mathcal{F}' \subseteq \mathcal{F}$ be a subset of factors, $G \overset{def}{=} \mathcal{F} \setminus \mathcal{F}'$ and $\eta \overset{def}{=} \|\theta_G\|_1 - \langle \mu_G, \theta_G \rangle \geq 0$. Then*

1. *for the KL divergence between $\mathcal{F}'$ and the full network $\mathcal{F}$ we have:*

$$D_{KL}\left(p_{\mathcal{F}'} || p_{\mathcal{F}}\right) \leq \eta.$$

2. *for the error we make when estimating ϕ_i's true expectation $\mu_i^{\mathcal{F}}$ by $\mu_i^{\mathcal{F}'}$ we have:*

$$-\left(e^{\eta} - 1\right)\mu_{\neg i}^{\mathcal{F}'} \leq \mu_i^{\mathcal{F}} - \mu_i^{\mathcal{F}'} \leq \left(e^{\eta} - 1\right)\mu_i^{\mathcal{F}'}.$$

This says that (1) we get closer to the full distribution and that (2) our marginals closer to the true marginals, if the remaining factors G either have a low total weight $\|\theta_G\|$, or the current belief μ_G already assigns high probability to the features ϕ_G being active (and hence $-\langle\mu_G, \theta_G\rangle$ is small). The latter condition is the probabilistic analog to constraints already being satisfied. Finally, since η can be easily calculated, we plan to investigate its utility as a convergence criterion in future work.

4.4 Related Work

Our approach is inspired by earlier work on relaxation algorithms for performing MAP inference by incrementally tightening relaxations of a graphical model (Anguelov et al., 2004; Riedel, 2008), weighted Finite State Machine (Tromble and Eisner, 2006), Integer Linear Program (Riedel and Clarke, 2006) or Marginal Polytope (Sontag et al., 2008). However, none of these methods apply to marginal inference.

Sontag and Jaakkola (2007) compute marginal probabilities by using a cutting plane approach that starts with the local polytope and then optimizes some approximation of the log partition function. Cycle consistency constraints are added if they are violated by the current marginals, and the process is repeated until no more violations appear. While this approach does tackle marginalization, it is focused on improving its accuracy. In particular, the optimization problems they solve in each iteration are in fact larger than the problem we want to relax.

Our approach is also related to edge deletion in Bayesian networks (Choi and Darwiche, 2006). Here edges are removed from a Bayesian network in order to find a close approximation to the full network useful for other inference-related tasks (such as combined marginal and MAP inference). The core difference to our approach is the fact that they ask which edges to *remove* from the full graph, instead of which to *add* to a partial graph. This requires inference in the full model—the very operation we want to avoid.

5 Experiments

In our experiments we seek to answer the following questions. First, how fast is our relaxation approach compared to full marginal inference at comparable dependency accuracy? This requires us to find the best tree in terms of marginal probabilities on the link variables (Smith and Eisner, 2008). Second, how good is the final relaxed graph as an approximation of the full graph? Finally, how does incremental relaxation scale with sentence length?

5.1 Data and Models

We trained and tested on a subset of languages from the CoNLL Dependency Parsing Shared Tasks (Nivre et al., 2007): Dutch, Danish, Italian, and English. We apply non-projective second order models for Dutch, Danish and Italian, and a projective second order model for English. To be able to compare inference on the same model, we trained using BP on the full set of LINK, GRAND, and SIB factors.

Note that our models would rank highly among the shared task submissions, but could surely be further improved. For example, we do not use any language specific features. Since our focus in this paper is speeding up marginal inference, we will search for better models in future work.

5.2 Runtime and Dependency Accuracy

In our first set of experiments we explore the speed and accuracy of relaxed BP in comparison to full BP. To this end we first tested BP configurations with at most 5, at most 10, and at most 50 iterations to find the best setup in terms of speed and accuracy. Smith and Eisner (2008) use 5 iterations but we found that by using 10 iterations accuracy could be slightly improved. Running at most 50 iterations led to the same accuracy but was significantly slower. Hence we only report BP results with 10 iterations here.

For relaxed BP we tested along three dimensions: the threshold ϵ on the gain of factors, the maximum number of BP iterations in the inner loop of relaxed BP, and the maximum number of relaxation iterations. A configuration with maximum relaxation iterations R, threshold ϵ, and maximum BP iterations B will be identified by $\text{Rel}_{R,\epsilon,B}$. In all settings we use the LINK factors and the hard factors as initial graph $\mathcal{F}'$.

Table 1 shows the results for several configurations and our four languages in terms of unlabeled dependency accuracy (percentage of correctly iden-

	Dutch		Danish		English		Italian	
Configuration	Acc.	Time	Acc.	Time	Acc.	Time	Acc.	Time
BP	84.9	0.665	88.1	1.44	88.3	2.43	87.4	1.68
$\text{Rel}_{\infty,0.0001,5}$	85.0	0.120	88.1	0.234	88.2	0.575	87.4	0.261
$\text{Rel}_{\infty,0.0001,50}$	84.9	0.121	88.2	0.236	88.3	0.728	87.4	0.266
$\text{Rel}_{1,0.0001,50}$	84.9	0.060	88.2	0.110	88.4	0.352	87.4	0.132

Table 1: Dependency accuracy (%) and average parsing time (sec.) using second order models.

tified heads) in comparison to the gold data, and average parsing time in seconds. Here parsing time includes both time spent for marginal inference and the MBR decoding step after the marginals are available.

We notice that by relaxing BP with no limit on the number of iterations we gain a 4-6 fold increase in parsing speed across all languages when using the threshold $\epsilon = 0.0001$, while accuracy remains as high as for full BP. This can be achieved with fewer BP iterations (at most 5) in each round of relaxation than full BP needs per sentence (at most 10). Intuitively this makes sense: since our factor graphs are smaller in each iteration there will be fewer cycles to slow down convergence. This only has a small impact on overall parsing time for languages other than English, since for most sentences even full BP converges after less than 10 iterations.

We also observe that running just one iteration of our relaxation algorithm ($\text{Rel}_{1,0.0001,50}$) is enough to achieve accurate solutions. This leads to a twofold speed-up in comparison to running relaxation until convergence (primarily because of fewer calls to the separation routine), and a 7-13 fold speed-up (tenfold on average) when compared to full BP.

5.3 Quality of Relaxed Subgraphs

How large is the fraction of the full graph needed for accurate marginal probabilities? And do we really need our relaxation algorithm with repeated inference or could we instead just prune the graph in advance? Here we try to answer these questions, and will focus on the Danish dataset. Note that our results for the other languages follow the same pattern.

In table 2, we present the average ratio of the sizes of the partial and the full graph in terms of the second order factors. We also show the total runtime needed to find the subgraph and run inference in it.

Configuration	Size	Time	Err.	Acc.
BP	100%	1.44	—	88.1
$\text{Rel}_{\infty,0.1,50}$	$\approx 0\%$	0.12	0.20	87.5
$\text{Rel}_{\infty,0.0001,50}$	0.8%	0.24	0.012	88.2
$\text{Rel}_{1,0.0001,50}$	0.8%	0.11	0.015	88.2
$\text{Pruned}_{0.1}$	42%	0.56	0.022	88.0
$\text{Pruned}_{0.5}$	22%	0.40	0.098	87.7

Table 2: Ratio of partial and full graph size (Size), runtime in seconds (Time), avg. error on marginals (Err.) and tree accuracy (Acc.) for Danish.

As a measure of accuracy for marginal probabilities we find the average error in marginal probability for the variables of a sentence. Note that this measure does not necessarily correspond to the true error of our marginals because BP itself is approximate and may not return the correct marginals.

The first row shows the full BP system, working on 100% of the factor graph. The next three rows look at relaxed marginal inference. We notice that with a low threshold $\epsilon = 0.1$ we pick almost no additional factors (0.003%), and this does affect accuracy. However, by lowering the threshold to 0.0001 and adding about 0.8% of the second order factors, we already match the dependency accuracy of full BP. On average we are also very close to the BP marginals.

Can we find such small graphs without running extra iterations of inference? One approach could be to simply cut off factors Ψ_i with absolute weights $|\theta_i|$ that fall under a certain threshold t. In the final rows of the table we test such an approach with $t = 0.1, 0.5$.

We notice that pruning can reduce the second order factors to 42% while yielding (almost) the same accuracy, and close marginals. However, it is 5 times slower than our fastest approach. When reducing

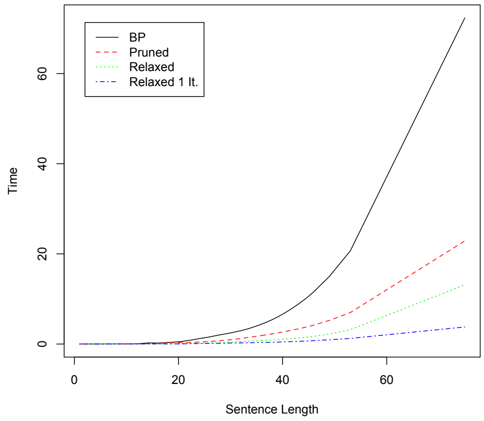

Figure 1: Total runtimes by sentence length.

size further to about 20%, accuracy drops below the values we achieved with our relaxation approach at 0.8% of the second order factors. Hence simple pruning removes factors that do have a low weight, but are still important to keep.

5.4 Runtime with Varying Sentence Length

We have seen how relaxed BP is faster than full BP on average. But how does its speed scale with sentence length? To answer this question figure 1 shows a plot of runtime by sentence length for full BP, pruned BP with threshold 0.1, $\mathrm{Rel}_{\infty,0.0001,50}$ and $\mathrm{Rel}_{1,0.0001,50}$.

The graph indicates that the advantage of relaxed BP over both full BP and Pruned BP becomes even more significant for longer sentences, in particular when running only one iteration. This shows that by using our technique, second order parsing becomes more practical, in particular for very long sentences.

6 Conclusion

We have presented a novel incremental relaxation algorithm that can be applied to marginal inference. Instead of adding violated constraints in each iteration, it adds factors that significantly change the distribution of the graph. This notion is formalized by the introduction of a gain function that calculates the KL divergence between the current network with and without the candidate factor. We show how this gain can be calculated and provide bounds on the error made by the marginals of the relaxed graph in place of the full one.

Our algorithm led to a tenfold reduction in runtime at comparable accuracy when applied to multilingual dependency parsing with Belief Propagation. It is five times faster than pruning factors by their absolute weight, and results in smaller graphs with better marginals.

In future work we plan to apply relaxed marginal inference to larger joint inference problems within NLP, and test its effectiveness with other marginal inference algorithms as solvers in the inner loop.

Appendix: Proof Sketches

For Proposition 1 we use the primal form of the KL divergence (Wainwright and Jordan, 2008)

$$D\left(p'_{\mathcal{F}} \| p_{\mathcal{F}}\right) = \log\left(Z_{\mathcal{F}} Z_{\mathcal{F}'}^{-1}\right) - \langle \mu_{F'}, \theta_{\mathcal{F}} - \theta_{\mathcal{F}'} \rangle$$

and represent the ratio $Z_{\mathcal{F}} Z_{\mathcal{F}'}^{-1}$ of partition functions as

$$\frac{Z_{\mathcal{F}}}{Z_{\mathcal{F}'}} = \sum_{\mathbf{y}} \frac{e^{\left\langle \theta_{\mathcal{F}'}, \phi_{\mathcal{F}'}(\mathbf{y}) \right\rangle}}{Z_{\mathcal{F}'}} e^{\langle \theta_G, \phi_G(\mathbf{y}) \rangle} = E_{\mathcal{F}'}\left[e^{\langle \theta_G, \phi_G \rangle}\right]$$

where $G \overset{\text{def}}{=} \mathcal{F} \setminus \mathcal{F}'$. With $G = \{i\}$ we get the desired gain.

For Proposition 2, part 1, we first pick a simple upper bound on $Z_{\mathcal{F}} Z_{\mathcal{F}'}^{-1}$ by replacing the expectation with $e^{\|\theta_G\|_1}$. Inserting this into the primal form KL divergence leads to the given bound. For part 2 we represent $p_{\mathcal{F}}$ using $p_{\mathcal{F}'}$

$$p_{\mathcal{F}}(\mathbf{y}) = Z_{\mathcal{F}'} Z_{\mathcal{F}}^{-1} e^{\langle \theta_G, \phi_G(\mathbf{y}) \rangle} p_{\mathcal{F}'}(\mathbf{y})$$

and reuse our above representation of $Z_{\mathcal{F}} Z_{\mathcal{F}'}^{-1}$. This gives

$$p_{\mathcal{F}}(\mathbf{y}) = E_{\mathcal{F}'}\left[e^{\langle \theta_G, \phi_G(\mathbf{y}) \rangle}\right]^{-1} p_{\mathcal{F}'}(\mathbf{y})\, e^{\langle \theta_G, \phi_G(\mathbf{y}) \rangle}$$

which can be upper bounded by lower bounding the expectation and upper bounding the log-linear term. For the latter we use $e^{\|\theta_G\|_1}$, for the first Jensen's inequality gives

$$E_{\mathcal{F}'}\left[e^{\langle \theta_G, \phi_G(\mathbf{y}) \rangle}\right]^{-1} \geq e^{E_{\mathcal{F}'}[\langle \theta_G, \phi_G(\mathbf{y}) \rangle]} = e^{\left\langle \theta_G, \mu_G^{\mathcal{F}'} \right\rangle}$$

where the equality follows from linearity of expectations. This yields $p_{\mathcal{F}}(\mathbf{y}) \leq p_{\mathcal{F}'}(\mathbf{y})\, e^{\eta}$ and therefore upper bounds on $\mu_i^{\mathcal{F}}$ and $\mu_{\neg i}^{\mathcal{F}}$. Basic algebra then gives the desired error interval for $\mu_i^{\mathcal{F}}$ in terms of $\mu_i^{\mathcal{F}'}$.

Optimal Parsing Strategies for Linear Context-Free Rewriting Systems

Daniel Gildea

University of Rochester
Rochester, NY 14627

Abstract

Factorization is the operation of transforming a production in a Linear Context-Free Rewriting System (LCFRS) into two simpler productions by factoring out a subset of the nonterminals on the production's righthand side. Factorization lowers the rank of a production but may increase its fan-out. We show how to apply factorization in order to minimize the *parsing complexity* of the resulting grammar, and study the relationship between rank, fan-out, and parsing complexity. We show that it is always possible to obtain optimum parsing complexity with rank two. However, among transformed grammars of rank two, minimum parsing complexity is not always possible with minimum fan-out. Applying our factorization algorithm to LCFRS rules extracted from dependency treebanks allows us to find the most efficient parsing strategy for the syntactic phenomena found in non-projective trees.

1 Introduction

Gómez-Rodríguez et al. (2009a) recently examined the problem of transforming arbitrary grammars in the Linear Context-Free Rewriting System (LCFRS) formalism (Vijay-Shankar et al., 1987) in order to reduce the rank of a grammar to 2 while minimizing its fan-out. The work was motivated by the desire to develop efficient chart-parsing algorithms for non-projective dependency trees (Kuhlmann and Nivre, 2006) that do not rely on the independence assumptions of spanning tree algorithms (McDonald et al., 2005). Efficient parsing algorithms for general LCFRS are also relevant in the context of Synchronous Context-Free Grammars (SCFGs) as a formalism for machine translation, as well as the desire to handle even more general synchronous grammar formalisms which allow nonterminals to cover discontinuous spans in either language (Melamed et al., 2004; Wellington et al., 2006). LCFRS provides a very general formalism which subsumes SCFGs, the Multitext Grammars of Melamed et al. (2004), as well as mildly context-sensitive monolingual formalisms such as Tree Adjoining Grammar (Joshi and Schabes, 1997). Thus, work on transforming general LCFRS grammars promises to be widely applicable in both understanding how these formalisms interrelate, and, from a more practical viewpoint, deriving efficient parsing algorithms for them.

In this paper, we focus on the problem of transforming an LCFRS grammar into an equivalent grammar for which straightforward application of dynamic programming to each rule yields a tabular parsing algorithm with minimum complexity. This is closely related, but not equivalent, to the problem considered by Gómez-Rodríguez et al. (2009a), who minimize the fan-out, rather than the parsing complexity, of the resulting grammar. In Section 4, we show that restricting our attention to factorized grammars with rank no greater than 2 comes at no cost in parsing complexity. This result may be surprising, as Gómez-Rodríguez et al. (2009a) comment that "there may be cases in which one has to find an optimal trade-off between rank and fan-out" in order to minimize parsing complexity – in fact, no such trade-off is necessary, as rank 2 is always sufficient for optimal parsing complexity. Given this fact, we show how to adapt the factorization algorithm of Gómez-Rodríguez et al. (2009a) to return a transformed grammar with minimal parsing complexity and rank 2. In Section 5, we give a

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 769–776,
Los Angeles, California, June 2010.

counterexample to the conjecture that minimal parsing complexity is possible among binarizations with minimal fan-out.

2 Background

A linear context-free rewriting system (LCFRS) is defined as a tuple $G = (V_N, V_T, P, S)$, where V_T is a set of terminal symbols, V_N is a set of nonterminal symbols, P is a set of productions, and $S \in V_N$ is a distinguished start symbol. Associated with each nonterminal B is a **fan-out** $\varphi(B)$, which tell how many discontinuous spans B covers. Productions $p \in P$ take the form:

$$p : A \rightarrow g(B_1, B_2, \ldots, B_r) \qquad (1)$$

where $A, B_1, \ldots B_r \in V_N$, and g is a function

$$g : (V_T^*)^{\varphi(B_1)} \times \ldots \times (V_T^*)^{\varphi(B_r)} \rightarrow (V_T^*)^{\varphi(A)}$$

which specifies how to assemble the $\sum_{i=1}^{r} \varphi(B_i)$ spans of the righthand side nonterminals into the $\varphi(A)$ spans of the lefthand side nonterminal. The function g must be **linear, non-erasing**, which means that if we write

$$g(\langle x_{1,1}, \ldots, x_{1,\varphi(B_1)}\rangle, \ldots, \langle x_{1,1}, \ldots, x_{1,\varphi(B_r)}\rangle) \\ = \langle t_1, \ldots, t_{\varphi(A)}\rangle$$

the tuple of strings $\langle t_1, \ldots, t_{\varphi(A)}\rangle$ on the righthand side contains each variable $x_{i,j}$ from the lefthand side exactly once, and may also contain terminals from V_T.

We call r, the number of nonterminals on the righthand side of a production p, the **rank** of p, $\rho(p)$. The fan-out of a production, $\varphi(p)$ is the fan-out of its lefthand side, $\varphi(A)$. The rank of a grammar is the maximum rank of its rules,

$$\rho(G) = \max_{p \in P} \rho(p)$$

and similarly the fan-out of a grammar is the maximum fan-out of its rules, or equivalently, of its nonterminals:

$$\varphi(G) = \max_{B \in V_N} \varphi(B)$$

3 Parsing LCFRS

A bottom-up dynamic programming parser can be produced from an LCFRS grammar by generalizing the CYK algorithm for context-free grammars. We convert each production of the LCFRS into a deduction rule with variables for the left and right endpoints of each of the $\varphi(B_i)$ spans of each of the nonterminals $B_i, i \in [r]$ in the righthand side of the production.

The computational complexity of the resulting parser is polynomial in the length of the input string, with the degree of the polynomial being the number of distinct endpoints in the most complex production. Thus, for input of length n, the complexity is $O(n^c)$ for some constant c which depends on the grammar.

For a given rule, each of the r nonterminals has $\varphi(B_i)$ spans, and each span has a left and right endpoint, giving an upper bound of $c \leq 2 \sum_{i=1}^{r} \varphi(B_i)$. However, some of these endpoints may be shared between nonterminals on the righthand side. The exact number of distinct variables for the dynamic programming deduction rule can the written

$$c(p) = \varphi(A) + \sum_{i=1}^{r} \varphi(B_i) \qquad (2)$$

where $c(p)$ is the **parsing complexity** of a production p of the form of eq. 1 (Seki et al., 1991). To see this, consider counting the left endpoint of each span on the lefthand side of the production, and the right endpoint of each span on the righthand side of the production. Any variable corresponding to the left endpoint of a span of a righthand side nonterminal will either be shared with the right endpoint of another span if two spans are being joined by the production, or, alternatively, will form the left endpoint of a span of A. Thus, each distinct endpoint in the production is counted exactly once by eq. 2.

The parsing complexity of a grammar, $c(G)$, is the maximum parsing complexity of its rules. From eq. 2, we see that $c(G) \leq (\rho(G) + 1)\varphi(G)$. While we focus on the time complexity of parsing, it is interesting to note the space complexity of the DP algorithm is $O(n^{2\varphi(G)})$, since the DP table for each nonterminal is indexed by at most $2\varphi(G)$ positions in the input string.

4 Binarization Minimizes Parsing Complexity

An LCFRS production of rank r can be **factorized** into two productions of the form:

$$\begin{aligned} p_1 &: A \rightarrow g_1(B_1, \ldots, B_{r-2}, X) \\ p_2 &: X \rightarrow g_2(B_{r-1}, B_r) \end{aligned}$$

This operation results in new productions that have lower rank, but possibly higher fan-out, than the original production.

If we examine the DP deduction rules corresponding to the original production p, and the first new production p_1 we find that

$$c(p_1) \leq c(p)$$

regardless of the function g of the original production, or the fan-out of the production's nonterminals. This is because

$$\varphi(X) \leq \varphi(B_{r-1}) + \varphi(B_r)$$

that is, our newly created nonterminal X may join spans from B_{r-1} and B_r, but can never introduce new spans. Thus,

$$\begin{aligned} c(p_1) &= \varphi(A) + \left(\sum_{i=1}^{r-2} \varphi(B_i) \right) + \varphi(X) \\ &\leq \varphi(A) + \sum_{i=1}^{r} \varphi(B_i) \\ &= c(p) \end{aligned}$$

As similar result holds for the second newly created production:

$$c(p_2) \leq c(p)$$

In this case, the fan-out of the newly created nonterminal, $\varphi(X)$ may be greater than $\varphi(A)$. Let us consider the left endpoints of the spans of X. Each left endpoint is either also the left endpoint of a span of A, or is the right endpoint of some nonterminal not included in X, that is, one of $B_1, \ldots B_{r-2}$. Thus,

$$\varphi(X) \leq \varphi(A) + \sum_{i=1}^{r-2} \varphi(B_i)$$

and applying this inequality to the definition of $c(p_2)$ we have:

$$\begin{aligned} c(p_2) &= \varphi(X) + \varphi(B_{r-1}) + \varphi(B_{r-2}) \\ &\leq \varphi(A) + \sum_{i=1}^{r} \varphi(B_i) \\ &= c(p) \end{aligned}$$

For notational convenience, we have defined the factorization operation as factoring out the last two nonterminals of a rule; however, the same operation can be applied to factor out any subset of the original nonterminals. The same argument that parsing complexity cannot increase still applies.

We may apply the factorization operation repeatedly until all rules have rank 2; we refer to the resulting grammar as a **binarization** of the original LCFRS. The factorization operation may increase the fan-out of a grammar, but never increases its parsing complexity. This guarantees that, if we wish to find the transformation of the original grammar having the lowest parsing complexity, it is sufficient to consider only binarizations. This is because any transformed grammar having more than two nonterminals on the righthand side can be binarized without increasing its parsing complexity.

5 The relationship between fan-out and parsing complexity

Gómez-Rodríguez et al. (2009a) provide an algorithm for finding the binarization of an LCFRS having minimal fan-out. The key idea is to search over ways of combining subsets of a rule's righthand side nonterminals such that subsets with low fan-out are considered first; this results in an algorithm with complexity polynomial in the rank of the input rule, with the exponent depending on the resulting minimum fan-out.

This algorithm can be adapted to find the binarization with minimum parsing complexity, rather than minimum fan-out. We simply use $c(p)$ rather than $\varphi(p)$ as the score for new productions, controlling both which binarizations we prefer and the order in which they are explored.

An interesting question then arises: does the binarization with minimal parsing complexity also have minimal fan-out? A binarization into a grammar of

$$
\begin{aligned}
&A \rightarrow g(B_1, B_2, B_3, B_4)\\
&g(\langle x_{1,1}, x_{1,2}\rangle,\ \langle x_{2,1}, x_{2,2}, x_{2,3}\rangle,\ \langle x_{3,1}, x_{3,2}, x_{3,3}, x_{3,4}, x_{3,5}\rangle,\ \langle x_{4,1}, x_{4,2}, x_{4,3}\rangle) =\\
&\qquad\qquad \langle x_{4,1}x_{3,1}, x_{2,1}, x_{4,2}x_{1,1}x_{2,2}x_{4,3}x_{3,2}x_{2,3}x_{3,3}, x_{1,2}x_{3,4}, x_{3,5}\rangle
\end{aligned}
$$

Figure 2: A production for which minimizing fan-out and minimizing parsing complexity are mutually exclusive.

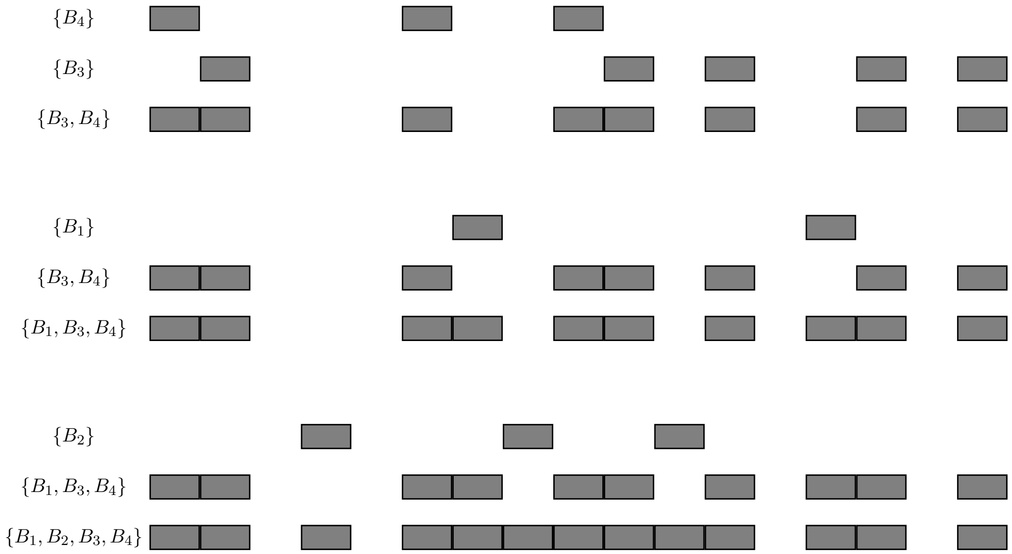

Figure 3: The binarization of the rule from Figure 2 that minimizes parsing complexity. In each of the three steps, we show the spans of each of the two subsets of the rule's righthand-side nonterms being combined, with the spans of their union (corresponding to a nonterminal created by the binarization) below.

```
function MINIMAL-BINARIZATION($p$, $\prec$)
  workingSet $\leftarrow \emptyset$;
  agenda $\leftarrow$ priorityQueue($\prec$);
  for $i$ from 1 to $\rho(p)$ do
    workingSet $\leftarrow$ workingSet $\cup \{B_i\}$;
    agenda $\leftarrow$ agenda $\cup \{B_i\}$;
  while agenda $\neq \emptyset$ do
    $p' \leftarrow$ pop minimum from agenda;
    if nonterms($p'$) $= \{B_1, \ldots B_{\rho(p)}\}$ then
      return $p'$;
    for $p_1 \in$ workingSet do
      $p_2 \leftarrow$ newProd($p'$, $p_1$);
      find $p'_2 \in$ workingSet :
                    nonterms($p'_2$) $=$ nonterms($p_2$);
      if $p_2 \prec p'_2$ then
        workingSet $\leftarrow$ workingSet $\cup \{p_2\} \setminus \{p'_2\}$;
        push(agenda, $p_2$);
```

Figure 1: Algorithm to compute best binarization according to a user-specified ordering $\prec$ over productions.

fan-out f' cannot have parsing complexity higher than $3f'$, according to eq. 2. Thus, minimizing fan-out puts an upper bound on parsing complexity, but is not guaranteed to minimize it absolutely. Binarizations with the same fan-out may in fact vary in their parsing complexity; similarly binarizations with the same parsing complexity may vary in their fan-out. It is not immediately apparent whether, in order to find a binarization of minimal parsing complexity, it is sufficient to consider only binarizations of minimal fan-out.

To test this conjecture, we adapted the algorithm of Gómez-Rodríguez et al. (2009a) to use a priority queue as the agenda, as shown in Figure 1. The algorithm takes as an argument an arbitrary partial ordering relation on productions, and explores possible binarized rules in the order specified by this relation. In Figure 1, "workingSet" is a set of singleton nonterminals and binarized productions which are guaranteed to be optimal for the subset of nonterminals that they cover. The function "nonterms" returns, for a newly created production, the subset of the original nonterminals $B_1, \ldots B_r$ that it generates, and returns subsets of singleton nonterminals directly.

To find the binarization with the minimum fan-out f' and the lowest parsing complexity among binarizations with fan-out f', we use the following comparison operation in the binarization algorithm:

$$p_1 \prec_{\varphi c} p_2 \text{ iff } \varphi(p_1) < \varphi(p_2) \vee \\ (\varphi(p_1) = \varphi(p_2) \wedge c(p_1) < c(p_2))$$

guaranteeing that we explore binarizations with lower fan-out first, and, among binarizations with equal fan-out, those with lower parsing complexity first. Similarly, we can search for the binarization with the lowest parsing complexity c' and the lowest fan-out among binarizations with complexity c', we use

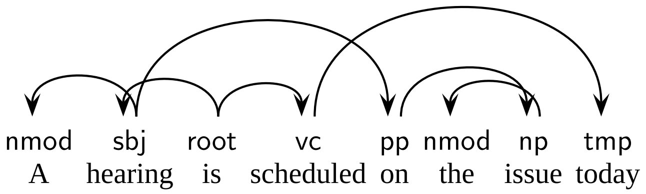
$$p_1 \prec_{c\varphi} p_2 \text{ iff } c(p_1) < c(p_2) \vee \\ (c(p_1) = c(p_2) \wedge \varphi(p_1) < \varphi(p_2))$$

We find that, in fact, it is sometimes necessary to sacrifice minimum fan-out in order to achieve minimum parsing complexity. An example of an LCFRS rule for which this is the case is shown in Figure 2. This production can be binarized to produce a set of productions with parsing complexity 14 (Figure 3); among binarizations with this complexity the minimum fan-out is 6. However, an alternative binarization with fan-out 5 is also possible; among binarizations with this fan-out, the minimum parsing complexity is 15. This binarization (not pictured) first joins B_1 and B_2, then adds B_4, and finally adds B_3.

Given the incompatibility of optimizing time complexity and fan-out, which corresponds to space complexity, which should we prefer? In some situations, it may be desirable to find some trade-off between the two. It is important to note, however, that if optimization of space complexity is the sole objective, factorization is unnecessary, as one can never improve on the fan-out required by the original grammar nonterminals.

6 A Note on Generative Capacity

Rambow and Satta (1999) categorize the generative capacity of LCFRS grammars according to their rank and fan-out. In particular, they show that grammars can be arranged in a two-dimensional grid, with languages of rank r and fan-out f having greater generative capacity than both grammars of rank r and fan-out $f-1$ and grammars of rank $r-1$



$$\begin{array}{rr}
\mathsf{nmod} \to g_1 & g_1 = \langle\, A \,\rangle \\
\mathsf{sbj} \to g_2(\mathsf{nmod}, \mathsf{pp}) & g_2(\langle x_{1,1}\rangle, \langle x_{2,1}\rangle) = \langle x_{1,1}\ \mathit{hearing}\ , x_{2,1}\rangle \\
\mathsf{root} \to g_3(\mathsf{sbj}, \mathsf{vc}) & g_3(\langle x_{1,1}, x_{1,2}\rangle, \langle x_{2,1}, x_{2,2}\rangle) = \langle x_{1,1}\ \mathit{is}\ x_{2,1} x_{1,2} x_{2,2}\rangle \\
\mathsf{vc} \to g_4(\mathsf{tmp}) & g_4(\langle x_{1,1}\rangle) = \langle\, \mathit{scheduled}\ , x_{1,1}\rangle \\
\mathsf{pp} \to g_5(\mathsf{tmp}) & g_5(\langle x_{1,1}\rangle) = \langle\, \mathit{on}\ x_{1,1}\rangle \\
\mathsf{nmod} \to g_6 & g_6 = \langle\, \mathit{the} \,\rangle \\
\mathsf{np} \to g_7(\mathsf{nmod}) & g_7(\langle x_{1,1}\rangle) = \langle x_{1,1}\ \mathit{issue} \,\rangle \\
\mathsf{tmp} \to g_8 & g_8 = \langle\, \mathit{today} \,\rangle
\end{array}$$

Figure 4: A dependency tree with the LCFRS rules extracted for each word (Kuhlmann and Satta, 2009).

and fan-out f, with two exceptions: with fan-out 1, all ranks greater than one are equivalent (context-free languages), and with fan-out 2, rank 2 and rank 3 are equivalent.

This classification is somewhat unsatisfying because minor changes to a grammar can change both its rank and fan-out. In particular, through factorizing rules, it is always possible to decrease rank, potentially at the cost of increasing fan-out, until a binarized grammar of rank 2 is achieved.

Parsing complexity, as defined above, also provides a method to compare the generative capacity of LCFRS grammars. From Rambow and Satta's result that grammars of rank two and increasing fan-out provide an infinite hierarchy of increasing generative capacity, we see that parsing complexity also provides such an infinite hierarchy. Comparing grammars according to the parsing complexity amounts to specifying a normalized binarization for grammars of arbitrary rank and fan-out, and comparing the resulting binarized grammars. This allows us to arrange LCFRS grammars into total ordering over generative capacity, that is a one-dimensional hierarchy, rather than a two-dimensional grid. It also gives a way of categorizing generative capacity that is more closely tied to algorithmic complexity.

It is important to note, however, that parsing complexity as calculated by our algorithm remains a function of the grammar, rather than an intrinsic function of the language. One can produce arbitrarily complex grammars that generate the simple language a^*. Thus the parsing complexity of a grammar, like its rank and fan-out, can be said to categorize its *strong* generative capacity.

7 Experiments

A number of recent papers have examined dynamic programming algorithms for parsing non-projective dependency structures by exploring how well various categories of polynomially-parsable grammars cover the structures found in dependency treebanks for various languages (Kuhlmann and Nivre, 2006; Gómez-Rodríguez et al., 2009b).

Kuhlmann and Satta (2009) give an algorithm for extracting LCFRS rules from dependency structures. One rule is extracted for each word in the dependency tree. The rank of the rule is the number of children that the word has in the dependency tree, as shown by the example in Figure 4. The fan-out of the symbol corresponding to a word is the number of continuous intervals in the sentence formed by the word and its descendants in the tree. Projec-

Table 1: Number of productions with specified parsing complexity

tive trees yield LCFRS rules of fan-out one and parsing complexity three, while the fan-out and parsing complexity from non-projective trees are in principle unbounded.

Extracting LCFRS rules from treebanks allows us to study how many of the rules fall within certain constraints. Kuhlmann and Satta (2009) give an algorithm for binarizing LCRFS rules without increasing the rules' fan-out; however, this is not always possible, and the algorithm does not succeed even in some cases for which such a binarization is possible. Kuhlmann and Satta (2009) find that all but 0.02% of productions in the CoNLL 2006 training data, which includes various languages, can be binarized by their algorithm, but they do not give the fan-out or parsing complexity of the resulting rules. In related work, Gómez-Rodríguez et al. (2009b) define the class of *mildly ill-nested dependency structures* of varying gap degrees; gap degree is essentially fan-out minus one. For a given gap degree k, this class of grammars can be parsing in time $O(n^{3k+4})$ for lexicalized grammars. Gómez-Rodríguez et al. (2009b) study dependency treebanks for nine languages and find that all dependency structures meet the mildly ill-nested condition in the dependency treebanks for some gap degree. However, they do not report the maximum gap degree or parsing complexity.

We extracted LCFRS rules from dependency treebanks using the same procedure as Kuhlmann and Satta (2009), and applied the algorithm of Figure 1 directly to calculate their minimum parsing complexity. This allows us to characterize the parsing complexity of the rules found in the treebank without needing to define specific conditions on the rules, such as well-nestedness (Kuhlmann and Nivre, 2006) or mildly ill-nestedness, that may not be necessary for all efficiently parsable grammars. The numbers of rules of different complexities are shown in Table 1.

As found by previous studies, the vast majority of productions are context-free (projective trees, parsable in $O(n^3)$). Of non-projective rules, the vast majority can be parsed in $O(n^6)$, including the well-nested structures of gap degree one defined by Kuhlmann and Nivre (2006). The single most complex rule had parsing complexity of $O(n^{20})$, and was derived from a Swedish sentence which turns out to be so garbled as to be incomprehensible (taken from the high school essay portion of the Swedish treebank). It is interesting to note that, while the binarization algorithm is exponential in the worst case, it is practical for real data: analyzing all the rules extracted from the various treebanks takes only a few minutes. We did not find any cases in rules extracted from Treebank data of rules where minimizing parsing complexity is inconsistent with minimizing fan-out, as is the case for the rule of Figure 2.

8 Conclusion

We give an algorithm for finding the optimum parsing complexity for an LCFRS among grammars obtained by binarization. We find that minimum parsing complexity is always achievable with rank 2, but is not always achievable with minimum fan-out. By applying the binarization algorithm to productions found in dependency treebanks, we can completely characterize the parsing complexity of the extracted LCFRS grammar.

The viability of web-derived polarity lexicons

Abstract

We examine the viability of building large polarity lexicons semi-automatically from the web. We begin by describing a graph propagation framework inspired by previous work on constructing polarity lexicons from lexical graphs (Kim and Hovy, 2004; Hu and Liu, 2004; Esuli and Sabastiani, 2009; Blair-Goldensohn et al., 2008; Rao and Ravichandran, 2009). We then apply this technique to build an English lexicon that is significantly larger than those previously studied. Crucially, this web-derived lexicon does not require WordNet, part-of-speech taggers, or other language-dependent resources typical of sentiment analysis systems. As a result, the lexicon is not limited to specific word classes – e.g., adjectives that occur in WordNet – and in fact contains slang, misspellings, multiword expressions, etc. We evaluate a lexicon derived from English documents, both qualitatively and quantitatively, and show that it provides superior performance to previously studied lexicons, including one derived from WordNet.

1 Introduction

Polarity lexicons are large lists of phrases that encode the polarity of each phrase within it – either positive or negative – often with some score representing the magnitude of the polarity (Hatzivassiloglou and McKeown, 1997; Wiebe, 2000; Turney, 2002). Though classifiers built with machine learning algorithms have become commonplace in the sentiment analysis literature, e.g., Pang et al. (2002), the core of many academic and commercial sentiment analysis systems remains the polarity lexicon, which can be constructed manually (Das and Chen, 2007), through heuristics (Kim and Hovy, 2004; Esuli and Sabastiani, 2009) or using machine learning (Turney, 2002; Rao and Ravichandran, 2009). Often lexicons are combined with machine learning for improved results (Wilson et al., 2005). The pervasiveness and sustained use of lexicons can be ascribed to a number of reasons, including their interpretability in large-scale systems as well as the granularity of their analysis.

In this work we investigate the viability of polarity lexicons that are derived solely from unlabeled web documents. We propose a method based on graph propagation algorithms inspired by previous work on constructing polarity lexicons from lexical graphs (Kim and Hovy, 2004; Hu and Liu, 2004; Esuli and Sabastiani, 2009; Blair-Goldensohn et al., 2008; Rao and Ravichandran, 2009). Whereas past efforts have used linguistic resources – e.g., WordNet – to construct the lexical graph over which propagation runs, our lexicons are constructed using a graph built from co-occurrence statistics from the entire web. Thus, the method we investigate can be seen as a combination of methods for propagating sentiment across lexical graphs and methods for building sentiment lexicons based on distributional characteristics of phrases in raw data (Turney, 2002). The advantage of breaking the dependence on WordNet (or related resources like thesauri (Mohammad et al., 2009)) is that it allows the lexicons to include non-standard entries, most notably spelling mistakes and variations, slang, and multiword expressions.

The primary goal of our study is to understand the characteristics and practical usefulness of such a lexicon. Towards this end, we provide both a qualitative and quantitative analysis for a web-derived English

lexicon relative to two previously published lexicons – the lexicon used in Wilson et al. (2005) and the lexicon used in Blair-Goldensohn et al. (2008). Our experiments show that a web-derived lexicon is not only significantly larger, but has improved accuracy on a sentence polarity classification task, which is an important problem in many sentiment analysis applications, including sentiment aggregation and summarization (Hu and Liu, 2004; Carenini et al., 2006; Lerman et al., 2009). These results hold true both when the lexicons are used in conjunction with string matching to classify sentences, and when they are included within a contextual classifier framework (Wilson et al., 2005).

Extracting polarity lexicons from the web has been investigated previously by Kaji and Kitsuregawa (2007), who study the problem exclusively for Japanese. In that work a set of positive/negative sentences are first extracted from the web using cues from a syntactic parser as well as the document structure. Adjectives phrases are then extracted from these sentences based on different statistics of their occurrence in the positive or negative set. Our work, on the other hand, does not rely on syntactic parsers or restrict the set of candidate lexicon entries to specific syntactic classes, i.e., adjective phrases. As a result, the lexicon built in our study is on a different scale than that examined in Kaji and Kitsuregawa (2007). Though this hypothesis is not tested here, it also makes our techniques more amenable to adaptation for other languages.

2 Constructing the Lexicon

In this section we describe a method to construct polarity lexicons using graph propagation over a phrase similarity graph constructed from the web.

2.1 Graph Propagation Algorithm

We construct our lexicon using graph propagation techniques, which have previously been investigated in the construction of polarity lexicons (Kim and Hovy, 2004; Hu and Liu, 2004; Esuli and Sabastiani, 2009; Blair-Goldensohn et al., 2008; Rao and Ravichandran, 2009). We assume as input an undirected edge weighted graph $G = (V, E)$, where $w_{ij} \in [0, 1]$ is the weight of edge $(v_i, v_j) \in E$. The node set V is the set of candidate phrases for inclusion in a sentiment lexicon. In practice, G should encode semantic similarities between two nodes, e.g., for sentiment analysis one would hope that $w_{ij} > w_{ik}$ if v_i=*good*, v_j=*great* and v_k=*bad*. We also assume as input two sets of *seed phrases*, denoted P for the positive seed set and N for the negative seed set. The common property among all graph propagation algorithms is that they attempt to propagate information from the seed sets to the rest of the graph through its edges. This can be done using machine learning, graph algorithms or more heuristic means.

The specific algorithm used in this study is given in Figure 1, which is distinct from common graph propagation algorithms, e.g., label propagation (see Section 2.3). The output is a polarity vector $\mathbf{pol} \in \mathbb{R}^{|V|}$ such that $\mathbf{pol}_i$ is the polarity score for the i^{th} candidate phrase (or the i^{th} node in G). In particular, we desire $\mathbf{pol}$ to have the following semantics:

$$\mathbf{pol}_i = \begin{cases} > 0 & i^{th} \text{ phrase has positive polarity} \\ < 0 & i^{th} \text{ phrase has negative polarity} \\ = 0 & i^{th} \text{ phrase has no sentiment} \end{cases}$$

Intuitively, the algorithm works by computing both a positive and a negative polarity magnitude for each node in the graph, call them $\mathbf{pol}^+_i$ and $\mathbf{pol}^-_i$. These values are equal to the sum over the max weighted path from every seed word (either positive or negative) to node v_i. Phrases that are connected to multiple positive seed words through short yet highly weighted paths will receive high positive values. The final polarity of a phrase is then set to $\mathbf{pol}_i = \mathbf{pol}^+_i - \beta\mathbf{pol}^-_i$, where β a constant meant to account for the difference in overall mass of positive and negative flow in the graph. Thus, after the algorithm is run, if a phrase has a higher positive than negative polarity score, then its final polarity will be positive, and negative otherwise.

There are some implementation details worth pointing out. First, the algorithm in Figure 1 is written in an iterative framework, where on each iteration, paths of increasing lengths are considered. The input variable T controls the max path length considered by the algorithm. This can be set to be a small value in practice, since the multiplicative path weights result in long paths rarely contributing to polarity scores. Second, the parameter γ is a threshold that defines the minimum polarity magnitude a

```
Input:       $G = (V, E)$, $w_{ij} \in [0, 1]$,
             $P, N, \gamma \in \mathbb{R}, T \in \mathbb{N}$
Output:      $\mathbf{pol} \in \mathbb{R}^{|V|}$
Initialize:  $\mathbf{pol}_i, \mathbf{pol}^+_i, \mathbf{pol}^-_i = 0$, for all $i$
             $\mathbf{pol}^+_i = 1.0$ for all $v_i \in P$ and
             $\mathbf{pol}^-_i = 1.0$ for all $v_i \in N$

1.   set $\alpha_{ij} = 0$ for all $i, j$
2.   for $v_i \in P$
3.     $F = \{v_i\}$
4.     for $t : 1 \ldots T$
5.       for $(v_k, v_j) \in E$ such that $v_k \in F$
6.         $\alpha_{ij} = \max\{\alpha_{ij},\ \alpha_{ik} \cdot w_{kj}\}$
           $F = F \cup \{v_j\}$
7.   for $v_j \in V$
8.     $\mathbf{pol}^+_j = \sum_{v_i \in P} \alpha_{ij}$
9.   Repeat steps 1-8 using $N$ to compute $\mathbf{pol}^-$
10.  $\beta = \sum_i \mathbf{pol}^+_i / \sum_i \mathbf{pol}^-_i$
11.  $\mathbf{pol}_i = \mathbf{pol}^+_i - \beta\mathbf{pol}^-_i$, for all $i$
12.  if $|\mathbf{pol}_i| < \gamma$ then $\mathbf{pol}_i = 0.0$, for all $i$
```

Figure 1: Graph Propagation Algorithm.

phrase must have to be included in the lexicon. Both T and γ were tuned on held-out data.

To construct the final lexicon, the remaining nodes – those with polarity scores above γ – are extracted and assigned their corresponding polarity.

2.2 Building a Phrase Graph from the Web

Graph propagation algorithms rely on the existence of graphs that encode meaningful relationships between candidate nodes. Past studies on building polarity lexicons have used linguistic resources like WordNet to define the graph through synonym and antonym relations (Kim and Hovy, 2004; Esuli and Sabastiani, 2009; Blair-Goldensohn et al., 2008; Rao and Ravichandran, 2009). The goal of this study is to examine the size and quality of polarity lexicons when the graph is induced automatically from documents on the web.

Constructing a graph from web-computed lexical co-occurrence statistics is a difficult challenge in and of itself and the research and implementation hurdles that arise are beyond the scope of this work (Alfonseca et al., 2009; Pantel et al., 2009). For this study, we used an English graph where the node set V was based on all n-grams up to length 10 extracted from 4 billion web pages. This list was filtered to 20 million candidate phrases using a number of heuristics including frequency and mutual information of word boundaries. A context vector for each candidate phrase was then constructed based on a window of size six aggregated over all mentions of the phrase in the 4 billion documents. The edge set E was constructed by first, for each potential edge (v_i, v_j), computing the cosine similarity value between context vectors. All edges (v_i, v_j) were then discarded if they were not one of the 25 highest weighted edges adjacent to either node v_i or v_j. This serves to both reduce the size of the graph and to eliminate many spurious edges for frequently occurring phrases, while still keeping the graph relatively connected. The weight of the remaining edges was set to the corresponding cosine similarity value.

Since this graph encodes co-occurrences over a large, but local context window, it can be noisy for our purposes. In particular, we might see a number of edges between positive and negative sentiment words as well as sentiment words and non-sentiment words, e.g., sentiment adjectives and all other adjectives that are distributionally similar. Larger windows theoretically alleviate this problem as they encode semantic as opposed to syntactic similarities. We note, however, that the graph propagation algorithm described above calculates the sentiment of each phrase as the aggregate of all the best paths to seed words. Thus, even if some local edges are erroneous in the graph, one hopes that, globally, positive phrases will be influenced more by paths from positive seed words as opposed to negative seed words. Section 3, and indeed this paper, aims to measure whether this is true or not.

2.3 Why Not Label Propagation?

Previous studies on constructing polarity lexicons from lexical graphs, e.g., Rao and Ravichandran (2009), have used the label propagation algorithm, which takes the form in Figure 2 (Zhu and Ghahramani, 2002). Label propagation is an iterative algorithm where each node takes on the weighted average of its neighbour's values from the previous iteration. The result is that nodes with many paths to seeds get high polarities due to the influence from their neighbours. The label propagation algorithm is known to have many desirable properties including convergence, a well defined objective function

```
Input:       $G = (V, E), w_{ij} \in [0, 1], P, N$
Output:      $\mathbf{pol} \in \mathbb{R}^{|V|}$
Initialize:  $\mathbf{pol}_i = 1.0$ for all $v_i \in P$ and
             $\mathbf{pol}_i = -1.0$ for all $v_i \in N$ and
             $\mathbf{pol}_i = 0.0 \; \forall v_i \notin P \cup N$

for : t .. T
    $\mathbf{pol}_i = \frac{\sum_{(v_i,v_j) \in E} w_{ij} \times \mathbf{pol}_j}{\sum_{(v_i,v_j)} w_{ij}}, \forall v_i \in V$
    reset $\mathbf{pol}_i = 1.0 \; \forall v_i \in P$
    reset $\mathbf{pol}_i = -1.0 \; \forall v_i \in N$
```

Figure 2: The label propagation algorithm (Zhu and Ghahramani, 2002).

(minimize squared error between values of adjacent nodes), and an equivalence to computing random walks through graphs.

The primary difference between standard label propagation and the graph propagation algorithm given in Section 2.1, is that a node with multiple paths to a seed will be influenced by all these paths in the label propagation algorithm, whereas only the single path from a seed will influence the polarity of a node in our proposed propagation algorithm – namely the path with highest weight. The intuition behind label propagation seems justified. That is, if a node has multiple paths to a seed, it should be reflected in a higher score. This is certainly true when the graph is of high quality and all paths trustworthy. However, in a graph constructed from web co-occurrence statistics, this is rarely the case.

Our graph consisted of many dense subgraphs, each representing some semantic entity class, such as actors, authors, tech companies, etc. Problems arose when polarity flowed into these dense subgraphs with the label propagation algorithm. Ultimately, this flow would amplify since the dense subgraph provided exponentially many paths from each node to the source of the flow, which caused a reinforcement effect. As a result, the lexicon would consist of large groups of actor names, companies, etc. This also led to convergence issues since the polarity is divided proportional to the size of the dense subgraph. Additionally, negative phrases in the graph appeared to be in more densely connected regions, which resulted in the final lexicons being highly skewed towards negative entries due to the influence of multiple paths to seed words.

For best path propagation, these problems were less acute as each node in the dense subgraph would only get the polarity a single time from each seed, which is decayed by the fact that edge weights are smaller than 1. Furthermore, the fact that edge weights are less than 1 results in most long paths having weights near zero, which in turn results in fast convergence.

3 Lexicon Evaluation

We ran the best path graph propagation algorithm over a graph constructed from the web using manually constructed positive and negative seed sets of 187 and 192 words in size, respectively. These words were generated by a set of five humans and many are morphological variants of the same root, e.g., excel/excels/excelled. The algorithm produced a lexicon that contained 178,104 entries. Depending on the threshold γ (see Figure 1), this lexicon could be larger or smaller. As stated earlier, our selection of γ and all hyperparameters was based on manual inspection of the resulting lexicons and performance on held-out data.

In the rest of this section we investigate the properties of this lexicon to understand both its general characteristics as well as its possible utility in sentiment applications. To this end we compare three different lexicons:

1. **Wilson et al.**: Described in Wilson et al. (2005). Lexicon constructed by combining the lexicon built in Riloff and Wiebe (2003) with other sources[1]. Entries are are coarsely rated – strong/weak positive/negative – which we weighted as 1.0, 0.5, -0.5, and -1.0 for our experiments.

2. **WordNet LP**: Described in Blair-Goldensohn et al. (2008). Constructed using label propagation over a graph derived from WordNet synonym and antonym links. Note that label propagation is not prone to the kinds of errors discussed in Section 2.3 since the lexical graph is derived from a high quality source.

3. **Web GP**: The web-derived lexicon described in Section 2.1 and Section 2.2.

[1] See http://www.cs.pitt.edu/mpqa/

3.1 Qualitative Evaluation

Table 1 breaks down the lexicon by the number of positive and negative entries of each lexicon, which clearly shows that the lexicon derived from the web is more than an order of magnitude larger than previously constructed lexicons.[2] This in and of itself is not much of an achievement if the additional phrases are of poor quality. However, in Section 3.2 we present an empirical evaluation that suggests that these terms provide both additional *and* useful information. Table 1 also shows the recall of the each lexicon relative to the other. Whereas the Wilson et al. (2005) and WordNet lexicon have a recall of only 3% relative to the web lexicon, the web lexicon has a recall of 48% and 70% relative to the two other lexicons, indicating that it contains a significant amount of information from the other lexicons. However, this overlap is still small, suggesting that a combination of all the lexicons could provide the best performance. In Section 3.2 we investigate this empirically through a meta classification system.

Table 2 shows the distribution of phrases in the web-derived lexicon relative to the number of tokens in each phrase. Here a token is simply defined by whitespace and punctuation, with punctuation counting as a token, e.g., "half-baked" is counted as 3 tokens. For the most part, we see what one might expect, as the number of tokens increases, the number of corresponding phrases in the lexicon also decreases. Longer phrases are less frequent and thus will have both fewer and lower weighted edges to adjacent nodes in the graph. There is a single phrase of length 9, which is "motion to dismiss for failure to state a claim". In fact, the lexicon contains quite a number of legal and medical phrases. This should not be surprising, since in a graph induced from the web, a phrase like "cancer" (or any disease) should be distributionally similar to phrases like "illness", "sick", and "death", which themselves will be similar to standard sentiment phrases like "bad" and "terrible". These terms are predominantly negative in the lexicon representing the broad notion that legal and medical events are undesirable.

Phrase length	1	2	3	4	5	6	7	8	9
# of phrases	37,449	108,631	27,822	3,489	598	71	29	4	1

Table 2: Number of phrases by phrase length in lexicon built from the web.

Perhaps the most interesting characteristic of the lexicon is that the most frequent phrase length is 2 and not 1. The primary reason for this is an abundance of adjective phrases consisting of an adverb and an adjective, such as "more brittle" and "less brittle". Almost every adjective of length 1 is frequently combined in such a way on the web, so it not surprising that we see many of these phrases in the lexicon. Ideally we would see an order on such phrases, e.g., "more brittle" has a larger negative polarity than "brittle", which in turn has a larger negative polarity than "less brittle". However, this is rarely the case and usually the adjective has the highest polarity magnitude. Again, this is easily explained. These phrases are necessarily more common and will thus have more edges with larger weights in the graph and thus a greater chance of accumulating a high sentiment score. The prominence of such phrases suggests that a more principled treatment of them should be investigated in the future.

Finally, Table 3 presents a selection of phrases from both the positive and negative lexicons categorized into revealing verticals. For both positive and negative phrases we present typical examples of phrases – usually adjectives – that one would expect to be in a sentiment lexicon. These are phrases not included in the seed sets. We also present multiword phrases for both positive and negative cases, which displays concretely the advantage of building lexicons from the web as opposed to using restricted linguistic resources such as WordNet. Finally, we show two special cases. The first is spelling variations (and mistakes) for positive phrases, which were far more prominent than for negative phrases. Many of these correspond to social media text where one expresses an increased level of sentiment by repeating characters. The second is vulgarity in negative phrases, which was far more prominent than for positive phrases. Some of these are clearly appropri-

[2] This also includes the web-derived lexicon of (Kaji and Kitsuregawa, 2007), which has 10K entries. A recent study by Mohammad et al. (2009) generated lexicons from thesauri with 76K entries.

				Recall wrt other lexicons		
	All Phrases	Pos. Phrases	Neg. Phrases	Wilson et al.	WordNet LP	Web GP
Wilson et al.	7,628	2,718	4,910	100%	37%	2%
WordNet LP	12,310	5,705	6,605	21%	100%	3%
Web GP	178,104	90,337	87,767	70%	48%	100%

Table 1: Lexicon statistics. Wilson et al. is the lexicon used in Wilson et al. (2005), WordNet LP is the lexicon constructed by Blair-Goldensohn et al. (2008) that uses label propagation algorithms over a graph constructed through WordNet, and Web GP is the web-derived lexicon from this study.

POSITIVE PHRASES			**NEGATIVE PHRASES**		
Typical	**Multiword expressions**	**Spelling variations**	**Typical**	**Multiword expressions**	**Vulgarity**

stupendous	more good than bad	sikk	wretched	pain in my ass	sonuvabitch

Table 3: Example positive and negative phrases from web lexicon.

ate, e.g., "shitty", but some are clearly insults and outbursts that are most likely included due to their co-occurrence with angry texts. There were also a number of derogatory terms and racial slurs in the lexicon, again most of which received negative sentiment due to their typical disparaging usage.

3.2 Quantitative Evaluation

To determine the practical usefulness of a polarity lexicon derived from the web, we measured the performance of the lexicon on a sentence classification/ranking task. The input is a set of sentences and the output is a classification of the sentences as being either positive, negative or neutral in sentiment. Additionally, the system outputs two rankings, the first a ranking of the sentence by positive polarity and the second a ranking of the sentence by negative polarity. Classifying sentences by their sentiment is a subtask of sentiment aggregation systems (Hu and Liu, 2004; Gamon et al., 2005). Ranking sentences by their polarity is a critical sub-task in extractive sentiment summarization (Carenini et al., 2006; Lerman et al., 2009).

To classify sentences as being positive, negative or neutral, we used an augmented vote-flip algorithm (Choi and Cardie, 2009), which is given in Figure 3. This intuition behind this algorithm is simple. The number of matched positive and negative phrases from the lexicon are counted and whichever has the most votes wins. The algorithm flips the decision if the number of negations is odd. Though this algorithm appears crude, it benefits from not relying on threshold values for neutral classification, which is difficult due to the fact that the polarity scores in the three lexicons are not on the same scale.

To rank sentences we defined the purity of a sentence X as the normalized sum of the sentiment scores for each phrase x in the sentence:

$$\mathsf{purity}(\mathsf{X}) = \frac{\sum_{\mathsf{x} \in \mathsf{X}} \mathbf{pol}_{\mathsf{x}}}{\delta + \sum_{\mathsf{x} \in \mathsf{X}} |\mathbf{pol}_{\mathsf{x}}|}$$

This is a normalized score in the range $[-1, 1]$. Intuitively, sentences with many terms of the same polarity will have purity scores at the extreme points of the range. Before calculating purity, a simple negation heuristic was implemented that reversed the sentiment scores of terms that were within the scope of negations. The term δ helps to favor sentences with multiple phrase matches. Purity is a common metric used for ranking sentences for inclusion in sentiment summaries (Lerman et al., 2009). Purity and negative purity were used to rank sentences as being positive and negative sentiment, respectively.

The data used in our initial English-only experi-

Figure 3: Vote-flip algorithm (Choi and Cardie, 2009).

ments were a set of 554 consumer reviews described in (McDonald et al., 2007). Each review was sentence split and annotated by a human as being positive, negative or neutral in sentiment. This resulted in 3,916 sentences, with 1,525, 1,542 and 849 positive, negative and neutral sentences, respectively.

The first six columns of Table 4 shows: 1) the positive/negative precision-recall of each lexicon-based system where sentence classes were determined using the vote-flip algorithm, and 2) the average precision for each lexicon-based system where purity (or negative purity) was used to rank sentences. Both the Wilson et al. and WordNet LP lexicons perform at a similar level, with the former slightly better, especially in terms of precision. The web-derived lexicon, Web GP, outperforms the other two lexicons across the board, in particular when looking at average precision, where the gains are near 10% absolute. If we plot the precision-recall graphs using purity to classify sentences – as opposed to the vote-flip algorithm, which only provides an unweighted classification – we can see that at almost all recall levels the web-derived lexicon has superior precision to the other lexicons (Figure 4). Thus, even though the web-derived lexicon is constructed from a lexical graph that contains noise, the graph propagation algorithms appear to be fairly robust to this noise and are capable of producing large and accurate polarity lexicons.

The second six columns of Table 4 shows the performance of each lexicon as the core of a contextual classifier (Wilson et al., 2005). A contextual classifier is a machine learned classifier that predicts the polarity of a sentence using features of that sentence and its context. For our experiments, this was a maximum entropy classifier trained and evaluated using 10-fold cross-validation on the evaluation data. The features included in the classifier were the purity score, the number of positive and negative lexicon matches, and the number of negations in the sentence, as well as concatenations of these features within the sentence and with the same features derived from the sentences in a window of size 1.

For each sentence, the contextual classifier predicted either a positive, negative or neutral classification based on the label with highest probability. Additionally, all sentences were placed in the positive and negative sentence rankings by the probability the classifier assigned to the positive and negative classes, respectively. Mirroring the results of Wilson et al. (2005), we see that contextual classifiers improve results substantially over lexical matching. More interestingly, we see that the a contextual classifier over the web-derived lexicons maintains the performance edge over the other lexicons, though the gap is smaller. Figure 5 plots the precision-recall curves for the positive and negative sentence rank-

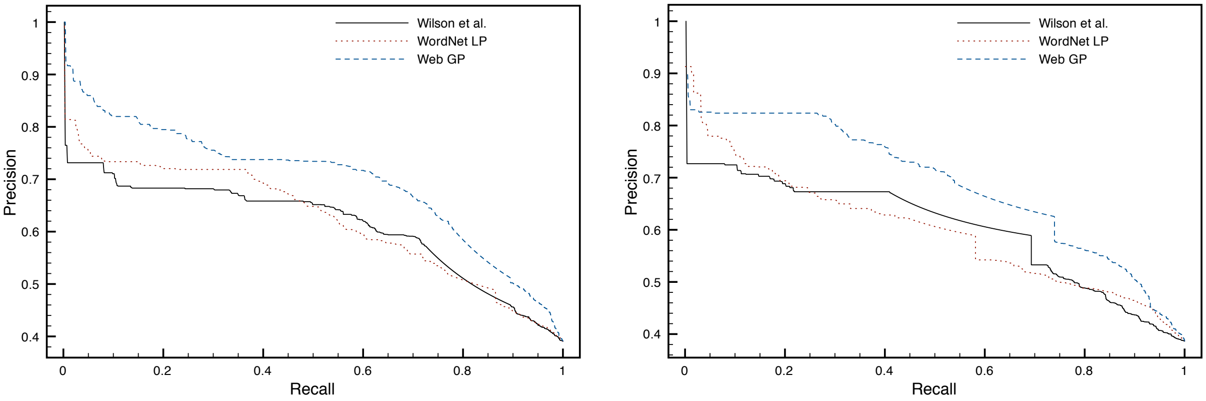

Figure 4: Lexicon classifier precision/recall curves for positive (left) and negative (right) classes.

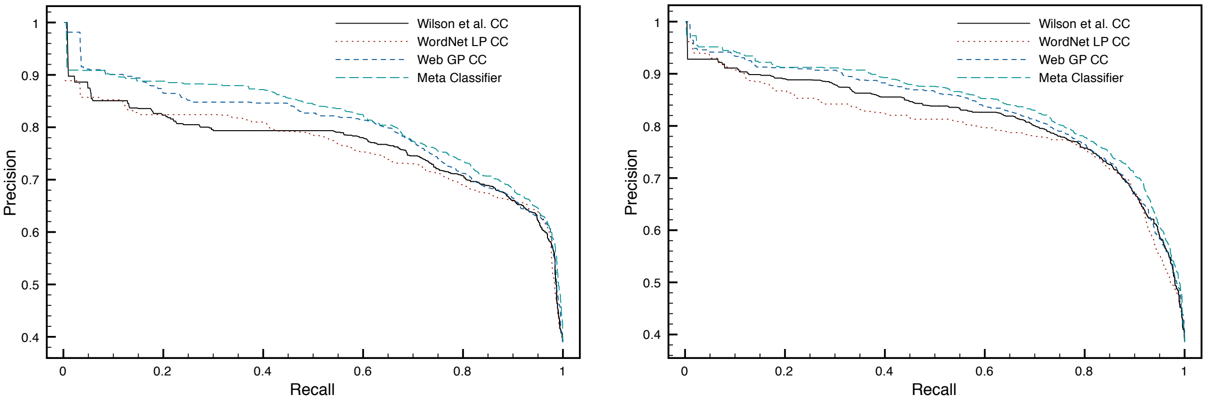

Figure 5: Contextual classifier precision/recall curves for positive (left) and negative (right) classes

ings, again showing that at almost every level of recall, the web-derived lexicon has higher precision.

For a final English experiment we built a meta-classification system that is identical to the contextual classifiers, except it is trained using features derived from all lexicons. Results are shown in the last row of Table 4 and precision-recall curves are shown in Figure 5. Not surprisingly, this system has the best performance in terms of average precision as it has access to the largest amount of information, though its performance is only slightly better than the contextual classifier for the web-derived lexicon.

4 Conclusions

In this paper we examined the viability of sentiment lexicons learned semi-automatically from the web, as opposed to those that rely on manual annotation and/or resources such as WordNet. Our qualitative experiments indicate that the web derived lexicon can include a wide range of phrases that have not been available to previous systems, most notably spelling variations, slang, vulgarity, and multi-word expressions. Quantitatively, we observed that the web derived lexicon had superior performance to previously published lexicons for English classification. Ultimately, a meta classifier that incorporates features from all lexicons provides the best performance. In the future we plan to investigate the construction of web-derived lexicons for languages other than English, which is an active area of research (Mihalcea et al., 2007; Jijkoun and Hofmann, 2009; Rao and Ravichandran, 2009). The advantage of the web-derived lexicons studied here is that they do not rely on language specific resources besides unlabeled data and seed lists. A primary question is whether such lexicons improve performance over a translate-to-English strategy (Banea et al., 2008).

Abstract

In this paper, we present a dependency tree-based method for sentiment classification of Japanese and English subjective sentences using conditional random fields with hidden variables. Subjective sentences often contain words which reverse the sentiment polarities of other words. Therefore, interactions between words need to be considered in sentiment classification, which is difficult to be handled with simple bag-of-words approaches, and the syntactic dependency structures of subjective sentences are exploited in our method. In the method, the sentiment polarity of each dependency subtree in a sentence, which is not observable in training data, is represented by a hidden variable. The polarity of the whole sentence is calculated in consideration of interactions between the hidden variables. Sum-product belief propagation is used for inference. Experimental results of sentiment classification for Japanese and English subjective sentences showed that the method performs better than other methods based on bag-of-features.

1 Introduction

Sentiment classification is a useful technique for analyzing subjective information in a large number of texts, and many studies have been conducted (Pang and Lee, 2008). A typical approach for sentiment classification is to use supervised machine learning algorithms with bag-of-words as features (Pang et al., 2002), which is widely used in topic-based text classification. In the approach, a subjective sentence is represented as a set of words in the sentence, ignoring word order and head-modifier relation between words. However, sentiment classification is different from traditional topic-based text classification. Topic-based text classification is generally a linearly separable problem ((Chakrabarti, 2002), p.168). For example, when a document contains some domain-specific words, the document will probably belong to the domain. However, in sentiment classification, sentiment polarities can be reversed. For example, let us consider the sentence "The medicine kills cancer cells." While the phrase *cancer cells* has negative polarity, the word *kills* reverses the polarity, and the whole sentence has positive polarity. Thus, in sentiment classification, a sentence which contains positive (or negative) polarity words does not necessarily have the same polarity as a whole, and we need to consider interactions between words instead of handling words independently.

Recently, several methods have been proposed to cope with the problem (Zaenen, 2004; Ikeda et al., 2008). However, these methods are based on flat bag-of-features representation, and do not consider syntactic structures which seem essential to infer the polarity of a whole sentence. Other methods have been proposed which utilize composition of sentences (Moilanen and Pulman, 2007; Choi and Cardie, 2008; Jia et al., 2009), but these methods use rules to handle polarity reversal, and whether polarity reversal occurs or not cannot be learned from labeled data. Statistical machine learning can learn useful information from training data and generally robust for noisy data, and using it instead of rigid rules seems useful. Wilson et al. (2005) proposed a method for sentiment classification which utilizes head-modifier relation and machine learning. However, the method is based on bag-of-features and polarity reversal occurred by content words is not handled. One issue of the approach to use sentence composition and machine learning is that only the whole sentence is labeled with its polarity in general corpora for sentiment classification, and each component of the sentence is not labeled, though such information is necessary for supervised ma-

chine learning to infer the sentence polarity from its components.

In this paper, we propose a dependency tree-based method for Japanese and English sentiment classification using conditional random fields (CRFs) with hidden variables. In the method, the sentiment polarity of each dependency subtree, which is not observable in training data, is represented by a hidden variable. The polarity of the whole sentence is calculated in consideration of interactions between the hidden variables.

The rest of this paper is organized as follows: Section 2 describes a dependency tree-based method for sentiment classification using CRFs with hidden variables, and Section 3 shows experimental results on Japanese and English corpora. Section 4 discusses related work, and Section 5 gives conclusions.

2 Dependency Tree-based Sentiment Classification using CRFs with Hidden Variables

In this study, we handle a task to classify the polarities (positive or negative) of given subjective sentences. In the rest of this section, we describe a probabilistic model for sentiment classification based on dependency trees, methods for inference and parameter estimation, and features we use.

2.1 A Probabilistic Model based on Dependency Trees

Let us consider the subjective sentence "It prevents cancer and heart disease." In the sentence, *cancer* and *heart disease* have themselves negative polarities. However, the polarities are reversed by modifying the word *prevents*, and the dependency subtree "prevents cancer and heart disease" has positive polarity. As a result, the whole dependency tree "It prevents cancer and heart disease." has positive polarity (Figure 1). In such a way, we can consider the sentiment polarity for each dependency subtree of a subjective sentence. Note that we use phrases as a basic unit instead of words in this study, because phrases are useful as a meaningful unit for sentiment classification[1]. In this paper, a *dependency subtree* means the subtree of a dependency tree whose root node is one of the phrases in the sentence.

We use a probabilistic model as shown in Figure 2. We consider that each phrase in the subjective sentence has a random variable (indicated by a circle in Figure 2). The random variable represents the polarity of the dependency subtree whose root node is the corresponding phrase. Two random variables are dependent (indicated by an edge in Figure 2) if their corresponding phrases have head-modifier relation in the dependency tree. The node denoted as <*root*> in Figure 2 indicates a virtual phrase which represents the root node of the sentence, and we regard that the random variable of the root node is the polarity of the whole sentence. In usual annotated corpora for sentiment classification, only each sentence is labeled with its polarity, and each phrase (dependency subtree) is not labeled, so all the random variables except the one for the root node are

[1] From an empirical view, in our preliminary experiments with the proposed method, phrase-based processing performed better than word-based processing in accuracy and in computational efficiency.

hidden variables that cannot be observed in labeled data (indicated by gray circles in Figure 2). With such a probabilistic model, it is possible to utilize properties such that phrases which contain positive (or negative) words tend to have positive (negative) polarities, and two phrases with head-modifier relation tend to have opposite polarities if the head contains a word which reverses sentiment polarity.

Next, we define the probabilistic model as shown in Figure 2 in detail. Let n denote the number of phrases in a subjective sentence, w_i the i-th phrase, and h_i the head index of the i-th phrase. Let s_i denote the random variable which represents the polarity of the dependency subtree whose root is the i-th phrase ($s_i \in \{+1, -1\}$), and let p denote the polarity of the whole sentence ($p \in \{+1, -1\}$). We regard the 0-th phrase as a virtual phrase which represents the root of the sentence. $\mathbf{w}, \mathbf{h}, \mathbf{s}$ respectively denote the sequence of w_i, h_i, s_i.

$$\mathbf{w} = w_1 \cdots w_n, \quad \mathbf{h} = h_1 \cdots h_n, \quad \mathbf{s} = s_0 \cdots s_n,$$
$$p = s_0.$$

For the example sentence in Figure 1, w_1 =*It*, w_2 =*prevents*, w_3 =*cancer*, w_4 =*and heart disease.*, $h_1 = 2$, $h_2 = 0$, $h_3 = 2$, $h_4 = 2$. We define the joint probability distribution of the sentiment polarities of dependency subtrees $\mathbf{s}$, given a subjective sentence $\mathbf{w}$ and its dependency tree $\mathbf{h}$, using log-linear models:

$$P_\Lambda(\mathbf{s}|\mathbf{w}, \mathbf{h}) = \frac{1}{Z_\Lambda(\mathbf{w}, \mathbf{h})} \exp\left\{\sum_{k=1}^{K} \lambda_k F_k(\mathbf{w}, \mathbf{h}, \mathbf{s})\right\}, \tag{1}$$

$$Z_\Lambda(\mathbf{w}, \mathbf{h}) = \sum_{\mathbf{s}} \exp\left\{\sum_{k=1}^{K} \lambda_k F_k(\mathbf{w}, \mathbf{h}, \mathbf{s})\right\}, \tag{2}$$

$$F_k(\mathbf{w}, \mathbf{h}, \mathbf{s}) = \sum_{i=1}^{n} f_k(i, \mathbf{w}, \mathbf{h}, \mathbf{s}), \tag{3}$$

where $\Lambda = \{\lambda_1, \cdots, \lambda_K\}$ is the set of parameters of the model. $f_k(i, \mathbf{w}, \mathbf{h}, \mathbf{s})$ is the feature function of the i-th phrase, and is classified to *node feature* which considers only the corresponding node, or *edge feature* which considers both the corresponding node and its head, as follows:

$$f_k(i, \mathbf{w}, \mathbf{h}, \mathbf{s}) = \begin{cases} f_k^{\mathrm{n}}(w_i, s_i) & (k \in \mathbf{K}^{\mathrm{n}}), \\ f_k^{\mathrm{e}}(w_i, s_i, w_{h_i}, s_{h_i}) & (k \in \mathbf{K}^{\mathrm{e}}), \end{cases} \tag{4}$$

where $\mathbf{K}^{\mathrm{n}}$ and $\mathbf{K}^{\mathrm{e}}$ respectively represent the sets of indices of node features and edge features.

2.2 Classification of Sentiment Polarity

Let us consider how to infer the sentiment polarity $p \in \{+1, -1\}$, given a subjective sentence $\mathbf{w}$ and its dependency tree $\mathbf{h}$. The polarity of the root node (s_0) is regarded as the polarity of the whole sentence, and p can be calculated as follows:

$$p = \operatorname*{argmax}_{p'} P_\Lambda(p'|\mathbf{w}, \mathbf{h}), \tag{5}$$

$$P_\Lambda(p|\mathbf{w}, \mathbf{h}) = \sum_{\mathbf{s}: s_0 = p} P_\Lambda(\mathbf{s}|\mathbf{w}, \mathbf{h}). \tag{6}$$

That is, the polarity of the subjective sentence is obtained as the marginal probability of the root node polarity, by summing the probabilities for all the possible configurations of hidden variables. However, enumerating all the possible configurations of hidden variables is computationally hard, and we use sum-product belief propagation (MacKay, 2003) for the calculation.

Belief propagation enables us to efficiently calculate marginal probabilities. In this study, the graphical model to be solved has a tree structure (identical to the syntactic dependency tree) which has no loops, and an exact solution can be obtained using belief propagation. Dependencies among random variables in Figure 2 are represented by a factor graph in Figure 3. The factor graph consists of variable nodes s_i indicated by circles, and factor (feature) nodes g_i indicated by squares. In the example in Figure 3, $g_i (1 \le i \le 4)$ correspond to the node features in Equation (4), and $g_i (5 \le i \le 8)$ correspond to the edge features. In belief propagation, marginal distribution is calculated by passing messages (beliefs) among the variables and factors connected by edges in the factor graph (Refer to (MacKay, 2003) for detailed description of belief propagation).

2.3 Parameter Estimation

Let us consider how to estimate model parameters Λ, given L training examples $D = \{\langle \mathbf{w}^l, \mathbf{h}^l, p^l \rangle\}_{l=1}^{L}$. In this study, we use the maximum a posteriori estimation with Gaussian priors for parameter estimation. We define the following objective function $\mathcal{L}_\Lambda$, and calculate the parameters $\hat{\Lambda}$ which maximize the value:

$$\mathcal{L}_\Lambda = \sum_{l=1}^{L} \log P_\Lambda(p^l|\mathbf{w}^l, \mathbf{h}^l) - \frac{1}{2\sigma^2}\sum_{k=1}^{K}\lambda_k^2, \quad (7)$$

$$\hat{\Lambda} = \underset{\Lambda}{\operatorname{argmax}}\, \mathcal{L}_\Lambda, \quad (8)$$

where σ is a parameter of Gaussian priors and is set to 1.0 in later experiments. The partial derivatives of $\mathcal{L}_\Lambda$ are as follows:

$$\frac{\partial \mathcal{L}_\Lambda}{\partial \lambda_k} = \sum_{l=1}^{L}\left[\sum_{\mathbf{s}} P_\Lambda(\mathbf{s}|\mathbf{w}^l, \mathbf{h}^l, p^l) F_k(\mathbf{w}^l, \mathbf{h}^l, \mathbf{s}) - \sum_{\mathbf{s}} P_\Lambda(\mathbf{s}|\mathbf{w}^l, \mathbf{h}^l) F_k(\mathbf{w}^l, \mathbf{h}^l, \mathbf{s})\right] - \frac{1}{\sigma^2}\lambda_k. \quad (9)$$

The model parameters can be calculated with the L-BFGS quasi-Newton method (Liu and Nocedal, 1989) using the objective function and its partial derivatives. While the partial derivatives contain summation over all the possible configurations of hidden variables, it can be calculated efficiently using belief propagation as explained in Section 2.2. This parameter estimation method is same to one used for Latent-Dynamic Conditional Random Field (Morency et al., 2007). Note that the objective function $\mathcal{L}_\Lambda$ is not convex, and there is no guarantee for global optimality. The estimated model parameters depend on the initial values of the parameters, and the setting of the initial values of model parameters will be explained in Section 2.4.

2.4 Features

Node Features	
a	s_i
b	$s_i \& q_i$
c	$s_i \& q_i \& r_i$
d	$s_i \& u_{i,1}, \cdots, s_i \& u_{i,m_i}$
e	$s_i \& c_{i,1}, \cdots, s_i \& c_{i,m_i}$
f	$s_i \& f_{i,1}, \cdots, s_i \& f_{i,m_i}$
g	$s_i \& u_{i,1} \& u_{i,2}, \cdots, s_i \& u_{i,m_i-1} \& u_{i,m_i}$
h	$s_i \& b_{i,1} \& b_{i,2}, \cdots, s_i \& b_{i,m_i-1} \& b_{i,m_i}$

Edge Features	
A	$s_i \& s_j$
B	$s_i \& s_j \& r_j$
C	$s_i \& s_j \& r_j \& q_j$
D	$s_i \& s_j \& b_{i,1}, \cdots, s_i \& s_j \& b_{i,m_i}$
E	$s_i \& s_j \& b_{j,1}, \cdots, s_i \& s_j \& b_{j,m_j}$

Table 1: Features Used in This Study

Table 1 shows the features used in this study. Features (a)–(h) in Table 1 are used as the node features (Equation (4)) for the i-th phrase, and features (A)–(E) are used as the edge features for the i-th and j-th phrases (j=h_i). In Table 1, s_i denotes the hidden variable which represents the polarity of the dependency subtree whose root node is the i-th phrase, q_i denotes the prior polarity of the i-th phrase (explained later), r_i denotes the polarity reversal of the i-th phrase (explained later), m_i denotes the number of words in the i-th phrase, $u_{i,k}$, $b_{i,k}$, $c_{i,k}$, $f_{i,k}$ respectively denote the surface form, base form, coarse-grained part-of-speech (POS) tag, fine-grained POS tag of the k-th word in the i-th phrase.

We used the morphological analysis system JUMAN and the dependency parser KNP[2] for processing Japanese data, and the POS tagger MXPOST (Ratnaparkhi, 1996) and the dependency parser MaltParser[3] for English data. KNP outputs phrase-based dependency trees, but MaltParser outputs word-based dependency trees, and we converted the word-based ones to phrase-based ones using simple heuristic rules explained in Appendix A.

The prior polarity of a phrase $q_i \in \{+1, 0, -1\}$ is the innate sentiment polarity of a word contained in the phrase, which can be obtained from sentiment polarity dictionaries. We used sentiment polarity dictionaries made by Kobayashi et al. (2007) and Higashiyama et al. (2008)[4] for Japanese experiments (The resulting dictionary contains 6,974 positive expressions and 8,428 negative expressions), and a dictionary made by Wilson et al. (2005)[5] for English experiments (The dictionary contains 2,289 positive expressions and 4,143 negative expressions). When a phrase contains the words registered in the dictionaries, its prior polarity is set to the registered polarity, otherwise the prior polarity is set to 0. When a phrase contains multiple words in the dictionaries, the registered polarity of the last (nearest to the end

[2] http://nlp.kuee.kyoto-u.ac.jp/nl-resource/

[3] http://maltparser.org/

[4] http://cl.naist.jp/˜inui/research/EM/sentiment-lexicon.html

[5] http://www.cs.pitt.edu/mpqa/

of the sentence) word is used.

The polarity reversal of a phrase $r_i \in \{0, 1\}$ represents whether it reverses the polarities of other phrases (1) of not (0). We prepared polarity reversing word dictionaries, and the polarity reversal of a phrase is set to 1 if the phrase contains a word in the dictionaries, otherwise set to 0. We constructed polarity reversing word dictionaries which contain such words as *decrease* and *vanish* that reverse sentiment polarity. A Japanese polarity reversing word dictionary was constructed from an automatically constructed corpus, and the construction procedure is described in Appendix B (The dictionary contains 219 polarity reversing words). An English polarity reversing word dictionary was constructed from the General Inquirer dictionary[6] in the same way as Choi and Cardie (2008), by collecting words which belong to either NOTLW or DECREAS categories (The dictionary contains 121 polarity reversing words).

Choi and Cardie (2008) categorized polarity reversing words into two categories: function-word negators such as *not* and content-word negators such as *eliminate*. The polarity reversal of a phrase r_i explained above handles only the content-word negators, and function-word negators are handled in another way, since the scope of a function-word negator is generally limited to the phrase containing it in Japanese, and the number of function-word negators is small. The prior polarity q_i and the polarity reversal r_i of a phrase are changed to the following q'_i and r'_i, if the phrase contains a function-word negator (in Japanese) or if the phrase is modified by a function-word negator (in English):

$$q'_i = -q_i, \tag{10}$$

$$r'_i = 1 - r_i. \tag{11}$$

In this paper, unless otherwise noted, the word *polarity reversal* is used to indicate polarity reversing caused by content-word negators, and function-word negators are assumed to be applied to q_i and r_i in the above way beforehand.

As described in Section 2.3, there is no guarantee of global optimality for estimated parameters, since the objective function is not convex. In our preliminary experiments, L-BFGS often did not converge and classification accuracy was unstable when the initial values of parameters were randomly set. Therefore, in later experiments, we set the initial values in the following way. For the feature (A) in Table 1 in which s_i and s_j are equal, we set the initial parameter λ_i of the feature to a random number in $[0.9, 1.1]$, otherwise we set to a random number in $[-0.1, 0.1]$[7]. By setting such initial values, the initial model parameters have a property that two phrases with head-modifier relation tend to have the same polarity, which is intuitively reasonable.

3 Experiments

We conducted experiments of sentiment classification on four Japanese corpora and four English corpora.

3.1 Data

We used four corpora for experiments of Japanese sentiment classification: the Automatically Constructed Polarity-tagged corpus (ACP) (Kaji and Kitsuregawa, 2006), the Kyoto University and NTT Blog corpus (KNB) [8], the NTCIR Japanese opinion corpus (NTC-J) (Seki et al., 2007; Seki et al., 2008), the 50 Topics Evaluative Information corpus (50 Topics) (Nakagawa et al., 2008). The ACP corpus is an automatically constructed corpus from HTML documents on the Web using lexico-syntactic patterns and layout structures. The size of the corpus is large (it consists of 650,951 instances), and we used $1/100$ of the whole corpus. The KNB corpus consists of Japanese blogs, and is manually annotated. The NTC-J corpus consists of Japanese newspaper articles. There are two NTCIR Japanese opinion corpora available, the NTCIR-6 corpus and the NTCIR-7 corpus; and we combined the two corpora. The 50 Topics corpus is collected from various pages on the Web, and is manually annotated.

We used four corpora for experiments of English sentiment classification: the Customer Review data

[6] http://www.wjh.harvard.edu/ inquirer/

[7] The values of most learned parameters distributed between -1.0 and 1.0 in our preliminary experiments. Therefore, we decided to give values around the upper bound (1.0) and the mean (0.0) to the features in order to incorporate minimal prior knowledge into the model.

[8] http://nlp.kuee.kyoto-u.ac.jp/kuntt/

(CR)[9], the MPQA Opinion corpus (MPQA)[10], the Movie Review Data (MR) [11], and the NTCIR English opinion corpus (NTC-E) (Seki et al., 2007; Seki et al., 2008). The CR corpus consists of review articles about products such as digital cameras and cellular phones. There are two customer review datasets, the 5 products dataset and the 9 products dataset, and we combined the two datasets. In the MPQA corpus, sentiment polarities are attached not to sentences but expressions (sub-sentences), and we regarded the expressions as sentences and classified the polarities. There are two NTCIR English corpora available, the NTCIR-6 corpus and the NTCIR-7 corpus, and we combined the two corpora.

The statistical information of the corpora we used is shown in Table 2. We randomly split each corpus into 10 portions, and conducted 10-fold cross validation. Accuracy of sentiment classification was calculated as the number of correctly predicted labels (polarities) divided by the number of test examples.

3.2 Compared Methods

We compared our method to 6 baseline methods, and this section describes them. In the following, $p_0 \in \{+1, -1\}$ denotes the major polarity in training data, $\mathbf{H}_i$ denotes the set consisting of all the ancestor nodes of the i-th phrase in the dependency tree, and sgn(x) is defined as below:

$$\text{sgn}(x) = \begin{cases} +1 & (x > 0), \\ 0 & (x = 0), \\ -1 & (x < 0). \end{cases}$$

Voting without Polarity Reversal The polarity of a subjective sentence is decided by voting of each phrase's prior polarity. In the case of a tie, the major polarity in the training data is adopted.

$$p = \text{sgn}\left(\sum_{i=1}^{n} q_i + 0.5 p_0\right). \tag{12}$$

Voting with Polarity Reversal Same to *Voting without Polarity Reversal*, except that the polarities of phrases which have odd numbers of reversal phrases in their ancestors are reversed before voting.

$$p = \text{sgn}\left(\sum_{i=1}^{n} q_i \prod_{j \in \mathbf{H}_i} (-1)^{r_j} + 0.5 p_0\right). \tag{13}$$

Rule The polarity of a subjective sentence is deterministically decided basing on rules, by considering the sentiment polarities of dependency subtrees. The polarity of the dependency subtree whose root is the i-th phrase is decided by voting the prior polarity of the i-th phrase and the polarities of the dependency subtrees whose root nodes are the modifiers of the i-th phrase. The polarities of the modifiers are reversed if their head phrase has a reversal word. The decision rule is applied from leaf nodes in the dependency tree, and the polarity of the root node is decided at the last.

$$s_i = \text{sgn}\left(q_i + \sum_{j : h_j = i} s_j (-1)^{r_i}\right), \tag{14}$$

$$p = \text{sgn}(s_0 + 0.5 p_0). \tag{15}$$

Bag-of-Features with No Dictionaries The polarity of a subjective sentence is classified using Support Vector Machines. Surface forms, base forms, coarse-grained POS tags and fine-grained POS tags of word unigrams and bigrams in the subjective sentence are used as features[12]. The second order polynomial kernel is used and the cost parameter C is set to 1.0. No prior polarity information (dictionary) is used.

Bag-of-Features without Polarity Reversal Same to *Bag-of-Features with No Dictionaries*, except that the voting result of prior polarities (one of positive, negative or tie) is also used as a feature.

Bag-of-Features with Polarity Reversal Same to *Bag-of-Features without Polarity Reversal*, except that the polarities of phrases which have

odd numbers of reversal phrases in their ancestors are reversed before voting.

Tree-CRF The proposed method based on dependency trees using CRFs, described in Section 2.

3.3 Experimental Results

The experimental results are shown in Table 3. The proposed method Tree-CRF obtained the best accuracies for all the four Japanese corpora and the four English corpora, and the differences against the second best methods were statistically significant ($p < 0.05$) with the paired t-test for the six of the eight corpora. Tree-CRF performed better for the Japanese corpora than for the English corpora. For both the Voting methods and the Bag-of-Features methods, the methods with polarity reversal performed better than those without it[13].

Both BoF-w/ Rev. and Tree-CRF use supervised machine learning and the same dictionaries (the prior polarity dictionaries and the polarity reversing word dictionaries), but the latter performed better than the former. Our error analysis showed that BoF-w/ Rev. was not robust for erroneous words in the prior polarity dictionaries. BoF-w/ Rev. uses the voting result of the prior polarities as a feature, and the feature is sensitive to the errors in the dictionary, while Tree-CRF uses several information as well as the prior polarities to decide the polarities of dependency subtrees, and was robust to the dictionary errors. We investigated the trained model parameters of Tree-CRF, and found that the features (E) in Table 1, in which the head and the modifier have opposite polarities and the head word is such as *protect* and *withdraw*, have large positive weights. Although these words were not included in the polarity reversing word dictionary, the property that these words reverse polarities of other words seems to be learned with the model.

4 Related Work

Various studies on sentiment classification have been conducted, and there are several methods pro-

[13] The Japanese polarity reversing word dictionary was constructed from the ACP corpus as described in Appendix B, and it is not reasonable to compare the methods with and without polarity reversal on the ACP corpus. However, the tendency can be seen on the other 7 corpora.

posed for handling reversal of polarities. In this paper, our method was not directly compared with the other methods, since it is difficult to completely implement them or conduct experiments with exactly the same settings.

Choi and Cardie (2008) proposed a method to classify the sentiment polarity of a sentence basing on compositional semantics. In their method, the polarity of the whole sentence is determined from the prior polarities of the composing words by pre-defined rules, and the method differs from ours which uses the probabilistic model to handle interactions between hidden variables. Syntactic structures were used in the studies of Moilanen and Pulman (2007) and, Jia et al. (2009), but their methods are based on rules and supervised learning was not used to handle polarity reversal. As discussed in Section 1, Wilson et al. (2005) studied a bag-of-features based statistical sentiment classification method incorporating head-modifier relation.

Ikeda et al. (2008) proposed a machine learning approach to handle sentiment polarity reversal. For each word with prior polarity, whether the polarity is reversed or not is learned with a statistical learning algorithm using its surrounding words as features. The method can handle only words with prior polarities, and does not use syntactic dependency structures.

Conditional random fields with hidden variables have been studied so far for other tasks. Latent-Dynamic Conditional Random Fields (LDCRF) (Morency et al., 2007; Sun et al., 2008) are probabilistic models with hidden variables for sequential labeling, and belief propagation is used for inference. Out method is similar to the models, but there are several differences. In our method, only one variable which represents the polarity of the whole sentence is observable, and dependency relation among random variables is not a linear chain but a tree structure which is identical to the syntactic dependency.

5 Conclusion

In this paper, we presented a dependency tree-based method for sentiment classification using conditional random fields with hidden variables. In this method, the polarity of each dependency subtree of a subjective sentence is represented by a hidden variable. The values of the hidden variables are calculated in consideration of interactions between variables whose nodes have head-modifier relation in the dependency tree. The value of the hidden variable of the root node is identified with the polarity of the whole sentence. Experimental results showed that the proposed method performs better for Japanese and English data than the baseline methods which represents subjective sentences as bag-of-features.

Appendix

A Rules for Converting Word Sequence to Phrase Sequence

Let $v_1, \cdots, v_N$ denote an English word sequence, y_i the part-of-speech of the i-th word, and z_i the head index of the i-th word. The word sequence was converted to a phrase sequence as follows, by applying rules which combine two adjacent words:

```
$LT \equiv$ {“,(,-LRB-,-LSB-,-LCB-,CC}
$RT \equiv$ {”,),,,--,.,:,POS,-RRB-,-RSB-,-RCB-}
$PP \equiv$ {IN,RP,TO,DT,PDT,PRP,WDT,WP,WP$,WRB}
$NN \equiv$ {CD,FW,NN,NNP,NNPS,NNS,SYM,JJ}
do
  for $i$ := $1$ to $N - 1$
    if $x_i$ and $x_{i+1}$ are not yet combined $\wedge$
      $(x_i \in LT \vee$
       $x_{i+1} \in RT \vee$
       $((y_i = y_{i+1} \vee y_i = i + 1 \vee y_{i+1} = i) \wedge$
        $(x_i \in PP \vee$
         $(x_i \in NN \wedge x_{i+1} \in NN))))$ then
      Combine the words $v_i$ and $v_{i+1}$
until No rules are applied
```

B Construction of Japanese Polarity Reversing Word Dictionary

We constructed a Japanese polarity reversing word dictionary from the Automatically Constructed Polarity-tagged corpus (Kaji and Kitsuregawa, 2006). First, we collected sentences, each of which contains just one phrase having prior polarity, and the phrase modifies a phrase which modifies the root node. Among them, we selected sentences in which the prior polarity is not equal to the polarity of the whole sentence. We extracted all the words in the head phrase, and manually checked them whether they should be put into the dictionary or not. The rationale behind the procedure is that the prior polarity can be considered to be reversed by a certain word in the head phrase.

Convolution Kernels for Opinion Holder Extraction

Michael Wiegand and **Dietrich Klakow**
Spoken Language Systems

{Michael.Wiegand|Dietrich.Klakow}@lsv.uni-saarland.de

Abstract

Opinion holder extraction is one of the important subtasks in sentiment analysis. The effective detection of an opinion holder depends on the consideration of various cues on various levels of representation, though they are hard to formulate explicitly as features. In this work, we propose to use convolution kernels for that task which identify meaningful fragments of sequences or trees by themselves. We not only investigate how different levels of information can be effectively combined in different kernels but also examine how the scope of these kernels should be chosen. In general relation extraction, the two candidate entities thought to be involved in a relation are commonly chosen to be the boundaries of sequences and trees. The definition of boundaries in opinion holder extraction, however, is less straightforward since there might be several expressions beside the candidate opinion holder to be eligible for being a boundary.

1 Introduction

In recent years, there has been a growing interest in the automatic detection of opinionated content in natural language text. One of the more important tasks in sentiment analysis is the extraction of opinion holders. Opinion holder extraction is one of the critical components of an opinion question-answering system (i.e. systems which automatically answer opinion questions, such as “What does [X] like about [Y]?”). Such systems need to be able to distinguish which entities in a candidate answer sentence are the sources of opinions (= opinion holder) and which are the targets.

On other NLP tasks, in particular, on relation extraction, there has been much work on *convolution kernels*, i.e. kernel functions exploiting huge amounts of features without an explicit feature representation. Previous research on that task has shown that convolution kernels, such as sequence and tree kernels, are quite effective when compared to manual feature engineering (Moschitti, 2008; Bunescu and Mooney, 2005; Nguyen et al., 2009). In order to effectively use convolution kernels, it is often necessary to choose appropriate substructures of a sentence rather than represent the sentence as a whole structure (Bunescu and Mooney, 2005; Zhang et al., 2006; Moschitti, 2008). As for tree kernels, for example, one typically chooses the syntactic subtree immediately enclosing two entities potentially expressing a specific relation in a given sentence. The opinion holder detection task is different from this scenario. There can be *several* cues within a sentence to indicate the presence of a genuine opinion holder and these cues need not be member of a particular word group, e.g. they can be opinion words (see Sentences 1-3), communication words, such as *maintained* in Sentence 2, or other lexical cues, such as *according* in Sentence 3.

1. The U.S. commanders consider$_{opinion}$ the prisoners to be unlawful_combatants$_{opinion}$ as opposed to prisoners of war.

2. During the summit, Koizumi maintained$_{communication}$ a clear-cut_collaborative_stance$_{opinion}$ towards the U.S. and emphasized that the President was objective$_{opinion}$ and circumspect.

3. According$_{cue}$ to Fernandez, it was the worst_mistake$_{opinion}$ in the history of the Argentine economy.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 795–803,
Los Angeles, California, June 2010.

Thus, the definition of boundaries of the structures for the convolution kernels is less straightforward in opinion holder extraction.

The aim of this paper is to explore in how far convolution kernels can be beneficial for effective opinion holder detection. We are not only interested in how far different kernel types contribute to this extraction task but we also contrast the performance of these kernels with a manually designed feature set used as a standard vector kernel. Finally, we also examine the effectiveness of expanding word sequences or syntactic trees by additional prior knowledge.

2 Related Work

Choi et al. (2005) examine opinion holder extraction using CRFs with various manually defined linguistic features and patterns automatically learnt by the AutoSlog system (Riloff, 1996). The linguistic features focus on named-entity information and syntactic relations to opinion words. In this paper, we use very similar settings. The features presented in Kim and Hovy (2005) and Bloom et al. (2007) resemble very much Choi et al. (2005). Bloom et al. (2007) also consider communication words to be predictive cues for opinion holders.

Kim and Hovy (2006) and Bethard et al. (2005) explore the usefulness of semantic roles provided by FrameNet (Fillmore et al., 2003) for both opinion holder and opinion target extraction. Due to data sparseness, Kim and Hovy (2006) expand FrameNet data by using an unsupervised clustering algorithm.

Choi et al. (2006) is an extension of Choi et al. (2005) in that opinion holder extraction is learnt jointly with opinion detection. This requires that opinion expressions and their relations to opinion holders are annotated in the training data. Semantic roles are also taken as a potential source of information. In our work, we deliberately work with minimal annotation and, thus, do not consider any labeled opinion expressions and relations to opinion holders in the training data. We exclusively rely on entities marked as opinion holders. In many practical situations, the annotation beyond opinion holder labeling is too expensive.

Complex convolution kernels have been successfully applied to various NLP tasks, such as relation extraction (Bunescu and Mooney, 2005; Zhang et al., 2006; Nguyen et al., 2009), question answering (Zhang and Lee, 2003; Moschitti, 2008), and semantic role labeling (Moschitti et al., 2008). In all these tasks, they offer competitive performance to manually designed feature sets. Bunescu and Mooney (2005) combine different sequence kernels encoding different contexts of candidate entities in a sentence. They argue that several kernels encoding different contexts are more effective than just using one kernel with one specific context. We build on that idea and compare various scopes eligible for opinion holder extraction. Moschitti (2008) and Nguyen et al. (2009) suggest that different kinds of information, such as word sequences, part-of-speech tags, syntactic and semantic information should be contained in separate convolution kernels. We also adhere to this notion.

3 Data

As labeled data, we use the sentiment annotation of the *MPQA 2.0 corpus*[1]. Opinion holders are not explicitly labeled as such. However sources of *private states* and *subjective speech events* (Wiebe et al., 2003) are a fairly good approximation of the task. Previous work (Choi et al., 2005; Kim and Hovy, 2005; Choi et al., 2006) uses similar approximations.

4 Method

In this work, we consider all noun phrases (NPs) as possible candidate opinion holders. Therefore, the set of all data instances is the set of the NPs within the MPQA 2.0 corpus. Each NP is labeled as to whether it is a genuine opinion holder or not. Throughout this section, we will use Sentence 2 from Section 1 as an example.

4.1 The Different Levels of Representation

Several levels of representation are important for opinion holder extraction. Table 1 lists all the different levels that are used in this work. Generalized sequences employ *named-entity tags*, an OPINION tag for *opinion words* and a COMM tag for *communication words*[2]. Thus, in a generalized word se-

[1] `www.cs.pitt.edu/mpqa/databaserelease`

[2] Note that all candidate tokens are reduced to one generic CAND token. Thus, we hope to account for data sparseness in

quence (WRD_{GN}) a word is replaced by a generalized token whereas in a generalized part-of-speech sequence (POS_{GN}) a part-of-speech tag is replaced. For augmented constituent trees ($CONST_{AUG}$), the same sources of information are used. The difference to generalizing sequences is that instead of replacing words by generalized tokens, we add a node in the syntax tree with a generalized token so that it dominates the pertaining leaf node (see also nodes marked with $_{AUG}$ in Figure 2). All sources used for this type of generalization are known to be predictive for opinion holder classification (Choi et al., 2005; Kim and Hovy, 2005; Choi et al., 2006; Kim and Hovy, 2006; Bloom et al., 2007).

Note that the grammatical relation paths, i.e. $GRAM_{WRD}$ and $GRAM_{POS}$, can only be applied in case there is another expression in the focus in addition to the candidate of the data instance itself, e.g. the nearest opinion expression to the candidate. Section 4.4 explains in detail how this is done.

Predicate-argument structures (PAS) are represented by PropBank trees (Kingsbury and Palmer, 2002).

4.2 Support Vector Machines and Kernel Methods

Support Vector Machines (SVMs) are one of the most robust supervised machine learning techniques in which training data instances $\vec{x}$ are separated by a hyperplane $H(\vec{x}) = \vec{w} \cdot \vec{x} + b = 0$ where $w \in \mathbb{R}^n$ and $b \in \mathbb{R}$. One advantage of SVMs is that kernel methods can be applied which map the data to other feature spaces in which they can be separated more easily. Given a feature function $\phi : \mathbb{O} \rightarrow \mathbb{R}$, where $\mathbb{O}$ is the set of the objects, the kernel trick allows the decision hyperplane to be rewritten as:

$$H(\vec{x}) = \left(\sum_{i=1 \dots l} y_i \alpha_i \vec{x}_i \right) \cdot \vec{x} + b =$$

$$\sum_{i=1 \dots l} y_i \alpha_i \vec{x}_i \cdot \vec{x} + b = \sum_{i=1 \dots l} y_i \alpha_i \phi\left(o_i\right) \cdot \phi\left(o\right) + b$$

where y_i is equal to 1 for positive and -1 for negative examples, $\alpha_i \in \mathbb{R}$ with $\alpha_i \geq 0, o_i \forall_i \in \{1, \dots, l\}$ are the training instances and the product $K(o_i, o) = \langle \phi(o_i) \cdot \phi(o) \rangle$ is the kernel function associated with the mapping ϕ.

4.3 Sequence and Tree Kernels

A sequence kernel (SK) measures the similarity of two sequences by counting the number of common subsequences. We use the kernel by Taylor and Christianini (2004) which has the advantage that it also considers subsequences of the original sequence with some elements missing. The extent of these *gaps* in a sequence is suitably reflected by a weighting function incorporated into the kernel.

Tree kernels (TKs) represent trees by their substructures. The feature space of these substructures, or fragments, is mapped onto a vector space. The kernel function computes the similarity of pairs of trees by counting the number of common fragments. In this work, we evaluate two tree kernels: Subset Tree Kernel (STK) (Collins and Duffy, 2002) and Partial Tree Kernel (PTK_{basic}) (Moschitti, 2006).

In STK, a tree fragment can be any set of nodes and edges of the original tree provided that every node has either all or none of its children. This constraint makes that kind of kernel well-suited for constituency trees which have been generated by context free grammars since the constraint corresponds to the restriction that no grammatical rule must be broken. For example, STK enforces that a subtree, such as *[VP [VBZ, NP]]*, cannot be matched with *[VP [VBZ]]* since the latter *VP* node only possesses one of the children of the former.

PTK_{basic} is more flexible since the constraint of STK on nodes is relaxed. This makes this type of tree kernel less suitable for constituency trees. We, therefore, apply it only to trees representing predicate-argument structures (PAS) (see Figure 1). Note that a data instance is represented by a set of those structures[3] rather than a single structure. Thus, the actual partial tree kernel function we use for this task, PTK, sums over all possible pairs PAS_l and PAS_m of two data instances x_i and x_j: $PTK(x_i, x_j) = \sum_{PAS_l \in x_i} \sum_{PAS_m \in x_j} PTK_{basic}(PAS_l, PAS_m)$.

To summarize, Table 2 lists the different kernel types we use coupled with the suitable levels of representation. This choice of pairing has already been motivated and empirically proven suitable on other

case there are several tokens making up the candidate.

4.4 The Different Scopes

We argue that using the entire word sequence or syntax tree of the sentence in which a candidate opinion holder is situated to represent a data instance produces too large structures for a convolution kernel. Since a classifier based on convolution kernels has to derive meaningful features by itself, the larger these structures are, the more likely noise is included in the model. Previous work in relation extraction has also shown that the usage of more focused substructures, e.g. the smallest subtree containing the two candidate entities of a relation, is more effective (Zhang et al., 2006). Unfortunately, in our task there is only one explicit entity we know of for each data instance which is the candidate opinion holder. However, there are several indicative cues within the context of the candidate which might be considered important. We identify three different cues being the nearest *predicate*, i.e. full verb or nominalization, *opinion word* and *communication word*[4]. For each of these expressions, we define a scope where the boundaries are the candidate opinion holder and the pertaining cue. Given these scopes, we can define resulting subsequences/subtrees and combine them. We further add two *background scopes*, one being the semantic scope of the candidate opinion holder and the entire sentence. As semantic scope we consider the subclause in which a candidate opinion holder is situated[5].

Figure 2 illustrates the different scopes. Abbreviations are explained in Table 3. As already mentioned in Section 4.1 for grammatical relation paths, a second expression in addition to the candidate opinion holder is required. These expressions can be derived from the different scopes, i.e. for $PRED$ it

[4] These three expressions may coincide but do not have to.

[5] Typically, the subtree representing a subclause has the closest S node dominating the candidate opinion holder as the root node and it contains only those nodes from the original sentence parse which are also dominated by that S node and whose path to that node does not contain another S node.

is the nearest predicate to the candidate, for OP it is the nearest opinion word and for $COMM$ it is the nearest communication word. For the background scopes SEM and $SENT$, however, there is no second expression in focus. Therefore, grammatical relation paths cannot be defined for these scopes.

Type	**Description**
$PRED$	scope with the boundaries being the candidate opinion holder and the nearest predicate
OP	scope with the boundaries being the candidate opinion holder and nearest opinion word
$COMM$	scope with the boundaries being the candidate opinion holder and the nearest communication word
SEM	semantic scope of the candidate opinion holder, i.e. subclause containing the candidate
$SENT$	entire sentence in which in the opinion holder occurs

Table 3: The different types of scope.

4.5 Manually Designed Feature Set for a Standard Vector Kernel

In addition to the different types of convolution kernels, we also define an explicit feature set for a vector kernel (VK). Many of these features mainly describe properties of the relation between the candidate and the nearest predicate[6] since in our initial experiments the nearest predicate has always been the strongest cue. Adding these types of features for other cues, e.g. the nearest opinion or communication word, only resulted in a decrease in performance. Table 4 lists all the features we use. Note that this manual feature set employs all those sources of information which are also exploited by the convolution kernels. Some of the information contained in the convolution kernels can, however, only be represented in a more simplified fashion when using a manual feature set. For example, the first PAS in Figure 1(a) is converted to just the pair of predicate and argument representing the candidate (i.e. *REL:maintain_A0:Koizumi*). The entire PAS is not used since it would create too sparse features. Convolution kernels can cope with fairly complex structures as input since they internally match substructures. Manual features are less flexible since they do not account for partial matches.

headword/governing category of CAND
is CAND capitalized/a person?
is CAND *subj*|*dobj*|*iobj*|*pobj* of OPINION/COMM?
is CAND preceded by *according to*? (Choi et al., 2005)
does CAND contain possessive and is followed by OPINION/COMM? (Choi et al., 2005)
is CAND preceded by *by* which is attached to OPINION/COMM? (Choi et al., 2005)
predicate-argument pairs in which CAND occurs
lemma/part-of-speech tag/subcategorization frame/voice of nearest predicate
is nearest predicate OPINION/COMM?
does CAND precede/follow nearest predicate?
words between nearest predicate and CAND (bag of words)
part-of-speech sequence between nearest predicate and CAND
constituency path/grammatical relation path from predicate to CAND

Table 4: Manually designed feature set.

5 Experiments

We used 400 documents of the MPQA corpus for five-fold crossvalidation and 133 documents as a development set. We report statistical significance on the basis of a paired t-test using 0.05 as the significance level. All experiments were done with the *SVM-Light-TK* toolkit[7]. We evaluated on the basis of exact phrase matching. We set the trade-off parameter $j = 5$ for all feature sets. For the manual feature set we used a polynomial kernel of third degree. These two critical parameters were tuned on the development set. As far as the sequence and tree kernels are concerned, we used the parameter settings from Moschitti (2008), i.e. $\lambda = 0.4$ and $\mu = 0.4$. Kernels were combined using plain summation. The documents were parsed using the Stanford Parser (Klein and Manning, 2003). Named-entity information was obtained by the Stanford tagger (Finkel et al., 2005). Semantic roles were obtained by using the parser by Zhang et al. (2008). Opinion expressions were identified using the Subjectivity Lexicon from the MPQA project (Wilson et al., 2005). Communication words were obtained by using the Appraisal Lexicon (Bloom et al., 2007). Nominalizations were recognized by looking

[6] We select the nearest predicate by using the syntactic parse tree. Thus, we hope to select the predicate which syntactically relates to the candidate opinion holder.

up nouns in NOMLEX (Macleod et al., 1998).

5.1 Notation

Each kernel is represented as a triple $\langle$*levelOfRepresentation* (Table 1), *Scope* (Table 3), *typeOfKernel* (Table 2)$\rangle$, e.g. $\langle CONST, SENT, STK\rangle$ is a Subset Tree Kernel of a constituency parse having the scope of the entire sentence. Note that not all combinations of these three parameters are meaningful. In the following, we will just focus on important and effective combinations. The kernel composed of manually designed features is denoted by just VK. The kernel composed of predicate-argument structures is denoted by $\langle PAS, SENT, PTK\rangle$.

5.2 Vector Kernel (VK)

The first line in Table 7 displays the result of the vector kernel using a manually designed feature set. It should be interpreted as a baseline. Due to the high class imbalance we will focus on the comparison of F(1)-Score throughout this paper rather than accuracy which is fairly biased on this data set. The F-Score of this classifier is at 56.16%.

5.3 Sequence Kernels (SKs)

For both sequence and tree kernels we need to find out what the best scope is, whether it is worthwhile to combine different scopes and what different layers of representation can be usefully combined.

The upper part of Table 5 lists the results of simple word kernels using the different scopes. The performance of the kernels using individual scopes varies greatly. The best scope is $PRED$ (1), the second best is SEM (2). The good performance of $PRED$ does not come as a surprise since the sequence is the smallest among the different scopes, so this scope is least affected by data sparseness. Moreover, this result is consistent with our initial experiments on the manual feature set (see Section 4.5).

Using different combinations of the word sequence kernels shows that $PRED$ and SEM (6) are a good combination, whereas OP, $COMM$, and $SENT$ (7;8;9) do not positively contribute to the overall performance which is consistent which the individual scope evaluation. Apparently, these scopes capture less linguistically relevant structure.

The next part of Table 5 shows the contribution of POS kernels when added to WRD kernels. Adding the corresponding POS kernel to the WRD kernel with $PRED$ scope (10) results in an improvement by more than 5% in F-Score. We get another improvement by approx. 3% when the corresponding SEM kernels (11) are added. This suggests that POS is an effective generalization and that the two scopes $PRED$ and SEM are complementary.

For the $GRAM_{WRD}$ kernel, the $PRED$ scope (12) is again most effective. We assume that this kernel most likely expresses meaningful syntactic relationships for our task. Adding the $GRAM_{POS}$ kernel (14) gives another boost by almost 4%.

Generalized sequence kernels are important.

Adding the corresponding WRD_{GN} kernels to the WRD kernel with $PRED$ and SEM scope results in an improvement from 47.77% (1) to 53.00% (15) which is a bit less than the combination of WRD and $POS_{(GN)}$ kernels (16). However, these types of kernels seem to be complementary since their combination provides an F-Score of 56.06% (17). This kernel combination already performs on a par with the manually designed vector kernel though less information is taken into consideration.

Finally, the best combination of sequence kernels (18) comprises WRD, WRD_{GN}, POS, and POS_{GN} kernels with $PRED$ and SEM scope combined with a $GRAM_{WRD}$ and a $GRAM_{POS}$ kernel with $PRED$ scope. The performance of 58.70% significantly outperforms the vector kernel.

5.4 Tree Kernels (TKs)

Table 6 shows the results of the different tree kernels. The table is divided into two halves. The left half (A) are plain tree kernels, whereas the right half (B) are the augmented tree kernels. As far as $CONST$ kernels are concerned, there is a systematic improvement by approximately 2% using tree augmentation. This proves that further non-syntactic knowledge added to the tree itself results in an improved F-Score. However, tree augmentation does not have any impact on the PAS kernels.

The overall performance of the tree kernels shows that they are much more expressive than sequence kernels. For instance, in order to obtain the same performance as of $\langle CONST_{AUG}, PRED, STK\rangle$ (19B), i.e. a single kernel with an F-Score 56.52, it requires several sequence kernels, hence much more effort. The performance of the different $CONST$ kernels relative to each other resembles the results of the WRD kernels. The best scope is $PRED$ (19). By far the worst performance is obtained by the $SENT$ scope (23). The combination of $PRED$ and SEM scope achieves an F-Score of 59.67% (25B) which is already slightly better than the best configuration of sequence kernels (18).

The performance of the PAS kernel (28A) with an F-Score of 53.51% is slightly worse than the best single plain $CONST$ kernel (19A). The PAS kernel and the $CONST$ kernels are complementary, since their best combination (29B) achieves an F-Score of 61.67% which is significantly better than the best combination of $CONST$ kernels (25B) or sequence kernels (18).

Combination	**Acc.**	**Prec.**	**Rec.**	**F1**
VK	93.63	53.28	59.37	56.16
best SKs	94.21	57.64	59.81	58.70
best TKs	94.16	56.18	**68.36**	61.67*
VK + best SKs	94.34	58.44	61.27	59.82*
VK + best TKs	94.33	57.41	68.03	62.27*
best SKs + best TKs	94.49	**59.22**	63.96	61.49*
VK + best SKs + best TKs	**94.53**	59.10	66.57	**62.61***†

Table 7: Results of kernel combinations (*: significantly better than best SKs; †: significantly better than best TKs; all convolution kernels are significantly better than VK).

5.5 Combinations

Table 7 lists the results of the different kernel type combinations. If VK is added to the best TKs, the best SKs, or both, a slight increase in F-Score is achieved. The best performance with an F-Score of 62.61% is obtained by combining all kernels.

6 Conclusion

In this paper, we compared convolution kernels for opinion holder extraction. We showed that, in general, a combination of two scopes, namely the scope immediately encompassing the candidate opinion holder and its nearest predicate and the subclause containing the candidate opinion holder provide best performance. Tree kernels containing constituency parse information and semantic roles achieve better performance than sequence kernels or vector kernels using a manually designed feature set. Best performance is achieved if all kernels are combined.

Abstract

With the increase in popularity of online review sites comes a corresponding need for tools capable of extracting the information most important to the user from the plain text data. Due to the diversity in products and services being reviewed, supervised methods are often not practical. We present an unsupervised system for extracting aspects and determining sentiment in review text. The method is simple and flexible with regard to domain and language, and takes into account the influence of aspect on sentiment polarity, an issue largely ignored in previous literature. We demonstrate its effectiveness on both component tasks, where it achieves similar results to more complex semi-supervised methods that are restricted by their reliance on manual annotation and extensive knowledge sources.

1 Introduction

Online review sites continue to grow in popularity as more people seek the advice of fellow users regarding services and products. Unfortunately, users are often forced to wade through large quantities of written data in order to find the information they want. This has led to an increase in research in the areas of opinion mining and sentiment analysis, with the aim of providing systems that can automatically analyze user reviews and extract the information most relevant to the user.

One example of such an application is generating a summary of the important factors mentioned in the reviews of a product (see Lerman et al. 2009). Another application is comparing two similar products. In this case, it is important to present to the user the aspects in which the products differ, rather than just provide a general star rating. A third example is systems for generating automatic recommendations, based on similarity between products, user reviews, and history of previous purchases. These types of application require an underlying framework to identify the important aspects of the product (also known as *features* or *attributes*), and the sentiment expressed by the review writer.

Unsupervised Methods are desirable for this task, for two reasons. First, due to the wide range and variety of products and services being reviewed, the framework must be robust and easily transferable between domains. The second reason is the nature of the data. Online reviews are often short and unstructured, and may contain many spelling and grammatical errors, as well as slang or specialized jargon. These factors often present a problem to methods relying exclusively on dictionaries, manually-constructed knowledge resources, and gazetteers, as they may miss out on an important aspect of the product or an indicator of sentiment. Unsupervised methods, on the other hand, are not influenced by the lexical form, and can handle unknown words or word-forms, provided they occur frequently enough. This insures that any emergent topic that is salient in the data will be addressed by the system.

In this paper, we present an unsupervised system which addresses the core tasks necessary to enable advanced applications to handle review data. We introduce a local topic model, which works at the sentence level and employs a small number of topics, to automatically infer the aspects. For sentiment detection, we present a method for automatically deriving an unsupervised seed set of positive and negative adjectives that replaces the manually constructed ones commonly used in the literature. Our approach is specifically designed to take into account the inter-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 804–812,
Los Angeles, California, June 2010.

action between the two tasks.

The rest of the paper is structured as follows. In Sec. 2 we provide relevant background, and place our method in the context of previous work in the field. We describe the data we used in Sec. 3, and our experiments on the aspect and sentiment-polarity components in Sec. 4 and 5, respectively. We conclude in Sec. 6 with a discussion of our results and findings and directions for future research.

2 Previous Approaches

In this paper, we focus on the detection of two principle elements in the review text: aspects and sentiment. In previous work these elements have been treated, for the most part, as two separate tasks.

Aspect The earliest attempts at aspect detection were based on the classic information extraction (IE) approach of using frequently occurring noun phrases (e.g., Hu and Liu 2004). Such approaches work well in detecting aspects that are strongly associated with a single noun, but are less useful when aspects encompass many low frequency terms (e.g., the *food* aspect of restaurants, which involves many different dishes), or are abstract (e.g. *ambiance* can be described without using any concrete nouns at all). Common solutions to this problem involve clustering with the help of knowledge-rich methods, involving manually-constructed rules, semantic hierarchies, or both (e.g., Popescu and Etzioni 2005, Fahrni and Klenner 2008). Titov and McDonald (2008b) underline the need for unsupervised methods for aspect detection. However, according to the authors, existing topic models, such as standard Latent Dirichlet Allocation (LDA) (Blei et al., 2003), are not suited to the task of aspect detection in reviews, because they tend to capture global topics in the data, rather than rateable aspects pertinent to the review. To address this problem, they construct a multi-grain topic model (MG-LDA), which attempts to capture two layers of topics - global and local, where the local topics correspond to rateable aspects. MG-LDA distinguishes tens of local topics, but the many-to-one mapping between these and rateable aspects is not explicit in the system. To resolve this issue, the authors extend their model in Titov and McDonald (2008a) and attempt to infer such a mapping with the help of aspect-specific ratings provided along with the review text.

Sentiment Sentiment analysis has been the focus of much previous research. In this discussion, we will only mention work directly related to our own. For a comprehensive survey of the subject, the reader is directed to Pang and Lee (2008).

Most previous approaches rely on a manually constructed lexicon of terms which are strongly positive or negative regardless of context. This information on its own is usually insufficient, due to lack of coverage and the fact that sentiment is often expressed through words whose polarity is highly domain and context specific. If a sentiment lexicon is available for one domain, domain adaptation can be used, provided the domains are sufficiently similar (Blitzer et al., 2007). Another common solution is through bootstrapping - using a seed group of terms with known polarity to infer the polarity of domain specific terms (e.g., Fahrni and Klenner 2008; Jijkoun and Hofmann 2009). The most minimalist example of this approach is Turney (2002), who used only a single pair of adjectives (*good* and *poor*) to determine the polarity of other terms through mutual information. For Chinese, Zagibalov and Carroll (2008) use a single seed word meaning *good*, and six common indicators of negation in their bootstrapping approach. Often, when using a context independent seed, large amounts of domain-specific data are required, in order to obtain sufficient co-occurrence statistics. Commonly, web queries are used to obtain such data.

Independently of any specific task, Hatzivassiloglou and McKeown (1997) present a completely unsupervised method for determining the polarity of adjectives in a large corpus. A graph is created, in which adjectives are nodes, and edges between them are weighted according to a (dis)similarity function based primarily on whether the two adjectives occurred in a conjunction or disjunction in the corpus. A heuristic approach is then used to split the graph in two. The group containing the adjectives with the higher average frequency is labeled as positive, and the other as negative.

Combined Approaches Aspects can influence sentiment polarity within a single domain. For example, in the restaurant domain, *cheap* is usually positive when discussing food, but negative when discussing the decor or ambiance. Many otherwise neutral terms (e.g., *warm, heavy, soft*) acquire a sentiment polarity in the context of a specific aspect.

Recent work has addressed this interaction in different ways. Mei et al. (2007) present a form of domain adaptation using an LDA model which treats positive and negative sentiment as two additional topics. Fahrni and Klenner (2008) directly address the specificity of sentiment to the word it is modifying. Aspects are defined by a manually specified subset of the Wikipedia category hierarchy. For sentiment, the authors use a seed set of positive and negative adjectives, and iteratively propagate sentiment polarity through conjunction relations (like those used by Hatzivassiloglou and McKeown 1997, above). Web queries are used to overcome the sparsity issue of these highly-specific patterns. In the IE setting, Popescu and Etzioni (2005) extract frequent terms, and cluster them into aspects. The sentiment detection task is formulated as a Relaxation Labeling problem of finding the most likely sentiment labels for opinion-bearing terms, while satisfying as many local constraints as possible. The authors use a variety of knowledge sources, web queries, and hand crafted rules to detect relations between terms (e.g., meronymy). These relations are used both for the clustering, and as a basis for the constraints.

Our approach is designed to be as unsupervised and knowledge-lean as possible, so as to make it transferable across different types of products and services, as well as across languages. Aspects are determined via a local version of LDA, which operates on sentences, rather than documents, and employs a small number of topics that correspond directly to aspects. This approach overcomes the problems of frequent-term methods, as well as the issues raised by Titov and McDonald (2008b). We use morphological negation indicators to automatically create a seed set of highly relevant positive and negative adjectives, which are guaranteed to be pertinent to the aspect at hand. These automatically-derived seed sets achieve comparable results to the use of manual ones, and the work of Zagibalov and Carroll (2008) suggests that the use of negation can be easily transfered to other languages.

3 Data

Our primary dataset is the publicly available corpus used in Ganu et al. (2009). It contains over 50,000 restaurant reviews from Citysearch New York[1]. Additionally, to demonstrate the domain independence of our system, we collected 1086 reviews for four leading netbook computers from Amazon.com.

For evaluation purposes, we used the annotated dataset from Ganu et al. (2009), which is a subset of 3,400 sentences from the Citysearch corpus. These sentences were manually labeled for aspect and sentiment. There were six manually defined aspect labels - *Food & Drink*, *Service*, *Price*, *Atmosphere*, *Anecdotes* and *Miscellaneous*. A sentence could contain multiple aspects, but, for our evaluation, we used only sentences with a single label. For sentiment, each sentence was given a single value - *Positive, Negative, Neutral* or *Conflict* (indicating a mixture of positive and negative sentiment).

We were also provided with a seed set of 128 positive and 88 negative adjectives used by Fahrni and Klenner (2008), which were specifically selected to be domain and target independent.

For the purpose of the experiments presented here, we focused on sentences containing noun-adjective pairs. Such pairs are one of the most common way of expressing sentiment about an aspect and allow us to capture the interaction between the two.

4 Aspect

4.1 Methodology

In order to infer the salient aspects in the data, we employed the following steps:

Local LDA We used a standard implementation[2] of LDA. In order to prevent the inference of global topics and direct the model towards rateable aspects (see Sec. 2), we treated each sentence as a separate document. The output of the model is a distribution over inferred aspects for each sentence in the data. The parameters we employed were standard, out-of-the-box settings ($\alpha = 0.1, \beta = 0.1$, 3000 iterations), with no specific tuning to our data. We ran the algorithm with the number of aspects ranging from 10 to 20, and employed a cluster validation scheme (see below) to determine the optimal number.

Model Order The issue of model order, i.e., determining the correct number of clusters, is an important element in unsupervised learning. A common

[1] http://newyork.citysearch.com/

[2] GibbsLDA++, by Xuan-Hieu Phan. Available at http://gibbslda.sourceforge.net/.

approach (Levine and Domany, 2001; Lange et al., 2004; Niu et al., 2007) is to use a cluster validation procedure. In such a procedure, different model orders are compared, and the one with the most consistent clustering is chosen. For the purpose of the validation procedure, we have a cluster corresponding to each aspect, and we label each sentence as belonging to the cluster of the most probable aspect.

Given the collection of sentences in our data, D, and two connectivity matrices C and $\hat{C}$, where a cell i,j contains 1 if sentences d_i and d_j belong to the same cluster, we define a consistency function F (following Niu et al. 2007):

$$F(C,\hat{C}) = \frac{\sum_{i,j} 1\{C_{i,j} = \hat{C}_{i,j} = 1, d_i, d_j \in \hat{D}\}}{\sum_{i,j} 1\{C_{i,j} = 1, d_i, d_j \in \hat{D}\}} \quad (1)$$

We then employ the following procedure:

1. Run the LDA model with k topics on D to obtain connectivity matrix C_k.
2. Create a comparison connectivity matrix R_k based on uniformly drawn random assignments of the instances.
3. Sample random subset D^i of size $\delta|D|$ from D.
4. Run the LDA model on D^i to obtain connectivity matrix C_k^i.
5. Create a comparison matrix R_k^i based on uniformly drawn random assignments of the instances in D^i.
6. Calculate $score_i(k) = F(\hat{C},C) - F(\hat{R},R)$ where F is given in Eq. 1.
7. Repeat steps 3 to 6 q times.
8. Return the average score over q iterations.

This procedure calculates the consistency of our clustering solution, using a similar sized random assignment for comparison. It does this on q subsets to reduce the effects of chance. The k with the highest score is chosen. In our experiments, we used $q = 5, \delta = 0.9$. For both our datasets (restaurants and netbooks), the highest-scoring k was 14.

Determining Representative Words For each aspect, we list all the nouns in the data according to a score based on their mutual information with regard to that aspect.

$$Score_a(w) = p(w,a) \cdot log \frac{p(w,a)}{p(w) \cdot p(a)} \quad (2)$$

Where $p(w), p(a), p(w,a)$ are the probabilities, according to the LDA model, of the word w, the aspect a, and the word w labeled with aspect a, respectively.

We then select, for each aspect, the top k_a ranking words, such that they cover 75% of the word-instances labeled by the LDA model with aspect label a. Due to the skewed frequency distribution of words, this is a relatively small portion of the words (typically 100-200). This set of representative words for each aspect is used in the sentiment component of our system (see Sec. 5.1).

4.2 Inferred Aspects

Table 1 presents the aspects inferred by our system for the restaurant domain. The inferred aspects cover all those defined in the manual annotation, but also distinguish between a finer granularity of aspects, based solely on the review text, e.g., between physical environment and ambiance, and between the attitude of the staff and the quality of the service.

In order to demonstrate that our method can be transfered between very different domains and categories of products, we also ran our algorithm on our set of netbook reviews. The inferred aspects are presented in Table 2. The system identifies important aspects relevant to our data. Some of these (e.g., software, hardware) might be suggested by human annotators, but some would probably be missed unless the annotators carefully read through all the reviews, e.g., the *Memory* aspect, which includes advice about upgrading specific models. This capability of our system is important, as it demonstrates that our method can be used to produce customized comparisons for the user and will take into account the important common factors, as well as the unique aspects of each item.

4.3 Evaluation

To determine the quality of our automatically inferred aspects, we compared the output of our system to the sentence-level manual annotation of Ganu et al. (2009). To each sentence in the data, the LDA model assigns a distribution $\{P(a)\}_{a \in A}$ over the set A of inferred aspects. By defining a threshold t_a for each aspect, we can label a sentence as belonging to aspect a if $P(a) > t_a$. By varying the threshold t_a we created precision-recall curves for the top three rateable aspects in the restaurant domain, shown in

Inferred Aspect	Representative Words	Manual Aspect
Main Dishes	chicken, sauce, rice, cheese, spicy, salad,	Food & Drink
Bakery	hot, delicious, dessert, bagels, bread, chocolate	
Food - General	menu, fresh, sushi, fish, chef, cuisine	
Wine & Drinks	wine, list, glass, drinks, beer, bottle	
Ambiance / Mood	great, atmosphere, wonderful, music, experience, relaxed	Atmosphere
Physical Atmosphere	bar, room, outside, seating, tables, cozy, loud	
Staff	service, staff, friendly, attentive, busy, slow	Staff
Service	table, order, wait, minutes, reservation, forgot	
Value	portions, quality, worth, size, cheap	Price
Anecdotes	dinner, night, group, friends, date, family	Anecdotes
Anecdotes	out, back, definitely, around, walk, block	
General	best, top, favorite, city, NYC	Misc.
Misc. - Location	never, restaurant, found, Paris, (New) York, location	
Misc.	place, eat, enjoy, big, often, stuff	

Table 1: List of automatically inferred aspects for the restaurant domain, with some representative words for each aspect (middle), and the corresponding aspect label from the manual annotation (right). Labels (left) were assigned by the authors.

Aspect	Representative Words	Aspect	Representative Words
Performance	power, performance, mode, fan, quiet	Mouse	mouse, right, touchpad, pad, buttons, left
Hardware	drive, wireless, bluetooth, usb, speakers, webcam	General	great, little, machine, price, netbook, happy
Memory	ram, 2GB, upgrade, extra, 1GB, speed	Purchase	amazon, purchased, bought, weeks, ordered
Software	using, office, software, installed, works, programs	Looks	looks, feel, white, finish, blue, solid, glossy
Usability	internet, video, web, movies, music, email, play	OS	windows, xp, system, boot, linux, vista, os
Portability	around, light, work, portable, weight, travel	Battery	battery, life, hours, time, cell, last
Comparison	netbooks, best, reviews, read, decided, research	Size	screen, keyboard, size, small, enough, big

Table 2: List of automatically inferred aspects for the netbook dataset, with representative words for each aspect .

Figure 1[3]. Although the data used in Titov and McDonald (2008a) was unavailable for direct comparison, our method exhibits similar behavior and performance (compare Fig. 4, there) on a domain with similar characteristics (abstract aspects which encompass many low frequency words). This demonstrates that our local version of LDA with few topics overcomes the issues which confronted the authors of that work (i.e., global topics and many-to-one mapping of topics to aspects), without requiring specially designed models or additional information in the form of user-provided aspect-specific ratings (see Sec. 2).

We believe the reason for this stems from the composition of online reviews. Since many reviews have similar mixtures of local topics (e.g., food, service), standard LDA prefers global topics, which distinguish more strongly between *reviews* (e.g., cuisine type, restaurant type). However, when employed at the sentence level, local topics (corresponding to rateable aspects) provide a stronger way to distinguish between individual *sentences*.

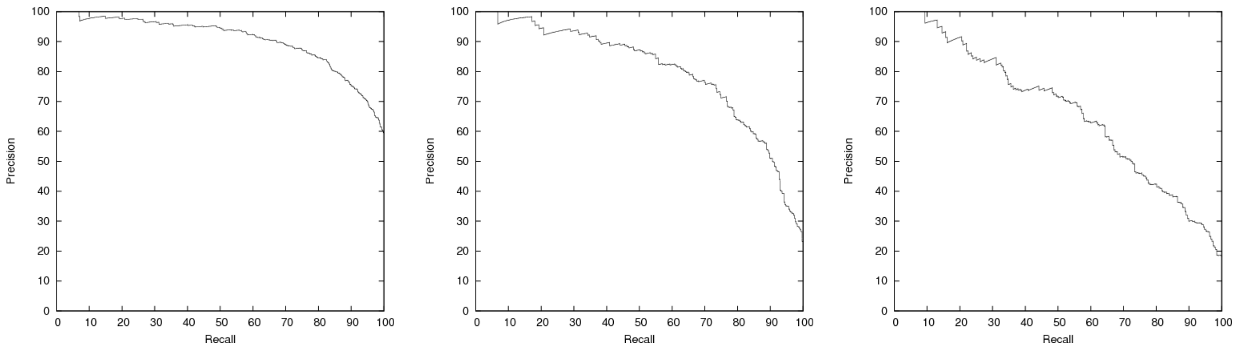
5 Sentiment

5.1 Methodology

For determining sentiment polarity, we developed the following procedure. For each aspect, we extracted the relevant adjectives, built a conjunction graph, automatically determined the seed set (or used a manual one, for comparison), and propagated the polarity scores to the rest of the adjectives. Details of each step are described below.

Extracting Adjectives As a pre-processing step, we parsed our data (using RASP, Briscoe and Carroll 2002). The parsed output was used to detect negation and conjunction. If an adjective *A* partic-

[3] We combined the probabilities of all the inferred aspects that match a single manually assigned aspect, according to the mapping in Table 1.



(a)

(b)

(c)

Figure 1: Precision / Recall curves for the top three rateable aspects: (a) *Food*, (b) *Service*, and (c) *Atmosphere*.

ipated in a negation in the sentence, it was replaced by a new adjective *not-A*. We then extract all cases where an adjective modified a noun. For example, from the sentence *"The food was tasty and hot, but our waiter was not friendly."* we can extract the pairs *(tasty, food), (hot, food), (not-friendly, waiter).*

Building the Graph Our method for determining sentiment polarity is based on an adaptation of Hatzivassiloglou and McKeown (1997) (see Sec. 2).

Several issues confronted us when attempting to adapt their method to our task. In the original article, adjectives with no orientation were ignored. It is unclear how this can be easily done in an unsupervised fashion, and such sentiment-neutral adjectives are ubiquitous in real-world data. Furthermore, adjectives whose orientation depended on the context were also ignored. These are of particular interest in our task, and are likely to be missing or incorrectly labeled in standard sentiment dictionaries. For our purposes, since we need to handle adjectives expressing various shades of sentiment, not only strongly positive or negative ones, we are interested in a scoring method, rather than a binary labeling. Also, we do not want to use a general corpus, but rather the text from the reviews themselves. This usually means a much smaller corpus than the one used in the original paper, but has the advantage of being domain specific.

Our method of building the polarity graph differed in several ways from the original. First, we did not use disjunctions (e.g., 'but') as indicators of opposite polarity. The reason for this was that, in our domain of online reviews, disjunctions often did not convey contrast in polarity, but rather in perceived expectations, e.g., *"dainty but strong necklace"*, and *"cheap but delicious food"*.

Instead of using regular expressions to capture explicit conjunctions, we retrieved all cases where our parser indicated that two adjectives modified a single noun in the same sentence.

To ensure that aspect-specific adjectives are handled correctly, we built a separate graph for each aspect, by selecting the cases where the modified noun was one of the representative words for that aspect (see Sec. 4.1).

Constructing a Seed Set We used morphological information and explicit negation to find pairs of opposite polarity. Specifically, adjective pairs which were distinguished only by one of the prefixes *'un', 'in', 'dis', 'non',* or by the negation marker *'not-'* were selected for the seed set. Starting with the most frequent pair, we assigned a positive polarity to the more frequent member of the pair.

Then, in order of decreasing frequency, we assigned polarity to the other seed pairs, based on the shortest path either of the members had to a previously labeled adjective. That member received its neighbor's polarity, and the other member of the pair received the opposite polarity. When all pairs were labeled, we corrected for misclassifications by iterating through the pairs and reversing the polarity if that improved consistency, i.e., if it caused the members of the pair to match the polarities of more of their neighbors. Finally, we reverse the polarity of the seed groups if the negative group has a higher total frequency.

Propagating Polarity Our propagation method is based on the label propagation algorithm of Zhu and Ghahramani (2002). The adjectives in the positive and negative seed groups are assigned a polarity score of 1 and 0, respectively. All the rest start with a score of 0.5. Then, an update step is repeated. In update iteration t, for each adjective x that is *not in the seed*, the following update rule is applied:

$$p^t(x) = \frac{\Sigma_{y \in N(x)} w(y,x) \cdot p^{t-1}(y)}{\Sigma_{y \in N(x)} w(y,x)} \tag{3}$$

Where $p^t(x)$ is the polarity of adjective x at step t, $N(x)$ is the set of the neighbors of x, and $w(y,x)$ is the weight of the edge connecting x and y. We set this weight to be $1 + log(\#mod(y,x))$ where $\#mod(y,x)$ is the number of times y and x both modified a single noun. The update step is repeated to convergence.

5.2 Aspect-Specific Gold Standard

To evaluate the performance of the sentiment component of our system, we created an aspect-specific gold standard. For each of the top eight automatically inferred aspects (corresponding to the *Food, Service* and *Atmosphere* aspects in the annotation), we constructed a polarity graph, as described in Sec. 5.1. We retrieved a list of all adjectives that participated in five or more modifications of nouns from that specific aspect). Table 3 lists the number of such adjectives in each aspect. We split the data into ten portions and, for each portion, asked two volunteers to rate each adjective according to the polarity of the sentiment it expresses *in the context of the specified aspect*. The judges could select from the following ratings: *Strongly Negative*, *Weakly Negative*, *Neutral*, *Weakly Positive*, *Strongly Positive*, and *N/A*. As expected, exact inter-annotator agreement was low - only 54%, but when considering two adjacent ratings as equivalent (i.e, Strongly vs. Weakly Negative or Positive, and Neutral vs. Weakly Negative or Positive), agreement was 93.3%. This indicates there is some difficulty distinguishing between the fine-grained categories we specified, but high agreement at a coarser level, which advocates using a ranking approach for evaluation (see also Pang and Lee 2005). We therefore translated the annotator ratings to a numerical scale, from -2 (Strongly Negative) to $+2$ (Strongly Positive) at unit intervals. After discarding adjectives where one or more annotators gave a 'N/A' tag, we averaged the two annotator numerical scores, and used this data as the gold standard for our evaluation.

Aspect	# Adj.	# Rated	% Neu.
Mood	293	206	17%
Staff	155	122	3%
Main Dishes	287	185	25%
Physical Atmo.	161	103	21%
Bakery	180	129	23%
Food - General	192	144	28%
Wine & Drinks	111	75	18%
Service	89	57	5%
Total	1468	1021	–

Table 3: For each aspect, the number of frequently occurring adjectives for each aspect (# Adj.), number of adjectives remaining after removing those labeled 'N/A' (# Rated), and percent of rated adjectives labeled 'Neutral' by both annotators (% Neu.).

	Auto.		Manual	
Aspect	τ_k	D_k	τ_k	D_k
Mood	0.53	0.23	0.56	0.22
Staff	0.57	0.22	0.60	0.20
Main Dishes	0.19	0.40	0.38	0.31
Physical Atmo.	0.34	0.33	0.25	0.37
Bakery	0.33	0.33	0.35	0.33
Food - General	0.19	0.41	0.41	0.30
Wine & Drinks	0.32	0.34	0.52	0.24
Service	0.41	0.30	0.54	0.23
Average	0.36	0.32	0.45	0.27

Table 4: Kendall coefficient and distance scores for eight inferred aspects.

5.3 Evaluation Measures

Kendall's tau coefficient (τ_k) and Kendall's distance (D_k) are commonly used (e.g., Jijkoun and Hofmann 2009) to compare rankings. These measures look at the number of pairs of ranked items that agree or disagree with the ordering in the gold standard. The value of τ_k ranges from -1 (perfect disagreement) to 1 (perfect agreement), with 0 indicating an almost random ranking. The value of D_k ranges from 0 (perfect agreement) to 1 (perfect disagreement). It is important to note that only pairs that are ordered in the gold standard are used in the comparison.

5.4 Evaluation Results

Table 4 reports Kendall's coefficient (τ_k) and distance (D_k) values for our method when using our automatically derived seed set (Auto.). For comparison, we ran our procedure using the manually compiled seed set (Manual) of Fahrni and Klenner

Food - General: Mexican, *French*, Eastern, Turkish, European, Tuscan, Mediterranean, American, Cuban, Thai, Peruvian, Spanish, Korean, Vietnamese, Indian, African, Japanese, Italian, *Chinese*, Asian
Mood: Vietnamese, Brazilian, Turkish, Eastern, Caribbean, Cuban, Italian, Spanish, Japanese, European, Mediterranean, Colombian, Mexican, Asian, Indian, Thai, British, American, *French*, Korean, *Chinese*, Russian, Moroccan
Staff: British, European, *Chinese*, Indian, American, Spanish, Asian, Italian, *French*

Table 5: Polarity ranking of cuisine adjectives (from most positive) for three aspects.

(2008). Using the manual seed set obtains results that correspond better to our gold standard. Our automatic method also achieves good results, and can be used when a manual seed set is not available. More importantly, correlation with the gold standard may not indicate better suitability to the sentiment detection task in reviews. For instance, it is interesting to note that the worst correlation scores were on the *Main Dishes* and *Food - General* aspects. If we compare to Table 3, we can see these aspects have the highest percentage of adjectives rated as neutral by the annotators. However, in many cases, these adjectives actually carry some sentiment in their context. An example of this are adjectives describing the type of cuisine, which are objective, and therefore usually considered neutral by annotators. Table 5 shows the automatic ranking of cuisine type from positive to negative in three aspects. It is interesting to see that the rankings change according to the aspect, and certain cuisines are strongly associated with specific aspects and not with others. This is supported by Ganu et al. (2009), who observed during the annotation that, in the restaurant corpus, French and Italian restaurants were strongly associated with the service aspect. This trend can be identified automatically by our method, and at a much more detailed level than that noticed by a human analyzing the data.

6 Discussion & Future Work

Our experiments confirm the value of a fully unsupervised approach to the tasks of aspect detection and sentiment analysis. The aspects are inferred from the data, and are more representative than manually derived ones. For instance, in our restaurant domain, the manually constructed aspect list omitted or over-generalized some important aspects, while over-representing others. There was no separate *Drinks* category, even though it was strongly present in the data. The *Service* aspect, dealing with waiting time, reservations, and mistaken orders, was an important emergent aspect on its own, but was grouped under *Staff* in the manual annotation.

Adjectives can convey different sentiments depending on the aspect being discussed. For example, the adjective *'warm'* was ranked very positive in the *Staff* aspect, but slightly negative in the *General Food* aspect. A knowledge-rich approach might ignore such adjectives, thereby missing important elements of the review.

Finally, as online reviews belong to an informal genre, with inventive spelling and specialized jargon, it may be insufficient, for both aspect and sentiment, to rely only on lexicons. For example, our restaurant reviews included spelling errors such as *desert, decour/decore, anti-pasta, creme-brule, sandwhich, omlette, exelent, tastey,* as well as at least six different common misspellings of *restaurant*. There were also specialized terms, such as *Korma, Edamame, Dosa* and *Pho*, all of which do not appear in common dictionaries, and creative use of adjectives, such as *orgasmic* and *New-Yorky*.

This work has opened many avenues for future research and improvements. So far, we focused on adjectives as sentiment indicators, however, there have been studies showing that other parts of speech can be very helpful for this task (e.g., Pang et al. 2002; Benamara et al. 2007). Also, it would be interesting to take a closer look at the interactions between aspect and sentiment, especially at a multiple-sentence level (see Snyder and Barzilay 2007). Finally, we feel that the true test of the usability of our system should be through an application, and intend to proceed in that direction.

Acknowledgments

We'd like to thank Angela Fahrni and Manfred Klenner for kindly allowing us access to their data and annotation. We also wish to thank the volunteer annotators. This work was partially supported by a Google Research Award.

Abstract

Knowledge extraction from online repositories such as PubMed holds the promise of dramatically speeding up biomedical research and drug design. After initially focusing on recognizing proteins and binary interactions, the community has recently shifted their attention to the more ambitious task of recognizing complex, nested event structures. State-of-the-art systems use a pipeline architecture in which the candidate events are identified first, and subsequently the arguments. This fails to leverage joint inference among events and arguments for mutual disambiguation. Some joint approaches have been proposed, but they still lag much behind in accuracy. In this paper, we present the first joint approach for bio-event extraction that obtains state-of-the-art results. Our system is based on Markov logic and adopts a novel formulation by jointly predicting events and arguments, as well as individual dependency edges that compose the argument paths. On the BioNLP'09 Shared Task dataset, it reduced F1 errors by more than 10% compared to the previous best joint approach.

1 Introduction

Extracting knowledge from unstructured text has been a long-standing goal of NLP and AI. The advent of the World Wide Web further increases its importance and urgency by making available an astronomical number of online documents containing virtually unlimited amount of knowledge (Craven et al., 1999). A salient example domain is biomedical literature: the PubMed[1] online repository contains over 18 million abstracts on biomedical research, with more than two thousand new abstracts added each day; the abstracts are written in grammatical English, which enables the use of advanced NLP tools such as syntactic and semantic parsers.

Traditionally, research on knowledge extraction from text is primarily pursued in the field of information extraction with a rather confined goal of extracting instances for flat relational schemas with no nested structures (e.g, recognizing protein names and protein-protein interaction (PPI)). This restriction mainly stems from limitations in available resources and algorithms. The BioNLP'09 Shared Task (Kim et al., 2009) is one of the first that faced squarely information needs that are complex and highly structured. It aims to extract nested bio-molecular events from research abstracts, where an event may have variable number of arguments and may contain other events as arguments. Such nested events are ubiquitous in biomedical literature and can effectively represent complex biomedical knowledge and subsequently support reasoning and automated discovery. The task has generated much interest, with twenty-four teams having submitted their results. The top system by UTurku (Bjorne et al., 2009) attained the state-of-the-art F1 of 52.0%.

The nested event structures make this task particularly attractive for applying joint inference. By allowing information to propagate among events and arguments, joint inference can facilitate mutual disambiguation and potentially lead to substantial gain

in predictive accuracy. However, joint inference is underexplored for this task. Most participants either reduced the task to classification (e.g., by using SVM), or used heuristics to combine manual rules and statistics. The previous best joint approach was Riedel et al. (2009). While competitive, it still lags UTurku by more than 7 points in F1.

In this paper, we present the first joint approach that achieves state-of-the-art results for bio-event extraction. Like Riedel et al. (2009), our system is based on Markov logic, but we adopted a novel formulation that models dependency edges in argument paths and jointly predicts them along with events and arguments. By expanding the scope of joint inference to include individual argument edges, our system can leverage fine-grained correlations to make learning more effective. On the development set, by merely adding a few joint inference formulas to a simple logistic regression model, our system raised F1 from 28% to 54%, already tying UTurku.

We also presented a heuristic method to fix errors in syntactic parsing by leveraging available semantic information from task input, and showed that this in turn led to substantial performance gain in the task. Overall, our final system reduced F1 error by more than 10% compared to Riedel et al. (2009).

We begin by describing the shared task and related work. We then introduce Markov logic and our Markov Logic Network (MLN) for joint bio-event extraction. Finally, we present our experimental results and conclude.

2 Bio-Event Extraction

We follow the BioNLP'09 Shared Task (Kim et al., 2009) on problem setup for bio-event extraction. A bio-molecular event (bio-event) refers to the change of state for bio-molecules such as DNAs and proteins. The goal is to extract these events from unstructured text such as biomedical abstracts. For each event, one needs to identify the trigger words that signifies the event and the theme arguments that undergo the change. In addition, for regulation events, the cause argument also needs to be identified if it is present. The task considers nine event types: `Expression`, `Transcription`, `Localization`, `Phosphorylation`, `Catabolism`, `Binding`, `Regulation`, `Positive_regulation`, and `Negative_regulation`. Only `Binding` can take multiple themes. Regulation events may take events as arguments. To facilitate evaluation, the task fixes the type of non-event arguments to protein and provides ground truth of protein mentions as input. [2]

Like any NLP task, ambiguity is a central problem. The same event can be expressed in many variations. For example, a `Negative_regulation` event may be signified by "inhibition", "down-regulation", "is abrogated by", to name a few. On the other hand, depending on the context, the same expression may represent different events. For example, "level" may signify any one of five event types in the training set, or signify none.

In addition, the nested event structures present new challenges to knowledge extraction systems. To recognize a complex event, besides from identifying the event type and trigger words, one also needs to identify its arguments and recursively identify their event structures. A mistake in any part will render a failure in this extraction.

The interdependencies among events and arguments naturally argue for joint predictions. For example, given the snippet "the level of VCAM-1 mRNA", knowing that "level" might signify an event helps to recognize the prepositional phrase (PP) as its theme. Conversely, the presence of the PP suggests that "level" is likely an event. Moreover, the word "mRNA" in the PP indicates that the event type is probably `Transcription`.

Most existing systems adopt a pipeline architecture and reduce the task to independent classifications of events and arguments. For example, the best system UTurku (Bjorne et al., 2009) first extracts a list of candidate triggers with types, and then determines for each pair of candidate triggers or proteins whether one is a theme or cause of the other. The triggers missed in the first stage can never be recovered in the second one. Moreover, since the second stage is trained with gold triggers as input, any trigger identified in the first stage tends to get at least

[2] The Shared Task also defines two other tasks (Tasks 2 and 3), which aim either to extract additional arguments (e.g., sites), or to determine if an event is a negation or speculation. In this paper, we focus on the core task (Task 1) as it is what most systems participate in, but our approach can be extended straightforwardly to handle the other tasks.

one argument, even though it may not be an event at all. As a result, the authors had to use an ad hoc procedure to trade off precision and recall for the final prediction task while training the first-stage extractor. In addition, each trigger or argument is classified independently using a multi-class SVM.

While joint inference can potentially improve accuracy, in practice, it is often very challenging to make it work (Poon and Domingos, 2007). The previous best joint approach for this task was proposed by Riedel et al. (2009) (labeled UT+DBLS in Kim et al. (2009)). Their system is also based on Markov logic (Domingos and Lowd, 2009). While competitive (ranked fourth in the evaluation), their system still lags UTurku by more than 7 points in F1.

Most systems, Riedel et al.'s included, classify each candidate argument path as a whole. A notable exception is the UTokyo system (Saetre et al., 2009), which incorporated sequential modeling by adapting a state-of-the-art PPI system based on MEMM. But they considered adjacent words in the sentence, which offered little help in this task, and their system trailed UTurku by 15 points in F1.

All top systems for event extraction relied heavily on syntactic features. We went one step further by formulating joint predictions directly on dependency edges. While this leverages sequential correlation along argument paths, it also makes our system more prone to the adverse effect of syntactic errors. Joint syntactic and semantic processing has received much attention lately (Hajic et al., 2009). In this paper, we explore using a heuristic method to correct syntactic errors based on semantic information, and show that it leads to significant performance gain for event extraction.

3 Markov Logic

In many NLP applications, there exist rich relation structures among objects, and recent work in statistical relational learning (Getoor and Taskar, 2007) and structured prediction (Bakir et al., 2007) has shown that leveraging these can greatly improve accuracy. One of the leading frameworks for joint inference is Markov logic, a probabilistic extension of first-order logic (Domingos and Lowd, 2009). A *Markov logic network (MLN)* is a set of weighted first-order clauses. Together with a set of constants, it defines a Markov network with one node per ground atom and one feature per ground clause. The weight of a feature is the weight of the first-order clause that generated it. The probability of a state x in such a network is given by $P(x) = (1/Z) \exp\left(\sum_i w_i f_i(x)\right)$, where Z is a normalization constant, w_i is the weight of the ith clause, $f_i = 1$ if the ith clause is true, and $f_i = 0$ otherwise.

Markov logic makes it possible to compactly specify probability distributions over complex relational domains. Efficient inference can be performed using MC-SAT (Poon and Domingos, 2006). MC-SAT is a "slice sampling" Markov chain Monte Carlo algorithm that uses an efficient satisfiability solver to propose the next sample. It is orders of magnitude faster than previous MCMC algorithms like Gibbs sampling, making efficient sampling possible on a scale that was previously out of reach.

Supervised learning for Markov logic maximizes the conditional log-likelihood of query predicates given the evidence in the train data. This learning objective is convex and can be optimized using gradient descent, where the gradient is estimated using MC-SAT.

In practice, it is often difficult to tune the learning rate, especially when the number of groundings varies widely among clauses (known as *ill-conditioning* in numerical optimization). This problem is particularly severe in relational domains. One remedy is to apply preconditioning to the gradient. For example, Poon & Domingos (2007) divided the global learning rate by the number of true groundings of the corresponding clause in the training data, whereas Lowd & Domingos (2007) divided it by the variance of the clause (also estimated using MC-SAT). The latter can be viewed as approximating the Hessian with its diagonal, and is guaranteed optimal when the weights are not correlated (e.g., in logistic regression). Lowd & Domingos (2007) also used a scaled conjugate gradient algorithm to incorporate second-order information and further adapt the search direction.

The open-source Alchemy package (Kok et al., 2009) provides implementations of existing algorithms for Markov logic.

4 An MLN for Joint Bio-Event Extraction

In this section, we present our MLN for joint bio-event extraction. As standard for this task, we assume that Stanford dependency parses are available in the input. Our MLN jointly makes the following predictions: for each token, whether it is a trigger word (and if so, what is the event type), and for each dependency edge, whether it is in an argument path leading to a theme or cause.

To the best of our knowledge, the latter part makes this formulation a novel one. By breaking the prediction of an argument path into that on individual dependency edges, it can leverage the correlation among adjacent edges and make learning more effective. Indeed, compared to other top systems, our MLN uses a much simpler set of features, but is still capable of obtaining state-of-the-art results.[3] Computationally, this formulation is also attractive. The number of predictions is bounded by the number of tokens and edges, and is linear in sentence length, rather than quadratic.

Our MLN also handles the regulation events differently. We notice that events of the three regulation types often occur in similar contexts, and sometimes share trigger words (e.g., "involve"). Therefore, our MLN merges them into a single event type Regulation, and additionally predicts the regulation direction (Positive or Negative). This allows it to pool information shared by the three types.

Base MLN: The following are the main query predicates we used, along with descriptions:

$\mathtt{Event}(\mathtt{i})$**:** token i signifies an event;

$\mathtt{EvtType}(\mathtt{i},\mathtt{e})$**:** i is of event type e;

$\mathtt{RegType}(\mathtt{i},\mathtt{r})$**:** i is of regulation type r;

$\mathtt{InArgPath}(\mathtt{i},\mathtt{j},\mathtt{a})$**:** the dependency edge from i to j is in an argument path of type a, with a being either Theme or Cause.

If event i has type Positive_regulation, both $\mathtt{EvtType}(\mathtt{i},\mathtt{Regulation})$ and $\mathtt{RegType}(\mathtt{i},\mathtt{Positive})$ are true. Similarly for Negative_regulation. If the type is Regulation, only $\mathtt{EvtType}(\mathtt{i},\mathtt{Regulation})$ is true.

Table 1: Formulas in the base MLN.

$\mathtt{Token}(\mathtt{i},+\mathtt{t}) \Rightarrow \mathtt{EvtType}(\mathtt{i},+\mathtt{e})$
$\mathtt{Token}(\mathtt{i},+\mathtt{t}) \Rightarrow \mathtt{RegType}(\mathtt{i},+\mathtt{r})$
$\mathtt{Token}(\mathtt{j},+\mathtt{t}) \wedge \mathtt{Dep}(\mathtt{i},\mathtt{j},\mathtt{d}) \Rightarrow \mathtt{EvtType}(\mathtt{i},+\mathtt{e})$
$\mathtt{Dep}(\mathtt{i},\mathtt{j},+\mathtt{d}) \Rightarrow \mathtt{InArgPath}(\mathtt{i},\mathtt{j},+\mathtt{a})$
$\mathtt{Dep}(\mathtt{i},\mathtt{j},+\mathtt{d}) \wedge \mathtt{Prot}(\mathtt{i}) \Rightarrow \mathtt{InArgPath}(\mathtt{i},\mathtt{j},+\mathtt{a})$
$\mathtt{Dep}(\mathtt{i},\mathtt{j},+\mathtt{d}) \wedge \mathtt{Prot}(\mathtt{j}) \Rightarrow \mathtt{InArgPath}(\mathtt{i},\mathtt{j},+\mathtt{a})$
$\mathtt{Token}(\mathtt{i},+\mathtt{t}) \wedge \mathtt{Dep}(\mathtt{i},\mathtt{j},+\mathtt{d}) \Rightarrow \mathtt{InArgPath}(\mathtt{i},\mathtt{j},+\mathtt{a})$
$\mathtt{Token}(\mathtt{j},+\mathtt{t}) \wedge \mathtt{Dep}(\mathtt{i},\mathtt{j},+\mathtt{d}) \Rightarrow \mathtt{InArgPath}(\mathtt{i},\mathtt{j},+\mathtt{a})$

The main evidence predicates are:

$\mathtt{Token}(\mathtt{i},\mathtt{w})$**:** token i has word w;

$\mathtt{Dep}(\mathtt{i},\mathtt{j},\mathtt{d})$**:** there is a dependency edge from i to j with label d; [4]

$\mathtt{Prot}(\mathtt{i})$**:** i is a protein.

Our base MLN is a logistic regression model, and can be succintly captured by eight formulas in Table 1. All free variables are implicitly universally quantified. The "+" notation signifies that the MLN contains an instance of the formula, with a separate weight, for each value combination of the variables with a plus sign. The first three formulas predict the event type and regulation direction based on the token word or its neighbor in the dependency tree. The next five formulas predict whether a dependency edge is in an argument path, based on some combinations of token word, dependency label, and whether the nodes are proteins.

By default, we also added the unit formulas: $\mathtt{Theme}(\mathtt{x},\mathtt{y})$, $\mathtt{Cause}(\mathtt{x},\mathtt{y})$, $\mathtt{EventType}(\mathtt{x},+\mathtt{e})$, $\mathtt{RegType}(\mathtt{x},+\mathtt{r})$, which capture default regularities.

Joint Inference: Like any classification system, the formulas in the base MLN make independent predictions at inference time. This is suboptimal, because query atoms are interdependent due to either hard constraints (e.g., an event must have a type) or soft correlation (e.g., "increase" signifies an event and the dobj edge from it leads to a theme). We thus

[3] In future work, we plan to incorporate a much richer set of features; Markov logic makes such extensions straightforward.

[4] For convenience, we include the reverse dependency edges in the evidence. For example, if $\mathtt{Dep}(\mathtt{i},\mathtt{j},\mathtt{nn})$ is true, then so is $\mathtt{Dep}(\mathtt{j},\mathtt{i},-\mathtt{nn})$.

augment the base MLN with two groups of joint-inference formulas. First we incorporate the following hard constraints.

$$\mathtt{Event(i)} \Rightarrow \exists \mathtt{t}.\ \mathtt{EvtType(i,t)}$$

$$\mathtt{EvtType(i,t)} \Rightarrow \mathtt{Event(i)}$$

$$\mathtt{RegType(i,r)} \Rightarrow \mathtt{EvtType(i,Regulation)}$$

$$\begin{gathered}\mathtt{InArgPath(i,j,Theme)} \Rightarrow \mathtt{Event(i)} \\ \vee\ \ \exists\, \mathtt{k} \neq \mathtt{j}.\ \mathtt{InArgPath(k,i,Theme)}\end{gathered}$$

$$\begin{gathered}\mathtt{InArgPath(i,j,Cause)} \\ \Rightarrow \mathtt{EvtType(i,Regulation)} \\ \vee\ \ \exists\, \mathtt{k} \neq \mathtt{j}.\ \mathtt{InArgPath(k,i,Cause)}\end{gathered}$$

$$\begin{gathered}\mathtt{InArgPath(i,j,Theme)} \Rightarrow \mathtt{Prot(j)} \\ \vee\ \ \exists\, \mathtt{k} \neq \mathtt{i}.\ \mathtt{InArgPath(j,k,Theme)}\end{gathered}$$

$$\begin{gathered}\mathtt{InArgPath(i,j,Cause)} \Rightarrow \mathtt{Event(j)} \vee \mathtt{Prot(j)} \\ \vee\ \ \exists\, \mathtt{k} \neq \mathtt{i}.\ \mathtt{InArgPath(j,k,Cause)}\end{gathered}$$

The first three formulas enforce that events must have a type, that a token assigned an event (regulation) type must be an (regulation) event. The next four formulas enforce the consistency of argument path assignments: an argument path must start with an event, in particular, a cause path must start with a regulation event; a theme path must eventually trace to a protein, whereas a cause path may also stop at an event (which does not have a cause itself). To avoid looping, we forbid reverse edges in a path.[5]

Notice that with these constraints, adjacent edges in the dependency tree correlate with each other in their InArgPath assignments, much like in an HMM for linear sequences. Moreover, these assignments correlate with the event and event-type ones; knowing that i probably signifies an event makes it easier to detect an argument path, and vice versa. In addition, events that share partial argument paths can inform each other through the predictions on edges. In the experiments section, we will see that merely adding these hard constraints leads to 26-point gain in F1.

We also notice that different trigger words may use different dependencies to start an argument path of a particular type. For example, for many verbs, nsubj tends to start a cause path and dobj a theme path. However, for "bind" that signifies a Binding event, both lead to themes, as in "A binds B". Such soft regularities can be captured by a single joint formula: $\mathtt{Token(i,+w)} \wedge \mathtt{Dep(i,j,+d)} \Rightarrow \mathtt{Event(i)} \wedge \mathtt{InArgPath(i,j,+a)}$, which correlates event and argument type with token and dependency.

Linguistically-Motivated Formulas: Natural languages often possess systematic syntactic alternations. For example, for the word "increase", if both subject and object are present, as in "A increases the level of B", the subject is the cause whereas the object is the theme. However, if only subject is present, as in "The level of B increases", the subject is the theme. We thus augment the MLN with a number of context-specific formulas such as: $\mathtt{Token(i,increase)} \wedge \mathtt{Dep(i,j,nsubj)} \wedge \mathtt{Dep(i,k,dobj)} \wedge \mathtt{Event(i)} \wedge \mathtt{Cause(i,j)}$.[6]

5 Learning And Inference

When training data comprises of many independent subsets (e.g., individual abstracts), stochastic gradient descent (SGD) is often a favorable method for parameter learning. By adopting small and frequent updates, it can dramatically speed up learning and sometimes even improve accuracy. Moreover, it easily scales to large datasets since each time it only needs to bring a few subsets into the memory.

In this paper, we used SGD to learn weights for our MLN. During this process, we discovered some general challenges for applying SGD to relational domains. For example, the ill-conditioning problem is particularly severe, and using a single learning rate either makes learning extremely slow or leads to divergence. Like Lowd & Domingos (2007), we combat this by dividing the learning rate by the variance. However, this still leads to divergence as learning progresses. The reason is that some weights are strongly correlated due to the joint formulas, especially the hard constraints. Therefore, the diagonal approximates the Hessian poorly. Inspired by Poon & Domingos (2007), for each formula, we count the numbers of true and false groundings in the train data, and add the smaller of the two plus one to the variance, before dividing the global rate by it.

[5] This is violated in some cases, and can be relaxed. We enforced it for simplicity in this paper.

[6] Available at http://research.microsoft.com/-en-us/people/lucyv/naacl10.

We found that this is effective for making learning stable in our experiments.

To compute the most probable state, we used MC-SAT to estimate the marginal probability of each query atom, and returned the ones with probability above a threshold. This allows us to easily trade off precision and recall by varying the threshold. To speed up burn-in, we followed Poon et al. (2009) and first ran MC-SAT with deterministic annealing for initialization.

6 Correcting Syntactic Errors With Semantic Information

Two typical types of syntactic errors are PP-attachment and coordination. For semantic tasks such as bio-event extraction, these errors also have the most adverse impact to performance. For example, for the snippet "involvement of p70 activation in IL-10 up-regulation by gp41", the Stanford parser makes two errors by attaching "up-regulation" to "activation" instead of "involvement", and attaching "gp41" to "involvement" instead of "up-regulation". This makes it very difficult to predict that "gp41" is the cause of "up-regulation", and that "up-regulation" is the theme of "involvement". For conjucts such as "IL-2 and IL-4 expressions", the parser will align "IL-2" with "expressions", which makes it difficult to recognize the expression event on "IL-2". For nested events like "gp41 regulates IL-2 and IL-4 expressions", this results in three extraction errors: IL-2 expression and the regulation event on it are missing, whereas an erroneous regulation event on IL-2 is predicted.

Syntactic errors are often incurred due to lack of semantic information during parsing (e.g., the knowledge that IL-2 and IL-4 are both proteins). In this paper, we used a heuristic method to fix such errors by incorporating two sources of semantic information: argument paths in training data and input protein labels. For conjuncts (signified by prefix `conj` in Stanford dependencies) between a protein and a non-protein, we check whether the non-protein has a protein child, if so, we remove the conjunct and reattach the first protein to the non-protein. For PP-attachments, we notice that often the errors can be fixed by reattaching the child to the closest node that fits a known attachment pattern (e.g., "up-regulation by PROTEIN"). We used the following heuristics to gather attachment patterns. For each argument path in the training data, if it consists of a single PP edge, then we add the combination of governor, dependency label, and dependent to the pattern. (Protein names are replaced with a special string.) If a path contains multiple edges, but a PP edge attaches to a word to the left of the event trigger (e.g., "gp41" attached to "involvement"), our system concludes that the dependent should instead be attached to the trigger and adds the corresponding pattern. In addition, we added a few default patterns like "involvement in" and "effect on". For each PP edge, the candidates for reattachment include the current governor, and the governor's parent and all rightmost descendants (i.e., its rightmost child, the rightmost child of that child, etc.) that are to the left of the dependent. We reattach the dependent to the closest candidate that fits an attachment pattern. If there is none, the attachment remains unchanged. In total, the fraction of reattachments is about 4%.

7 Experiments

We evaluated our system on the dataset for Task 1 in the BioNLP'09 Shared Task (Kim et al., 2009). It consists of 800 abstracts for training, 150 for development and 260 for test. We conducted feature development and tuned hyperparameters using the development set, and evaluated our final system on test using the online tool provided by the organizers. (The test annotations are not released to the public.) All results reported were obtained using the main evaluation criteria for the shared task.[7]

7.1 System

Our system first carries out lemmatization and breaks up hyphenated words.[8] It then uses the Stanford parser (de Marneffe et al., 2006) to generate dependencies. For simplicity, if an event contains multiple trigger words, only the head word is labeled.[9]

[7] Namely, "Approximate Span/Approximate Recursive Matching". See Kim et al. (2009) for details.

[8] E.g., "gp41-induced" becomes "gp41" and "induced", with a new dependency edge labeled `hyphen` from "induced" to "gp41". To avoid breaking up protein names with hyphens, we only dehyphenate words with suffix in a small hand-picked list.

[9] Most events have only one trigger, and the chosen words only need to lie within an approximate span in evaluation.

Table 2: Comparison of our full system with its variants and with UTurku on the development set.

	Rec.	Prc.	F1
BASE	17.4	67.2	27.7
BASE+HARD	49.4	58.5	53.6
FULL	51.5	60.0	**55.5**
−LING	50.5	59.6	54.7
−SYN-FIX	48.2	54.6	51.2
UTurku	51.5	55.6	53.5

We implemented our system as an extension to the Alchemy system (Kok et al., 2009). In particular, we developed an efficient parallelized implementation of our stochastic gradient descent algorithm using the message-passing interface (MPI). For learning, we used a mini-batch of 20 abstracts and iterated through the training files twice. For each mini-batch, we estimated the gradient by running MC-SAT for 300 samples; the initialization was done by running annealed MC-SAT for 200 samples, with temperature dropping from 10 to 0.1 at 0.05 decrements. For inference, we initialized MC-SAT with 1000 annealed samples, with temperature dropping from 10 to 0.1 at 0.01 decrements, we then ran MC-SAT for 5000 samples to compute the marginal probabilities. This implementation is very efficient: learning took about 20 minutes in a 32-core cluster with 800 training files; inference took a few minutes in average.

To obtain the final assignment, we set the query atoms with probability no less than 0.4 to true and the rest to false. The threshold is chosen to maximize F1 in the development set. To generate the events, we first found arguments for each trigger `i` by gathering all proteins and event triggers that were accessible from `i` along an argument path without first encountering another trigger. For triggers of base event types, we dropped other triggers from its argument list. For nested triggers, we generated events recursively by first processing argument triggers and generating their events, and then generating events for the parent trigger by including all combinations of argument events. For `Binding` triggers, we group its arguments by the first dependency labels in the argument paths, and generate events by a cross-product of the group members.

Table 3: Per-type recall/precision/F1 for our full system on the development set.

	Rec.	Prc.	F1
`Expression`	75.6	79.1	77.3
`Transcription`	69.5	73.1	71.3
`Phosphorylation`	87.2	87.2	87.2
`Catabolism`	85.7	100	92.3
`Localization`	66.0	85.4	74.5
`Binding`	39.1	61.8	47.9
`Positive_regulation`	41.8	51.0	46.0
`Negative_regulation`	39.3	56.2	46.3
`Regulation`	41.4	33.2	36.8

7.2 Results

We first conducted experiments on the development set to evaluate the contributions of individual components. Table 2 compares their performances along with that of UTurku. The base MLN (**BASE**) alone performed rather poorly. Surprisingly, by just adding the hard constraints to leverage joint inference (**BASE+HARD**), our system almost doubled the F1, and tied UTurku. In addition, adding the soft joint-inference formula results in further gain, and our full system (**FULL**) attained an F1 of 55.5. This is two points higher than UTurku and the best reported result on this dataset. The linguistically-motivated formulas are beneficial, as can seen by comparing with the system without them (−**LING**), although the difference is small. Fixing the syntactic errors with semantic information, on the other hand, leads to substantial performance gain. Without doing it (−**SYN-FIX**), our system suffers an F1 loss of more than four points. This verifies that the quality of syntactic analysis is important for event extraction. The differences between FULL and other variants (except -LING) are all statistically significant at 1% level using McNemar's test.

To understand the performance bottlenecks, we show the per-type results in Table 3 and the results at the predicate level in Table 4.[10] Both trigger and argument-edge detections leave much room for improvement. In particular, the system proposed many incorrect regulation triggers, partly because regulation triggers have the most variations

[10] Numbers in Table 3 refer to events, whereas in Table 4 to triggers. A trigger may signify multiple events, so numbers in Table 4 can be smaller than that in Table 3.

Table 4: Predicate recall/precision/F1 for our full system on the development set.

	Rec.	Prc.	F1
Expression	80.1	82.0	81.0
Transcription	68.8	71.0	69.8
Phosphorylation	87.5	92.1	89.7
Catabolism	84.2	100	91.4
Localization	62.5	86.2	72.5
Binding	62.4	82.4	71.1
Positive_regulation	65.8	70.7	68.2
Negative_regulation	58.3	71.7	64.3
Regulation	61.7	43.4	50.9
All triggers	68.1	71.7	69.9
Argument edge	69.0	71.8	70.4

Table 5: Comparison of our full system with top systems on the test set.

	Rec.	Prc.	F1
UTurku	46.7	58.5	52.0
JULIELab	45.8	47.5	46.7
ConcordU	35.0	61.6	44.6
Riedel et al.	36.9	55.6	44.4
FULL MLN	43.7	58.6	50.0

among all types. Our system did well in recognizing Binding triggers, but performed much poorer at the event level. This indicates that the bottleneck lies in correctly identifying all arguments for multi-theme events. Indeed, if we evaluate on individual event-theme pairs for Binding, the F1 jumps 15 points to 62.8%, with precision 82.7% and recall 50.6%.

Finally, Table 5 compares our system with the top systems on the test set. Our system trailed UTurku due to a somewhat lower recall, but substantially outperformed all other systems. In particular, it reduced F1 error by more than 10% compared to the previous best joint approach by Riedel et al. (2009).

7.3 Error Analysis

Through manual inspection, we found that many remaining errors were related to syntactic parses. The problem is particularly severe when there are nested or co-occuring PP-attachments and conjuncts (e.g., "increased levels of IL-2 and IL-4 mRNA and protein in the cell"). Our rule-based procedure in Section 6 has high precision in fixing some of these errors, but the coverage is limited. It also makes hard decisions in a preprocessing step, which cannot be reverted. A principled solution is to resolve syntactic and semantic ambiguities in a joint model that integrates reattachment decisions and extractions. This can potentially resolve more syntactic errors, as extraction makes more semantic information available, and is more robust to reattachment uncertainty.

In some challenging cases, we found further opportunities for joint inference. For example, in the sentence "These cells are deficient in FasL expression, although their cytokine IL-2 production is normal", "normal" signifies a Positive_regulation event over "IL-2 production" because of its contrast with "deficient". Such events can be detected by introducing additional joint inference rules that leverage syntactic structures such as subclauses.

We also found many cases where the annotations differ for the same expressions. For example, "cotransfection with PROTEIN" is sometimes labeled as both an Expression event and a Positive_regulation event, and sometimes not labeled at all. This occurs more often for regulation events, which partly explains the low precision for them.

8 Conclusion

This paper presents the first joint approach for bio-event extraction that achieves state-of-the-art results. This is made possible by adopting a novel formulation that jointly predicts events, arguments, as well as individual dependency edges in argument paths. Our system is based on Markov logic and can be easily extended to incorporate additional knowledge and linguistic features to further improve accuracy.

Directions for future work include: leveraging additional joint-inference opportunities, better integration of syntactic parsing and event extraction, and applying this approach to other extraction tasks and domains.

Abstract

In evidence-based medicine, clinical questions involve four aspects: Patient/Problem (P), Intervention (I), Comparison (C) and Outcome (O), known as PICO elements. In this paper we present a method that extends the language modeling approach to incorporate both document structure and PICO query formulation. We present an analysis of the distribution of PICO elements in medical abstracts that motivates the use of a location-based weighting strategy. In experiments carried out on a collection of 1.5 million abstracts, the method was found to lead to an improvement of roughly 60% in MAP and 70% in P@10 as compared to state-of-the-art methods.

1 Introduction

As the volume of published medical literature continues to grow exponentially, there is more and more research for physicians to assess and evaluate and less time to do so. Evidence-based medicine (EBM) (Sackett et al., 1996) is a widely accepted paradigm in medical practice that relies on evidence from patient-centered clinical research to make decisions. Taking an evidence-based approach to searching means doing a systematic search of all the available literature, individually critically appraising each research study and then applying the findings in clinical practice. However, this is a time consuming activity. One way to facilitate searching for a precise answer is to formulate a well-focused and structured question (Schardt et al., 2007).

Physicians are educated to formulate their clinical questions according to several well defined aspects in EBM: Patient/Problem (P), Intervention (I), Comparison (C) and Outcome (O), which are called PICO elements. In many documents in medical literature (e.g. MEDLINE), one can find the elements of the PICO structure, but rarely explicitly annotated (Dawes et al., 2007). To identify documents corresponding to a patient's state, physicians also construct their queries according to the PICO structure. For example, in the question "*In children with pain and fever how does paracetamol compared with ibuprofen affect levels of pain and fever?*" one can identify the following PICO elements:

Patient/Problem: *children/pain and fever*
Intervention: *paracetamol*
Comparison: *ibuprofen*
Outcome: *levels of pain and fever*

Very little work, if any, has been carried out on the use of these elements in the Information Retrieval (IR) process. There are several reasons for that. It is not easy to identify PICO elements in documents, as well as in the question if these are not explicitly separated in it. Several studies have been performed on identifying PICO elements in abstracts (Demner-Fushman and Lin, 2007; Hansen et al., 2008; Chung, 2009). However, all of them are reporting coarse-grain (sentence-level) tagging methods that have not yet been shown to be sufficient for the purpose of IR. Moreover, there is currently no standard test collection of questions in PICO structure available for evaluation. On the other hand, the most critical aspect in IR is term weighting. One of the purpose of tagging PICO elements is to assign appropriate weights to these elements during the retrieval process. From this perspective, a semantic tagging of PICO elements may be a task that goes well beyond

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 822–830,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

that is required for IR. It may be sufficient to have a method that assigns appropriate weights to elements rather than recognizing their semantic roles. In this paper, we will propose an approach to determine term weights according to document structure. This method will be compared to that using tagging of PICO elements.

In this paper, we first report an attempt to manually annotate the PICO elements in documents by physicians and use them as training data to build an automatic tagging tool. It turns out that there is a high disagreement rate between human annotators. The utilization of the automatic tagging tool in an IR experiment shows only a small gain in retrieval effectiveness. We therefore propose an alternative to PICO element detection that uses the structural information of documents. This solution turns out to be robust and effective. The alternative approach is motivated by a strong trend that we observe in the distribution of PICO elements in documents. We then make use of both PICO query and document structure to extend the classical language modeling approach to IR. Specifically, we investigate how each element of a PICO query should be weighted and how a location-based weighting strategy can be used to emphasize the most informative parts (i.e. containing the most PICO elements) of documents.

The paper is organized as follows. We first briefly review the previous work, followed by a description of the method we propose. Next, we present our experiments and results. Lastly, we conclude with a discussion and directions for future work.

2 Related work

There have been only a few studies trying to use PICO elements in the retrieval process. (Demner-Fushman and Lin, 2007) is one of the few such studies. The method they describe consists in re-ranking an initial list of retrieved citations. To this end, the relevance of a document is scored by the use of detected PICO elements, among other things. Several other studies aimed to build a Question-Answering system for clinical questions (Demner-Fushman and Lin, 2006; Andrenucci, 2008). But again, the focus has been set on the post-retrieval step, while the document retrieval step only uses a standard approach. In this paper, we argue that IR has much to gain by using PICO elements.

The task of identifying PICO elements has however gain more attention. In their paper, (Demner-Fushman and Lin, 2007) presented a method that uses either manually crafted pattern-matching rules or a combination of basic classifiers to detect PICO elements in medical abstracts. Prior to that, biomedical concepts are labelled by Metamap (Aronson, 2001) while relations between these concepts are extracted with SemRep (Rindflesch and Fiszman, 2003). Recently, supervised classification using Support Vector Machines (SVM) was proposed by (Hansen et al., 2008) to extract the number of trial participants. In a later study, (Chung, 2009) extended this work to other elements using Conditional Random Fields. Although these studies are reporting interesting results, they are limited in several aspects. First, many are restricted to some segments of the medical documents (e.g. Method section) (Chung, 2009), and in most cases, the test collection is very small (a few hundreds abstracts). Second, the precision and granularity of these methods have not yet been shown to be sufficient for the purpose of IR.

The structural information provided by markup languages (e.g. XML) has been successfully used to improve the IR effectiveness (INEX, 2002 2009). For such documents, the structure information can be used to emphasize some particular parts of the document. Thereby, a given word should not have the same importance depending on its position in the document structure.

Taking into account the structure can be done either at the step of querying or at the step of indexing. One way to integrate the structure at querying is to adapt query languages (Fuhr and Großjohann, 2001). These approaches follow the assumption that the user knows where the most relevant information is located. However, (Kamps et al., 2005) showed that it is preferable to use structure as a search hint, and not as a strict search requirement

The second approach consists in integrating the document structure at the indexing step by introducing a structure weighting scheme (Wilkinson, 1994). In such a scheme, the weight assigned to a word is not only based on its frequency but also on its position in the document. The structure of a document can be defined in terms of tags (e.g. title, section), each of those having a weight chosen either empirically or automatically by the use of optimizing techniques such as genetic algorithms (Trotman, 2005).

3 Using PICO elements in retrieval

In this section, we present an experiment on the manual annotation of PICO elements. We then describe an approach to detect these elements in documents and give some results on the use of these tagged elements in the retrieval process.

3.1 Manual annotation of PICO elements

We asked medical professionals to manually annotate the PICO elements in a small collection of abstracts from PubMed[1]. The instructions given to the annotators were fairly simple. They were asked to precisely annotate all PICO elements in abstracts with no restriction about the size of the elements (i.e. they could be words, phrases or sentences). More than 50 abstracts were manually annotated this way by at least two different annotators. Two annotations by two annotators are considered to agree if they share some words (i.e. they overlap). We computed the well known Cohen's kappa measure as well as an ad-hoc measure called loose. The latter uses PICO elements as units and estimates the proportion of elements that have been annotated by both raters.

Measure	P-element	I/C-element	O-element
kappa	0.687	0.539	0.523
loose	0.363	0.136	0.140

Table 1: Agreement measures computed for each element. Cohen's kappa and loose agreement are presented.

We can observe that there is a very low agreement rate between human annotators. The loose measure indicates that less than 15% of the I, C and O elements have been marked by both annotators. This fact shows that such human annotations can be hardly used to develop an automatic tagging tool for PICO elements, which requires consistent training data. We therefore try to develop a coarser-grained tagging method.

3.2 Automatic detection of PICO elements

Similarly to previous work, we propose a sentence-level detection method. The identification of PICO elements can be seen as a classification task. Even for a coarser-grain classification task, we are still lack of annotated data. One solution is to use the structural information embedded in some medical abstracts for which the authors have clearly stated distinctive sentence headings. Some recent abstracts in PubMed do contain explicit headings such as "PATIENTS", "SAMPLE" or "OUTCOMES", that can be used to locate sentences corresponding to PICO elements. Using that information, we extracted three sets of abstracts: Patient/Problem (14 279 abstracts), Intervention/Comparison (9 095) and Outcome (2 394).

Tagging each document goes through a three steps process. First, the document is segmented into plain sentences. Then each sentence is converted into a feature vector using statistical (e.g. position, length) and knowledge-based features (e.g. MeSH semantic type). Knowledge-based features were derived either from manually crafted cue-words/verbs lists or semantic types within the MeSH ontology[2]. Finally, each vector is submitted to multiple classifiers, one for each element, allowing to label the corresponding sentence. We use several algorithms implemented in the Weka toolkit[3]: decision trees, SVM, multi-layer perceptron and Naive Bayes. Combining multiple classifiers using a weighted linear combination of their prediction scores achieves the best results with a f-measure score of 86.3% for P, 67% for I/C and 56.6% for O in 10-fold cross-validation.

3.3 Use of detected elements in IR

We use language modeling approach to IR in this work. The idea is that a document is a good match to a query if its language model is likely to generate the query (Ponte and Croft, 1998). It is one of the state-of-the-art approaches in current IR research. Most language modeling work in IR use unigram language models –also called bags-of-words models– assuming that there is no structure in queries or documents. A typical way to score a document d as relevant to a query q is to use the *Kullback-Leibler*

[1] www.pubmed.gov, PubMed is a service of the US National Library of Medicine that includes over 19 million citations from MEDLINE and other life science journals.

[2] www.nlm.nih.gov/mesh/

[3] www.cs.waikato.ac.nz/ml/index.html

divergence between their respective LMs:

$$\mathsf{score}(q, d) = \sum_{w \in q} P(w \mid M_q) \cdot \log P(w \mid M_d) \quad (1)$$
$$\propto -\mathrm{KL}(M_q \parallel M_d)$$

where M_q is the LM of the query and M_d the LM of the document. $P(w \mid M_\rho)$ estimates the probability of the word w given the language model M_ρ. The most direct way to estimate these models is to use Maximum Likelihood estimation over the words:

$$P(w \mid M_\rho) = \frac{\mathsf{count}(w, \rho)}{\mid \rho \mid}$$

where ρ is the observed document, $\mathsf{count}(w, \rho)$ the number of times the word w occurs in ρ and $\mid \rho \mid$ the length of the document. Bayesian smoothing using *Dirichlet* priors is then applied to the maximum likelihood estimator to compensate for data sparseness.

We propose an approach that extend the basic LM approach to take into consideration the PICO element annotation. We assume that each element in the document has a different importance weight. Four more LMs are created, one for each elements. Given ω_e the weight of the PICO element e, $P(w \mid M_d)$ in equation 1 is re-defined as:

$$P_1(w \mid M_d) \propto P(w \mid M_d) + \sum_{e \in [P,I,C,O]} \omega_e \cdot P(w \mid M_e)$$

The right hand of the above equation is not a probability function. We could use a normalization to transform it. However, for the purpose of document ranking, this will not make any difference. Therefore, we will keep the un-normalized value.

We performed an extensive series of experiments using this model on the test collection described in Section 5. The results are shown in Table 2. It turns out that the best improvement we were able to obtain is very small (0.5% of MAP increase). There may be several reasons for that. First, the accuracy of the automatic document tagging may be insufficient. Second, even if elements are correctly identified in documents, if queries are treated as bags-of-words then any PICO element can match with any identical word in the query, whether it describe the same element or not. However, we also tested a naïve approach that matches the PICO elements in queries with the corresponding elements in documents. But this approach quickly turns out to be too restrictive and leads to bad results.

Measure	**Weighted elements**			
	P	I / C	O	Best†
MAP increase	0.0%	−0.2%	−0.1%	+0.5%

Table 2: Results using the PICO elements automatically detected in documents (†: $w_P = 0.5$, $w_I = 0.2$).

As we can see, this approach only brings limited improvement in retrieval effectiveness. This rises the question of the usability of such tagging method in its current performance state. We will see in the next section an alternative solution to this problem that relies on the distribution of PICO elements in documents.

4 Method

4.1 Distribution of PICO elements

PICO elements are not evenly distributed in medical documents, which often follow some implicit writing convention. An intuitive method is to weight higher a segment that is more probable to contain PICO elements. The distribution of PICO elements is likely to correlate to the position within the document. This intuition has been used in most of the supervised PICO detection methods which use location-based features. There has been several studies that cover the PICO extraction problem. However, as far as we know, none of them analyses and uses the positional ditribution of these elements within the documents for the purpose of IR. Biomedical abstracts can be typically represented by four ordered rhetorical categories which are Introduction, Methods, Results and Discussion (IMRAD) (Sollaci and Pereira, 2004). The reason is found in the need for speed when reviewing literature, as this format allows readers to pick those parts of particular interest. Besides, many scientific journals explicitly recommended this ordered structure.

The PICO dispersion is highly correlated to these rhetorical categories as some elements are more likely to occur in certain categories. For example, outcomes are more likely to appear in Results and/or Discussion parts. One could also expect to infer the role played by PICO elements in a clinical study. For example, the drug *pioglitazone* has not the same role in a clinical study if it appears as the main intervention (likely to occur in all parts) or as a comparative treatment (Methods and/or Results parts).

Instead of analysing the dispersion of PICO elements into the four IMRAD categories, we choose to the use automatically splitted parts. There are several reasons for that. First, the IMRAD categories are not explicitely marked in abstracts. An automatic tagging of these would surely result in some errors. Second, using a low granularity approach would provide more precise statistics. Furthermore, if one would use the dispersion of elements as a criterion to estimate how important each part is, an automatic partition would be a good choice because of its repeatability and ease to implement.

We divided each manually annotated abstract into 10 parts of equal length (P1 being the begining and P10 the ending) and computed statistics on the number of elements than occur in each of these parts. The Figure 1 shows the proportion of elements for each part. We can observe that PICO elements are not evenly distributed throughout the abstracts. Universally accepted rules that govern medical writing styles would be the first reason for that. It is clear that the beginning and ending parts of abstracts do contain most of the PICO elements. This gives us a clear indication on which parts should be enhanced when searching for these elements.

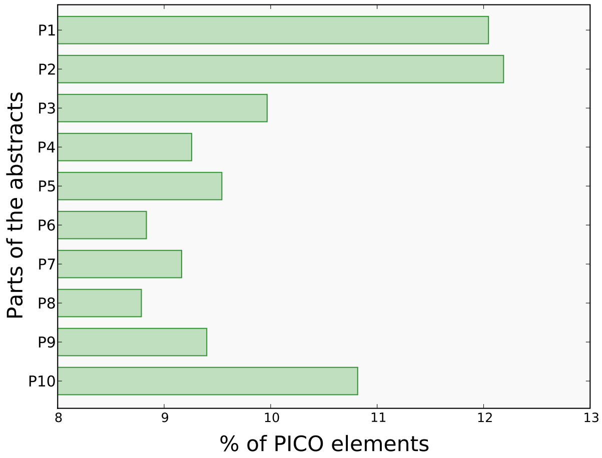

Figure 1: Proportion of PICO elements computed for each different part of abstracts.

Therefore, there may be several levels of granularity when using the PICO framework in IR. One can identify each PICO element in the document, whether it is described by a word, a phrase or a complete sentence. One can also use a coarser-grain approach, estimating from the distribution across documents the probability that each part contains a PICO element. As attempts to precisely locate PICO elements have shown that this task is particularly difficult, we propose to get rid this issue by using the second method.

4.2 Model definitions

We propose three different models that extend the classical language modeling approach. The first uses the structural information of documents, the second takes advantage of the PICO query structure while the third simply combine the first two models.

Model-1

Attempts to precisely locate PICO elements in documents have shown that this task is particularly difficult. We propose to get around this issue by introducing structural markers to convey document structure and use them as a means of providing location information. Accordingly, each document is represented as a series of successive parts. To integrate document structure into the ranking function, we estimate a series of probabilities that constraints the word counts to a specific part instead of the entire document. Each document d is then ranked by a weighted linear interpolation. Intuitively, the weight of a part should depend on how much information is conveyed by its words. Given γ_p the weight of the part $p \in [\text{TITLE}, \text{P1} \cdots \text{P10}]$, $P(w \mid M_d)$ in equation 1 is re-defined as:

$$P_2(w \mid M_d) \propto P(w \mid M_d) + \sum_{p \in d} \gamma_p \cdot P(w \in p \mid M_d)$$

Model-2

The PICO formulation of queries provides information about the role of each query word. One idea is to use this structural decomposition to thoroughly balance elements in the ranking function. For example, the weight given to the drug *fluoxetine* should be different depending on whether it refers to the intervention or comparison concept. The same goes for *obesity* which can be a problem or an outcome. To integrate this in the ranking function, we define a parameter δ_e that represents the weight given to query words belonging to the element $e \in [P, I, C, O]$. $f(w, e) = 1$ if $w \in e$, 0 otherwise. We re-defined $P(w \mid M_d)$ in equation 1 as:

$$P_3(w \mid M_q) \propto P(w \mid M_q) + \sum_{e \in [P,I,C,O]} \delta_e \cdot f(w, e) \cdot P(w \mid M_q)$$

Model-1+2

This is the combination of the two previously described models. We re-defined the scoring function as:

$$\text{score}(q, d) = \sum_{w \in q} P_3(w \mid M_q) \cdot \log P_2(w \mid M_d)$$

5 Experiments

In this section, we describe the details of our experimental protocol. We then present the results obtained with the three proposed models.

Experimental settings

We gathered a collection of nearly 1.5 million abstracts from PubMed with the following requirements: with abstract, humans subjects, in english and selecting the following publication types: RCT, reviews, clinical trials, letters, practice guidelines, editorials and meta-analysis. Prior to the index construction, each abstract is automatically divided into 10 parts of equal length, abstracts containing less than 10 words are discarded. The following fields are then marked: TITLE, P1, P2, ... P10 with P1 being the begining of the document and P10 the ending.

Unfortunately, there is no standard test collection appropriate for testing the use of PICO in IR and we had to manually create one. For queries, we use the Cochrane systematic reviews[4] on 10 clinical questions about different aspects of "*diabetes*". These reviews contain the best available information about an healthcare intervention and are designed to facilitate the choices that doctors face in health care. All the documents in the "Included studies" section are judged to be relevant for the question. These included studies are selected by the reviewers (authors of the review article) and judged to be highly related to the clinical question. In our experiments, we consider these documents as relevant ones. From the 10 selected questions, professors in family medicine have formulated a set of 52 queries, each of which was manually annotated according to the PICO structure. The resulting testing corpus is composed of 52 queries (average length of 14.7 words) and 378 relevant documents. Below are some of the alternative formulations of queries for the question "*Pioglitazone for type 2 diabetes mellitus*":

In patients with type 2 diabetes $^{(P)}$ | *does pioglitazone* $^{(I)}$ | *compared to placebo* $^{(C)}$ | *reduce stroke and myocardial infarction* $^{(O)}$

In patients with type 2 diabetes who have a high risk of macrovascular events $^{(P)}$ | *does pioglitazone* $^{(I)}$ | *compared to placebo* $^{(C)}$ | *reduce mortality* $^{(O)}$

We use cross-validation to determine reasonable weights and avoid over-fitting. We have divided the queries into two groups of 26 queries: Qa and Qb. The best parameters found for Qa are used to test on Qb, and vice versa. In our experiments, we use the KL divergence ranking (equation 1) as baseline. The following evaluation measures are considered relevant:

Precision at n ($P@n$). Precision computed on only the n topmost retrieved documents.

Mean Average Precision (MAP). Average of precisions computed at the point of each relevant document in the ranked list of retrieved documents.

MAP is a popular measure that gives a global quality score of the entire ranked list of retrieved documents. In the case of clinical searches, one could also imagine this scenario: a search performed by a physician who does not have the time to look into large sets of results, but for whom it is important to have relevant results in the top 10. In such case, $P@10$ is also an appropriate measure.

Student's t-test is performed to determine statistical significance. The Lemur Toolkit[5] was used for

[4] www.cochrane.org/reviews/

[5] www.lemurproject.org

all retrieval tasks. Experiments were performed with an "out-of-the-box" version of Lemur, using its tokenization algorithm and porter stemmer. The Dirichlet prior smoothing parameter was set to its default value $\mu = 2500$.

Experiments with model-1

We first investigated whether assigning a weight to each part of the document can improve the retrieval accuracy. It is however difficult to determine a set of reasonable values for all the parts together, as the value of one part will affect those of the others. In this study, we perform a two pass tuning. First, we consider the γ_p weights to be independent. By doing so, searching for the optimal weight distribution can be seen as tuning the weight of each part separately. When searching the optimal weight of a part, the weight for other parts is assigned 0. Second, these approximations of the optimum values are used as initial weights prior to the second pass. The final weight distribution is obtained by searching for the best weight combination around the initial values.

The Figure 2 shows the optimal weight distributions along with the best relative MAP increase for each part. A noticeable improvement is obtained by increasing the weights associated to the title/introduction and conclusion of documents. This is consistent with the results observed on the distribution of PICO elements in abstracts. Boosting middle parts of documents seems to have no impact at all. We can see that the two γ_p weight distributions (1-pass and 2-pass) are very close.

Performance measures obtained by model-1 are presented in Table 3. With 1-pass tuning, we observe a MAP score increase of 37.5% and a $\mathrm{P@10}$ increase of 64.1%. After the second pass, scores are lower with 35% and 60.5% for MAP and $\mathrm{P@10}$ respectively. This result indicates that there is possibly overfitting when we perform the two pass parameter tuning. It could also be caused by the limited number of query in our test collection. However, we can determine reasonable weights by tuning each part weight separately.

Experiments with model-2

We have seen that a large improvement could come from weighting each part accordingly. In a second series of experiments, we try to assign a different weight to each PICO element in queries. A grid search was used to find the optimal δ_e weights combination. The results are shown in Table 3.

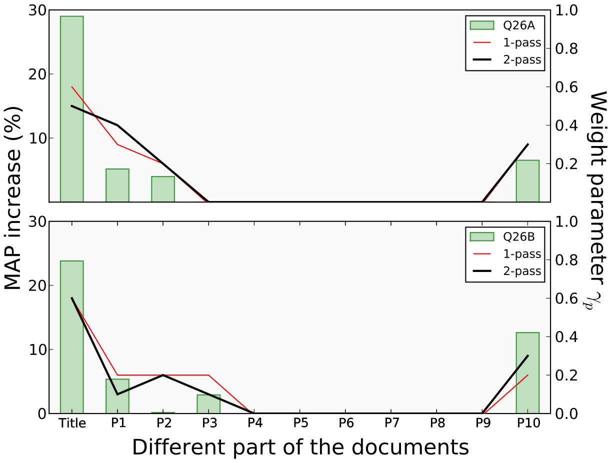

Figure 2: Best MAP increase for each part p (bar charts), corresponding 1 and 2-pass γ_p weights are also given.

We observe a MAP score increase of 22.5% and an increase of 11% in $\mathrm{P@10}$. Though the use of a PICO weighting scheme increases the retrieval accuracy, there is clearly much to gain by using the document structure. The optimal $[\delta_p, \delta_i, \delta_c, \delta_o]$ weights distribution is $[0.3, 1.2, 0, 0.1]$ for Qa and $[0.2, 1, 0, 0.2]$ for Qb. That means that the most important words in queries belong to the Intervention element. This supports the manual search strategy proposed by (Weinfeld and Finkelstein, 2005), in which they suggested that I and P elements should be used first to construct queries, and only if too many results are obtained that other elements should be considered.

It is interesting to see that query words belonging to the Comparison element have to be considered as the least important part of a query. Even more so because they are in the same semantic group as the Intervention words. A reason for that could be the use of vague words such as "*no-intervention*" or "*placebo*". The methodology employed to construct the queries is also responsible. Indeed, physicians have focused on producing alternative formulations of 10 general clinical questions by predominantly modifying the one of the PICO elements. As a result, some of them do share the same vague Comparison words.

Experiments	MAP			P@10		
	Qb→Qa	Qa→Qb	% Avg.	Qb→Qa	Qa→Qb	% Avg.

Model-1+2	0.198	0.202	+61.5%‡	0.385	0.392	+70.0%‡

Table 3: Cross-validation (train→test) scores for the baseline (Kullback-Leibler divergence), **model-1** with 1 and 2-pass tuning, **model-2** and their combination (**model-1+2**). Relative increase over the baseline is also given (averaged between Qa and Qb). (‡: t.test < 0.01)

Experiments with model-1+2

We have seen that both the use of a location-based weighting and a PICO-structure weighting scheme increase the retrieval accuracy. In this last series of experiments, we analyse the results of their combination. We can observe that fusing model-1 and model-2 allows us to obtain the best retrieval accuracy with a MAP score increase of 61.5% and a P@10 increase of 70.0%. It is a large improvement over the baseline as it means that instead of about two relevant documents in the top 10, our system can retrieve nearly four. These results confirm that both PICO framework and document structure can be very helpful for the IR process.

6 Conclusion

We presented a language modeling approach that integrates document and PICO structure for the purpose of clinical IR. A straightforward idea is to detect PICO elements in documents and use the elements in the retrieval process. However, this approach does not work well because of the difficulty to arrive at a consistent tagging of these elements. Instead, we propose a less demanding approach which assigns different weights to different parts of a document.

We first analysed the distribution of PICO elements in a manually annotated abstracts collection. The observed results led us to believe that a location-based weighting scheme can be used instead of a PICO detection approach. We then explored whether this strategy can be used as an indicator to refine document relevance. We also proposed a model to integrate the PICO information provided in queries and investigated how each element should be balanced in the ranking function. On a data set composed of 1.5 million abstracts extracted from PubMed, our method obtains an increase of 61.5% for MAP and 70% for P@10 over the classical language modeling approach.

This work can be much improved in the future. For example, the location-based weighting method can be improved in order to model a different weight distribution for each PICO element. As the distribution in abstracts is not the same among PICO elements, it is expected that differentiated weighting schemes could result in better retrieval effectiveness. In a similar perspective, we are continuing our efforts to construct a larger manually annotated collection of abstracts. It will be thereafter conceivable to use this data to infer the structural weighting schemes or to train a more precise PICO detection method. The focused evaluation described in this paper is a first step. Although the queries are limited to diabetes, this does not affect the general PICO structure in queries. We plan to extend the coverage of queries to other topics in the future.

Abstract

Image annotation, the task of automatically generating description words for a picture, is a key component in various image search and retrieval applications. Creating image databases for model development is, however, costly and time consuming, since the keywords must be hand-coded and the process repeated for new collections. In this work we exploit the vast resource of images and documents available on the web for developing image annotation models without any human involvement. We describe a probabilistic model based on the assumption that images and their co-occurring textual data are generated by mixtures of latent topics. We show that this model outperforms previously proposed approaches when applied to image annotation and the related task of text illustration despite the noisy nature of our dataset.

1 Introduction

Recent years have witnessed the rapid growth of image collections available for searching and browsing over the Internet. Although image search engines are still in their infancy, initial research suggests that the deployed algorithms are not very accurate (Hawking et al., 1999). Given a query, search engines retrieve relevant pictures by analyzing the image caption (if it exists), textual descriptions found adjacent to the image, and other text-related factors such as the file name of the image. However, since they do not analyze the actual content of the images, search engines cannot be used to retrieve pictures from unannotated collections. The ability to perform the annotation task *automatically* would be of significant practical import for many image-based applications. Besides search and retrieval, other examples include browsing support (e.g., by clustering images into groups that are visually and semantically coherent) and story picturing (i.e., automatically suggesting images to illustrate text).

Automatic image annotation is a popular task in computer vision; a large number of approaches have been proposed in the literature under many distinct learning paradigms. These range from supervised classification (Smeulders et al., 2000; Vailaya et al., 2001) to instantiations of the noisy-channel model (Duygulu et al., 2002), to clustering (Barnard et al., 2002), and methods inspired by information retrieval (Feng et al., 2004; Lavrenko et al., 2003). Despite differences in application and formulation, all these methods essentially attempt to learn the correlation between image features and words from examples of annotated images. The Corel database has been extensively used as a testbed for the development and evaluation of image annotation models. It is a collection of stock photographs, divided into themes (e.g., *tigers*, *sunsets*) each of which are associated with keywords (e.g., *sun*, *sea*) that are considered appropriate descriptors for all images belonging to the same theme.

Unfortunately, the Corel database is not representative of the size or content of real-world image collections. It has a small number of themes with many closely related images which in turn share keyword descriptions. It is therefore relatively easy to learn the associations between images and keywords and do well on annotation and retrieval tasks (Tang and Lewis, 2007; Westerveld and de Vries, 2003). An appealing alternative is the use of resources where images and their annotations co-occur naturally. Examples include images found in news documents, consumer photo collections, Wikipedia articles, illustrated stories and so on. The key idea here is to treat the words in the surrounding text as annotations for the image. These annotations are undoubt-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 831–839,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

edly noisy, but plenty and cost-free. Moreover, the collateral text is often longer and more informative in comparison to the few keywords reserved for each image in Corel.

In this paper we propose a probabilistic image annotation model that learns to automatically label images under such noisy conditions. We use the database created in Feng and Lapata (2008) which consists of news articles, images, and their captions. Our model exploits the redundancy inherent in this multimodal dataset by assuming that images and their surrounding text are generated by a shared set of latent variables or topics. Specifically, we describe documents and images by a common multimodal vocabulary consisting of textual words and *visual terms* (visiterms). Due to polysemy and synonymy many words in this vocabulary will refer to the same underlying concept. Using Latent Dirichlet Allocation (LDA, Blei and Jordan 2003), a probabilistic model of text generation, we represent visual and textual meaning *jointly* as a probability distribution over a set of topics. Our annotation model takes these topic distributions into account while finding the most likely keywords for an image and its associated document. We also show how the model can be straightforwardly modified to perform automatic text illustration.[1] The task is routinely performed by news writers who often have to search large image collections in order to find suitable pictures for their text. Here, the model takes a document as input and suggests images that match its content. Experimental results on both tasks bring improvements over competitive models.

2 Related Work

A variety of learning methods have been applied to the image annotation task. These generally fall under two broad categories. Supervised methods define annotation as a classification task, e.g., by assuming a one-to-one correspondence between vocabulary words and classes or by grouping several words into a single class (see Chai and Hung 2008 for an overview). Unsupervised approaches attempt to discover the underlying connections between visual features and words, typically by introducing latent variables. Standard latent semantic analysis (LSA) and its probabilistic variant (PLSA) have been applied to this task (Hofmann, 2001; Monay and Gatica-Perez, 2007; Pan et al., 2004). More sophisticated models estimate the joint distribution of words and regional image features, whilst treating annotation as a problem of statistical inference in a graphical model (Barnard et al., 2002; Blei and Jordan, 2003; Wang et al., 2009).

Irrespectively of the underlying model or task at hand, much work has focused how to best represent the visual and textual modalities in order to exploit their synergy. Several approaches attempt to render images more word-like, by reducing the dimensionality of the image feature space (Bosch et al., 2008; Fei-Fei and Perona, 2005) or by learning a single representation for both visual and textual features (Monay and Gatica-Perez, 2007; Zhao and Grosky, 2003).

Our own work approaches the image annotation (and related story picturing) task from a slightly different angle. We train and test our model on images that contain implicit (and thus noisy) annotations that have not been specifically created for our task. On account of this, our model has access to knowledge sources other than the image and its keywords (i.e., the news article containing the image we wish to annotate). In Feng and Lapata (2008) we addressed this problem with a modified version of the continuous relevance annotation model (Lavrenko et al., 2003). Unlike other unsupervised approaches where a set of latent variables is introduced, each defining a joint distribution on the space of keywords and image features, the relevance model captures the joint probability of images and annotated words *directly*, without requiring an intermediate clustering stage (i.e., each annotated image in the training set is treated as a latent variable). We modified this model so as to exploit the information present in the document in two ways. First, in estimating the conditional probability of a keyword given an image, we also considered its likelihood in the collateral document. Secondly, we used an LDA model (trained on the document collection) to prune from the model's output words that are not representative of the document's topics.

The proposed approach differs from Feng and Lapata (2008) in three important respects: (a) document-based information is an integral part of our model as we predict caption words given the image *and* its accompanying document (b) LDA is no longer a post-processing step; our model relies on LDA to infer meaningful topics that capture the co-occurrence of visual features and words; (c) beyond image annotation, we show how the same framework can be applied to story picturing (Joshi et al., 2006), a task which has received less attention in the literature.

In terms of model structure, Blei and Jordan

[1] We use the terms "text illustration" and "story picturing" interchangeably throughout the paper.

(2003) and Monay and Gatica-Perez (2007) are closest to our work. The first model, known as correspondence LDA (CorrLDA), has been successfully employed for modeling annotated images in the Corel domain. CorrLDA also uses the notion of topic to model the generation of images and their captions. In this model, the visual modality drives the definition of the latent space to which the textual modality is linked. The second model is based on PLSA and learns a representation similar to ours consisting of textual and visual features. It is also trained using captioned images from the Corel database. We work with noisier and larger datasets. Our model exploits the captions accompanying the images as well as their surrounding documents. As a result, we obtain a similar number of textual and visual words; these are often imbalanced in the Corel database, where visual words are nearly 50 times more than textual words. The different nature of our data dictates the use of a model where the visual and textual modality are given equal importance in defining the latent space.

3 Problem Formulation

In this section we give a brief description of the image database we employ and also define the image annotation and story picturing tasks we are attempting here. As mentioned earlier, we use the dataset created in Feng and Lapata (2008).[2] It contains 3,361 articles that have been downloaded from the BBC News website[3]. Each article contains a news image which in turn is associated with a caption. The images are usually 203 pixels wide and 152 pixels high. The average caption length is 5.35 tokens, and the average document length 133.85 tokens. The captions vocabulary is 2,167 words and the document vocabulary is 6,253. The vocabulary shared between captions and documents is 2,056 words. In contrast to the Corel database, this dataset contains more complex images (with many objects) and has a larger vocabulary (Corel's vocabulary is approximately 300 words). An example of an abridged database entry is shown in Figure 1.

Due to the non-standard nature of the database we assume that the caption and news article describe the content of the image either directly or indirectly. It also follows that we may not be able to name all objects depicted in the image. Now, given these constraints our goal is twofold. Firstly, we will perform image annotation. Our model is trained on document-image-caption tuples like the one shown in Table 1. During testing, we must infer the caption for an image. Secondly, we use the same dataset to perform automatic text illustration. During training, the model has access to the same collection of image-caption-document tuples. During testing, we are given a document and must find the images that best illustrate it.

Osborne the emu will grow to over 6ft tall

A woman from East Sussex who bought an emu egg sold as a novelty food item on a farm on the Isle of Wight has managed to hatch it into a chick. Gillian Stone, from Bexhill, who breeds chickens, brought home three large green emu eggs from a holiday and put them in an incubator in her kitchen. Two turned out to be infertile, but after 52 days little Osborne hatched

Table 1: Each entry in the BBC News database contains a document, an image, and its caption (shown in boldface).

4 Image and Document Representation

Words and images represent distinct modalities, images live in a continuous feature space, whereas words are discrete. Yet, both modalities on some level capture the same underlying concepts as they are used to describe the same objects. A common first step to all previous methods is the segmentation of the image into regions, using either a fixed-grid layout or an image segmentation algorithm. Regions are usually described by a standard set of features including color, texture, and shape which are treated as continuous vectors (e.g., Barnard et al. 2002; Blei and Jordan 2003) or in quantized form (e.g., Duygulu et al. 2002). Through this process, the low-level image features are made to resemble word-like units.

Here, we go one step further and represent each image by a bag of visual words, thereby converting visual features from a continuous onto a discrete space. In order to do this we use the Scale Invariant Feature Transform (SIFT) algorithm (Lowe, 1999). The general idea behind the algorithm is to first sample an image with the difference-of-Gaussians point detector at different scales and locations. Importantly, this detector is, to some extent, invariant to translation, scale, rotation and illumination changes. Each detected region is represented with a SIFT descriptor which is a histogram of edge directions at

[2] Available from `http://homepages.inf.ed.ac.uk/s0677528/data.html`.

[3] http://news.bbc.co.uk/

different locations. SIFT descriptors are quantized using the K-means clustering algorithm to obtain a discrete set of visual terms (visiterms) which form our visual vocabulary Voc_v. Each entry in this vocabulary stands for a group of image regions which are similar in content or appearance and assumed to originate from similar objects. More formally, each image I is expressed in a bag-of-words format vector, $[w_{v1}, w_{v2}, ..., w_{v_L}]$, where $w_{v_i} = n$ only if I has n regions labeled with v_i.

Since visual and textual modalities have now the same status—they are both represented as bags-of-words—we can also represent any image-caption-document tuple *jointly* as a mixed document d_{Mix}. The underlying assumption is that the two modalities express the same meaning which, as we explain below, can be operationalized as a probability distribution over a set of topics.

5 Modeling

Latent Dirichlet Allocation For ease of exposition, we first describe the basics of Latent Dirichlet Allocation (LDA; Blei et al. 2003), a probabilistic model of text generation and then move on to discuss our models which make use of probabilities estimated by LDA.

LDA can be represented as a three level hierarchical Bayesian model. Given a corpus consisting of M documents, Blei et al. (2003) define the generative process for a document d as follows:

1. Choose $\theta|\alpha \sim Dir(\alpha)$
2. For $n \in 1, 2, ..., N$:
   (a) Choose topic $z_n|\theta \sim Mult(\theta)$
   (b) Choose a word $w_n|z_n, \beta_{1:K} \sim Mult(\beta_{z_n})$

The mixing proportion over topics θ is drawn from a Dirichlet prior with parameters α whose role is to create a smoothed topic distribution. Once α and β are sampled, then each document is generated according to the topic proportions $z_{1:K}$ and word probabilities over topics β. The probability of a document d in a corpus is defined as:

$$P(d|\alpha,\beta) = \int_\theta P(\theta|\alpha)\left(\prod_{n=1}^{N}\sum_{z_k} P(z_k|\theta)P(w_n|z_k,\beta)\right)d\theta$$

Computing the posterior distribution $P(\theta, z|d, \alpha, \beta)$ of the hidden variables given a document is intractable in general. However, a variety of approximate inference algorithms have been proposed in the literature including variational inference which our model adopts (Blei et al., 2003). In this case, training an LDA model on a document collection will give two sets of parameters, the word probabilities given topics, $p(w|z_{1:K})$, and the topic proportions given documents, $P(z_{1:K}|d)$. The latter are document-specific, whereas the former represent the set of topics learned from the document collection.

Given a trained model, it is possible to do inference on an unseen document d_{new}:

$$p(w|d_{new}) \approx \sum_{k=1}^{K} P(w|z_k)\frac{\gamma_k}{\sum_{j=1}^{K}\gamma_j} \quad (1)$$

where $P(w|z_{1:K})$ are word probabilities over topics $z_{1:K}$ estimated during model training, and $\gamma_{1:K}$ are variational Dirichlet parameters obtained during inference on the new document (and can be considered as the posteriors of topic proportions over documents).

Image Annotation In the standard image annotation setting, a hypothetical model is given an image I and a set of keywords W, and must find the subset W_I ($W_I \subseteq W$) which appropriately describes image I:

$$W_I^* = \arg\max_W P(W|I) \quad (2)$$

The keywords are usually assumed to be conditionally independent on each other, so Equation (2) simplifies to:

$$W_I^* = \arg\max_W \prod_{w \in W} P(w|I) \quad (3)$$

Each entry in our database is an image-caption-document tuple (I, C, D). In this setting, we must find the subset of keywords W_I which appropriately describe image I with the help of the accompanying document D:

$$W_I^* = \arg\max_{W_t} P(W_t|I, D) \quad (4)$$

Here, W_t denotes a set of textual words (we use the subscript t to discriminate from the visual words which are not part of the model's output). We also assume that the keywords are conditionally independent of each other:

$$W_I^* = \arg\max_{W_t} P(W_t|I,D) = \arg\max_{W_t} \prod_{w_t \in W_t} P(w_t|I,D) \quad (5)$$

Since I and D are represented jointly as the concatenation of textual and visual terms, we may intuitively simplify the problem and use the mixed document representation d_{Mix} directly in estimating the conditional probabilities $P(w_t|I,D)$:

$$P(w_t|I,D) \approx P(w_t|d_{Mix}) \quad (6)$$

Substituting Equation (6) into (5) yields:

$$W_I^* \approx \arg\max_{W_t} \prod_{w_t \in W_t} P(w_t|d_{Mix}) \tag{7}$$

As mentioned earlier, we assume that the image and its associated text are generated by a mixture of latent topics which we infer using LDA. Specifically, we select the number of topics K and apply the LDA algorithm to a corpus consisting of documents $\{d_{Mix}\}$ in order to obtain the multimodal word distributions over topics $P(w|z_{1:K})$, and the estimated posterior of the topic proportions over documents $P(z_{1:K}|d_{Mix})$. We infer the topic proportions $P(z_{1:K}|d_{Mix_{new}})$ on a new document-image pair $d_{Mix_{new}}$ approximately using Equations (1) and (7):[4]

$$\begin{aligned} W_I^* &\approx \arg\max_{W_t} \prod_{w_t \in W_t} P(w_t|d_{Mix}) \qquad (8)\\ &= \arg\max_{W_t} \prod_{w_t \in W_t} \sum_{k=1}^{K} P(w_t|z_k) P(z_k|d_{Mix}) \\ &\approx \arg\max_{W_t} \prod_{w_t \in W_t} \sum_{k=1}^{K} P(w_t|z_k) \frac{\gamma_k}{\sum_{j=1}^{K} \gamma_j} \end{aligned}$$

where $P(w_t|z_k)$ are obtained during training, and $\gamma_{1:K}$ are inferred on the image-document test pair.

However, note that for an unseen image d_I and accompanying document d_D, the estimated topic proportions are solely based on variational inference which is an approximate algorithm. In order to render the model more robust, we smooth the topic proportions $P(z_{1:K}|d_{Mix})$ with probabilities based on a single modality:

$$\begin{aligned} &P^*(z_{1:K}|d_{Mix}) \approx \qquad (9)\\ &q_1 P(z_{1:K}|d_{Mix}) + q_2 P(z_{1:K}|d_D) + q_3 P(z_{1:K}|d_I) \end{aligned}$$

where $P(z_{1:K}|d_D)$ and $P(z_{1:K}|d_I)$ are inferred on d_D and d_I, respectively, and q_1, q_2, q_3 are smoothing parameters (which we tune experimentally on held-out data); q_3 is a shorthand for $(1 - q_1 - q_2)$.

In sum, calculating $P(W_t|I,D)$ boils down to estimating the probabilities $P(w_t|d_{Mix})$ according to Equations (8) and (9) which we obtain using the LDA model. We train LDA on the document collection $\{d_{Mix}\}$ and use inference to obtain the topic distributions of unseen image-document pairs. In the end, we obtain a ranked list of textual words w_t, the n-best of which are the annotations for image I.

Text Illustration Previous text illustration models are based on Corel-like databases with manual image descriptions (Barnard and Forsyth, 2001; Blei and Jordan, 2003) or instance-based learning using complex learning schemes (Joshi et al., 2006). Here, we present a relatively simple model, again under the topic mixture framework.

Given a test document D and a candidate image database $I_{1...N}$ with captions C, we must find the image or images which best describe the document. We can simply compute the probability of each visual term in the vocabulary given D by marginalizing over the document topics $z_{1:K}$:

$$P(w_v|D) = \sum_{z_{1:K}} P(w_v|z_k) P(z_k|d_D) \tag{10}$$

where w_v is a visual term and $P(w_v|z_k)$ the probability of w_v given topic z_k (as estimated on the training set).

Equation (10) delivers a ranked list of visual terms according to a given document. We could multiply these probabilities together mirroring Equation (7), however this is not reliable. In contrast to textual words, for which we may infer whether they are linguistically meaningful (e.g., by resorting to their part of speech), there is no easy way of knowing which visual words are important. Relying solely on frequency is not reliable either, as frequent visiterms may simply represent features common in all images (e.g., most images have some white color). To avoid a bias towards frequent but potentially irrelevant visual words, we output a fixed number of visual terms and select the image with the highest overlap as the correct illustration.

6 Experimental Setup

In this section we discuss our experimental design for assessing the performance of the models presented above. We give details on our training procedure and parameter estimation, describe our features, and present the baseline methods used for comparison with our models.

Data We evaluated the image annotation and text illustration tasks on the dataset described in Section 3. Documents and captions were part-of-speech tagged and lemmatized with Tree Tagger (Schmid, 1994). We excluded from the vocabulary low frequency words (appearing fewer than five times) and words other than nouns, verbs, and adjectives. For the image annotation task we follow the data split used in Feng and Lapata (2008). The training set contains 2,881 image-caption-document tuples; 240 tuples are reserved for development and 240 for

[4] During training, the model has access to all three elements (I,C,D), so the mixed document d_{Mix} is the concatenation of the visual terms and words in the caption and document. During testing, the model is given an image and its accompanying document, so d_{Mix} contains words based on I and D, but not C.

testing. Our text illustration experiments, used 2,881 image-caption-document tuples for training. For the purposes of simulating a real story picturing engine environment, we created a large image pool of 450 image-caption pairs and tested on 300 of them.

Model Parameters For each image we extracted 150 (on average) SIFT features. These were quantized into a discrete set of visual terms using K-means. We varied K from 100 to 2,000. We trained the LDA topic model on the multimodal document collection $\{d_{Mix}\}$ and varied the number of topics from 15 to 1,000. The hyperparameter α was initialized to 0.1; the β probabilities were initialized randomly. The maximum number of iterations for variational inference was set to 1,000. We tuned the smoothing parameters q_1, q_2, and q_3 (see Equation (9)) on the development set. The best values were $q_1 = 0.84$, $q_2 = 0.12$, and $q_3 = 0.04$ (for both tasks). As the number of visual terms and topics are interrelated we exhaustively examined all possible combinations on the development set. We obtained best results on image annotation with 1,000 topics and 750 visual terms. On text illustration the best parameters were 1,000 topics and 2,000 visual terms.

Baselines For the image annotation experiments, we compared our model against the following baselines. Firstly, we trained a vanilla LDA model on the document collection without taking the images into account. This model estimates $P(w_t|D) = \sum_{k=1}^{K} P(w_t|z_k)P(z_k|D)$, the probability of textual word w_t given text document D. We assume that the most probable words are the captions for the accompanying image. Our second baseline is the extended relevance model (Feng and Lapata, 2008) that also takes the document into account but crucially assumes that the process of generating the images is independent from the process of generating its keywords.

We also compared our approach with two closely related latent variable models (developed for image-caption pairs), a PLSA-based model (Monay and Gatica-Perez, 2007) and CorrLDA (Blei and Jordan, 2003). The former model is an asymmetric version of PLSA; it estimates the topic structure solely from the textual modality and keeps it fixed for the visual modality. The technique is similar to *folding-in* (Hofmann, 2001), the standard PLSA procedure for inference in unseen documents and allows modeling an image as a mixture of latent topics that is defined only by one modality (in this case the caption words). CorrLDA first generates image regions from a Gaussian multinomial distribution parametrized with Dirichlet priors. Then, for each annotation word, it uniformly selects a region from the image and generates a word according to the topic used to generate that region. We optimized the parameters for both models on the development set. For CorrLDA, we followed the mean-field variational inference strategy proposed in Blei (2004). The optimal number of topics for PLSA, was 200 (with 2000 visual terms) and for CorrLDA 50.

For the text illustration experiments, the proposed model was compared with three baselines. The first one is essentially word overlap. We select the image whose caption has the largest number of words in common with the test document. The second one is a straightforward implementation of the vector space model (Salton and McGill, 1983) where documents and captions are represented by vectors whose components correspond to term-document co-occurrences. We followed common practice in weighting terms by their tf-idf values, and used the cosine similarity measure to find the image whose caption is most similar to the test document. Our third baseline uses a text-based LDA model to estimate document-caption similarity probabilistically, through topic sharing. The images most relevant to a document are found by maximizing the conditional probability of the candidate captions C given the document d_D: $P(C|d_D) = \prod_{w_c \in C} \sum_{k=1}^{K} P(w_c|z_k)P(z_k|d_D)$ (where w_c are the caption words, $P(w_c|z_k)$ the conditional distribution of each w_c given a topic z_k, and $P(z_k|d_D)$ the conditional distribution of z_k given d_D, the document we wish to illustrate.

Evaluation In the image annotation task we follow the evaluation methodology proposed in Duygulu et al. (2002). We are given an un-annotated image I and asked to automatically produce the n-best keywords. For all models discussed here, we report results with the top 10 annotation words using precision, recall and F1. In the text illustration task, we are given a test document d and a pool of candidate images $I_{1...N}$ with captions $C_{1...N}$. The model is expected to find an image from the candidate pool that matches the test document. We use equation (10) to output a ranked list of M_I visual terms. The image having the highest overlap with the top 30 visual terms is selected as the illustration for the test document. All illustration models were evaluated using top 1 accuracy, which is the percentage of successfully matched image-document pairs in the test set.

Model	Top 10		
	Precision	Recall	F1
CorrLDA	5.33	11.80	7.36
TxtLDA	7.30	16.90	10.20
PLSA	10.26	22.60	14.12
ExtRel	14.70	27.90	19.80
MixLDA	16.30	33.10	21.60

Table 2: Automatic image annotation results.

7 Results

Our results on the image annotation task are summarized in Table 2. Here, we compare our own model (MixLDA) which is trained on both visual and textual information against an LDA model based solely on textual information (TxtLDA), an extended version of the Continuous Relevance model that also exploits collateral document information (ExtRel; Feng and Lapata 2008), a PLSA model that prioritizes the textual over visual modality (Monay and Gatica-Perez, 2007), and CorrLDA (Blei and Jordan, 2003) which does the opposite. We performed significance testing on F1 using stratified shuffling (Noreen, 1989), an instance of assumption-free approximative randomization testing.

Let us first discuss the performance of TxtLDA and MixLDA. These two models are closely related — they both rely on the probabilities $P(w_t|d)$ to generate the image keywords — save one important difference. MixLDA uses a concatenated representation of words and visual features assuming that the two modalities have equal importance in defining the latent space, whereas TxtLDA considers only the textual modality. Our results show that MixLDA outperforms TxtLDA in terms of precision (by 9%), recall (by 16.2%). MixLDA improves F1 by 11.4%, and the difference is significant ($p < 0.01$).

PLSA significantly ($p < 0.01$) improves upon TxtLDA. The key difference is the visual information which makes up (to a certain extent) for the lack of richer textual data. Interestingly, CorrLDA performs significantly ($p < 0.01$) worse than both PLSA and TxtLDA. Recall that in CorrLDA word topic assignments are drawn from the image regions which are in turn drawn from a Gaussian distribution. Although this modeling choice delivers better results on the simpler Corel dataset, it does not seem able to capture the characteristics of our images which are noisier and more complex. Moreover, CorrLDA assumes that annotation keywords *must correspond* to image regions. This assumption is too restrictive in our setting where a single keyword may refer to many objects or persons in an image (e.g.,the word *badminton* is used to collectively describe an image depicting players, shuttlecocks, and rackets). As an aside, it is interesting to note, that neither PLSA nor CorrLDA achieve better results, when modified to take the captions *and* associated documents into account. PLSA scores are in the same ballpark (see Table 2), whereas CorrLDA performs worse, F1 decreases by 2%.

TxtLDA	
Afghanistan, Taleban, soldier, British, zone, kill, force, Microsoft, **troop**, NATO	police, Burgess, time, letter, **crash**, case, death, operation, investigation, jail
MixLDA	
Afghanistan, **troop**, Blair, British, NATO, **helicopter**, soldier, support, **operation**, commander	**Diana**, police, case, **crash**, **Princess**, report, **death**, inquest, **Paris**, Burgess
Caption	
Troops need more Chinook helicopters to carry out operations	Princess Diana died in a car crash in Paris in 1997

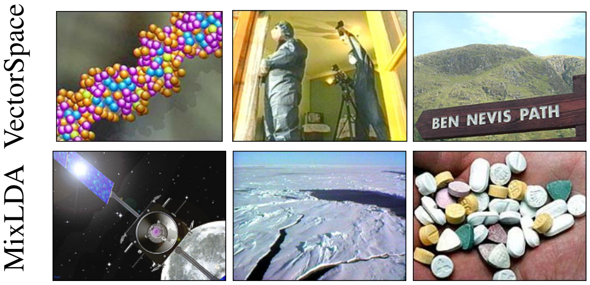
Figure 1: Annotations generated by the TxtLDA and MixLDA models. Words in bold face indicate exact matches. The original captions are in the last row.

The extended relevance model improves considerably upon TxtLDA, CorrLDA, and PLSA but is significantly worse ($p < 0.01$) than MixLDA. On the surface, MixLDA seems similar to ExtRel, both models take advantage of visual and textual information. ExtRel smooths the conditional probability of a word given an image with the conditional probability of the same word given the document and uses an LDA model (trained on the document collection) to remove non-topical keywords from the model's output. MixLDA is conceptually simpler, LDA is the actual model rather than a post-processing step, and exploits the synergy between visual and textual information more directly. Topics are created based on both modalities which are treated on an equal footing. Compared to ExtRel, MixLDA improves precision by 1.6%, recall by 5.2% and the overall F1 by 1.8%.

Figure 1 illustrates examples of annotations gen-

Model	Accuracy
TxtLDA	31.0
Overlap	31.3
VectorSpace	38.7
MixLDA	57.3

Table 3: Text Illustration results.



Europe's lunar satellite, the Smart 1 probe, is about to end its mission by crashing onto the Moon's surface. It will be a spectacular end for the robot which has spent the past 16 months testing innovative and miniaturized space technologies. Smart 1 has also produced detailed maps of the Moon's chemical make-up.

Figure 2: Top-3 illustrations for document in bottom row.

erated by TxtLDA and MixLDA for two images. For comparison, we also show the goldstandard image captions. Note that TxtLDA fails to generate any words relating to the objects shown in the image. It finds primarily words relating to the topics of the associated articles such as *troops* and *crash*. On the contrary, MixLDA is more successful at identifying the depicted objects, since it takes visual information into account.

Table 3 presents our results on the automatic text illustration task. Here, we compare our multimodal topic model (MixLDA) against three text-based baselines, namely word overlap (Overlap) a standard vector space model (VectorSpace), and TxtLDA. We examined whether differences in performance are statistically significant using a χ^2 test. As can be seen, MixLDA significantly ($p < 0.01$) outperforms these models by a wide margin (accuracy is 57.3% for MixLDA vs. 31.0% for TxtLDA, 38.7% for the vector space model, and 31.3% for word overlap). These results are encouraging given the simplicity of our model. They also indicate that substantial mileage can be gained by taking into account the visual modality.

Figure 2 shows the three best illustrations found by MixLDA and VectorSpace (incidentally, Overlap delivered the same ranking as VectorSpace). The images are presented in ranked order, i.e., the first image was given a higher score than the second one, etc. The document discusses Smart 1 Probe, a lunar satellite about to end its mission by crashing onto the moon's surface. MixLDA identifies an image depicting this satellite. The second best picture is also relevant, it resembles the moon's surface. The VectorSpace model does not find any related images, the first one is a DNA image, the second one depicts policemen at a crime scene and the third one Ben Nevis, the highest mountain in the British Isles.

8 Conclusions

In this paper we have presented a probabilistic approach for automatic image annotation and text illustration. Our model postulates that visual terms and words are generated by common (hidden) topics and is trained on a dataset consisting of images available on the Internet, their captions, and associated news articles. The annotations are implicit and the dataset is representative of the scale, diversity, and difficulty of real-world image collections. Overall, our results show that the model is robust to the noise inherent in such data. It improves upon competitive approaches that prioritize one modality over the other or exploit them indirectly. We also show that with minor modifications the model can be used to automatically illustrate a document with an appropriate image. Our method shows promise for multimodal search and image retrieval and other applications which have been traditionally text-based. An interesting future direction involves generating actual sentence descriptions rather than isolated keywords. Another relevant application is summarization. Our results suggest that taking visual information into account could potentially create more focused and accurate summaries.

The model presented here could be further improved in two ways. Firstly, we could allow an infinite number of topics and develop a nonparametric version that *learns* how many topics are optimal. Secondly, our model is based on word unigrams, and in this sense takes very little linguistic knowledge into account. Recent developments in topic modeling could potentially rectify this, e.g., by assuming that each word is generated by a distribution that combines document-specific topics and parse-tree-specific syntactic transitions (Boyd-Graber and Blei, 2009).

Abstract

In a Wizard-of-Oz experiment with multiple wizard subjects, each wizard viewed automated speech recognition (*ASR*) results for utterances whose interpretation is critical to task success: requests for books by title from a library database. To avoid non-understandings, the wizard directly queried the application database with the ASR hypothesis (*voice search*). To learn how to avoid misunderstandings, we investigated how wizards dealt with uncertainty in voice search results. Wizards were quite successful at selecting the correct title from query results that included a match. The most successful wizard could also tell when the query results did not contain the requested title. Our learned models of the best wizard's behavior combine features available to wizards with some that are not, such as recognition confidence and acoustic model scores.

1 Introduction

Wizard-of-Oz (*WOz*) studies have long been used for spoken dialogue system design. In a relatively new variant, a subject (the *wizard*) is presented with real or simulated automated speech recognition (*ASR*) to observe how people deal with incorrect speech recognition output (Rieser, Kruijff-Korbayová, & Lemon, 2005; Skantze, 2003; Stuttle, Williams, & Young, 2004; Williams & Young, 2003, 2004; Zollo, 1999). In these experiments, when a wizard could not interpret the ASR output (*non-understanding*), she rarely asked users to repeat themselves. Instead, the wizard found other ways to continue the task.

This paper describes an experiment that presented wizards with ASR results for utterances whose interpretation is critical to task success: requests for books from a library database, identified by title. To avoid non-understandings, wizards used *voice search* (Wang et al., 2008): they directly queried the application database with ASR output. To investigate how to avoid errors in understanding (*misunderstandings)*, we examined how wizards dealt with uncertainty in voice search results. When the voice search results included the requested title, all seven of our wizards were likely to identify it. One wizard, however, recognized far better than the others when the voice search results did not contain the requested title. The experiment employed a novel design that made it possible to include system features in models of wizard behavior. The principal result is that our learned models of the best wizard's behavior combine features that are available to wizards with some that are not, such as recognition confidence and acoustic model scores.

The next section of the paper motivates our experiment. Subsequent sections describe related work, the dialogue system and embedded wizard infrastructure, experimental design, learning methods, and results. We then discuss how to generalize from the results of our study for spoken dialogue system design. We conclude with a summary of results and their implications.

2 Motivation

Rather than investigate full dialogues, we addressed a single type of turn exchange or adjacency pair (Sacks et al., 1974): a request for a book by its

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 840–848,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

title. This allowed us to collect data exclusively about an utterance type critical for task success in our application domain. We hypothesized that low-level features from speech recognition, such as acoustic model fit, could independently affect voice search confidence. We therefore applied a novel approach, *embedded WOz*, in which a wizard and the system together interpret noisy ASR.

To address how to avoid misunderstandings, we investigated how wizards dealt with uncertainty in voice search returns. To illustrate what we mean by uncertainty, if we query our book title database with the ASR hypothesis:

```
  ROLL DWELL
```

our voice search procedure returns, in this order:

```
  CROMWELL
  ROBERT LOWELL
  ROAD TO WEALTH
```

The correct title appears last because of the score it is assigned by the string similarity metric we use.

Three factors motivated our use of voice search to interpret book title requests: noisy ASR, unusually long query targets, and high overlap of the vocabulary across different query types (e.g., author and title) as well as with non-query words in caller utterances (e.g., “Could you look up . . .”).

First, accurate speech recognition for a real-world telephone application can be difficult to achieve, given unpredictable background noise and transmission quality. For example, the 68% word error rate (*WER*) for the fielded version of Let’s Go Public! (Raux et al., 2005) far exceeded its 17% WER under controlled conditions. Our application handles library requests by telephone, and would benefit from robustness to noisy ASR.

Second, the book title field in our database differs from the typical case for spoken dialogue systems that access a relational database. Such systems include travel booking (Levin et al., 2000), bus route information (Raux et al., 2006), restaurant guides (Johnston et al., 2002; Komatani et al., 2005), weather (Zue et al., 2000) and directory services (Georgila et al., 2003). In general for these systems, a few words are sufficient to retrieve the desired attribute value, such as a neighborhood, a street, or a surname. Mean utterance length in a sample of 40,000 Let’s Go Public! utterances, for example, is 2.4 words. The average book title length in our database is 5.4 words.

Finally, our dialogue system, *CheckItOut*, allows users to choose whether to request books by title, author, or catalogue number. The database represents 5028 active patrons (with real borrowing histories and preferences but fictitious personal information), 71,166 book titles and 28,031 authors. Though much smaller than a database for a directory service application (Georgila et al., 2003), this is much larger than that of many current research systems. For example, Let’s Go Public! accesses a database with 70 bus routes and 1300 place names. Titles and author names contribute 50,394 words to the vocabulary, of which 57.4% occur only in titles, 32.1% only in author names, and 10.5% in both. Many book titles (e.g., *You See I Haven’t Forgotten, You Never Know*) have a high potential for confusability with non-title phrases in users’ book requests. Given the longer database field and the confusability of the book title language, integrating voice search is likely to have a relatively larger impact in CheckItOut.

We seek to minimize non-understandings and misunderstandings for several reasons. First, user corrections in both situations have been shown to be more poorly recognized than non-correction utterances (Litman et al., 2006). Non-understandings typically result in re-prompting the user for the same information. This often leads to hyper-articulation and concomitant degradation in recognition performance. Second, users seem to prefer systems that minimize non-understandings and misunderstandings, even at the expense of dialogue efficiency. Users of the TOOT train information spoken dialogue system preferred system-initiative to mixed- or user-initiative, and preferred explicit confirmation to implicit or no confirmation (Litman & Pan, 1999). This was true despite the fact that a mixed-initiative, implicit confirmation strategy led to fewer turns for the same task. Most of the more recent work on spoken dialogue systems focuses on mixed-initiative systems in laboratory settings. Still, recent work suggests that while mixed- or user-initiative is rated highly in usability studies, under real usage it “fails to provide [a] robust enough interface” (Turunen et al., 2006). Incorporating accurate voice search into spoken dialogue systems could lead to fewer non-understandings and fewer misunderstandings.

3 Related Work

Our approach to noisy ASR contrasts with many other information-seeking and transaction-based dialogue systems. Those systems typically perform natural language understanding on ASR output before database query with techniques that try to improve or expand ASR output. None that we know of use voice search. For one directory service application, users spell the first three letters of surnames, and then ASR results are expanded using frequently confused phones (Georgila et al., 2003). A two-pass recognition architecture added to Let's Go Public! improved concept recognition in post-confirmation user utterances (Stoyanchev & Stent, 2009). In (Komatani et al., 2005), a shallow semantic interpretation phase was followed by decision trees to classify utterances as relevant either to query type or to specific query slots, to narrow the set of possible interpretations. CheckItOut is most similar in spirit to the latter approach, but relies on the database earlier, and only for semantic interpretation, not to also guide the dialogue strategy.

Our approach to noisy ASR is inspired by previous WOz studies with real (Skantze, 2003; Zollo, 1999) or simulated ASR (Kruijff-Korbayová et al., 2005; Rieser et al., 2005; Williams & Young, 2004). Simulation makes it possible to collect dialogues without building a speech recognizer, and to control for WER. In the studies that involved task-oriented dialogues, wizards typically focused more on the task and less on resolving ASR errors (Williams & Young, 2004; Skantze, 2003; Zollo, 1999). In studies more like the information-seeking dialogues addressed here, an entirely different pattern is observed (Kruijff-Korbayová et al., 2005; Rieser et al., 2005).

Zollo collected seven dialogues with different human-wizard pairs to develop an evacuation plan. The overall WER was 30%. Of the 227 cases of incorrect ASR, wizard utterances indicated a failure to understand for only 35% of them. Wizards ignored words not salient in the domain and hypothesized words based on phonetic similarity. In (Skantze, 2003), both users and wizards knew there was no dialogue system; 44 direction-finding dialogues were collected with 16 subjects. Despite a WER of 43%, the wizard operators signaled misunderstanding only 5% of the time, in part because they often ignored ASR errors and continued the dialogue. For the 20% of non-understandings, operators continued a route description, asked a task-related question, or requested a clarification.

Williams and Young collected 144 dialogues simulating tourist requests for directions and other negotiations. WER was constrained to be high, medium, or low. Under medium WER, a task-related question in response to a non-understanding or misunderstanding led to full understanding more often than explicit repairs. Under high WER, however, the reverse was true. Misunderstandings significantly increased when wizards followed non-understandings or misunderstandings with a task-related question instead of a repair.

In (Rieser et al., 2005), wizards simulated a multimodal MP3 player application with access to a database of 150K music albums. Responses could be presented verbally or graphically. In the noisy transcription condition, wizards made clarification requests about twice as often as that found in similar human-human dialogue.

In a system like CheckItOut, user utterances that request database information must be understood. We seek an approach that would reduce the rate of misunderstandings observed for high WER in (Williams & Young, 2004) and the rate of clarification requests observed in (Rieser et al., 2005).

4 CheckItOut and Embedded Wizards

CheckItOut is modeled on library transactions at the Andrew Heiskell Braille and Talking Book Library, a branch of the New York Public Library and part of the National Library of Congress. Borrowing requests are handled by telephone. Books, mainly in a proprietary audio format, travel by mail. In a dialogue with CheckItOut, a user identifies herself, requests books, and is told which are available for immediate shipment or will go on reserve. The user can request a book by catalogue number, title, or author.

CheckItOut builds on the Olympus/RavenClaw framework (Bohus & Rudnicky, 2009) that has been the basis for about a dozen dialogue systems in different domains, including Let's Go Public! (Raux et al., 2005). Speech recognition relies on PocketSphinx. Phoenix, a robust context-free grammar (*CFG*) semantic parser, handles natural language understanding (Ward & Issar, 1994). The Apollo interaction manager (Raux & Eskenazi, 2007) detects utterance boundaries using information from speech recognition, semantic parsing, and Helios, an utterance-level confidence annotator (Bohus & Rudnicky, 2002). The dialogue manager is implemented in RavenClaw.

To design CheckItOut's dialogue manager, we recorded 175 calls (4.5 hours) from patrons to librarians. We identified 82 book request calls, transcribed them, aligned the utterances with the speech signal, and annotated the transcripts for dialogue acts. Because active patrons receive monthly newsletters listing new titles in the desired formats, patrons request specific items with advance knowledge of the author, title, or catalogue number. Most book title requests accurately reproduce the exact title, the title less an initial determiner ("the," "a"), or a subtitle.

We exploited the Galaxy message passing architecture of Olympus/RavenClaw to insert a wizard server into CheckItOut. The hub passes messages between the system and a wizard's graphical user interface *(GUI)*, allowing us to collect runtime information that can be included in models of wizards' actions.

For speech recognition, CheckItOut relies on PocketSphinx 0.5, a Hidden Markov Model-based recognizer. Speech recognition for this experiment, relied on the freely available Wall Street Journal "read speech" acoustic models. We did not adapt the models to our population or to spontaneous speech, thus insuring that wizards would receive relatively noisy recognition output.

We built trigram language models from the book titles using the CMU Statistical Language Modeling Toolkit. Pilot tests with one male and one female native speaker indicated that a language model based on 7500 titles would yield WER in the desired range. (Average WER for the book title requests in our experiment was 71%.) To model one aspect of the real world useful for an actual system, titles with below average circulation were eliminated. An offline pilot study had demonstrated that one-word titles were easy for wizards, so we eliminated those as well. A random sample of 7,500 was chosen from the remaining 19,708 titles to build the trigram language model.

We used Ratcliff/Obersherhelp (*R/O*) to measure the similarity of an ASR string to book titles in the database (Ratcliff & Metzener, 1988). R/O calculates the ratio *r* of the number of matching characters to the total length of both strings, but requires $O(r^2)$ time on average and $O(r^3)$ time in the worst case. We therefore computed an upper bound on the similarity of a title/ASR pair prior to full R/O to speed processing.

5 Experimental Design

In this experiment, a user and a wizard sat in separate rooms where they could not overhear one another. Each had a headset with microphone and a GUI. Audio input on the wizard's headset was disabled. When the user requested a title, the ASR hypothesis for the title appeared on the wizard's GUI. The wizard then selected the ASR hypothesis to execute a voice search against the database.

Given the ASR and the query return, the wizard's task was to guess which candidate in the query return, if any, matched the ASR hypothesis. Voice search accessed the full backend of 71,166 titles. The custom query designed for the experiment produced four types of return, in real time, based on R/O scores:

- *Singleton*: a single best candidate (R/O $\geq$ 0.85)
- *AmbiguousList*: two to five moderately good candidates (0.85 > R/O $\geq$ 0.55)
- *NoisyList*: six to ten poor but non-random candidates (0.55 > R/O $\geq$ 0.40)
- *Empty*: No candidate titles (max R/O < 0.40)

In pilot tests, 5%-10% of returns were empty versus none in the experiment. The distribution of other returns was: 46.7% Singleton, 50.5% AmbiguousList, and 2.8% NoisyList.

Seven undergraduate computer science majors at Hunter College participated. Two were nonnative speakers of English (one Spanish, one Romanian). Each of the possible 21 pairs of students met for five trials. During each trial, one student served as wizard and the other as user for a *session* of 20 title cycles. They immediately reversed roles for a second session, as discussed further below. The experiment yielded 4172 title cycles rather than the full 4200, because users were permitted to end sessions early. All titles were selected from the 7500 used to construct the language model.

Each user received a printed list of 20 titles and a brief synopsis of each book. The acoustic quality of titles read individually from a list is unlikely to approximate that of a patron asking for a specific title. Therefore, immediately before each session, the user was asked to read a synopsis of each book, and to reorder the titles to reflect some logical grouping, such as genre or topic. Users requested titles in this new order that they had created.

Participants were encouraged to maximize a session score, with a reward for the experiment winner. Scoring was designed to foster cooperative strategies. The wizard scored +1 for a correctly identified title, +0.5 for a thoughtful question, and -1 for an incorrect title. The user scored +0.5 for a successfully recognized title. User and wizard traded roles for the second session, to discourage participants from sabotaging the others' scores.

The wizard's GUI presented a real-time live feed of ASR hypotheses, weighted by grayscale to reflect acoustic confidence. Words in each candidate title that matched a word in the ASR appeared darker: dark black for Singleton or AmbiguousList, and medium black for NoisyList. All other words were in grayscale in proportion to the degree of character overlap. The wizard queried the database with a recognition hypothesis for one utterance at a time, but could concatenate successive utterances, possibly with some limited editing.

After a query, the wizard's GUI displayed candidate matches in descending order of R/O score. The wizard had four options: make a *firm choice* of a candidate, make a *tentative choice*, ask a *question*, or *give up* to end the title cycle. Questions were recorded. The wizard's GUI showed the success or failure of each title cycle before the next one began. The user's GUI posted the 20 titles to be read during the session. On the GUI, the user rated the wizard's title choices as correct or incorrect. Titles were highlighted green if the user judged a wizard's offered title correct, red if incorrect, yellow if in progress, and not highlighted if still pending. The user also rated the wizard's questions. Average elapsed time for each 20-title session was 15.5 minutes.

A questionnaire similar to the type used in PARADISE evaluations (Walker et al., 1998) was administered to wizards and users for each pair of sessions. On a 5-point Likert scale, the average response to the question "I found the system easy to use this time" was 4 (sd=0; 4=Agree), indicating that participants were comfortable with the task. All other questions received an average score of Neutral (3) or Disagree (2). For example, participants were neutral (3) regarding confidence in guessing the correct title, and disagreed (2) that they became more confident as time went on.

6 Learning Method and Goals

To model wizard actions, we assembled 60 features that would be available at run time. Part of our task was to detect their relative independence, meaningfulness, and predictive ability. Features described the wizard's GUI, the current title session, similarity between ASR and candidates, ASR relevance to the database, and recognition and confidence measures. Because the number of voice search returns varied from one title to the next, features pertaining to candidates were averaged.

We used three machine-learning techniques to predict wizards' actions: decision trees, linear regression, and logistic regression. All models were produced with the Weka data mining package, using 10-fold cross-validation (Witten & Frank, 2005). A decision tree is a predictive model that maps feature values to a target value. One applies a decision tree by tracing a path from the *root* (the top node) to a leaf, which provides the target value. Here the leaves are the wizard actions: firm choice, tentative choice, question, or give up. The algorithm used is a version of C4.5 (Quinlan, 1993), where gain ratio is the splitting criterion.

To confirm the learnability and quality of the decision tree models, we also trained logistic regression and linear regression models on the same data, normalized in [0, 1]. The logistic regression model predicts the probability of wizards' actions by fitting the data to a logistic curve. It generalizes the linear model to the prediction of categorical data; here, categories correspond to wizards' actions. The linear regression models represent wizards' actions numerically, in decreasing value: firm choice, tentative choice, question, give up.

Although analysis of individual wizards has not been systematic in other work, we consider the variation in human performance significant. Because we seek excellent, not average, teachers for CheckItOut, our focus is on understanding good wizardry. Therefore, we learned two kinds of models with each of the three methods: the *overall model* using data from all of our wizards, and individual *wizard models*.

Preliminary cross-correlation confirmed that many of the 60 features were heavily interdependent. Through an initial manual curation phase, we isolated groups of features with $R^2 > 0.5$. When these groups referenced semantically similar features, we selected a single representative from the group and retained only that one. For example, the features that described similarity between hypotheses and candidates were highly correlated, so we chose the most comprehensive one: the number of exact word matches. We also grouped together

Table 1. Raw session score, accuracy, proportion of offered titles that were listed first in the query return, and frequency of correct non-offers for seven participants.

Participant	Cycles	Session Score	Accuracy	Offered Return 1	Correct Non-Offers
W4	600	0.7585	0.8550	0.70	0.64
W5	600	0.7584	0.8133	0.76	0.43
W7	599	0.6971	0.7346	0.76	0.14
W1	593	0.6936	0.7319	0.79	0.16
W2	599	0.6703	0.7212	0.74	0.10
W3	581	0.6648	0.6954	0.81	0.20
W6	600	0.6103	0.6950	0.86	0.03

and represented by a single feature: three features that described the gaps between exact word matches, three that described the data presented to the wizard, nine that described various system confidence scores, and three that described the user's speaking rate. This left 28 features.

Next we ran CfsSubsetEval, a supervised attribute selection algorithm for each model (Witten & Frank, 2005). This greedy, hill-climbing algorithm with backtracking evaluates a subset of attributes by the predictive ability of each feature and the degree of redundancy among them. This process further reduced the 28 features to 8-12 features per model. Finally, to reduce overfitting for decision trees, we used pruning and subtree rising. For linear regression we used the M5 method, repeatedly removing the attribute with the smallest standardized coefficient until there was no further improvement in the error estimate given by the Akaike information criterion.

7 Results

Table 1 shows the number of title cycles per wizard, the raw session score according to the formula given to the wizards, and accuracy. *Accuracy* is the proportion of title cycles where the wizard found the correct title, or correctly guessed that the correct title was not present (asked a question or gave up). Note that score and accuracy are highly correlated (R=0.91, p=0.0041), indicating that the instructions to participants elicited behavior consistent with what we wanted to measure.

Wizards clearly differed in performance, largely due to their response when the candidate list did not include the correct title. Analysis of variance with wizard as predictor and accuracy as the dependent variable is highly significant (p=0.0006); significance is somewhat greater (p=0.0001) where session score is the dependent variable. Table 2 shows the distribution of correct actions: to offer a candidate at a given position in the query return (Returns 1 through 9), or to ask a question or give up. As reflected in Table 2, a baseline accuracy of about 65% could be achieved by offering the first return. The fifth column of Table 1 shows how often wizards did that (Offered Return 1), and clearly illustrates that those who did so most often (W3 and W6) had accuracy results closest to the baseline. The wizard who did so least often (W4) had the highest accuracy, primarily because she more often correctly offered no title, as shown in the last column of Table 1. We conclude that a spoken dialogue system would do well to emulate W4.

Overall, our results in modeling wizards' actions were uniform across the three learning methods, gauged by accuracy and F measure. For the combined wizard data, logistic regression had an accuracy of 75.2%, and F measures of 0.83 for firm choices and 0.72 for tentative choices; the decision tree accuracy was 82.2%, and the F measures for firm versus tentative choices were respectively 0.82 and 0.71. The decision tree had a root mean squared error of 0.306, linear regression 0.483. Table 3 shows the accuracy and F measures on firm choices for the decision trees by individual wizard, along with the numbers of attributes and nodes per

Table 2. Distribution of correct actions

Correct Action	N	%
Return 1	2722	65.2445
Return 2	126	3.0201
Return 3	56	1.3423
Return 4	46	1.1026
Return 5	26	0.6232
Return 7	7	0.1678
Return 8	1	0.0002
Return 9	2	0.0005
Question or Giveup	1186	28.4276
Total	4172	1.0000

Table 3. Learning results for wizards

Tree	Rank	Nodes	Attributes	Accuracy	F firm
W4	1	55	12	75.67	0.85
W5	2	21	10	76.17	0.85
W1	3	7	8	80.44	0.87
W7	4	45	11	73.62	0.83
W3	5	33	10	77.42	0.84
W2	6	35	10	78.49	0.85
W6	7	23	10	85.19	0.80

tree. Although relatively few attributes appeared in any one tree, most attributes appeared in multiple nodes. W1 was the exception, with a very small pruned tree of 7 nodes.

Accuracy of the decision trees does not correlate with wizard rank. In general, the decision trees could consistently predict a confident choice (0.80 ≤ F ≤ 0.87), but were less consistent on a tentative choice (0.60 ≤ F ≤ 0.89), and could predict a question only for W4, the wizard with the highest accuracy and greatest success at detecting when the correct title was not in the candidates.

What wizards saw on the GUI, their recent success, and recognizer confidence scores were key attributes in the decision trees. The five features that appeared most often in the root and top-level nodes of all tree models reported in Table 3 were:

- *DisplayType* of the return (Singleton, Ambiguous List, NoisyList)
- *RecentSuccess,* how often the wizard chose the correct title within the last three title cycles
- *ContiguousWordMatch,* the maximum number of contiguous exact word matches between a candidate and the ASR hypothesis (averaged across candidates)
- *NumberOfCandidates*, how many titles were returned by the voice search
- *Confidence,* the Helios confidence score

DisplayType, NumberOfCandidates and *ContiguousWordMatch* pertain to what the wizard could see on her GUI. (Recall that *DisplayType* is distinguished by font darkness, as well as by number of candidates.) The impact of *RecentSuccess* might result not just from the wizard's confidence in her current strategy, but also from consistency in the user's speech characteristics. The Helios confidence annotation uses a learned model based on features from the recognizer, the parser, and the dialogue state. Here confidence primarily reflects recognition confidence; due to the simplicity of our grammar, parse results only indicate whether there is a parse. In addition to these five features, every tree relied on at least one measure of similarity between the hypothesis and the candidates.

W4 achieved superior accuracy: she knew when to offer a title and when not to. In the learned tree for W4, if the *DisplayType* was *NoisyList*, W4 asked a question; if *DisplayType* was *AmbiguousList,* the features used to predict W4's action included the five listed above, along with the acoustic model score, word length of the ASR, number of times the wizard had asked the user to repeat, and the maximum size of the gap between words in the candidates that matched the ASR hypothesis.

To focus on W4's questioning behavior, we trained an additional decision tree to learn how W4 chose between two actions: offering a title versus asking a question. This 37-node, 8-attribute tree was based on 600 data points, with F=0.91 for making an offer and F=0.68 for asking a question. The tree is distinctive in that it splits at the root on the number of frames in the ASR. If the ASR is short (as measured both by the number of recognition frames and the words), W4 asks a question when *DisplayType* = *AmbiguousList* or *NoisyList,* either *RecentSuccess* ≤ 1 or *ContiguousWordMatch* = 0, and the acoustic model score is low. Note that shorter titles are more confusable. If the ASR is long, W4 asks a question when *ContiguousWordMatch* ≤ 1, *RecentSuccess* ≤ 2, and either *CandidateDisplay* = *NoisyList*, or *Confidence* is low, and there is a choice of titles.

8 Discussion

Our experiment addressed whether voice search can compensate for incorrect ASR hypotheses and permit identification of a user's desired book, given a request by title. The results show that with high WER, a baseline dialogue strategy that always offers the highest-ranked database return can nevertheless achieve moderate accuracy. This is true even with the relatively simplistic measure of similarity between the ASR hypothesis and candidate titles used here. As a result, we have integrated voice search into CheckItOut, along with a linguistically motivated grammar for book titles. Our current Phoenix grammar relies on CFG rules automatically generated from dependency parses of the book titles, using the MICA parser

(Bangalore et al., 2009). As described in (Gordon & Passonneau, 2010), a book title parse can contain multiple title slots that consume discontinuous sequences of words from the ASR hypothesis, thus accommodating noisy ASR. For the voice search phase, we now concatenate the words consumed by a sequence of title slots. We are also experimenting with a statistical machine learning approach that will replace or complement the semantic parsing.

Computers clearly do some tasks faster and more accurately than people, including database search. To benefit from such strengths, a dialogue system should also accommodate human preferences in dialogue strategy. Previous work has shown that user satisfaction depends in part on task success, but also on minimizing behaviors that can increase task success but require the user to correct the system (Litman et al., 2006).

The decision tree that models W4 has lower accuracy than other models' (see Table 3), in part because her decisions had finer granularity. A spoken dialogue system could potentially do as well as or better than the best human at detecting when the title is not present, given the proper training data. To support this, a dataset could be created that was biased toward a larger proportion of cases where not offering a candidate is the correct action.

9 Conclusion and Current Work

This paper presents a novel methodology that embeds wizards in a spoken dialogue system, and collects data for a single turn exchange. Our results illustrate the merits of ranking wizards, and learning from the best. Our wizards were uniformly good at choosing the correct title when it was present, but most were overly eager to identify a title when it was not among the candidates. In this respect, the best wizard (W4) achieved the highest accuracy because she demonstrated a much greater ability to know when *not* to offer a title. We have shown that it is feasible to replicate this ability in a model learned from features that include the presentation of the search results (length of the candidate list, amount of word overlap of candidates with the ASR hypothesis), recent success at selecting the correct candidate, and measures pertaining to recognition results (confidence, acoustic model score, speaker rate). If replicated in a spoken dialogue system, such a model could support integration of voice search in a way that avoids misunderstandings. We conclude that learning from embedded wizards can exploit a wider range of relevant features, that dialogue managers can profit from access to more fine-grained representations of user utterances, and that machine learners should be selective about which people to model.

That wizard actions can be modeled using system features bodes well for future work. Our next experiment will collect full dialogues with embedded wizards whose actions will again be restricted through an interface. This time, NLU will integrate voice search with the linguistically motivated CFG rules for book titles described earlier, and a larger language model and grammar for database entities. We will select wizards who perform well during pilot tests. Again, the goal will be to model the most successful wizards, based upon data from recognition results, NLU, and voice search results.

A Direct Syntax-Driven Reordering Model for Phrase-Based Machine Translation

Niyu Ge
IBM T.J.Watson Research
Yorktown Heights, NY 10598
niyuge@us.ibm.com

Abstract

This paper presents a direct word reordering model with novel syntax-based features for statistical machine translation. Reordering models address the problem of reordering source language into the word order of the target language. IBM Models 3 through 5 have reordering components that use surface word information but very little context information to determine the traversal order of the source sentence. Since the late 1990s, phrase-based machine translation solves much of the local reorderings by using phrasal translations. The problem of long-distance reordering has become a central research topic in modeling distortions. We present a syntax driven maximum entropy reordering model that directly predicts the source traversal order and is able to model arbitrarily long distance word movement. We show that this model significantly improves machine translation quality.

1 Introduction

Machine translation reordering models model the problem of the word order when translating a source language into a target language. For example in Spanish and Arabic, adjectives often come after the nouns they modify whereas in English modifying adjectives usually precede the nouns. When translating Spanish or Arabic into English, the position of the adjectives need to be properly reordered to be placed before the nouns to make fluent English.
In this paper, we present a word reordering model that models the word reordering process in translation. The paper is organized as follows. §2 outlines previous approaches to reordering. §3 details our model and its training and decoding process. §4 discusses experiments to evaluate the model and §5 presents machine translation results. §6 is discussion and conclusion.

2 Previous Work

The word reordering problem has been one of the major problems in statistical machine translation (SMT). Since exploring all possible reorderings of a source sentence is an NP-complete problem (Knight 1999), SMT systems limit words to be reordered within a window of length *k*. IBM Models 3 through 5 (Brown et.al. 1993) model reorderings based on surface word information. For example, Model 4 attempts to assign target-language positions to source-language words by modeling $d(j \mid i, l, m)$ where j is the target-language position, i is the source-language position, l and m are respectively source and target sentence lengths. These models are not effective in modeling reorderings because they don't have enough context and lack structural information.

Phrase-based SMT systems such as (Koehn et.al. 2003) move from using words as translation units to using phrases. One of the advantages of phrase-based SMT systems is that local reorderings are inherent in the phrase translations. However, phrase-based SMT systems capture reordering instances and not reordering phenomena. For example, if the Arabic phrase "*the car red*" and its English translation "the red car' is seen in the training data, phrase-based SMT is able to produce the correct English for the Arabic 'the car red'. However it will not be able to produce 'the blue car' for the Arabic '*the car blue*' if the training data does not contain this phrase pair. Phrases do not capture the phenomenon that Arabic adjectives and nouns need to be reordered. Another problem with phrase-based SMT is the problem of long-range reorderings. Recent work on reordering has been focusing on capturing general reordering

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 849–857,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

phenomena (as opposed to instances) and on solving long-range reordering problems.

(Al-onaizan et.al. 2006) proposes 3 distortion models, the inbound, outbound, and pair models. They together model the likelihood of translating a source word at position *i* given that the source word at position *j* has just been translated. These models perform better than n-gram based language models but are limited in their use of only the surface strings.

Instead of directly modeling the distance of word movement, phrasal level reordering models model how to move phrases, also called *orientations*. Orientations typically apply to adjacent phrases. Two adjacent phrases can be either placed monotonically (sometimes called *straight*) or swapped (non-monotonically or *inverted*). Early orientation models do not use lexical contents such as (Zens et. al., 2004). More recently, (Xiong et.al. 2006; Zens 2006; Och et. al, 2004; Tillmann, 2004; Kumar et al., 2005, Ni et al., 2009) all presented models that use lexical features from the phrases to predict their orientations. These models are very powerful in predicting local phrase placements. More recently (Galley et.al. 2008) introduced a hierarchical orientation model that captures some non-local phrase reorderings by a shift reduce algorithm. Because of the heavy use of lexical features, these models tend to suffer from data sparseness problems. Another limitation is that these models are restricted to reorderings with no gaps and phrases that are adjacent.

We present a probabilistic reordering model that models directly the source translation sequence and explicitly assigns probabilities to the reorderings of the source input with no restrictions on gap, length or adjacency. This is different from the approaches of pre-order such as (Xia and McCord 2004; Collins et.al. 2005; Kanthak et. al. 2005; Li et. al., 2007). Although our model can be used to produce top N pre-ordered source, the experiments reported here do not use the model in the pre-order mode. Instead, the reordering model is used to generate a reorder lattice which encodes many reorderings and their costs (negative log probability). This reorder lattice is independent of the translation decoder. In principle, any decoder can use this lattice for its reordering needs. We have integrated the reorder lattice into a phrase-based. The experiments reported here are from the phrase-based decoder.

We present the reordering model based on maximum entropy models. We then describe the syntactic features in the context of Chinese to English translation.

3 Maximum Entropy Reordering Model

The model takes a source sequence of length *n*:

$$S = [s_1, s_2, \ldots s_n]$$

and models its translation or *visit* order according to the target language:

$$V = [v_1, v_2, \ldots v_n]$$

where v_j is the source position for target position *j*. For example, if the 2nd source word is to be translated first, then $v_1 = 2$. We find V such that

$$\arg\max_{V \in \{v\}} p(V \mid S) \qquad (1)$$

$$= \max \prod_{j=1}^{n} p(v_j \mid S, v_{1\ldots} v_{j-1}) \qquad (2)$$

In equation (1) {υ} is the set of possible visit orders. We want to find a visit order V such that the probability p(V|S) is maximized. Equation (2) is a component-wise decomposition of (1).

Let

$$f = v_j \ \textit{and} \ \ h = (S, v_1 \ldots v_{j-1})$$

We use the maximum entropy model to estimate equation (2):

$$p(f \mid h) = \frac{1}{Z(h)} \exp\left(\sum_k \lambda_k \phi_k(f, h)\right) \qquad (3)$$

where *Z(h)* is the normalization constant

$$Z(h) = \sum_f \exp \sum_k \lambda_k \phi_k(f, h) \qquad (4)$$

In equation (3), $\phi_k(f, h)$ are binary-valued features. During training, instead of exploring all possible permutations, samples are drawn given the correct path only.

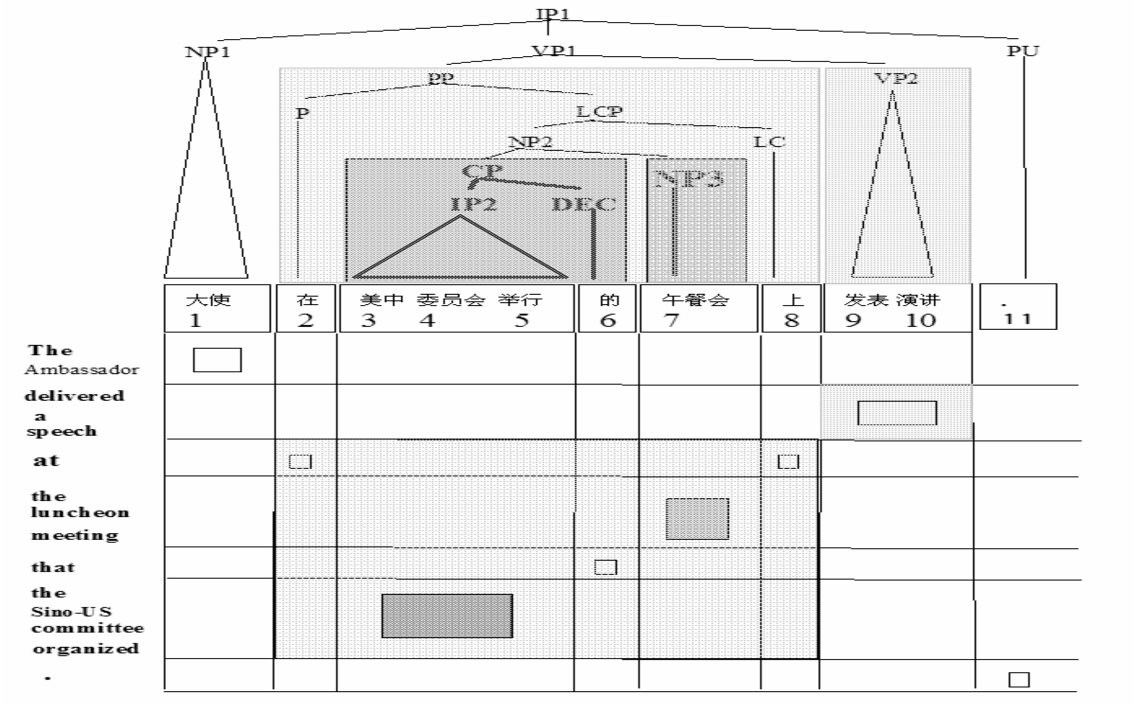
3.1 Feature Overview

Most of our features $\phi_k(f, h)$ are syntax-based. They examine how each parse node is reordered during translation. We also have a few non-syntax features that inspect the surface words and part-of-speech tags. They complement syntax features by capturing lexical dependencies and guarding against parsing errors. Instead of directly modeling the absolute source position v_j, we model the jump from the last source position v_{j-1}. All features share two common components: *j* (for *jump*), and *cov* (for *coverage*). *Jumps* are bucketed and capped at 4 to prevent data sparsity. *Coverage* is an integer indicating the visiting status of the words between the jump. Coverage is 0 if none of the words was visited prior to this step, 1 if all were visited, and 2 if some but not all were visited. (*j*, *cov*) are present in all features and are removed from the descriptions below. A couple of features use a variation of *Jump* and *Coverage*. These will be described in the feature description.

3.2 Parse-based Syntax Features

We use the sentence pair in Figure 1. as a working example when describing the features. Shown in the figure are a Chinese-English parallel sentence pair, the word alignments between them, and the Chinese parse tree. The parse tree is simplified. Some details such as part-of-speech tags are omitted and denoted by triangles. The first step is to determine the source visit sequence from the word alignment, also shown at the bottom of Figure 1. If a target is aligned to more than one source, we assume the visit order is left to right. In Figure 1, source words 2 and 8 are aligned to the English '*at*' and we define the visit sequence to be 8 following 2.

Chinese and English differ in the positioning of the modifiers. In English, non-adjectival modifiers follow the object they modify. This is most prominent in the use of relative clauses and prepositional phrases. Chinese in contrast is a premodification language where modifiers whether adjectival, clausal or prepositional typically precede the object they modify. In Figure 1., the Chinese prepositional phrase PP (in *lightly shaded* box in the parse tree) spanning range [2,8] precedes the verb phrase VP2 at positions [9,10]. These two phrases are swapped in English as shown by the two lightly shaded boxes in the alignment grid. The relative clause CP (in *dark shaded* box in the parse tree) in Chinese spanning range [3,6] precedes the noun phrase NP3 at position 7 whereas these two phrases are again swapped in English.



Step:	1	2	3	4	5	6	7	8	9	10	11
Visit Sequence:	1	9	10	2	8	7	6	3	4	5	11

Figure 1. A Chinese-English Parallel Sentence with Chinese Parse

The phenomenon for the reordering model to capture is that node VP1's two children PP and VP2 (*lightly shaded*) need to be swapped regardless of how long the PP phrase is. This is also true for node NP2 whose two children CP and NP3 (*dark shaded*) need to be reversed.

Parse-based features model how to reorder the constituents in the parse by learning how to walk the parse nodes. For every non-unary node in the parse we learn such features as which of its child is visited first and for subsequent visits how to jump from one child to another. For the treelet VP1 → PP VP2 in Figure 1, we learn to visit the child VP2 first, then PP.

We now define the notion of '*node visit*'. When a source word s_i is visited at step *j*, we find its path to root from the leaf node denoted as $PathToRoot_i$. We say all the nodes contained in $PathToRoot_i$ are being visited at that step. Parse-based features are applied to every qualifying node in $PathToRoot_i$. Unary extensions do not qualify and are ignored. Since part-of-speech tags are unary branches, parse-based features apply from the lowest-level labels. Another condition depends on the jump and is discussed in section §3.4. All our features are encoded by a vector of integers and are denoted as $\phi(\cdot)$ in this paper. We now describe the features.

3.2.1 First Child Features

The *first-child* feature applies when a node is visited for the first time. The feature learns which of the node's child to visit first. This feature learns such phenomena as translating the main verb first under a VP or translating the main NP first under an NP. The feature is defined as ϕ*(currentLabel, parentLabel, nthNode, j, cov)* where
currentLabel = label of the current parse node
parentLabel = label of the parent node
nthNode = an integer indicating the nth occurrence of the current node

In Figure 1, when source word 9 is visited at step 2, its *PathToRoot* is computed which is [VP2, VP1, IP1]. The *first-child* feature applied to VP2 is ϕ(VP2, VP1, 1, 4, 1) since
currentLabel = VP2; *parentLabel* = VP1;
nthChild = 1: VP2 is the 1st VP among its parent's children
j = 4: actual jump from 1 is 8 and is capped.
cov = 0: words in between the jump [1,9] are not yet visited at this step.
The semantics of this feature is that when a VP node is visited, the first VP child under it is visited first. This feature learns to visit the first VP first which is usually the head VP no matter where it is positioned or how many modifiers precede it.

3.2.2 Node Jump Features

This feature applies on all subsequent visits to the parse node. This feature models how to jump from one sibling to another sibling. This feature has these components: ϕ*(currentLabel, parentLabel, fromLable, nodeJump,cov)* where
fromLabel = the node label where the jump is from
nodeJump = node distance from that node
This feature effectively captures syntactic reorderings by looking at the node jump instead of surface distance jump. In our example, a *node-jump* feature for jumping from source 10 to 2 at step 4 at VP1 level is ϕ(PP, VP1, VP2, -1, 2) where
currentLabel = PP where source word 2 is under
parentLabel = VP1
fromLabel = VP2 where source word 10 is under
nodeJump = -1 since the jump is from VP2 to PP
cov = 2 because in between [2,10] word 9 has been visited and other words have not.

This feature captures the necessary information for the 'PP VP' reorderings regardless of how long the PP or VP phrase is.

3.2.3 Jump Over Sibling Features

To make a correct jump from one sibling to the other, siblings that are jumped over should also be considered. For example in Chinese, while jumping over a PP to cover a VP is a good jump, jumping over an ADVP to cover a VP may not be because adverbs in both Chinese and English often precede the verb they modify. The *jump-over-sibling* features help distinguish these cases. This feature's components are ϕ*(currentLabel, parentLabel, jumpOverSibling, siblingCov, j)* where *jumpOverSibling* is the label of the sibling that is jumped over and *siblingCov* is the coverage status of that sibling.

This feature applies to every sibling that is jumped over. At step 2 where the jump is from source 1 to 9, this feature at VP1 level is ϕ(VP2, VP1, PP, 0, 4) because PP is a sibling of VP2 and is jumped over, PP is not covered at this step, and the jump is capped to be 4.

3.2.4 Back Jump Sibling Features

For every forward jump of length greater than 1, there is a backward jump to cover those words that were skipped. In these situations we want to know how far we can move forward before we must jump backward. The *back-jump-sibling* feature applies when the jump is backward (distance is negative) and inspects the sibling to the right. It generates *ϕ(currentLabel, rightSiblingCov, j)*. When jumping from 10 to 2 at step 4, this feature is ϕ(PP, 1, -4) where -4 is the *jump* and *currentLabel* = PP where source word 2 is under *rightSiblingCoverage* = 1 since VP2 has been completed visited at this time. This feature learns to go back to PP when its right sibling (VP2) is completed.

3.2.5 Broken Features

Translations do not always respect the constituent boundaries defined by the source parse tree. Consider the fragment in Figure 2.

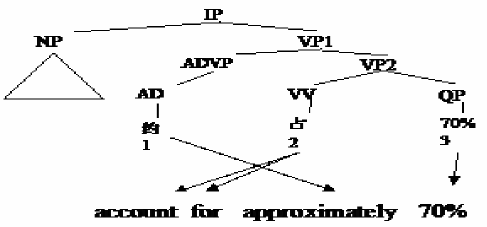


Figure 2. A '*Broken*' Tree

After the VV under VP2 is translated ("*account for*"), a transition is made to translate the ADVP ("*approximately*") leaving VP2 partially translated. We say that the node VP2 is *broken* at this step. This type of feature has been shown to be useful for machine translation (Marton & Resnik 2008). Here, *broken* features model the context under which a node is broken by observing the feature *ϕ(curTag, prevTag, parentLabel, j, cov)*. For the transition of source word 2 to source word 1 in Figure 2, a broken feature applies at VP2: ϕ(AD, VV, VP2, -1 ,1). This feature learns that a VP can be broken when making a jump from a verb (VV) to an adverb (AD).

3.3 Non-Parse Features

Non-parse features do not use or use less fine-grained information from the parse tree.

3.3.1 Barrier Features

Barrier features model the intuition that certain words such as punctuation should not move freely. This phenomenon has been observed and shown to be helpful in (Xiong et. al., 2008). We call these words *barrier* words. Barrier features are *ϕ(barrierWord, cov, j)*. All punctuations are barrier words.

3.3.2 Number of Zero Islands Features

Although word reorderings can involve words far apart, certain jump patterns are highly unlikely. For example, the coverage pattern '1010101010' where every other source word is translated would be very improbable. Let the right most covered source word be the *frontier*. For every jump, the *number-of-zero-islands* feature computes the number of uncovered source islands to the left of the frontier. Additionally it takes into account the number of parse nodes in between. This feature is defined as *ϕ(numZeroIslands, j, numParseNodesInBetween)*. The number of parse nodes is the number of maximum spanning nodes in between the jump. The jump at step 2 from source 1 to 9 triggers this number-zero-island feature ϕ(1, 4, 1). The source coverage status at step 2 is 10000000100 because the first source word has been visited and the current visit is source 9. All words in between have not been visited. There is 1 contiguous sequence of 0's between the first '1' and the last '1', hence the *numZeroIslands* = 1. There is one parse node PP that spans all the source words from 2 to 8, therefore the last argument to the feature is 1. If instead, the transition was from source 1 to 8, then there would be 2 maximum spanning parse nodes for source [2,7] which are nodes P and NP2. The feature would be ϕ(1, 4, 2). This feature discourages scattered jumps that leave lots of zero islands and jump over lots of parse nodes.

3.4 Training

Training the maximum entropy reordering model needs word alignments and source-side parses. We use hand alignments from LDC. The training data statistics are shown in Table 1. We use the (Levy and Manning 2003) parser on Chinese.

Data	#Sentences	#Words
LDC2006E93	10,408	230,764
LDC2008E57	11,463	194,024

Table 1. Training Data

From the word alignments we first determine the source visit sequence. Table 2 details how the visit sequence is determined in various cases.

Alignment Type S-T	Visit Sequence
1-1	Left to right from target
m-1	Left to right from source
1-m	Left most target link
Ø	Attaches left

Table 2. Determining visit sequence

The first column shows alignment type from source (S) to target (T). 1-1 means one source word aligns to one target word. m-1 means many source words align to one target and vice versa. Ø means unaligned source words.

After the source visit sequence is decided, features are generated. Note that the height of the tree is not uniform for all the words. To preserve the structure and also alleviate the depth problem, we use the *lowest-level-common-ancestor* approach. For every jump, we generate features bottom up until we reach the node that is the common ancestor of the origin and the destination of the jump. In Figure 1 there is a jump from source 7 to 6 at step 7. The *lowest-level-common-ancestor* for source 6 and 7 is the node NP2 and features are generated up to the level of NP2. Features on this training data are shown in the second column in Table 5.

The MaxEnt model on this data is efficiently trained at 15 minutes per iteration (24 sentences/sec or 471 words/sec).

4 Experiments

4.1 Reorder Evaluation

To evaluate how accurate the reordering model is, we first compute its prediction accuracy. We choose the first 100 sentences from NIST MT03 as our test set for this evaluation. We manually word align them to the first set of reference using LDC annotation guidelines version 1.0 of April 2006. An average of 73% of the training sentences contain unaligned source words and over 87% of the test sentences contain unaligned source words. The unaligned source words are mostly function words. Because the visit sequence of unaligned source words are determined not by truth but by heuristics (Table 2), they pose a problem in evaluation.

We thus evaluate the model by measuring the accuracy of its decision conditioned on true history. We measure performance on the model's top-N choices for N = 1,2, and 3. Results are in Table 3. The table also shows the accuracy of no reordering in the *Monotone* column.

Top-N	Accuracy	Monotone
1	80.56%	65.39%
2	90.66%	-
3	93.05%	-

Table 3. Reordering model performance

Figure 3 plots accuracy vs. MaxEnt training iteration. Accuracy starts low at 74.7% and reaches is highest at iteration 8 and fluctuates around 80.5% thereafter.

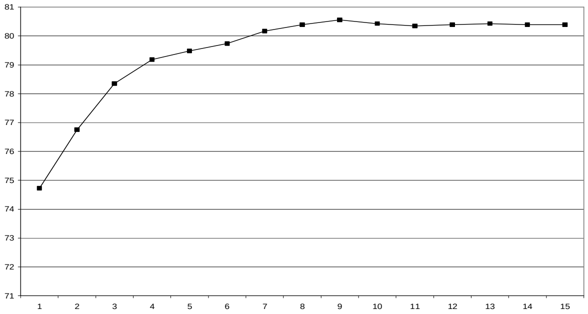

Figure 3. Accuracy vs. MaxEnt Training Iteration

We analyze 50 errors from the top-1 run. The errors are categorized and shown in Table 4.

Error Category	Percentage
Lexical	34%
Parse	30%
Model	20%
Reference	16%

Table 4. Error Analysis

'*Lexical*' errors are those that rise from lexical choice of source words. For example, an "ADVP VP" structure would normally be visited monotonically. However, in case of Chinese phrase '*so do*', they should be swapped. More than a third of the errors are of this nature. Errors in the *Refer-*

ence category are those that are marked wrong because of the particular English reference. The proposed reorderings are correct but they don't match the reference reorderings. Another 30% of the errors are due to parsing errors. The *Model* errors are due to two sources. One is the depth problem mentioned above. Local statistics for some very deep treelets overwhelm the global statistics and local jumps win over the long jumps in these cases. Another problem is the data sparseness. For example, the model has learned to reorder the 'PP VP' structure but there is not much data for 'PP ADVP VP'. The model fails to jump over PP into ADVP.

4.2 Feature Utility

We conduct ablation studies to see the utilities of each feature. We take the best feature set which gives the performance in Table 3 and takes away one feature type at a time. The results are in Table 5. The first row keeps all the features. The *Subtract* column shows performance after subtracting each feature while keeping all the other features. The *Add* column shows performance of adding the feature. Using just *first-child* features gets 75.97%. Adding *node-jump* features moves the accuracy to 78.40% and so on.

Features	**#Features**	**Sub-tract**	**Add**
-		80.56%	-
First Child	7,559	79.87%	75.97%
Node Jump	6,334	79.52%	78.40%
JumpOver Sib.	2,403	80.52%	79.00%
BackJump	602	80.48%	79.05%
Broken	15,183	80.30%	79.13%
Barrier	158	80.26%	79.22%
NumZ Islands	200	79.52%	80.56%

5 Translation Experiments

5.1 Reorder Lattice Generation

The reordering model is used to generate reorder lattices which are used by machine translation decoders. Reorder lattices have been frequently used in decoding in works such as (Zhang et. al 2007, Kumar et.al. 2005, Hildebrand et.al. 2008), to name just a few. The main difference here is that our lattices encode probabilities from the reordering model and are not used to preorder the source. The lattice contains reorderings and their cost (negative log probability). Figure 4 shows a reorder lattice example. Nodes are lattice states. Arcs store source word positions to be visited (translated) and their cost and they are delimited by comma in the figure. Lower cost indicates better choice. Figure 4 is much simplified for readability. It shows only the best path (highlighted) and a few neighboring arcs. For example, it shows source words 1, 2, and 8 are the top 3 choices at step 1. Position 1 is the best choice with the lowest cost of 0.302 and so on.

Figure 4. A lattice example

The sentence is shown at the bottom of the figure. The first part of the reference (true) path is indicated by the alignment which is source sequence 1, 8, 9, and 2. We see that this matches the lattice's top-1 choice.

Lattice generation takes source sentence and source parse as input. The lattice generation process makes use of a beam search algorithm. Every node in the lattice generates top-N next possible positions and the rest is pruned away. A coverage vector is maintained on each path to ensure each source word is visited exactly once. A wide beam width explores many source positions at any step and results in a bushy lattice. This is needed for machine translation because the parses are errorful. The structures that are hard for MT to reorder are also hard for parsers to parse. Labels critical to reordering such as CP are among the least accurate labels. Overall parsing accuracy is 83.63% but CP accuracy is 73.11%. We need a wide beam to include more long jumps to compensate the parsing errors.

5.2 Machine Translation

We run MT experiments on NIST Chinese-English test sets MT03-05. We compare the performance of using distance-based reordering and using maximum entropy reordering lattices. The decoder is a log-linear phrase based decoder. Translation models are trained from HMM alignments. A smoothed 5-gram English LM is built on the English Gigaword corpus and English side of the Chinese-English parallel corpora. In the experiments, lexicalized distance-based reordering allows up to 9 words to be jumped over. MT performance is measured by BLEUr4n4 (Papineni et.al. 2001).

The test set statistics and experiment results are show in Table 6. Decoding with MaxEnt reorder lattices shows significant improvement for all conditions.

Data	#Segs	Lex Skip-9	Reord Lattice	Gain
MT03	919	0.3005	0.3315	+3.1
MT04	1788	0.3250	0.3388	+1.38
MT05	1082	0.2957	0.3236	+2.79

Table 6. MT results

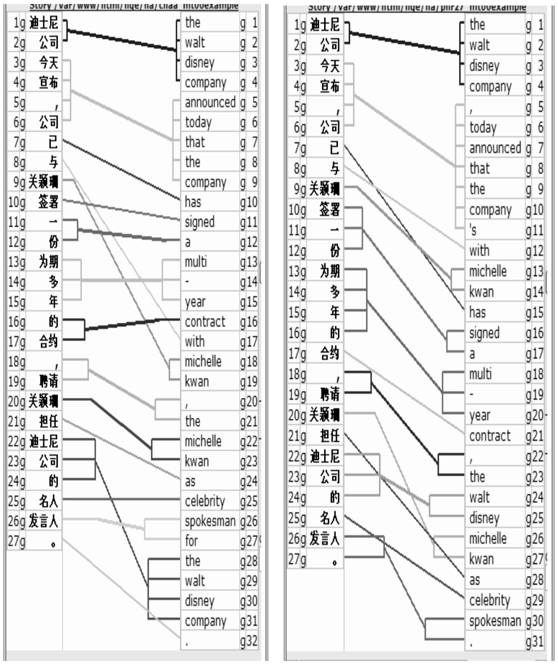
Figures 5 shows an example from MT output with word alignments to the Chinese input. The MaxEnt reordering model correctly reorders two source modifiers at source positions 8 and 22. The Skip9 output reorders locally whereas the MaxEnt lattice output shows much more complex reorderings.

6 Conclusions

We present a direct syntax-based reordering model that captures source structural information. The model is capable of handling reorderings of arbitrary length. Long-range reorderings are essential in translation between languages with great word order differences such as Chinese-English and Arabic-English. We have shown that phrase based SMT can benefit significantly from such a reordering model.

The current model is not regularized and feature selection by thresholding the feature counts is quite primitive. Regularizing the model will prevent overfitting, especially given the small training data set. Regularization will also make the ablation study more meaningful.

The reordering model presented here aims at capturing structural differences between source and target languages. It does not have enough lexical features to deal with lexical idiosyncrasies.



ME Lattice MT Skip9 MT

Figure 5. MT comparison

Our initial attempt at adding lexical pair jump features *ϕ(fromWord, toWord, j)* has not proved useful. It hurt accuracy by 3% (from 80% to 77%). We see from Table 4 that 34% of the errors are due to source lexical choices which indicates the weakness of the current lexical features. Regularization of the model might also make a difference with the lexical features.

Reordering and word choice in translation are not independent of each other. We have shown some initial success with a separate reordering model. In the future, we will build joint models on reordering and translation. This approach will also address some of the reordering problems due to source lexical idiosyncrasies.

Context-free reordering, finite-state translation

Chris Dyer and Philip Resnik

Abstract

We describe a class of translation model in which a set of input variants encoded as a context-free forest is translated using a finite-state translation model. The forest structure of the input is well-suited to representing word order alternatives, making it straightforward to model translation as a two step process: (1) tree-based source reordering and (2) phrase transduction. By treating the reordering process as a latent variable in a probabilistic translation model, we can learn a long-range source reordering model without example reordered sentences, which are problematic to construct. The resulting model has state-of-the-art translation performance, uses linguistically motivated features to effectively model long range reordering, and is significantly smaller than a comparable hierarchical phrase-based translation model.

1 Introduction

Translation models based on synchronous context-free grammars (SCFGs) have become widespread in recent years (Wu, 1997; Chiang, 2007). Compared to phrase-based models, which can be represented as finite-state transducers (FSTs, Kumar et al. (2006)), one important benefit that SCFG models have is the ability to process long range reordering patterns in space and time that is polynomial in the length of the displacement, whereas an FST must generally explore a number of states that is exponential in this length.[1] As one would expect, for language pairs with substantial structural differences (and thus requiring long-range reordering during translation), SCFG models have come to outperform the best FST models (Zollmann et al., 2008).

In this paper, we explore a new way to take advantage of the computational benefits of CFGs during translation. Rather than using a single SCFG to both reorder and translate a source sentence into the target language, we break the translation process into a two step pipeline where (1) the source language is reordered into a target-like order, with alternatives encoded in a context-free forest, and (2) the reordered source is transduced into the target language using an FST that represents phrasal correspondences.

While multi-step decompositions of the translation problem have been proposed before (Kumar et al., 2006), they are less practical with the rise of SCFG models, since the context-free languages are not closed under intersection (Hopcroft and Ullman, 1979). However, the CFLs are closed under intersection with regular languages. By restricting ourselves to a *finite-state* phrase transducer and representing reorderings of the source in a *context-free* forest, exact inference over the composition of the two models is possible.

The paper proceeds as follows. We first explore reordering forests and describe how to translate them with an FST (§2). Since we would like our reordering model to discriminate between good reorderings of the source and bad ones, we show how to train our reordering component as a latent variable in an end-to-end translation model (§3). We then presents experimental results on language pairs requiring small amounts and large amounts of reordering (§4). We conclude with a discussion of related

[1] Our interest here is the reordering made possible by varying the arrangement of the translation units, not the local word order differences captured inside memorized phrase pairs.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 858–866,
Los Angeles, California, June 2010.

work (§6) and possible extensions (§7).

2 Reordering forests and translation

In this section, we describe *source reordering forests*, a context-free representation of source language word order alternatives.[2] The basic idea is that for the source sentence, **f**, that is to be translated, we want to create a (monolingual) context-free grammar $\mathcal{F}$ that generates strings ($\mathbf{f}'$) of words in the source language that are permutations of the original sentence. Specifically, this forest should contain derivations that put the source words into an order that approximates how they will be ordered in the grammar of the target language.

For a concrete example, let us consider the task of English-Japanese translation.[3] Our input sentence is *John ate an apple*. Japanese is a *head-final language*, where the heads of phrases (such as the verb in a verb phrase) typically come last, and English is a *head-initial language*, where heads come first. As a result, the usual order for a declarative sentence in English is SVO (subject-verb-object), but in Japanese, it is SOV, and the desired translation is *John-ga ringo-o* [an apple] *tabeta* [ate]. In summary, when translating from English into Japanese, it is usually necessary to move verbs from their position between the subject and object to the end of the sentence.

This reordering can happen in two ways, which we depict in Figure 1. In the derivation on the left, a memorized phrase pair captures the movement of the verb (Koehn et al., 2003). In the other derivation, the source is first reordered into target word order and then translated, using smaller translation units. In addition, we have assumed that the phrase translations were learned from a parallel corpus that is in the original ordering, so the reordering forest $\mathcal{F}$ should include derivations of phrase-size units in the source order as well as the target order.

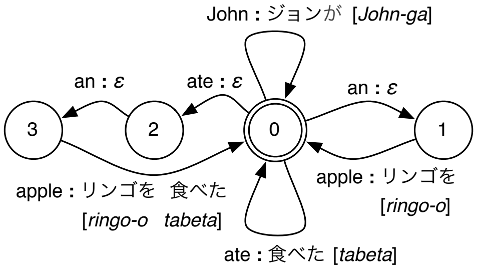

Figure 2: A fragment of a phrase-based English-Japanese translation model, represented as an FST. Japanese romanization is given in brackets.

A minimal reordering forest that supports the derivations depicted needs to include both an SOV and SVO version of the source. This could be accomplished trivially with the following grammar:

$$\begin{array}{rcl} \mathrm{S} & \rightarrow & \textit{John ate an apple} \\ \mathrm{S} & \rightarrow & \textit{John an apple ate} \end{array}$$

However, this grammar misses the opportunity to take advantage of the regularities in the permuted structure. A better alternative might be:

$$\begin{array}{rcl} \mathrm{S} & \rightarrow & \textit{John}\ \mathrm{VP} \\ \mathrm{VP} & \rightarrow & \textit{ate}\ \mathrm{NP} \\ \mathrm{VP} & \rightarrow & \mathrm{NP}\ \textit{ate} \\ \mathrm{NP} & \rightarrow & \textit{an apple} \end{array}$$

In this grammar, the phrases *John* and *an apple* are fixed and only the VP contains ordering ambiguity.

2.1 Reordering forests based on source parses

Many kinds of reordering forests are possible; in general, the best one for a particular language pair will be one that is easiest to create given the resources available in the source language. It will also be the one that most compactly expresses the source reorderings that are most likely to be useful for translation. In this paper, we consider a particular kind of reordering forest that is inspired by the reordering model of Yamada and Knight (2001).[4] These are generated by taking a source language parse tree and 'expanding' each node so that it

[2] Note that forests are isomorphic to context-free grammars. For example, what is referred to as the 'parse forest', and understood to encode all derivations of a sentence **s** under some grammar, can also be understood as being a context-free grammar itself that exactly generates **s**. We therefore refer to a forest as a grammar sometimes, or vice versa, depending on which characterization is clearer in context.

[3] We use English as the source language since we expect the parse structure of English sentences will be more familiar to many readers.

[4] One important difference is that our translation model is not restricted by the structure of the source parse tree; i.e., phrases used in transduction need not correspond to constituents in the source reordering forest. However, if a phrase does cross a constituent boundary between constituents A and B, then translations that use that phrase will have A and B adjacent.

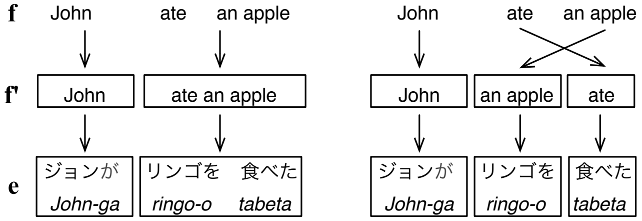

Figure 1: Two possible derivations of a Japanese translation of an English source sentence.

rewrites with different permutations of its children.[5]

For an illustration using our example sentence, refer to Figure 3 for the forest representation and Figure 4 for its isomorphic CFG representation. It is easy to see that this forest generates the two 'good' order variants from Figure 1; however, the forest includes many other derivations that will probably not lead to good translations. For this reason, it is helpful to associate the edges in the forest (that is, the rules in the CFG) with weights reflecting how likely that rule is to lead to a good translation. We discuss how these weights can be learned automatically in §3.

2.2 Translating reordering forests with FSTs

Having described how to construct a context-free reordering forest for the source sentence, we now turn to the problem of how to translate the source forest into the target language using a phrase-based translation model encoded as an FST, e.g. Figure 2. The process is quite similar to the one used when translating a source sentence with an SCFG, but with a twist: rather than representing the translation model as a grammar and parsing the source sentence, we represent the *source sentence* as a grammar (i.e. its reordering forest), and we use it to 'parse' the *translation model* (i.e. the FST representation of the phrase-based model). The end result (either way!) is a translation forest containing all possible target-language translations of the source.

Parsing can be understood as a means of computing the intersection of an FSA and a CFG (Grune and Jacobs, 2008). Since we are dealing with FSTs that define binary relations over strings, not FSAs defining strings, this operation is more properly *composition*. However, since CFG/FSA intersection is less cumbersome to describe, we present the algorithm in terms of intersection.

To compute the composition of a reordering forest, $\mathcal{G}$, with an FSA, F, we will make use of a variant of Earley's algorithm (Earley, 1970). Let weighted finite-state automaton $F = \langle \Sigma, Q, q_0, q_{\mathit{final}}, \delta, w \rangle$. Σ is a finite alphabet; Q is a set of states; q_0 and $q_{\mathit{final}} \in Q$ are start and accept states, respectively,[6] δ is the transition function $Q \times \Sigma \rightarrow 2^Q$, and w is the transition cost function $Q \times Q \rightarrow \mathbb{R}$. We use variables that refer to states in the FSA with the letters q, r, and s. We use x to represent a variable that is an element of Σ. Variables u and v represent costs. X and Y are non-terminals. Lowercase Greek letters are strings of terminals and non-terminals. The function $\delta(q, x)$ returns the state(s) that are reachable from state q by taking a transition labeled with x in the FSA.

Figure 5 provides the inference rules for a top-down intersection algorithm in the form of a weighted logic program; the three inference rules correspond to Earley's SCAN, PREDICT, and COMPLETE, respectively.

3 Reordering and translation model

As pointed out in §2.1, our reordering forests may contain many paths, some of which when translated will lead to good translations and others that will be bad. We would like a model to distinguish the two.

If we had a parallel corpus of source language sentences paired with 'reference reorderings', such a model could be learned directly as a supervised learning task. However, creating the optimal target-language reordering **f'** for some **f** is a nontrivial task.[7] Instead of trying to solve this problem, we opt to treat the reordered from of the source, **f'**, as a

[5] For computational tractability, we only consider all permutations only when the number of children is less than 5, otherwise we exclude permutations where a child moves more than 4 positions away from where it starts.

[6] Other FSA definitions permit sets of start and final states. We use the more restricted definition for simplicity and because in our FSTs $q_0 = q_{\mathit{final}}$.

[7] For a discussion of methods for generating reference re-

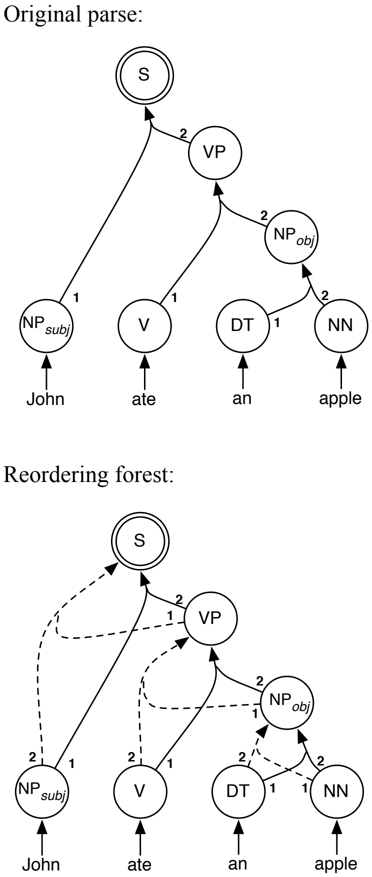

Figure 3: Example of a reordering forest. Linearization order of non-terminals is indicated by the index at the tail of each edge. The isomorphic CFG is shown in Figure 4; dashed edges correspond to reordering-specific rules.

Original parse grammar: S → NP$_{\text{subj}}$ VP

VP → V NP$_{\text{obj}}$ NP$_{\text{obj}}$ → DT NN

NP$_{\text{subj}}$ → *John* V → *ate*

DT → *an* NN → *apple*

Additional reordering grammar rules:

S → VP NP$_{\text{subj}}$

VP → NP$_{\text{obj}}$ V

NP$_{\text{obj}}$ → NN DT

Initialization:

$$\frac{}{[S' \to \bullet S, q_0, q_0] : \overline{1}}$$

Inference rules:

$$\frac{[X \to \alpha \bullet x\beta, q, r] : u}{[X \to \alpha x \bullet \beta, q, \delta(r, x)] : u \otimes w(\delta(r, x))}$$

$$\frac{[X \to \alpha \bullet Y\beta, q, r]}{[Y \to \bullet\gamma, r, r] : u} \quad Y \xrightarrow{u} \gamma \in \mathcal{G}$$

$$\frac{[X \to \alpha \bullet Y\beta, q, s] : u \quad [Y \to \gamma\bullet, s, r] : v}{[X \to \alpha Y \bullet \beta, q, r] : u \otimes v}$$

Goal state:

$$[S' \to S\bullet, q_0, q_{\mathit{final}}]$$

Figure 5: Weighted logic program for computing the intersection of a weighted FSA and a weighted CFG.

latent variable in a probabilistic translation model. By doing this, we only require a parallel corpus of translations to learn the reordering model. Not only does this make our lives easier, since 'reference reorderings' are not necessary, but it is also intuitively satisfying because from a task perspective, we are not concerned with values of $\mathbf{f}'$, but only with producing a good translation $\mathbf{e}$.

3.1 A probabilistic translation model with a latent reordering variable

The translation model we use is a two phase process. First, source sentence $\mathbf{f}$ is reordered into a target-like word order $\mathbf{f}'$ according to a reordering model $r(\mathbf{f}'|\mathbf{f})$. The reordered source is then transduced into the target language according to a translation model $t(\mathbf{e}|\mathbf{f}')$. We require that $r(\mathbf{f}'|\mathbf{f})$ can be represented by a recursion-free probabilistic context-free grammar, i.e. a forest as in §2.1, and that $t(\mathbf{e}|\mathbf{f}')$ is represented by a (cyclic) finite-state transducer, as in Figure 2.

Since the reordering forest may define multiple derivations $\mathbf{a}$ from $\mathbf{f}$ to a particular $\mathbf{f}'$, and the transducer may define multiple derivations $\mathbf{d}$ from $\mathbf{f}'$ to a particular translation $\mathbf{e}$, we marginalize over these nuisance variables as follows to define the probability of a translation given the source:

$$p(\mathbf{e}|\mathbf{f}) = \sum_{\mathbf{d}} \sum_{\mathbf{f}'} t(\mathbf{e}, \mathbf{d}|\mathbf{f}') \sum_{\mathbf{a}} r(\mathbf{f}', \mathbf{a}|\mathbf{f}) \qquad (1)$$

Crucially, since we have restricted $r(\mathbf{f}'|\mathbf{f})$ to have the form of a weighted CFG and $t(\mathbf{e}|\mathbf{f}')$ to be an

orderings from word aligned parallel corpora, refer to Tromble and Eisner (2009).

FST, the quantity (1), which sums over all reorderings (and derivations), can be computed in polynomial time with dynamic programming composition, as described in §2.2.

3.2 Conditional training

While it is straightforward to use expectation maximization to optimize the joint likelihood of the parallel training data with a latent variable model, instead we use a log-linear parameterization and maximize conditional likelihood (Blunsom et al., 2008; Petrov and Klein, 2008). This enables us to employ a rich set of (possibly overlapping, non-independent) features to discriminate among translations. The probability of a derivation from source to reordered source to target is thus written in terms of model parameters $\Lambda = \{\lambda_i\}$ as:

$$p(\mathbf{e}, \mathbf{d}, \mathbf{f}', \mathbf{a}|\mathbf{f}; \Lambda) = \frac{\exp \sum_i \lambda_i \cdot H_i(\mathbf{e}, \mathbf{d}, \mathbf{f}', \mathbf{a}, \mathbf{f})}{Z(\mathbf{f}; \Lambda)}$$

$$\text{where } H_i(\mathbf{e}, \mathbf{d}, \mathbf{f}', \mathbf{a}, \mathbf{f}) = \sum_{r \in \mathbf{d}} h_i(\mathbf{f}', r) + \sum_{s \in \mathbf{a}} h_i(\mathbf{f}, s)$$

The derivation probability is globally normalized by the partition $Z(\mathbf{f}; \Lambda)$, which is just the sum of the numerator for all derivations of **f** (corresponding to any **e**). The H_i (written below without their arguments) are real-valued feature functions that may be overlapping and non-independent. For computational tractability, we assume that the feature functions H_i decompose with the derivations of **f′** and **e** in terms of *local* feature functions h_i. We also define $Z(\mathbf{e}, \mathbf{f}; \lambda)$ to be the sum of the numerator over all derivations that yield the sentence pair $\langle \mathbf{e}, \mathbf{f} \rangle$. Rather than training purely to optimize conditional likelihood, we also make use of a spherical Gaussian prior on the value of Λ with mean **0** and variance σ^2, which helps prevent overfitting of the model (Chen and Rosenfeld, 1998). Our objective is thus to select Λ minimizing:

$$\begin{aligned} \mathcal{L} &= -\log \prod_{\langle \mathbf{e}, \mathbf{f} \rangle} p(\mathbf{e}|\mathbf{f}; \Lambda) - \frac{||\Lambda||^2}{2\sigma^2} \\ &= -\sum_{\langle \mathbf{e}, \mathbf{f} \rangle} [\log Z(\mathbf{e}, \mathbf{f}; \Lambda) - \log Z(\mathbf{f}; \Lambda)] - \frac{||\Lambda||^2}{2\sigma^2} \end{aligned}$$

The gradient of $\mathcal{L}$ with respect to the feature weights has a parallel form; it is the difference in feature expectations under the reference distribution and the translation distribution with a penalty term due to the prior:

$$\frac{\partial \mathcal{L}}{\partial \lambda_i} = \sum_{\langle \mathbf{e}, \mathbf{f} \rangle} \mathbb{E}_{p(\mathbf{d}, \mathbf{a}|\mathbf{e}, \mathbf{f}; \Lambda)}[h_i] - \mathbb{E}_{p(\mathbf{e}, \mathbf{d}, \mathbf{a}|\mathbf{f}; \Lambda)}[h_i] - \frac{\lambda_i}{\sigma^2}$$

The form of the objective and gradient are quite similar to the traditional fully observed training scenario for CRFs (Sha and Pereira, 2003). However, rather than matching the feature expectations in the model to an observable feature value, we have to sum over the latent structure that remains after observing our target **e**, which makes the form of the first summand an expectation rather than just a feature function value.

3.2.1 Computing the objective and gradient

The objective and gradient that were just introduced can be computed in two steps. Given a training pair $\langle \mathbf{e}, \mathbf{f} \rangle$, we generate the forest of reorderings $\mathcal{F}$ from **f** as described in §2.1. We then compose this grammar with T, the FST representing the translation model, which yields $\mathcal{F} \circ T$, a translation forest that contains all possible translations of **f** into the target language, as described in §2.2. Running the inside algorithm on the translation forest computes $Z(\mathbf{f}; \Lambda)$, the first term in the objective, and the inside-outside algorithm can be used to compute $\mathbb{E}_{p(\mathbf{e}, \mathbf{d}, \mathbf{a}|\mathbf{f})}[h_i]$. Next, to compute $Z(\mathbf{e}, \mathbf{f}; \Lambda)$ and the first expectation in the gradient, we need to find the subset of the translation forest $\mathcal{F} \circ T$ that exactly derives the reference translation **e**. To do this, we again rely on the fact that $\mathcal{F} \circ T$ is a forest and therefore itself a context-free grammar. So, we use *this* grammar to parse the target reference string **e**. The resulting forest, $\mathcal{F} \circ T \circ \mathbf{e}$, contains all and only derivations that yield the pair $\langle \mathbf{e}, \mathbf{f} \rangle$. Here, the inside algorithm computes $Z(\mathbf{e}, \mathbf{f}; \Lambda)$ and the inside-outside algorithm can be used to compute $\mathbb{E}_{p(\mathbf{e}, \mathbf{d}, \mathbf{a}|\mathbf{f})}[h_i]$.

Once we have an objective and gradient, we can apply any first-order numerical optimization technique.[8] Although the conditional likelihood surface of this model is non-convex (on account of the latent variables), we did not find a significant initialization effect. For the experiments below, we initialized $\Lambda = \mathbf{0}$ and set $\sigma^2 = 1$. Training generally converged in fewer than 1500 function evaluations.

[8] For our experiments we used L-BFGS (Liu and Nocedal, 1989).

4 Experimental setup

We now turn to an experimental validation of the models we have introduced. We define three conditions: a small data scenario consisting of a translation task based on the BTEC Chinese-English corpus (Takezawa et al., 2002), a large data Chinese-English condition designed to be more comparable to conditions in a NIST MT evaluation, and a large data Arabic-English task.

For each condition, phrase tables were extracted as described in Koehn et al. (2003) with a maximum phrase size of 5. The parallel training data was aligned using the Giza++ implementation of IBM Model 4 (Och and Ney, 2003). The Chinese text was segmented using a CRF-based word segmenter (Tseng et al., 2005). The Arabic text was segmented using the technique described in Lee et al. (2003). The Stanford parser was used to generate source parses for all conditions, and these were then used to generate the reordering forests as described in §2.1.

Table 1 summarizes statistics about the corpora used. The reachability statistic indicates what percentage of sentence pairs in the training data could be regenerated using our reordering/translation model.[9] To train the reordering model, we used all of the reachable sentence pairs from BTEC, 20% of the reachable set in the Chinese-English condition, and all reachable sentence pairs under 40 words (source) in length in the Arabic-English condition.

Error analysis indicates that a substantial portion of unreachable sentence pairs are due to alignment (word or sentence) or parse errors; however, in some cases the reordering forests did not contain an adequate source reordering to produce the necessary target. For example, in Arabic, which is a VSO language, the treebank annotation is to place the subject NP as the 'middle child' between the V and the object constituent. This can be reordered into an English SVO order using our child-permutation rules; however, if the source VP is modified by a modal particle, the parser makes the particle the parent of the VP, and it is no longer possible to move the subject to the first position in the sentence. Richer reordering rules are needed to address this problem. Other solutions to the reachability problem include targeting reachable oracles instead of the reference translation (Li and Khudanpur, 2009) or making use of alternative training criteria, such as minimum risk training (Li and Eisner, 2009).

4.1 Features

We briefly describe the feature functions we used in our model. These include the typical dense features used in translation: relative phrase translation frequencies $p(\overline{e}|\overline{f})$ and $p(\overline{f}|\overline{e})$, 'lexically smoothed' translation probabilities $p_{lex}(\overline{e}|\overline{f})$ and $p_{lex}(\overline{f}|\overline{e})$, and a phrase count feature. For the reordering model, we used a binary feature for each kind of rule used, for example $\phi_{\mathrm{VP}\rightarrow\mathrm{V\ NP}}(\mathbf{a})$ would fire once for each time the rule VP → V NP was used in a derivation, **a**. For the Arabic-English condition, we observed that the parse trees tended to be quite flat, with many repeated non-terminal types in one rule, so we augmented the non-terminal types with an index indicating where they were located in the original parse tree. This resulted in a total of 6.7k features for IWSLT, 18k features for the large Chinese-English condition, and 516k features for Arabic-English.[10] A target language model was not used during the training of the source reordering model, but it was used during the translation experiments (see below).

4.2 Qualitative assessment of reordering model

Before looking at the translation results, we examine what the model learns during training. Figure 6 lists the 10 most highly weighted reordering features learned by the BTEC model (above) and shows an example reordering using this model (below), with the most English-like reordering indicated with a star.[11] Keep in mind, we expect these features to reflect what the best *English-like* order of the input should be. All are almost surprisingly intuitive, but this is not terribly surprising since Chinese and English have very similar large-scale structures (both are head initial, both have adjectives and quantifiers that precede nouns). However, we see two entries in the list (starred) that correspond to an En-

[9] Only sentences that can be generated by the model can be used in training.

[10] The large number of features in the Arabic system was due to the relative flatness of the Arabic parse trees.

[11] The italicized symbols in the English gloss are functional elements with no precise translation. Q is an interrogative particle, and DE marks a variety of attributive roles and is used here as the head of a relative clause.

Table 1: Corpus statistics

Condition	Sentences	Source words	Target words	Reachability
BTEC	44k	0.33M	0.36M	81%
Chinese-English	400k	9.4M	10.9M	25%
Arabic-English	120k	3.3M	3.6M	66%

glish word order that is ungrammatical in Chinese: PP modifiers in Chinese typically precede the VPs they modify, and CPs (relative clauses) also typically precede the nouns they modify. In English, the reverse is true, and we see that the model has indeed learned to prefer this ordering. It was not necessary that this be the case: since our model makes use of phrases memorized from a non-reordered training set, it could hav relied on those for all its reordering. Yet these results provide evidence that it is learning large-scale reordering successfully.

Feature	λ	note
VP → VE NP	0.995	
VP → VV VP	0.939	modal + VP
VP → VV NP	0.895	
VP → VP PP*	0.803	PP modifier of VP

5 Translation experiments

We now consider how to apply this model to a translation task. The training we described in §3.2 is suboptimal for state-of-the-art translation systems, since (1) it optimizes likelihood rather than an MT metric and (2) it does not include a language model. We describe how we addressed these problems here, and then present our results in the three conditions defined above.

5.1 Training for Viterbi decoding

A language model was incorporated using cube pruning (Huang and Chiang, 2007), using a 200-best limit at each node during LM integration. To improve the ability of the phrase model to match reordered phrases, we extracted the 1-best reordering of the training data under the learned reordering model and generated the phrase translation model so that it contained phrases from both the original order and the 1-best reordering.

To be competitive with other state-of-the-art systems, we would like to use Och's minimum error training algorithm for training; however, we cannot tune the model as described with it, since it has far too many features. To address this, we converted the coefficients on the reordering features into a single reordering feature which then had a coefficient assigned to it. This technique is similar to what is done with logarithmic opinion pools, only the learned model is not a probability distribution (Smith et al., 2005). Once we collapsed the reordering weights into a single feature, we used the techniques described by Kumar et al. (2009) to optimize the feature weights to maximize corpus BLEU on a held-out development set.

5.2 Translation results

Scores on a held-out test set are reported in Table 2 using case-insensitive BLEU with 4 reference translations (16 for BTEC) using the original definition of the brevity penalty. We report the results of our model along with three baseline conditions, one with no-reordering at all (mono), the performance of a phrase-based translation model with distance-based distortion, the performance of our implementation of a hierarchical phrase-based translation model (Chiang, 2007), and then our model.

Table 2: Translation results (BLEU)

Condition	Mono	PB	Hiero	Forest
BTEC	47.4	51.8	52.4	**54.1**
Chinese-Eng.	29.0	30.9	32.1	**32.4**
Arabic-Eng.	41.2	45.8	**46.6**	44.9

6 Related work

A variety of translation processes can be formalized as the composition of a finite-state representation of input (typically just a sentence, but often a more complex structure, like a word lattice) with an SCFG (Wu, 1997; Chiang, 2007; Zollmann and Venugopal, 2006). Like these, our work uses parsing algorithms to perform the composition operation. But this is the first time that the *input* to a finite-state transducer has a context-free structure.[12] Although not described in terms of operations over formal languages, the model of Yamada and Knight (2001) can be understood as an instance of our class of models with a specific input forest and phrases restricted to match syntactic constituents.

In terms of formal similarity, Mi et al. (2008) use forests as input to a tree-to-string transducer process, but the forests are used to recover from 1-best parsing errors (as such, all derivations yield the same source string). Iglesias et al. (2009) use a SCFG-based translation model, but implement it using FSTs, although they use non-regular extensions that make FSTs equivalent to recursive transition networks. Galley and Manning (2008) use a context-free reordering model to score a phrase-based (exponential) search space.

Syntax-based preprocessing approaches that have relied on hand-written rules to restructure source trees for particular translation tasks have been quite widely used (Collins et al., 2005; Wang et al., 2007; Xu et al., 2009; Chang et al., 2009). Discriminatively trained reordering models have been extensively explored. A widely used approach has been to use a classifier to predict the orientation of phrases during decoding (Zens and Ney, 2006; Chang et al., 2009). These classifiers must be trained independently from the translation model using training examples extracted from the training data. A more ambitious approach is described by Tromble and Eisner (2009), who build a global reordering model that is learned automatically from reordered training data.

The latent variable discriminative training approach we describe is similar to the one originally proposed by Blunsom et al. (2008).

7 Discussion and conclusion

We have described a new model of translation that takes advantage of the strengths of context-free modeling, but splits reordering and phrase transduction into two separate models. This lets the context-free part handle what it does well, mid-to-long range reordering, and lets the finite-state part handle local phrasal correspondences. We have further shown that the reordering component can be trained effectively as a latent variable in a discriminative translation model using only conventional parallel training data.

This model holds considerable promise for future improvement. Not only does it already achieve quite reasonable performance (performing particularly well in Chinese-English, where mid-range reordering is often required), but we have only begun to scratch the surface in terms of the kinds of features that can be included to predict reordering, as well as the kinds of reordering forests used. Furthermore, by reintroducing the concept of a cascade of transducers into the context-free model space, it should be possible to develop new and more effective rescoring mechanisms. Finally, unlike SCFG and phrase-based models, our model does not impose any distortion limits.

Improved Models of Distortion Cost for Statistical Machine Translation

Abstract

The distortion cost function used in Moses-style machine translation systems has two flaws. First, it does not estimate the future cost of known required moves, thus increasing search errors. Second, all distortion is penalized linearly, even when appropriate re-orderings are performed. Because the cost function does not effectively constrain search, translation quality decreases at higher distortion limits, which are often needed when translating between languages of different typologies such as Arabic and English. To address these problems, we introduce a method for estimating future linear distortion cost, and a new discriminative distortion model that predicts word movement during translation. In combination, these extensions give a statistically significant improvement over a baseline distortion parameterization. When we triple the distortion limit, our model achieves a +2.32 BLEU average gain over Moses.

1 Introduction

It is well-known that translation performance in Moses-style (Koehn et al., 2007) machine translation (MT) systems deteriorates when high distortion is allowed. The *linear distortion cost model* used in these systems is partly at fault. It includes no estimate of future distortion cost, thereby increasing the risk of search errors. Linear distortion also penalizes all re-orderings equally, even when appropriate re-orderings are performed. Because linear distortion, which is a soft constraint, does not effectively constrain search, a *distortion limit* is imposed on the translation model. But hard constraints are ultimately undesirable since they prune the search space. For languages with very different word orders in which significant re-ordering is required, the distortion limit can eliminate the *oracle*, or "best," translation prior to search, placing an artificial limit on translation performance (Auli et al., 2009).

Figure 1: The oracle translation for this Arabic VOS sentence would be pruned during search using typical distortion parameters. The Arabic phrases read right-to-left, but we have ordered the sentence from left-to-right in order to clearly illustrate the re-ordering problem.

To illustrate this problem, consider the Arabic-English example in Figure 1. Assuming that the English translation is constructed left-to-right, the verb شارك *shaaraka* must be translated after the noun phrase (NP) subject. If P phrases are used to translate the Arabic source s to the English target t, then the (unsigned) linear distortion is given by

$$D(s,t) = p^1_{first} + \sum_{i=2}^{P} \left| p^{i-1}_{last} + 1 - p^i_{first} \right| \quad (1)$$

where p_{first} and p_{last} are the first and last source word indices, respectively, in phrase i. By this formula, the cost of the step to translate the NP subject before the verb is 9, which is high relative to the monotone translation path. Moreover, a conventional distortion limit (e.g., 5) would likely force translation of the verb prior to the full subject unless the exact subject phrase existed in the phrase table.[1] Therefore, the correct re-ordering is either improbable or impossible, depending on the choice of distortion parameters.

[1] Our constrained NIST MT09 Arabic-English system, which placed second, used a limit of 5 (Galley et al., 2009).

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 867–875,

The objective of this work is to develop a distortion cost model that allows the distortion limit to be raised significantly without a catastrophic decrease in performance. We first describe an admissible future cost heuristic for linear distortion that restores baseline performance at high distortion limits. Then we add a feature-rich discriminative distortion model that captures e.g. the tendency of Arabic verbs to move right during translation to English. Model parameters are learned from automatic bitext alignments. Together these two extensions allow us to triple the distortion limit in our NIST MT09 Arabic-English system while maintaining a statistically significant improvement over the low distortion baseline. At the high distortion limit, we also show a $+2.32$ BLEU average gain over Moses with an equivalent distortion parameterization.

2 Background

2.1 Search in Phrase-based MT

Given a J token source input string $\boldsymbol{f} = \{f_i^J\}$, we seek the most probable I token translation $\boldsymbol{e} = \{e_i^I\}$. The Moses phrase-based decoder models the posterior probability $p_\lambda\left(e_1^I|f_1^J\right)$ directly according to a log-linear model (Och and Ney, 2004), which gives the decision rule

$$\hat{e} = \arg\max_{I,e_1^I} \left\{ \sum_{m=1}^{M} \lambda_m h_m\left(e_1^I, f_1^J\right) \right\}$$

where $h_m\left(e_1^I, f_1^J\right)$ are M arbitrary feature functions over sentence pairs, and λ_m are feature weights set using a discriminative training method like MERT (Och, 2003). This search is made tractable by the use of beams (Koehn et al., 2003). Hypotheses are pruned from the beams according the sum of the current model score and a future cost estimate for the uncovered source words. Since the number of reordering possibilities for those words is very large—in theory it is exponential—an inadmissible heuristic is typically used to estimate future cost. The baseline distortion cost model is a weighted feature in this framework and affects beam pruning only through the current model score.

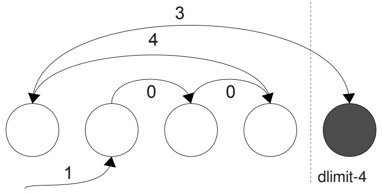
When we say *linear distortion*, we refer to the "simple distortion model" of Koehn et al. (2003) that is shown in Equation (1) and is converted to a cost by multiplying by -1. When extended to phrases, the key property of this model is that monotone decoding gives the least costly translation path. Reorderings internal to extracted phrases are not penalized. In practice, we commonly see n-best lists of hypotheses with linear distortion costs equal to zero. More sophisticated local phrase re-ordering models have been proposed (Tillmann, 2004; Zens and Ney, 2006; Koehn et al., 2007; Galley and Manning, 2008), but these are typically used in addition to linear distortion.

2.2 Arabic Linguistic Essentials

In this paper we use Arabic-English as a case study since we possess a strong experimental baseline. But we expect that the technique presented could be even more effective for high distortion language pairs such as Chinese-English and Hindi-English. Since the analysis that follows is framed in terms of Arabic, we point out several linguistic features that motivate our approach. From the perspective of the three criteria used to specify basic word order typology (Greenberg, 1966), Arabic is somewhat unusual in its combination of features: it has prepositions (not postpositions), adjectives post-modify nouns, and the basic word order is VSO, but SVO and VOS configurations also appear.

The implications for translation to English are: (1) prepositions remain in place, (2) NPs are inverted, and most importantly, (3) basic syntactic constituents must often be identified and precisely re-ordered. The VOS configuration is especially challenging for Arabic-English MT. It usually appears when the direct object is short—e.g., pronominal—and the subject is long. For example, translation of the VOS sentence in Figure 1 requires both a high distortion limit to accommodate the subject movement and tight restrictions on the movement of the PP. The particularity of these requirements in Arabic and other languages, and the difficulty of modeling them in phrase-based systems, has inspired significant work in source language preprocessing (Collins et al., 2005; Habash and Sadat, 2006; Habash, 2007).

Finally, we observe that target language models cannot always select appropriate translations when basic word order transformation is required. By not modeling source side features like agreement—which, in Arabic, appears between both verb and



step k	F_k	Δ_{cost}	$D(s,t)$	$D(s,t) + \Delta_{cost}$
0	3	3	1	4
1	5	2	0	2
2	7	2	0	2
3	0	-7	4	-3
4	0	0	3	3
			8	**8**

subject, and adjective and noun—baseline phrase-based systems rely on the language model to specify an appropriate target word order (Avramidis and Koehn, 2008). Returning to Figure 1, we could have an alternate hypothesis *They waited for the followers of the Christian and Islamic sects*, which is acceptable English and has low distortion, but is semantically inconsistent with the Arabic.

3 The Cost Model

In this section we describe the new distortion cost model, which has four independent components.

3.1 Future Cost Estimation

Despite its lack of sophistication, linear distortion is a surprisingly effective baseline cost model for phrase-based MT systems. It can be computed in constant time, gives non-decreasing values that are good for search, and does not require an ancillary feature to adjust for the number of components in the calculation (e.g., language model scores are adjusted by the word penalty). Moreover, when a large training bitext is used, many local re-orderings are captured in the phrase table, so the decoder can often realize competitive performance by finding a best set of phrases with low distortion. But linear distortion is not the only unlexicalized alternative: we can use any function of the jump width. Table 1 shows development set (MT04) performance for polynomials of degree 1.5 and degree 2. The linear model is more effective than the higher order functions, especially at a higher distortion limit.

Nevertheless, Table 1 shows an unacceptable decrease in translation performance at the high distortion limit for all three polynomial models. In Moses, the reason is due in part to a dramatic underestimation of future re-ordering cost. Consider Figure 2 in which a distortion limit of 4 is used. The first word is skipped, and translation proceeds monotonically until the distortion limit forces the decoder to cover the first word. At low distortion limits, single phrases often saturate the distortion window, so underestimation is not problematic. But at high distortion limits, the decoder can skip many source positions at low cost before the search is constrained by the distortion limit. Words and phrases sprinkled carelessly throughout the hypotheses are evidence of errant search directions that have not been appropriately penalized by the distortion cost model.

To constrain search, we add an admissible future cost estimate to the linear model.[2] By definition, the model has a least cost translation path: monotone. Therefore, we can add to the baseline calculation $D(s,t)$ the cost of skipping back to the first uncovered source word and then translating the remaining positions monotonically. It can be verified by induction on $|\boldsymbol{C}|$ that this is an admissible heuristic.

Formally, let j represent the first uncovered index in the source coverage set $\boldsymbol{C}$. Let $\boldsymbol{C}_j$ represent the subset of $\boldsymbol{C}$ starting from position j. Finally, let j' represent the leftmost position in phrase p applied at translation step k. Then the future cost estimate F_k

[2] Moore and Quirk (2007) propose an alternate future cost formulation. However, their model seems prone to the same deterioration in performance shown in Table 1. They observed decreased translation quality above a distortion limit of 5.

is

$$F_k = \begin{cases} |\boldsymbol{C}_j| + (j' + |p| + 1 - j) & \text{if } j' > j \\ 0 & \text{otherwise} \end{cases}$$

For $k > 0$, we add the difference between the current future cost estimate and the previous cost estimate $\Delta_{cost} = F_k - F_{k-1}$ to the linear penalty $D(s,t)$.[3] Table 2 shows that, as expected, the difference between the baseline and augmented models is statistically insignificant at a low distortion limit. However, at a very high distortion limit, the future cost estimate approximately restores baseline performance. While we still need a distortion limit for computational efficiency, it is no longer required to improve translation quality.

3.2 A Discriminative Distortion Model

So far, we have developed a search heuristic function that gives us a greater ability to control search at high distortion limits. Now we need a cost model that is sensitive to the behavior of certain words during translation. The model must accommodate a potentially large number of overlapping source-side features defined over the (possibly whole) translation sequence. Since we intend to train on automatic word alignments, data sparsity and noise are also risks. These requirements motivate two choices. First, we use a discriminative log-linear framework that predicts one of the nine discretized distortion classes in Figure 3. Let $d_{j,j'}$ indicate the class corresponding to a jump from source word j to j' computed as $(j + 1 - j')$. The discriminative distortion classifier is then

$$p_\lambda\left(d_{j,j'} | f_1^J, j, j'\right) = \frac{\exp\left[\sum_{m=1}^{M} \lambda_m h_m\left(f_1^J, j, j', d_{j,j'}\right)\right]}{\sum_{d^i_{j,j'}} \exp\left[\sum_{m=1}^{M} \lambda_m h_m\left(f_1^J, j, j', d^i_{j,j'}\right)\right]}$$

where λ_m are feature weights for the $h_m(f_1^J, j, j', d^i_{j,j'})$ arbitrary feature functions. This log conditional objective function is convex and can be optimized with e.g. a gradient-based procedure.

	dlimit = 5	dlimit = 15
BASELINE	51.65	49.35
FUTURECOST	51.73	51.65

Table 2: BLEU-4 [%] dev set scores (uncased) for the linear distortion with future cost estimation.

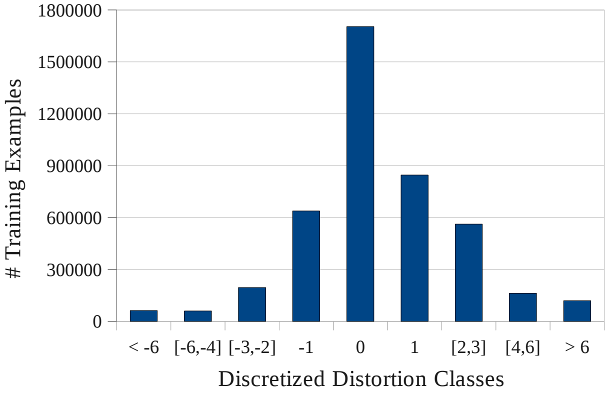

Figure 3: Distortion in Arabic-English translation is largely monotonic, but with noticeable right movement as verbs move around arguments and nouns around modifiers. The ability to predict movement decreases with the jump size, hence the increasing bin boundaries.

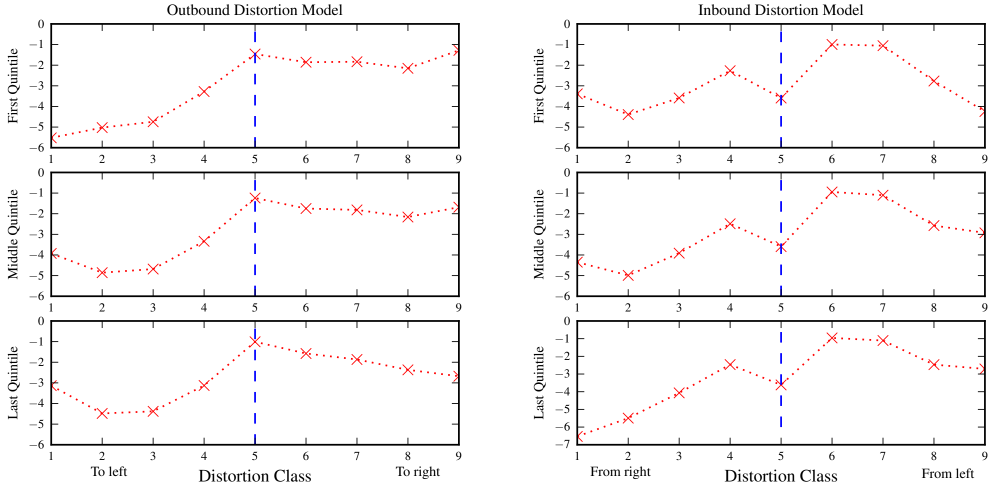
Second, we expect that many words will not be useful for predicting translation order.[4] In a large training bitext, it can be extremely tedious to identify informative words and word classes analytically. Our final decision is then to optimize the parameter weights λ_m using L_1 regularization (Andrew and Gao, 2007), a technique that can learn good models in the presence of many irrelevant features.[5] The L_1 regularizer saves us from filtering the training data (e.g., by discarding all words that appear less than an empirically-specified threshold), and provides sparse feature vectors that can be analyzed separately during feature engineering.

We train two independent distortion models. For a transition from source word j to j', we learn an *outbound* model in which features are defined with respect to word j. We have a corresponding *inbound*

[3] One implementation choice is to estimate future cost to an artificial end-of-sentence token. Here the decoder incurs a penalty for covering the last word prior to completing a hypothesis. Although this implementation is inconsistent with Moses linear distortion, we find that it gives a small improvement.

[4] To train the models, we inverted and sorted the intersection alignments in the bitext. In our baseline system, we observed no decrease in performance between intersection and e.g. grow-diag. However we do expect that our method could be extended to multi-word alignments.

[5] We also add a Gaussian prior $p(\lambda) \backsim \mathcal{N}(0,1)$ to the objective (Chen and Rosenfeld, 1999). Using both L_1 and L_2 regularization is mathematically odd, but often helps in practice.



(a) شارك / VBD *shaaraka* (“he engaged”) (b) الامريكي / JJ *al-aamriikii* (“American”)

Figure 4: Selected discriminative cost curves (log scale) over three quintiles of the relative position feature. We condition on the word, POS, and length features. The classes correspond to those shown in Figure 3. (4a) The VSO basic word order is evident: early in the sentence, there is a strong tendency towards right movement around arguments after covering the verb. However, right movement is increasingly penalized at the end of the sentence. (4b) Adjectives post-modify nouns, so the model learns high inbound probabilities for jumps from positions earlier in the sentence. However, the curve is bi-modal reflecting right inbound moves from other adjectives in NPs with multiple modifiers.

model trained on features with respect to j'. At training time, we also add sentence beginning and ending delimiters such that inbound probabilities are learned for words that begin sentences (e.g., nouns) and outbound probabilities are available for tokens that end sentences (e.g., punctuation).

As a baseline, we use the following binary features: words, part-of-speech (POS) tags, relative source sentence position, and source sentence length. Relative source sentence position is discretized into five bins, one for each quintile of the sentence. Source sentence length is divided into four bins with bounds set empirically such that training examples are distributed evenly. To simplify the decoder integration for this evaluation, we have chosen context-free features, but the framework permits many other promising possibilities such as agreement morphology and POS tag chains.

Our models reveal principled cost curves for specific words (Figure 4). However, monotonic decoding no longer gives the least costly translation path, thus complicating future cost estimation. We would need to evaluate all possible re-orderings within the k-word distortion window. For an input sentence of length n, Zens (2008) shows that the number of re-ordering possibilities r_n is

$$r_n = \begin{cases} k^{n-k} \cdot k! & n > k \\ n! & n \leq k \end{cases}$$

which has an asymptotic complexity $\Theta(k^n)$. Instead of using an inadmissible heuristic as is done in beam pruning, we take a shortcut: we include the linear future cost model as a separate feature. Then we add the two discriminative distortion features, which calculate the inbound and outbound log probabilities of the word alignments in a hypothesis. Since hypotheses may have different numbers of alignments, we also include an alignment penalty that adjusts the discriminative distortion scores for unaligned source words. The implementation and behavior of the alignment penalty is analogous to that of the word penalty. In total, the new distortion cost model has four independent MT features.

4 MT Evaluation

4.1 Experimental Setup

Our MT system is Phrasal (Cer et al., 2010), which is a Java re-implementation of the Moses

dlimit = 5	MT03	MT05	MT06	MT08	Avg

Table 4: BLEU-4 [%] scores (uncased) at a very high distortion limit (15). Discrim+Future also achieves a statistically significant gain over the MosesLinear dlimit=5 baseline for MT05 ($p \leq 0.06$), MT06 ($p \leq 0.01$), and MT08 ($p \leq 0.01$).

decoder with the same standard features: four translation features (phrase-based translation probabilities and lexically-weighted probabilities), word penalty, phrase penalty, linear distortion, and language model score. We disable baseline linear distortion when evaluating the other distortion cost models. To tune parameters, we run MERT with the Downhill Simplex algorithm on the MT04 dataset. For all models, we use 20 random starting points and generate 300-best lists.

We use the NIST MT09 constrained track training data, but remove the UN and comparable data.[6] The reduced training bitext has 181k aligned sentences with 6.20M English and 5.73M Arabic tokens. We create word alignments using the Berkeley Aligner (Liang et al., 2006) and take the intersection of the alignments in both directions. Phrase pairs with a maximum target or source length of 7 tokens are extracted using the method of Och and Ney (2004).

We build a 5-gram language model from the Xinhua and AFP sections of the Gigaword corpus (LDC2007T40), in addition to all of the target side training data permissible in the NIST MT09 constrained competition. We manually remove Gigaword documents that were released during periods that overlapped with the development and test sets. The language model is smoothed with the modified Kneser-Ney algorithm, retaining only trigrams, 4-grams, and 5-grams that occurred two, three, and three times, respectively, in the training data.

We remove from the test sets source tokens not present in the phrase tables. For the discriminative distortion models, we tag the pre-processed input using the log-linear POS tagger of Toutanova et al. (2003). After decoding, we strip any punctuation that appears at the beginning of a translation.

4.2 Results

In Table 3 we report uncased BLEU-4 (Papineni et al., 2001) scores at the distortion limit (5) of our most competitive baseline Arabic-English system. MosesLinear uses the linear distortion model present in Moses. Counts is a separate baseline with a discrete cost model that uses unlexicalized maximum likelihood estimates for the same classes present in the discriminative model. To show the effect of the components in our combined distortion model, we give separate results for linear distortion with future cost estimation (Future) and for the combined discriminative distortion model (Discrim+Future) with all four features: linear distortion with future cost, inbound and outbound proba-

[6] Removal of the UN data does not affect the baseline at a distortion limit of 5, and lowers the higher distortion baseline by −1.40 BLEU. The NIST MT09 data is available at http://www.itl.nist.gov/iad/mig/tests/mt/2009/.

Figure 5: Verb movement around both the subject and temporal NPs is impossible at a distortion limit of 5 (MOSESLINEAR-d5). The baseline system at a high distortion limit mangles the translation (MOSESLINEAR-d15). DISCRIM+FUTURE (dlimit=15) correctly guides the search. The Arabic source is written right-to-left.

bilities, and the alignment penalty.

The main objective of this paper is to improve performance at very high distortion limits. Table 4 shows performance at a distortion limit of 15. To the set of baselines we add LEX, which is the lexicalized re-ordering model of Galley and Manning (2008). This model was shown to outperform other lexicalized re-ordering models in common use.

Statistical significance was computed with the approximate randomization test of Riezler and Maxwell (2005), which is less sensitive to Type I errors than bootstrap re-sampling (Koehn, 2004).

5 Discussion

The new distortion cost model allows us to triple the distortion limit while maintaining a statistically significant improvement over the MOSESLINEAR baseline at the lower distortion limit for three of the four test sets. More importantly, we can raise the distortion limit in the DISCRIM+FUTURE configuration at minimal cost: a statistically insignificant -0.2 BLEU performance decrease on average. We also see a considerable improvement over both the MOSESLINEAR and LEX baselines at the high distortion limit (Figure 5). As expected, future cost estimation alone does not increase performance at the lower distortion limit.

We also observe that the effect of conditioning on evidence is significant: the COUNTS model is categorically worse than all other models. To understand why, we randomly sampled 500 sentences from the excluded UN data and computed the log-likelihoods of the alignments according to the different models.[7] In this test, COUNTS is clearly better with a score of -23388 versus, for example, the inbound model at -38244. The explanation is due in part to optimization. The two discriminative models often give very low probabilities for the outermost classes. Noise in the alignments along with the few cases of long-distance movement are penalized heavily. For Arabic, this property works in our favor as we do not want extreme movement (as we might with Chinese or German). But COUNTS applies a uniform penalty for all movement that exceeds the outermost class boundaries, making it more prone to search errors than even linear distortion despite its favorable performance when tested in isolation.

Finally, we note that previous attempts to improve re-ordering during search (particularly long-distance re-ordering (Chiang, 2007)) have delivered remarkable gains for languages like Chinese, but improvements for Arabic have been less exceptional. By relaxing the distortion limit, we have left room for more sophisticated re-ordering models in conventional phrase-based decoders while maintaining a significant performance advantage over hierarchical systems (Marton and Resnik, 2008).

6 Prior Work

There is an expansive literature on re-ordering in statistical MT. We first review the development of re-ordering constraints, then describe previous cost models for those constraints in beam search decoders. Because we allow re-ordering during search, we omit discussion of the many different methods for preprocessing the source input prior to monotonic translation. Likewise, we do not recite prior work in re-ranking translations.

Re-ordering constraints were first introduced by Berger et al. (1996) in the context of the IBM translation models. The *IBM constraints* treat the source

[7] We approximated linear distortion using a Laplacian distribution with estimated parameters $\hat{\mu} = 0.51$ and $\hat{b} = 1.76$ (Goodman, 2004).

word sequence as a coverage set $\boldsymbol{C}$ that is processed sequentially. A source token is "covered" when it is aligned with a new target token. For a fixed value of k, we may leave up to $k - 1$ positions uncovered and return to them later. We can alter the constraint slightly such that for the first uncovered position $u \notin \boldsymbol{C}$ we can cover position j when

$$j - u < k \qquad j \notin \boldsymbol{C}$$

which is the definition of the distortion limit used in Moses. Variations of the IBM constraints also exist (Kanthak et al., 2005), as do entirely different regimes like the hierarchical *ITG constraints*, which represent the source as a sequence of blocks that can be iteratively merged and inverted (Wu, 1996). Zens and Ney (2003) exhaustively compare the IBM and ITG constraints, concluding that although the ITG constraints permit more flexible re-orderings, the IBM constraints result in higher BLEU scores.

Since our work falls under the IBM paradigm, we consider cost models for those constraints. We have said that linear distortion is the simplest cost model. The primary criticism of linear distortion is that it is unlexicalized, thus penalizing all re-orderings equally (Khalilov et al., 2009). When extended to phrases as in Equation (1), linear distortion is also agnostic to internal phrase alignments.

To remedy these deficiencies, Al-Onaizan and Papineni (2006) proposed a lexicalized, generative distortion model. Maximum likelihood estimates for inbound, outbound, and pairwise transitions are computed from automatic word alignments. But no estimate of future cost is included, and their model cannot easily accommodate features defined over the entire translation sequence. As for experimental results, they use a distortion limit that is half of what we report, and compare against a baseline that lacks a distortion model entirely. Neither their model nor ours requires generation of lattices prior to search (Zhang et al., 2007; Niehues and Kolss, 2009).

Lexicalized re-ordering models are the other significant approach to re-ordering. These models make local predictions about the next phrase to be translated during decoding, typically assigning costs to one of three categories: *monotone*, *swap*, or *discontinuous*. Both generative (Tillmann, 2004; Och and Ney, 2004; Koehn et al., 2007) and discriminative training (Tillmann and Zhang, 2005; Zens and Ney, 2006; Liang et al., 2006) algorithms have been proposed. Recently, Galley and Manning (2008) introduced a hierarchical model capable of analyzing alignments beyond adjacent phrases. Our discriminative distortion framework is not designed as a replacement for lexicalized re-ordering models, but as a substitute for linear distortion.

Finally, we comment on differences between our Arabic-English results and the well-known high distortion system of Zollmann et al. (2008), who find optimal baseline performance at a distortion limit of 9. First, they use approximately two orders of magnitude more training data, which allows them to extract much longer phrases (12 tokens v. our maximum of 7). In this setting, many Arabic-English reorderings can be captured in the phrase table. Second, their "Full" system uses three language models each trained with significantly more data than our single model. Finally, although they use a lexicalized re-ordering model, no details are given about the baseline distortion cost model.

7 Conclusion

We have presented a discriminative cost framework that both estimates future distortion cost and learns principled cost curves. The model delivers a statistically significant +2.32 BLEU improvement over Moses at a high distortion limit. Unlike previous discriminative local orientation models (Zens and Ney, 2006), our framework permits the definition of global features. The evaluation in this paper used context-free features to simplify the decoder integration, but we expect that context-dependent features could result in gains for other language pairs with more complex re-ordering phenomena.

Why Synchronous Tree Substitution Grammars?

Andreas Maletti
Universitat Rovira i Virgili, Departament de Filologies Romàniques
Avinguda de Catalunya 35, 43002 Tarragona, Spain
andreas.maletti@urv.cat

Abstract

Synchronous tree substitution grammars are a translation model that is used in syntax-based machine translation. They are investigated in a formal setting and compared to a competitor that is at least as expressive. The competitor is the extended multi bottom-up tree transducer, which is the bottom-up analogue with one essential additional feature. This model has been investigated in theoretical computer science, but seems widely unknown in natural language processing. The two models are compared with respect to standard algorithms (binarization, regular restriction, composition, application). Particular attention is paid to the complexity of the algorithms.

1 Introduction

Every machine translation system uses a translation model, which is a formal model that describes the translation process. Either this system is handcrafted (in rule-based translation systems) or it is trained with the help of statistical processes. Brown et al. (1990) discuss automatically trainable translation models in their seminal paper on the latter approach. The IBM models of Brown et al. (1993) are string-based in the sense that they base the translation decision on the words and the surrounding context. In the field of syntax-based machine translation, the translation models have access to the syntax (in the form of parse trees) of the sentences. Knight (2007) presents a good exposition to both fields.

In this paper, we focus on syntax-based translation models, and in particular, synchronous tree substitution grammars (STSGs), or the equally powerful (linear and nondeleting) extended (top-down) tree transducers of Graehl et al. (2008). Chiang and Knight (2006) gives a good introduction to STSGs, which originate from the syntax-directed translation schemes of Aho and Ullman (1972) [nowadays more commonly known as synchronous context-free grammars]. Roughly speaking, an STSG has rules in which a nonterminal is replaced by two trees containing terminal and nonterminal symbols. In addition, the nonterminals in the two trees are linked and a rule is only applied to linked nonterminals.

Several algorithms for STSGs have been discussed in the literature. For example, we can

- train them [see Graehl et al. (2008)],
- attempt to binarize them using the methods of (Zhang et al., 2006; Huang et al., 2009; DeNero et al., 2009b),
- parse them [see DeNero et al. (2009a)], or
- attempt to compose them.

However, some important algorithms are partial because it is known that the construction might not be possible in general. This is the case, for example, for binarization and composition.

In the theoretical computer science community, alternative models have been explored. Such a model is the multi bottom-up tree transducer (MBOT) of Arnold and Dauchet (1982) and Lilin (1981), which essentially is the bottom-up analogue of STSGs with the additional feature that nonterminals can have an arbitrary rank (the rank of a nonterminal of an STSG can be considered to be fixed to 1). This model is even more expressive than STSGs, but still offers good computational properties. In this contribution, we will compare STSGs and MBOTs with respect to some standard algorithms. Generally, MBOTs offer algorithmic benefits over STSG, which can be summarized as fol-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 876–884,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

lows:

- Every STSG can be transformed into an equivalent MBOT in linear time.
- MBOTs can be fully binarized in linear time whereas only partial binarizations (or asynchronous binarizations) are possible for STSGs.
- The input language of an MBOT M can be regularly restricted in $\mathcal{O}(|M| \cdot |S|^3)$, whereas the corresponding construction for an STSG M is in $\mathcal{O}(|M| \cdot |S|^{2\,\mathrm{rk}(M)+5})$ where $\mathrm{rk}(M)$ is the maximal number of nonterminals in a rule of the STSG M.
- MBOTs can be composed, whereas this cannot be achieved for STSGs.

Overall, we thus conclude that, from an algorithmic perspective, it would be beneficial to work with MBOTs instead of STSGs. However, the full power of MBOTs should not be tapped because, in general, MBOTs have the finite-copying property [see Engelfriet et al. (1980)], which complicates the algorithms for forward and backward application (see Section 7).

2 Preliminary definitions

An *alphabet* is a finite set of symbols. Our weighted devices use real-number weights, but the results translate easily to the more general setting of commutative semirings [see Golan (1999)]. A *weighted string automaton* as in Schützenberger (1961) and Eilenberg (1974) is a system (S, Γ, I, τ, F) where

- S and Γ are alphabets of states and input symbols, respectively,
- $I, F \colon S \to \mathbb{R}$ assign initial and final weights, respectively, and
- $\tau \colon S \times \Gamma \times S \to \mathbb{R}$ assigns a weight to each transition.

Let $w = \gamma_1 \cdots \gamma_k \in \Gamma^*$ be an input string of length k. A *run* on w is $r \colon \{0, \dots, k\} \to S$. The *weight* of the run r is $\mathrm{wt}(r) = \prod_{i=1}^{k} \tau(r_{i-1}, \gamma_i, r_i)$. The semantics of the automaton A then assigns to w the weight

$$A(w) = \sum_{r \text{ run on } w} I(r_0) \cdot \mathrm{wt}(r) \cdot F(r_k) \enspace .$$

A good introduction to weighted string automata can be found in Mohri (2009) and Sakarovitch (2009).

To simplify the theoretical discussion, we assume that each symbol that we use in trees has a fixed rank, which determines the number of children of each node with that label. A *ranked alphabet* $\Sigma = \bigcup_{k \geq 0} \Sigma_k$ is an alphabet whose symbols have assigned ranks. The set Σ_k contains all symbols of rank k. The set $T_\Sigma(V)$ of Σ*-trees* indexed by a set V is the smallest set such that $V \subseteq T_\Sigma(V)$ and $\sigma(t_1, \dots, t_k) \in T_\Sigma(V)$ for every $\sigma \in \Sigma_k$ and $t_1, \dots, t_k \in T_\Sigma(V)$. The size $|t|$ of the tree $t \in T_\Sigma$ is the number of occurrences of symbols from $\Sigma \cup V$ that appear in t. A context c is a tree of $T_{\Sigma \cup \{\Box\}}(V)$, in which the nullary symbol $\Box$ occurs exactly once. The set of all such contexts is $C_\Sigma(V)$. The tree $c[t]$ is obtained from c by replacing the symbol $\Box$ by t.

A *weighted synchronous tree substitution grammar* (STSG) is a system $(N, \Sigma, \Delta, I, P)$ where

- N is an alphabet of nonterminals,
- Σ and Δ are ranked alphabets of input and output symbols, respectively,
- $I \colon N \to \mathbb{R}$ assigns initial weights, and
- P is a finite set of productions $n \colon t \overset{a}{\leftrightarrow} u$ with $n \in N$, $t \in T_\Sigma(N)$, $a \in \mathbb{R}$, and $u \in T_\Delta(N)$ such that
  - every $n' \in N$ that occurs in t occurs exactly once in u and vice versa, and
  - $t \notin N$ or $u \notin N$.

Note that our distinction between nonterminals and terminals is rather uncommon for STSG [see Chiang (2005)], but improves the generative power. We chose the symbol "$\leftrightarrow$" because STSG productions are symmetric. The size $|n \colon t \overset{a}{\leftrightarrow} u|$ of a production is $|t| + |u|$, and the size $|M|$ of the STSG M is $\sum_{p \in P} |p|$. It is a *weighted tree substitution grammar* (TSG) if $t = u$ for all productions $n \colon t \overset{a}{\leftrightarrow} u \in P$. Further, it is in *normal form* if for every production $n \colon t \overset{a}{\leftrightarrow} u \in P$ there exist $\sigma \in \Sigma_k$, $\delta \in \Delta_k$, and nonterminals $n_1, \dots, n_k, n'_1, \dots, n'_k \in N$ such that $t = \sigma(n_1, \dots, n_k)$ and $u = \delta(n'_1, \dots, n'_k)$. A detailed exposition to STSGs and STSGs in normal form (also called synchronous context-free grammars) can be found in Chiang (2005). Further details on TSGs can be found in Berstel and Reutenauer (1982) and Fülöp and Vogler (2009).

Equal nonterminals in t and u of a production $n \colon t \overset{a}{\leftrightarrow} u \in P$ are *linked*. To keep the presentation simple, we assume that those links are re-

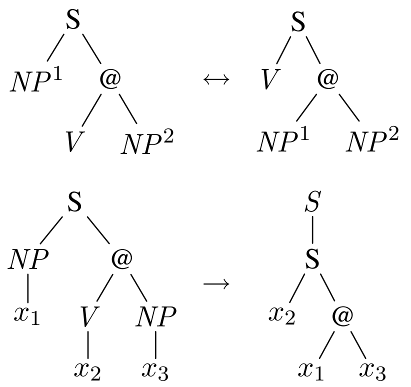

Figure 1: STSG production (top) and corresponding MBOT rule (bottom) where @ is an arbitrary symbol that is introduced during binarization.

membered also in sentential forms. In addition, we assume that $N \cap \Sigma = \emptyset$. For every $c, c' \in C_\Sigma(N)$ and $n \in N$, let $(c[n], c'[n]) \overset{a}{\Rightarrow} (c[t], c'[u])$ if

- there is a production $n \colon t \overset{a}{\leftrightarrow} u \in P$, and
- the explicit (the ones replacing □) occurrences of n in $c[n]$ and $c'[n]$ are linked.

Left-most derivations are defined as usual, and the weight of a derivation $D \colon \xi_0 \overset{a_1}{\Rightarrow} \cdots \overset{a_k}{\Rightarrow} \xi_k$ is $\mathrm{wt}(D) = \prod_{i=1}^{k} a_i$. The weight assigned by the grammar M to a pair $(t, u) \in T_\Sigma \times T_\Delta$ is

$$M(t,u) = \sum_{n \in N} I(n) \cdot \sum_{\substack{D \text{ left-most derivation} \\ \text{from } (n,n) \text{ to } (t,u)}} \mathrm{wt}(D) \enspace .$$

The second restriction on productions ensures that derivations are of finite length, and thus that the sums in the definition of $M(t, u)$ are finite.

In the following, we will use syntactic simplifications such as

- several occurrences of the same nonterminal in a tree (disambiguated by decoration).
- symbols that are terminals (of Σ and Δ) and nonterminals. We will print nonterminals in italics and terminal symbols upright.
- omission of the nonterminal n (or the weight a) of a rule $n \colon t \overset{a}{\leftrightarrow} u$ if the terminal n occurs at the root of t and u (or $a = 1$).
- $n \overset{a}{\to} t$ instead of $n \colon t \overset{a}{\leftrightarrow} t$ if it is a TSG.

A sample STSG production (using those simplifications) is displayed in Figure 1. Our STSGs are essentially equivalent to the (nondeleting and linear) extended tree transducers of Graehl et al. (2008) and Maletti et al. (2009).

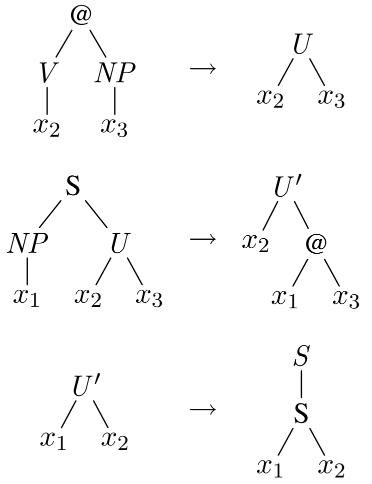

Figure 2: Sample MBOT rules in one-symbol normal form.

3 Multi bottom-up tree transducers

As indicated in the Introduction, we will compare STSGs to weighted multi bottom-up tree transducers, which have been introduced by Arnold and Dauchet (1982) and Lilin (1981). A more detailed (and English) presentation can be found in Engelfriet et al. (2009). Let us quickly recall the formal definition. We use a fixed set $X = \{x_1, x_2, \dots\}$ of (formal) variables. For a ranked alphabet S and $L \subseteq T_\Sigma(X)$ we let

$$S(L) = \{s(t_1, \dots, t_k) \mid s \in S_k, t_1, \dots, t_k \in L\}$$

and we treat elements of $S(L)$ like elements of $T_{\Sigma \cup S}(X)$.

Definition 1 *A* weighted multi bottom-up tree transducer *(MBOT) is a system* $(S, \Sigma, \Delta, F, R)$ *where*

- S*,* Σ*, and* Δ *are ranked alphabets of states, input symbols, and output symbols, respectively,*
- $F \colon S_1 \to \mathbb{R}$ *assigns final weights, and*
- R *is a finite set of rules* $l \overset{a}{\to} r$ *where* $a \in \mathbb{R}$*,* $l \in T_\Sigma(S(X))$*, and* $r \in S(T_\Delta(X))$ *such that*
  - *every* $x \in X$ *that occurs in* l *occurs exactly once in* r *and vice versa, and*
  - $l \notin S(X)$ *or* $r \notin S(X)$*.*

Roughly speaking, an MBOT is the bottom-up version of an extended top-down tree transducer, in which the states can have a rank different from 1. We chose the symbol "→" because rules have a distinguished left- and right-hand side. The size $|l \overset{a}{\to} r|$ of

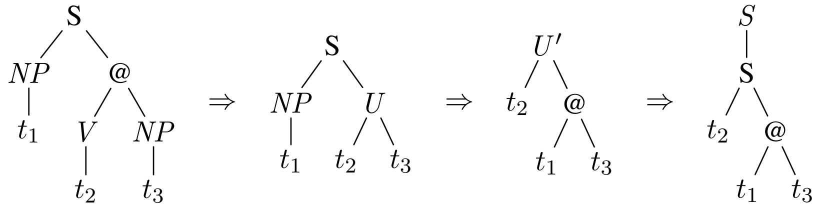

Figure 3: Derivation using the MBOT rules of Fig. 2.

a rule is $|l| + |r|$, and the size $|M|$ of an MBOT M is $\sum_{r \in R}|r|$. Again the second condition on the rules will ensure that derivations will be finite. Let us continue with the rewrite semantics for the MBOT $(S, \Sigma, \Delta, F, R)$. To simplify the presentation, we again assume that $S \cap (\Sigma \cup \Delta) = \emptyset$. We need the concept of substitution. Let $\theta \colon X \to T_\Delta$ and $t \in T_\Delta(X)$. Then $t\theta$ is the tree obtained by replacing every occurrence of $x \in X$ in t by $\theta(x)$.

Definition 2 *Let $c \in C_\Sigma(S(X))$ and $\theta \colon X \to T_\Delta$. Then $c[l\theta] \overset{a}{\Rightarrow} c[r\theta]$ if $l \overset{a}{\to} r \in R$. The weight of a derivation $D \colon \xi_0 \overset{a_1}{\Rightarrow} \cdots \overset{a_k}{\Rightarrow} \xi_k$ is $\mathrm{wt}(D) = \prod_{i=1}^{k} a_i$. The weight assigned by the MBOT M to a pair $(t, u) \in T_\Sigma \times T_\Delta$ is*

$$M(t, u) = \sum_{s \in S_1} F(s) \cdot \sum_{\substack{D \text{ left-most derivation} \\ \text{from } t \text{ to } s(u)}} \mathrm{wt}(D) \enspace .$$

We use the simplifications already mentioned in the previous section also for MBOTs. Figures 1 and 2 display example rules of an MBOT. The rules of Figure 2 are applied in a derivation in Figure 3. The first displayed derivation step uses the context $\mathrm{S}(\mathit{NP}(t_1), \square)$ and any substitution θ such that $\theta(x_2) = t_2$ and $\theta(x_3) = t_3$.

It is argued by Chiang (2005) and Graehl et al. (2008) that STSGs (and extended tree transducers) have sufficient power for syntax-based machine translation. Knight (2007) presents a detailed overview that also mentions short-comings. Since our newly proposed device, the MBOT, should be at least as powerful as STSGs, we quickly demonstrate how each STSG can be coded as an MBOT. An STSG production and the corresponding MBOT rule are displayed in Figure 1. Since the correspondence is rather trivial, we omit a formal definition.

Theorem 3 *For every STSG M, an equivalent MBOT can be constructed in time $\mathcal{O}(|M|)$.*

4 Binarization

Whenever nondeterminism enters the playfield, binarization becomes an important tool for efficiency reasons. This is based on the simple, yet powerful observation that instead of making 5 choices from a space of n in one instant (represented by n^5 rules), it is more efficient (Wang et al., 2007) to make them one-by-one (represented by $5n$ rules). Clearly, this cannot always be done but positive examples exist in abundance; e.g., binarization of context-free grammars [see CHOMSKY normal form in Hopcroft and Ullman (1979)].

Binarization of tree language devices typically consists of two steps: (i) binarization of the involved trees (using the auxiliary symbol @) and (ii) adjustment (binarization) of the processing device to work on (and fully utilize) the binarized trees. If successful, then this leads to binarized derivation trees for the processing device. In Figure 4 we show the binarization of the trees in an STSG production. Another binarization of the rule of Figure 4 is displayed in Figure 1. The binarization is evident enough, so we can assume that all trees considered in the following are binarized.

The binarization in Figure 1 is unfortunate because the obtained production cannot be factorized such that only two nonterminals occur in each rule. However, the binarization of Figure 4 allows the factorization into $\mathrm{S}(U, \mathit{NP}) \leftrightarrow \mathrm{S}(U, \mathit{NP})$ and $U \colon @(\mathit{NP}, V) \leftrightarrow @(V, \mathit{NP})$, which are fully binarized productions. However, in general, STSGs (or SCFGs or extended tree transducers) cannot be fully binarized as shown in Aho and Ullman (1972).

Zhang et al. (2006) and Wang et al. (2007) show the benefits of fully binarized STSGs and present a linear-time algorithm for the binarization of *binarizable* STSGs. We show that those benefits can be reaped for *all* STSGs by a simple change of model.

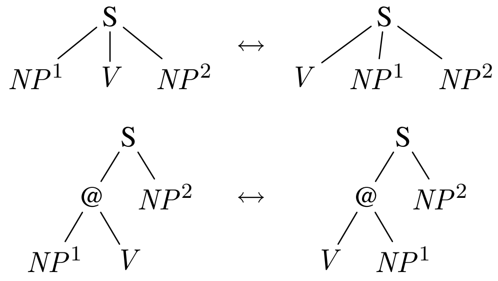

Figure 4: Binarization of trees in an STSG production. Top: Original — Bottom: Binarized trees.

We have already demonstrated that every STSG can be transformed into an equivalent MBOT in linear time. Next, we discuss binarization of MBOTs.

An MBOT is in *one-symbol normal form* if there is at most one input and at most one output symbol, but at least one symbol in each rule (see Figure 2). Raoult (1993) and Engelfriet et al. (2009) prove that every MBOT can be transformed into one-symbol normal form. The procedure presented there runs in linear time in the size of the input MBOT. Consequently, we can transform each STSG to an equivalent MBOT in one-symbol normal form in linear time. Finally, we note that a MBOT in one-symbol normal form has binarized derivation trees, which proves that we fully binarized the STSG.

Theorem 4 *For every STSG M an equivalent, fully binarized MBOT can be constructed in $\mathcal{O}(|M|)$.*

The construction of Engelfriet et al. (2009) is illustrated in Figure 2, which shows the rules of an MBOT in one-symbol normal form. Those rules are constructed from the unlucky binarization of Figure 1. In the next section, we show the benefit of the full binarization on the example of the BAR-HILLEL construction.

5 Input and output restriction

A standard construction for transformation devices (and recognition devices alike) is the regular restriction of the input or output language. This construction is used in parsing, integration of a language model, and the computation of certain metrics [see Nederhof and Satta (2003), Nederhof and Satta (2008), and Satta (2010) for a detailed account]. The construction is generally known as BAR-HILLEL construction [see Bar-Hillel et al. (1964) for the original construction on context-free grammars].

STSGs (and extended tree transducers) are symmetric, so that input and output can freely be swapped. Let M be an STSG and A a weighted string automaton with states S. In the BAR-HILLEL construction for M and A, the maximal rank $\mathrm{rk}(M)$ of a symbol in the derivation forest of M enters as an exponent into the complexity $\mathcal{O}(|M| \cdot |S|^{2\,\mathrm{rk}(M)+5})$. Since full binarization is not possible in general, the maximal rank cannot be limited to 2. In contrast, full binarization is possible for MBOTs (with only linear overhead), so let us investigate whether we can exploit this in a BAR-HILLEL construction for MBOTs.

Let $M = (S, \Sigma, \Delta, F, R)$ be an MBOT in one-symbol normal form. The symbols in $\Sigma \cup \Delta$ have rank at most 2. Moreover, let $G = (N, \Sigma, \Sigma, I, P)$ be a TSG in normal form. We want to construct an MBOT M' such that $M'(t, u) = M(t, u) \cdot G(t)$ for every $t \in T_\Sigma$ and $u \in T_\Delta$. In other words, each input tree should be rescored according to G; in the unweighted case this yields that the translation of M is filtered to the set of input trees accepted by G.

We occasionally write the pair (a, b) in angled parentheses ('$\langle$' and '$\rangle$'). In addition, we use the center line ellipsis '$\cdot\cdot$' (also with decoration) like a variable (especially for sequences).

Definition 5 *The input product* $\mathrm{Prod}(M, G)$ *is the MBOT* $\mathrm{Prod}(M, G) = (S \times N, \Sigma, \Delta, F', R')$ *where*

- $F'(\langle s, n\rangle) = F(s) \cdot I(n)$ *for every* $s \in S$ *and* $n \in N$,
- *for every rule* $s(\cdot\cdot) \xrightarrow{a} s'(\cdot\cdot') \in R$ *with* $s, s' \in S$ *and every* $n \in N$, *there exists a rule*

$$\langle s, n\rangle(\cdot\cdot) \xrightarrow{a} \langle s', n\rangle(\cdot\cdot') \in R' \enspace ,$$

- *for every rule* $\sigma(s_1(\cdot\cdot_1), \dots, s_k(\cdot\cdot_k)) \xrightarrow{a} s(\cdot\cdot)$ *in* R *with* $\sigma \in \Sigma_k$ *and* $s, s_1, \dots, s_k \in S$, *and every production* $n \xrightarrow{b} \sigma(n_1, \dots, n_k) \in P$, *the following rule is in* R':

$$\sigma(\langle s_1, n_1\rangle(\cdot\cdot_1), \dots, \langle s_k, n_k\rangle(\cdot\cdot_k)) \xrightarrow{ab} \langle s, n\rangle(\cdot\cdot) \enspace .$$

The first type of rule (second item) does not involve an input symbol, and thus the nonterminal of G is just forwarded to the new state. Since no step with respect to G is made, only the weight of the rule of M is charged. The second type of rule (third item) uses a rule of R with the input symbol σ

and a production of P that also contains σ. The rule and the production are executed in parallel in the resulting rule and its weight is thus the product of the weights of the original rule and production. Overall, this is a classical product construction, which is similar to other product constructions such as Borchardt (2004). A straightforward proof shows that $M'(t,u) = M(t,u) \cdot G(t)$ for every $t \in T_\Sigma$ and $u \in T_\Delta$, which proves the correctness.

Next, let us look at the complexity. The MBOT $\mathrm{Prod}(M,G)$ can be obtained in time $\mathcal{O}(|M| \cdot |G|)$. Furthermore, it is known [see, for example, Maletti and Satta (2009)] that for every weighted string automaton A with states S, we can construct a TSG G in normal form, which has size $\mathcal{O}(|\Sigma| \cdot |S|^3)$ and recognizes each tree of T_Σ with the weight that the automaton A assigns to its yield. The idea of this construction is illustrated in Figure 5. Consequently, our BAR-HILLEL construction has the well-known complexity $\mathcal{O}(|M| \cdot |S|^3)$. This should be compared to the complexity of the corresponding construction for an STSG M, which is in $\mathcal{O}(|M| \cdot |S|^{2\,\mathrm{rk}(M)+5})$ where $\mathrm{rk}(M)$ is the maximal number of (different) nonterminals in a production of M. Thus, the STSG should be transformed into an equivalent MBOT in one-symbol normal form, which can be achieved in linear time, and the BAR-HILLEL construction should be performed on this MBOT.

Since STSGs are symmetric, our approach can also be applied to the output side of an STSG. However, it should be noted that we can apply it only to one side (the input side) of the MBOT. A construction for the output side of the MBOT can be defined, but it would suffer from a similarly high complexity as already presented for STSGs. More precisely, we expect a complexity of roughly $\mathcal{O}(|M| \cdot |S|^{2\,\mathrm{rk}(M)+2})$ for this construction. The small gain is due to the one-symbol normal form and binarization.

6 Composition

Another standard construction for transformations is (relational) composition. Composition constructs a translation from a language L to L'' given translations from L to L' and from L' to L''. Formally, given transformations $M' \colon T_\Sigma \times T_\Delta \to \mathbb{R}$ and $M'' \colon T_\Delta \times T_\Gamma \to \mathbb{R}$, the composition of M' and M'' is a tranformation $M' \,;\, M'' \colon T_\Sigma \times T_\Gamma \to \mathbb{R}$ with

$$(M' \,;\, M'')(t,v) = \sum_{u \in T_\Delta} M'(t,u) \cdot M''(u,v)$$

for every $t \in T_\Sigma$ and $v \in T_\Gamma$. Mind that the summation might be infinite, but we will only consider compositions, in which it is finite.

Unfortunately, Arnold and Dauchet (1982) show that the composition of two transformations computed by STSGs cannot necessarily be computed by an STSG. Consequently, there cannot be a general composition algorithm for STSGs.

Let us consider the problem of composition for MBOTs. Essentially, we will follow the unweighted approach of Engelfriet et al. (2009) to obtain a composition construction, which we present next. Let

$$M' = (S', \Sigma, \Delta, F', R') \quad \text{and}$$
$$M'' = (S'', \Delta, \Gamma, F'', R'')$$

be MBOTs in one-symbol normal form. We extend the rewrite semantics (see Definition 2) to trees that include symbols foreign to a MBOT. In other words, we (virtually) extend the input and output alphabets to contain all used symbols (in particular also the states of another MBOT). However, since we do not extend the set of rules, the MBOT cannot process foreign symbols. Nevertheless it can perform rewrite steps on known symbols (or apply rules that do not contain input symbols). We use $\Rightarrow_{R'}$ and $\Rightarrow_{R''}$ for derivation steps

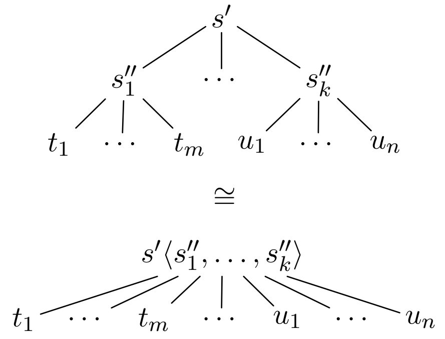

Figure 6: Identification in sentential forms.

that exclusively use rules of R' and R'', respectively. In addition, we identify $s'(s''_1(\cdot\cdot_1),\dots,s''_k(\cdot\cdot_k))$ with $s'\langle s''_1,\dots,s''_k\rangle(\cdot\cdot_1,\dots,\cdot\cdot_k)$ for $s' \in S'$ and $s''_1,\dots,s''_k \in S''$. This identification is illustrated in Figure 6.

Definition 6 *The MBOT $M' \,;M'' = (S,\Sigma,\Gamma,F,R)$ is such that*

- *for every $s' \in S'_k$ and $s''_1 \in S''_{\ell_1},\dots,s''_k \in S''_{\ell_k}$ we have $s'\langle s''_1,\dots,s''_k\rangle \in S_{\ell_1+\dots+\ell_k}$,*
- *$F(s'\langle s'\rangle) = F'(s')\cdot F''(s'')$ for every $s' \in S'_1$ and $s'' \in S''_1$, and*
- *the rules $l \xrightarrow{a} r$ of R, all of which are such that the variables in l occur in order $(x_1,\dots,x_k)$ from left-to-right, are constructed in 3 ways:*
  - *$l \overset{a}{\Rightarrow}_{R'} r$ by a single rule of R',*
  - *$l \overset{a}{\Rightarrow}_{R''} r$ by a single rule of R'', or*
  - *$l \overset{a_1}{\Rightarrow}_{R'} \xi \overset{a_2}{\Rightarrow}_{R''} r$ with $a = a_1 \cdot a_2$ and the applied rule of R' contains an output symbol.*

  If a rule $l \xrightarrow{a} r$ can be constructed in several ways (with exactly weight a), then the weights of all possibilities are added for the weight of the new rule.

Intuitively, a single rule of R' without output symbols is used in the first type (because otherwise r would have the wrong shape). In the second type, a single rule of R'' without input symbols is used. Finally, in the third type, first a rule of R' that produces an output symbol of Δ is used and then this symbol is processed by a single rule of R''. Note that every rule of R' can produce at most one output symbol and the rules of R'' either process none or one input symbol due to the assumption that M' and M'' are in one-symbol normal form. We illustrate a rule of the first in Figure 7.

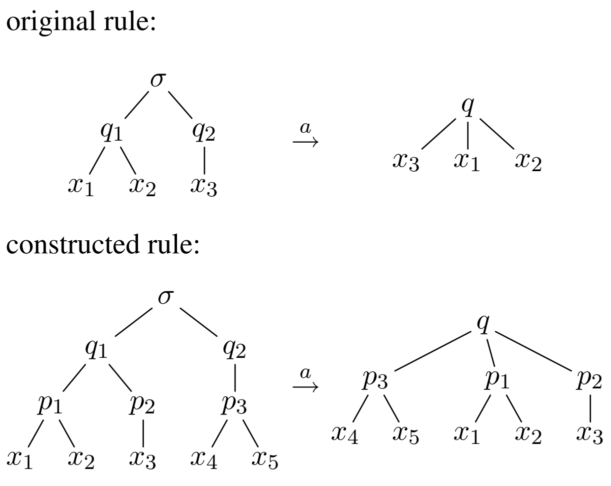

Figure 7: Example of a constructed rule of type 1.

The correctness proof of this construction can essentially (i.e., for the unweighted case) be found in Engelfriet et al. (2009). Before we can extend it to the weighted case, we need to make sure that the sum in the definition of composition is finite. We achieve this by requiring that

- for every $t \in T_\Sigma$ and $s \in S'_1$ there are finitely many $u \in T_\Delta$ such that $t \overset{a_1}{\Rightarrow} \cdots \overset{a_n}{\Rightarrow} s(u)$, or
- for every $v \in T_\Gamma$ and $s \in S''_1$ there are finitely many $u \in T_\Delta$ such that $u \overset{a_1}{\Rightarrow} \cdots \overset{a_n}{\Rightarrow} s(v)$.

In other words, M' may not have cyclic input ε-rules or M'' may not have cyclic output ε-rules. Now we can state the main theorem.

Theorem 7 *For all MBOTs M' and M'' with the above restriction the composition $M' \,; M''$ of their transformations can be computed by another MBOT.*

This again shows an advantage of MBOTs. The composition result relies essentially on the one-symbol normal form (or full binarization), which can always be achieved for MBOTs, but cannot for STSGs. Consequently, MBOTs can be composed, whereas STSGs cannot be composed in general. Indeed, STSGs in one-symbol normal form, which can be defined as for MBOTs, can be composed as well, which shows that the one-symbol normal form is the key for composition.

Finally, let us discuss the complexity of composition. Let $\mathrm{rk}(M')$ be the maximal rank of a state in S'. Then there are

- $\mathcal{O}(|M'| \cdot |S''|^{\mathrm{rk}(M')})$ rules of type 1,
- $\mathcal{O}(|M''| \cdot |S''|^{\mathrm{rk}(M')})$ rules of type 2, and

- $\mathcal{O}(|M'| \cdot |M''| \cdot |S''|^{\mathrm{rk}(M')})$ rules of type 3.

Each rule can be constructed in linear time in the size of the participating rules, so that we obtain a final complexity of $\mathcal{O}(|M'| \cdot |M''| \cdot |S''|^{\mathrm{rk}(M')})$. Note that if M' is obtained from an STSG M (via Theorem 4), then $\mathrm{rk}(M') \leq \mathrm{rk}(M)$. This shows that binarization does not avoid the exponent for composition, but at least enables composition in the general case. Moreover, the complexity could be slightly improved by the observation that our construction only relies on (i) M' having at most one output symbol per rule and (ii) M'' having at most one input symbol per rule.

7 Forward and backward application

We might want to apply a transformation not just to a single tree, but rather to a set of trees, which are, in some cases, already weighted. In general, the set of trees is given by a TSG G and we expect the result to be represented by a TSG as well. Forward and backward application amount to computing the image and pre-image of G under the transformation, respectively. Since STSG are symmetric, we need to solve only one of the problems if the transformation is given by an STSG. The other problem can then be solved by inverting the STSG (exchanging input and output) and using the method for the solved problem. We chose to address forward application here.

Forward application can be reduced to the problem of computing the co-domain (or range) with the help of a product construction for STSG, which is similar to the one presented in Definition 5. The co-domain cod_M of the tranformation computed by an STSG M assigns to each $t \in T_\Sigma$ the weight

$$\mathrm{cod}_M(t) = \sum_{u \in T_\Delta} M(t, u) \enspace .$$

This sum might not be well-defined. However, if $u \notin N$ for all productions $n\colon t \overset{a}{\leftrightarrow} u$ of the STSG, then the sum is well-defined and the output-side TSG (i.e., for every production $n\colon t \overset{a}{\leftrightarrow} u$ in the STSG there is a production $n \overset{a}{\to} u$ in the TSG) computes the co-domain. The restriction "$u \notin N$" guarantees that the output side is a TSG. Overall, domain, co-domain, and forward and backward applications (using the product construction) can be computed given such minor new requirements.

Also for transformations computed by MBOTs we can reduce the problem of forward application to the problem of computing the co-domain with the help of the product construction of Definition 5. However, the co-domain of an MBOT is not necessarily representable by a TSG, which is not due to well-definedness problems but rather the *finite-copying* property (Engelfriet et al., 1980) of MBOTs. This property yields that the co-domain might not be a regular tree language (or context-free string language). Consequently, we cannot compute forward or backward applications for arbitrary MBOT. However, if the MBOT is equivalent to an STSG (for example, because it was constructed by the method presented before Theorem 3), then forward and backward application can be computed essentially as for STSG. This can be understood as a warning. MBOT can efficiently be used (with computational benefits) as an alternative representation for transformations computed by STSG (or compositions of STSG). However, MBOT can also compute transformations, of which the domain or range cannot be represented by a TSG. Thus, if we train MBOT directly and utilize their full expressive power, then we might not be able to perform forward and backward application.

In the unweighted case, backward application can always be computed for MBOT. Moreover, it can be decided using (Ésik, 1984) whether all forward applications can be represented by TSGs. However, for a given specific TSG, it cannot be decided whether the forward application is representable by a TSG, which was proved by Fülöp (1994). A subclass of transformations computable by MBOT (that still contains all transformations computable by STSG), which allows all forward and backward applications, has been identified by Raoult (1993).

Conclusion and acknowledgement

We compared STSGs and MBOTs on several standard algorithms (binarization, regular restriction, composition, and application). We prove that MBOTs offer computational benefits on all mentioned algorithms as long as the original transformation is computable by an STSG.

An extractive supervised two-stage method for sentence compression

Dimitrios Galanis[*] and **Ion Androutsopoulos**[*+]
[*]Department of Informatics, Athens University of Economics and Business, Greece

Abstract

We present a new method that compresses sentences by removing words. In a first stage, it generates candidate compressions by removing branches from the source sentence's dependency tree using a Maximum Entropy classifier. In a second stage, it chooses the best among the candidate compressions using a Support Vector Machine Regression model. Experimental results show that our method achieves state-of-the-art performance without requiring any manually written rules.

1 Introduction

Sentence compression is the task of producing a shorter form of a single given sentence, so that the new form is grammatical and retains the most important information of the original one (Jing, 2000). Sentence compression is valuable in many applications, for example when displaying texts on small screens (Corston-Oliver, 2001), in subtitle generation (Vandeghinste and Pan, 2004), and in text summarization (Madnani et al., 2007).

People use various methods to shorten sentences, including word or phrase removal, using shorter paraphrases, and common sense knowledge. However, reasonable machine-generated sentence compressions can often be obtained by only removing words. We use the term *extractive* to refer to methods that compress sentences by only removing words, as opposed to *abstractive* methods, where more elaborate transformations are also allowed. Most of the existing compression methods are extractive (Jing, 2000; Knight and Marcu, 2002; McDonald, 2006; Clarke and Lapata, 2008; Cohn and Lapata, 2009). Although abstractive methods have also been proposed (Cohn and Lapata, 2008), and they may shed more light on how people compress sentences, they do not always manage to outperform extractive methods (Nomoto, 2009). Hence, from an engineering perspective, it is still important to investigate how extractive methods can be improved.

In this paper, we present a new extractive sentence compression method that relies on supervised machine learning.[1] In a first stage, the method generates candidate compressions by removing branches from the source sentence's dependency tree using a Maximum Entropy classifier (Berger et al., 2006). In a second stage, it chooses the best among the candidate compressions using a Support Vector Machine Regression (SVR) model (Chang and Lin, 2001). We show experimentally that our method compares favorably to a state-of-the-art extractive compression method (Cohn and Lapata, 2007; Cohn and Lapata, 2009), without requiring any manually written rules, unlike other recent work (Clarke and Lapata, 2008; Nomoto, 2009). In essence, our method is a two-tier over-generate and select (or rerank) approach to sentence compression; similar approaches have been adopted in natural language generation and parsing (Paiva and Evans, 2005; Collins and Koo, 2005).

2 Related work

Knight and Marcu (2002) presented a noisy channel sentence compression method that uses a language model $P(y)$ and a channel model $P(x|y)$, where x

[1] An implementation of our method will be freely available from http://nlp.cs.aueb.gr/software.html

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 885–893,
Los Angeles, California, June 2010.

is the source sentence and y the compressed one. $P(x|y)$ is calculated as the product of the probabilities of the parse tree tranformations required to expand y to x. The best compression of x is the one that maximizes $P(x|y) \cdot P(y)$, and it is found using a noisy channel decoder. In a second, alternative method Knight and Marcu (2002) use a tree-to-tree transformation algorithm that tries to rewrite directly x to the best y. This second method uses C4.5 (Quinlan, 1993) to learn when to perform tree rewriting actions (e.g., dropping subtrees, combining subtrees) that transform larger trees to smaller trees. Both methods were trained and tested on data from the Ziff-Davis corpus (Knight and Marcu, 2002), and they achieved very similar grammaticality and meaning preservation scores, with no statistically significant difference. However, their compression rates (counted in words) were very different: 70.37% for the noisy-channel method and 57.19% for the C4.5-based one.

McDonald (2006) ranks each candidate compression using a function based on the dot product of a vector of weights with a vector of features extracted from the candidate's n-grams, POS tags, and dependency tree. The weights were learnt from the Ziff-Davis corpus. The best compression is found using a Viterbi-like algorithm that looks for the best sequence of source words that maximizes the scoring function. The method outperformed Knight and Marcu's (2002) tree-to-tree method in grammaticality and meaning preservation on data from the Ziff-Davis corpus, with a similar compression rate.

Clarke and Lapata (2008) presented an unsupervised method that finds the best compression using Integer Linear Programming (ILP). The ILP obejctive function takes into account a language model that indicates which n-grams are more likely to be deleted, and a significance model that shows which words of the input sentence are important. Manually defined constraints (in effect, rules) that operate on dependency trees indicate which syntactic constituents can be deleted. This method outperformed McDonald's (2006) in grammaticality and meaning preservation on test sentences from Edinburgh's "written" and "spoken" corpora.[2] However, the compression rates of the two systems were different (72.0% vs. 63.7% for McDonald's method, both on the written corpus).

We compare our method against Cohn and Lapata's T3 system (Cohn and Lapata, 2007; Cohn and Lapata, 2009), a state-of-the-art extractive sentence compression system that learns parse tree transduction operators from a parallel extractive corpus of source-compressed trees. T3 uses a chart-based decoding algorithm and a Structured Support Vector Machine (Tsochantaridis et al., 2005) to learn to select the best compression among those licensed by the operators learnt.[3] T3 outperformed McDonald's (2006) system in grammaticality and meaning preservation on Edinburgh's "written" and "spoken" corpora, achieving comparable compression rates (Cohn and Lapata, 2009). Cohn and Lapata (2008) have also developed an abstractive version of T3, which was reported to outperform the original, extractive T3 in meaning preservation; there was no statistically significant difference in grammaticality.

Finally, Nomoto (2009) presented a two-stage extractive method. In the first stage, candidate compressions are generated by chopping the source sentence's dependency tree. Many ungrammatical compressions are avoided using hand-crafted drop-me-not rules for dependency subtrees. The candidate compressions are then ranked using a function that takes into account the inverse document frequencies of the words, and their depths in the source dependency tree. Nomoto's extractive method was reported to outperform Cohn and Lapata's abstractive version of T3 on a corpus collected via RSS feeds. Our method is similar to Nomoto's, in that it uses two stages, one that chops the source dependency tree generating candidate compressions, and one that ranks the candidates. However, we experimented with more elaborate ranking models, and our method does not employ any manually crafted rules.

3 Our method

As already mentioned, our method first generates candidate compressions, which are then ranked. The candidate compressions generator operates by removing branches from the dependency tree of the

[2] See http://homepages.inf.ed.ac.uk/s0460084/data/.

[3] T3 appears to be the only previous sentence compression method whose implementation is publicly available; see http://www.dcs.shef.ac.uk/∼tcohn/t3/.

input sentence (figure 1); this stage is discussed in section 3.1 below. We experimented with different ranking functions, discussed in section 3.2, which use features extracted from the source sentence s and the candidate compressions $c_1, \ldots, c_k$.

3.1 Generating candidate compressions

Our method requires a parallel training corpus consisting of sentence-compression pairs $\langle s, g \rangle$. The compressed sentences g must have been formed by only deleting words from the corresponding source sentences s. The $\langle s, g \rangle$ training pairs are used to estimate the propability that a dependency edge e of a dependency tree T_s of an input sentence s is retained or not in the dependency tree T_g of the compressed sentence g. More specifically, we want to estimate the probabilities $P(X_i|context(e_i))$ for every edge e_i of T_s, where X_i is a variable that can take one of the following three values: not_del, for not deleting e_i; del_u for deleting e_i along with its head; and del_l for deleting e along with its modifier. The head (respectively, modifier) of e_i is the node e_i originates from (points to) in the dependency tree. $context(e_i)$ is a set of features that represents e_i's local context in T_s, as well as the local context of the head and modifier of e_i in s.

The propabilities above can be estimated using the Maximum Entropy (ME) framework (Berger et al., 2006), a method for learning the distribution $P(X|V)$ from training data, where X is discrete-valued variable and $V = \langle V_1, \ldots, V_n \rangle$ is a real or discrete-valued vector. Here, $V = context(e_i)$ and $X = X_i$. We use the following features in V:

- The label of the dependency edge e_i, as well as the POS tag of the head and modifier of e_i.

- The entire head-label-modifier triple of e_i. This feature overlaps with the previous two features, but it is common in ME models to use feature combinations as additional features, since they may indicate a category more strongly than the individual initial features.[4]

- The POS tag of the father of e_i's head, and the label of the dependency that links the father to e_i's head.

- The POS tag of each one of the three previous and the three following words of e_i's head and modifier in s (12 features).

- The POS tag bi-grams of the previous two and the following two words of e_i's head and modifier in s (4 features).

- Binary features that show which of the possible labels occur (or not) among the labels of the edges that have the same head as e_i in T_s (one feature for each possible dependency label).

- Two binary features that show if the subtree rooted at the modifier of e_i or e_i's *uptree* (the rest of the tree, when e_i's subtree is removed) contain an important word. A word is considered important if it appears in the document s was drawn from significantly more often than in a background corpus. In summarization, such words are called signature terms and are thought to be descriptive of the input; they can be identified using the log-likelihood ratio λ of each word (Lin and Hovy, 2000; Gupta et al., 2007).

For each dependency edge e_i of a source training sentence s, we create a training vector V with the above features. If e_i is retained in the dependency tree of the corresponding compressed sentence g in the corpus, V is assigned the category not_del. If e_i is not retained, it is assigned the category del_l or del_u, depending on whether the head (as in the `ccomp` of "said" in Figure 1) or the modifier (as in the `dobj` of "attend") of e_i has also been removed. When the modifier of an edge is removed, the entire subtree rooted at the modifier is removed, and similarly for the uptree, when the head is removed. We do not create training vectors for the edges of the removed subtree of a modifier or the edges of the removed uptree of a head.

Given an input sentence s and its dependency tree T_s, the candidate compressions generator produces the candidate compressed sentences $c_1, \ldots, c_n$ by deleting branches of T_s and putting the remaining words of the dependency tree in the same order as in s. The candidates $c_1, \ldots, c_n$ correspond to possible assignments of values to the X_i variables (recall that $X_i = not\_del|del\_l|del\_u$) of the edges e_i of T_s.

[4] http://nlp.stanford.edu/pubs/maxent-tutorial-slides.pdf.

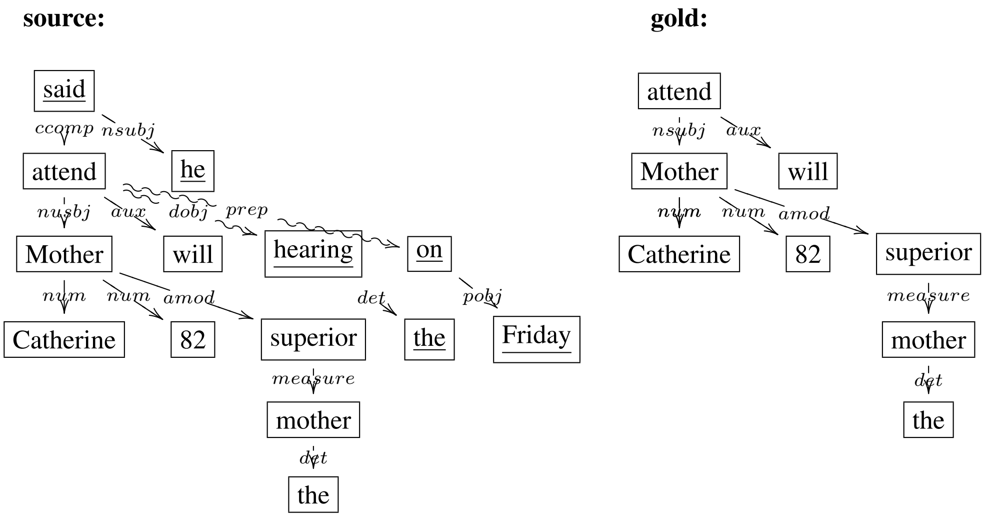

Figure 1: Dependency trees of a source sentence and its compression by a human (taken from Edinburgh's "written" corpus). The source sentence is: "Mother Catherine, 82, the mother superior, will attend the hearing on Friday, he said." The compressed one is: "Mother Catherine, 82, the mother superior, will attend." Deleted edges and words are shown curled and underlined, respectively.

Hence, there are at most 3^{m-1} candidate compressions, where m is the number of words in s. This is a large number of candidates, even for modestly long input sentences. In practice, the candidates are fewer, because del_l removes an entire subtree and del_u an entire uptree, and we do not need to make decisions X_i about the edges of the deleted subtrees and uptrees. To reduce the number of candidates further, we ignore possible assignments that contain decisions $X_i = x$ to which the ME model assigns probabilities below a threshold t; i.e., the ME model is used to prune the space of possible assignments.

When generating the possible assignments to the X_i variables, we examine the edges e_i of T_s in a top-down breadth-first manner. In the source tree of Figure 1, for example, we first consider the edges of "said"; the left-to-right order is random, but let us assume that we consider first the ccomp edge. There are three possible actions: retain the edge (not_del), remove it along with the head "said" (del_u), or remove it along with the modifier "attend" and its subtree (del_l). If the ME model assigns a low probability to one of the three actions, that action is ignored. For each one of the (remaining) actions, we obtain a new form of T_s, and we continue to consider its (other) edges. We process the edges in a top-down fashion, because the ME model allows del_l actions much more often than del_u actions, and when del_l actions are performed near the root of T_s, they prune large parts of the space of possible assignments to the X_i variables. Some of the candidate compressions that were generated for an input sentence by setting $t = 0.2$ are shown in Table 1, along with the gold (human-authored) compression.

3.2 Ranking candidate compressions

Given that we now have a method that generates candidate compressions $c_1, \ldots, c_k$ for a sentence s, we need a function $F(c_i|s)$ that will rank the candidate compressions. Many of them are ungrammatical and/or do not convey the most important information of s. $F(c_i|s)$ should help us select a short candidate that is grammatical and retains the most important information of s.

3.2.1 Grammaticality and importance rate

A simple way to rank the candidate compressions is to assign to each one a score intended to measure its *grammaticality* and *importance rate*. By grammaticality, $Gramm(c_i)$, we mean how grammatically well-formed candidate c_i is. A common way to obtain such a measure is to use an n-gram lan-

s: Then last week a second note, in the same handwriting, informed Mrs Allan that the search was on the wrong side of the bridge.
g: Last week a second note informed Mrs Allan the search was on the wrong side of the bridge.
c_1: Last week a second note informed Mrs Allan that the search was on the side. c_2: Last week a second note informed Mrs Allan that the search was. c_3: Last week a second note informed Mrs Allan the search was on the wrong side of the bridge. c_4: Last week in the same handwriting informed Mrs Allan the search was on the wrong side of the bridge.

Table 1: A source sentence s, its gold (human authored) compression g, and candidate compressions $c_1, \ldots, c_4$.

guage model trained on a large background corpus. However, language models tend to assign smaller probabilities to longer sentences; therefore they favor short sentences, but not necessarily the most appropriate compressions. To overcome this problem, we follow Cordeiro et al. (2009) and normalize the score of a trigram language model as shown below, where $w_1, \ldots, w_m$ are the words of candidate c_i.

$$\begin{aligned} &Gramm(c_i) = \log P_{LM}(c_i)^{1/m} = \\ &(1/m) \cdot \log(\prod_{j=1}^{m} P(w_j|w_{j-1}, w_{j-2})) \qquad (1) \end{aligned}$$

The importance rate $ImpRate(c_i|s)$, defined below, estimates how much information of the original sentence s is retained in candidate c_i. $tf(w_i)$ is the term frequency of w_i in the document that contained ξ ($\xi = c_i, s$), and $idf(w_i)$ is the inverse document frequency of w_i in a background corpus. We actually compute $idf(w_i)$ only for nouns and verbs, and set $idf(w_i) = 0$ for other words.

$$\begin{aligned} ImpRate(c_i|s) &= Imp(c_i)/Imp(s) \qquad (2) \\ Imp(\xi) &= \sum_{w_i \in \xi} tf(w_i) \cdot idf(w_i) \qquad (3) \end{aligned}$$

The ranking $F(c|s)$ is then defined as a linear combination of grammaticality and importance rate:

$$\begin{aligned} F(c_i|s) = \lambda \cdot Gramm(c_i) + (1 - \lambda) \cdot \\ \cdot ImpRate(c_i|s) - \alpha \cdot CR(c_i|s) \qquad (4) \end{aligned}$$

A compression rate penalty factor $CR(c_i|s) = |c|/|s|$ is included, to bias our method towards generating shorter or longer compressions; $|\cdot|$ denotes word length in words (punctuation is ignored). We explain how the weigths λ, α are tuned in following sections. We call LM-IMP the configuration of our method that uses the ranking function of equation 4.

3.2.2 Support Vector Regression

A more sophisticated way to select the best compression is to train a Support Vector Machines Regression (SVR) model to assign scores to feature vectors, with each vector representing a candidate compression. SVR models (Chang and Lin, 2001) are trained using l training vectors $(x_1, y_1), \ldots, (x_l, y_l)$, where $x_i \in \mathbb{R}^n$ and $y_i \in \mathbb{R}$, and learn a function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ that generalizes the training data. In our case, x_i is a feature vector representing a candidate compression c_i, and y_i is a score indicating how good a compression c_i is. We use 98 features:

- $Gramm(c_i)$ and $ImpRate(c_i|s)$, as above.
- 2 features indicating the ratio of important and unimportant words of s, identified as in section 3.1, that were deleted.
- 2 features that indicate the average depth of the deleted and not deleted words in the dependency tree of s.
- 92 features that indicate which POS tags appear in s and how many of them were deleted in c_i. For every POS tag label, we use two features, one that shows how many POS tags of that label are contained in s and one that shows how many of these POS tags were deleted in c_i.

To assign a regression score y_i to each training vector x_i, we experimented with the following functions that measure how similar c_i is to the gold compression g, and how grammatical c_i is.

- Grammatical relations overlap: In this case, y_i is the F_1-score of the dependencies of c_i against those of the gold compression g. This measure has been shown to correlate well with human judgements (Clarke and Lapata, 2006). As in the ranking function of section 3.2.1, we add a compression rate penalty factor.

$$y_i = F_1(d(c_i)), d(g)) - \alpha \cdot CR(c_i|s) \qquad (5)$$

$d(\cdot)$ denotes the set of dependencies. We call SVR-F1 the configuration of our system that uses equation 5 to rank the candidates.

- Tokens accuracy and grammaticality: Tokens accuracy, $TokAcc(c_i|s, g)$, is the percentage of tokens of s that were correctly retained or removed in c_i; a token was correctly retained or removed, if it was also retained (or removed) in the gold compression g. To calculate $TokAcc(c_i|s, g)$, we need the word-to-word alignment of s to g, and s to c_i. These alignments were obtained as a by-product of computing the corresponding (word) edit distances. We also want the regression model to favor grammatical compressions. Hence, we use a linear combination of tokens accuracy and grammaticality of c_i:

$$y_i = \lambda \cdot TokAcc(c_i|s, g) + \\ (1 - \lambda) \cdot Gramm(c_i) - \alpha \cdot CR(c_i|s) \qquad (6)$$

Again, we add a compression rate penalty, to be able to generate shorter or longer compressions. We call SVR-TokAcc-LM the configuration of our system that uses equation 6.

4 Baseline and T3

As a baseline, we use a simple algorithm based on the ME classifier of section 3.1. The baseline produces a single compression c for every source sentence s by considering sequentially the edges e_i of s's dependency tree in a random order, and performing at each e_i the single action (not_del, del_u, or del_l) that the ME model considers more probable; the words of the chopped dependency tree are then put in the same order as in s. We call this system Greedy-Baseline.

We compare our method against the extractive version of T3 (Cohn and Lapata, 2007; Cohn and Lapata, 2009), a state-of-the-art sentence compression system that applies sequences of transduction operators to the syntax trees of the source sentences. The available tranduction operators are learnt from the syntax trees of a set of source-gold pairs. Every operator transforms a subtree α to a subtree γ, rooted at symbols X and Y, respectively.

To find the best sequence of transduction operators that can be applied to a source syntax tree, a chart-based dynamic programming decoder is used, which finds the best scoring sequence q^*:

$$q^* = \arg\max_q score(q; w) \qquad (7)$$

where $score(q; w)$ is the dot product $\langle\Psi(q), w\rangle$. $\Psi(q)$ is a vector-valued feature function, and w is a vector of weights learnt using a Structured Support Vector Machine (Tsochantaridis et al., 2005).

$\Psi(q)$ consists of: (i) the log-probability of the resulting candidate, as returned by a tri-gram language model; and (ii) features that describe how the operators of q are applied, for example the number of the terminals in each operator's α and γ subtrees, the POS tags of the X and Y roots of α and γ etc.

5 Experiments

We used Stanford's parser (de Marneffe et al., 2006) and ME classifier (Manning et al., 2003).[5] For the (trigram) language model, we used SRILM with modified Kneser-Ney smoothing (Stolcke, 2002).[6] The language model was trained on approximately 4.5 million sentences of the TIPSTER corpus. To obtain $idf(w_i)$ values, we used approximately 19.5 million verbs and nouns from the TIPSTER corpus.

T3 requires the syntax trees of the source-gold pairs in Penn Treebank format, as well as a trigram language model. We obtained T3's trees using Stanford's parser, as in our system, unlike Cohn and Lapata (2009) that use Bikel's (2002) parser. The language models in T3 and our system are trained on the same data and with the same options used by Cohn and Lapata (2009). T3 also needs a word-to-word alignment of the source-gold pairs, which was obtained by computing the edit distance, as in Cohn and Lapata (2009) and SVR-TokAcc-LM.

We used Edinburgh's "written" sentence compression corpus (section 2), which consists of source-gold pairs (one gold compression per source

[5] Both available from http://nlp.stanford.edu/.

[6] See http://www.speech.sri.com/projects/srilm/.

sentence). The gold compressions were created by deleting words. We split the corpus in 3 parts: 1024 training, 324 development, and 291 testing pairs.

5.1 Best configuration of our method

We first evaluated experimentally the three configurations of our method (LM-IMP, SVR-F1, SVR-TOKACC-LM), using the $F1$-measure of the dependencies of the machine-generated compressions against those of the gold compressions as an automatic evaluation measure. This measure has been shown to correlate well with human judgements (Clarke and Lapata, 2006).

In all three configurations, we trained the ME model of section 3.1 on the dependency trees of the source-gold pairs of the training part of the corpus. We then used the trained ME classifier to generate the candidate compressions of each source sentence of the training part. We set $t = 0.2$, which led to at most 10,000 candidates for almost every source sentence. We kept up to 1.000 candidates for each source sentence, and we selected randonly approximately 10% of them, obtaining 18,385 candidates, which were used to train the two SVR configurations; LM-IMP requires no training.

To tune the λ parameters of LM-IMP and SVR-TOKACC-LM in equations 4 and 6, we initially set $\alpha = 0$ and we experimented with different values of λ. For each one of the two configurations and for every different λ value, we computed the average compression rate of the machine-generated compressions on the development set. In the rest of the experiments, we set λ to the value that gave an average compression rate approximatelly equal to that of the gold compressions of the training part.

We then experimented with different values of α in all three configurations, in equations 4–6, to produce smaller or longer compression rates. The α parameter provides a uniform mechanism to fine-tune the compression rate in all three configurations, even in SVR-F1 that has no λ. The results on the development part are shown in Figure 2, along with the baseline's results. The baseline has no parameters to tune; hence, its results are shown as a single point. Both SVR models outperform LM-IMP, which in turn outperforms the baseline. Also, SVR-TOKACC-LM performs better or as well as SVR-F1 for all compression rates. Note, also, that the perfomance of the two SVR configurations might be improved further by using more training examples, whereas LM-IMP contains no learning component.

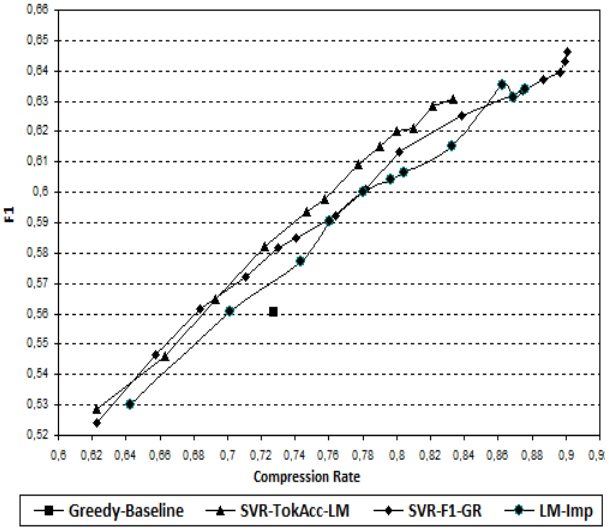

Figure 2: Evaluation results on the development set.

5.2 Our method against T3

We then evaluated the best configuration of our method (SVR-TOKACC-LM) against T3, both automatically ($F1$-measure) and with human judges. We trained both systems on the training set of the corpus. In our system, we used the same λ value that we had obtained from the experiments of the previous section. We then varied the values of our system's α parameter to obtain approximately the same compression rate as T3.

For the evaluation with the human judges, we selected randomly 80 sentences from the test part. For each source sentence s, we formed three pairs, containing s, the gold compression, the compression of SVR-TOKACC-LM, and the compression of T3, repsectively, 240 pairs in total. Four judges (graduate students) were used. Each judge was given 60 pairs in a random sequence; they did not know how the compressed sentenes were obtained and no judge saw more than one compression of the same source sentence. The judges were told to rate (in a scale from 1 to 5) the compressed sentences in terms of grammaticality, meaning preservation, and overall quality. Their average judgements are shown in Table 2, where the $F1$-scores are also included. Cohn and Lapata (2009) have reported very similar scores for T3 on a different split of the corpus (F1: 49.48%, CR: 61.09%).

system	G	M	Ov	F1 (%)	CR (%)
T3	3.83	3.28	3.23	47.34	59.16
SVR	4.20	3.43	3.57	52.09	59.85
gold	4.73	4.27	4.43	100.00	78.80

Table 2: Results on 80 test sentences. G: grammaticality, M: meaning preservation, Ov: overall score, CR: compression rate, SVR: SVR-TOKACC-LM.

Our system outperforms T3 in all evaluation measures. We used Analysis of Variance (ANOVA) followed by post-hoc Tukey tests to check whether the judge ratings differ significantly ($p < 0.1$); all judge ratings of gold compressions are significantly different from T3's and those of our system; also, our system differs significantly from T3 in grammaticality, but not in meaning preservation and overall score. We also performed Wilcoxon tests, which showed that the difference in the $F1$ scores of the two systems is statistically significant ($p < 0.1$) on the 80 test sentences. Table 3 shows the $F1$ scores and the average compression rates for all 291 test sentences. Both systems have comparable compression rates, but again our system outperforms T3 in $F1$, with a statistically significant difference ($p < 0.001$).

system	$F1$	CR
SVR-TOKACC-LM	53.75	63.72
T3	47.52	64.16

Table 3: $F1$ scores on the entire test set.

Finally, we computed the Pearson correlation r of the overall (Ov) scores that the judges assigned to the machine-generated compressions with the corresponding $F1$ scores. The two measures were found to corellate reliably ($r = 0.526$). Similar results have been reported (Clarke and Lapata, 2006) for Edinburgh's "spoken" corpus ($r = 0.532$) and the Ziff-Davis corpus ($r = 0.575$).

6 Conclusions and future work

We presented a new two-stage extractive method for sentence compression. The first stage generates candidate compressions by removing or not edges from the source sentence's dependency tree; an ME model is used to prune unlikely edge deletion or non-deletions. The second stage ranks the candidate compressions; we experimented with three ranking models, achieving the best results with an SVR model trained with an objective function that combines token accuracy and a language model. We showed experimentally, via automatic evaluation and with human judges, that our method compares favorably to a state-of-the-art extractive system. Unlike other recent approaches, our system uses no hand-crafted rules. In future work, we plan to support more complex tranformations, instead of only removing words and experiment with different sizes of training data.

The work reported in this paper was carried out in the context of project INDIGO, where an autonomous robotic guide for museum collections is being developed. The guide engages the museum's visitors in spoken dialogues, and it describes the exhibits that the visitors select by generating textual descriptions, which are passed on to a speech synthesizer. The texts are generated from logical facts stored in an ontology (Galanis et al., 2009) and from canned texts; the latter are used when the corresponding information is difficult to encode in symbolic form (e.g., to store short stories about the exhibits). The descriptions of the exhibits are tailored depending on the type of the visitor (e.g., child vs. adult), and an important tailoring aspect is the generation of shorter or longer descriptions. The parts of the descriptions that are generated from logical facts can be easily made shorter or longer, by conveying fewer or more facts. The methods of this paper are used to automatically shorten the parts of the descriptions that are canned texts, instead of requiring multiple (shorter and longer) hand-written versions of the canned texts.

Interpretation and Transformation for Abstracting Conversations

Abstract

We address the challenge of automatically abstracting conversations such as face-to-face meetings and emails. We focus here on the stages of *interpretation*, where sentences are mapped to a conversation ontology, and *transformation*, where the summary content is selected. Our approach is fully developed and tested on meeting speech, and we subsequently explore its application to email conversations.

1 Introduction

The dominant approach to the challenge of automatic summarization has been *extraction*, where informative sentences in a document are identified and concatenated to form a condensed version of the original document. Extractive summarization has been popular at least in part because it is a binary classification task that lends itself well to machine learning techniques, and does not require a natural language generation (NLG) component. There is evidence that human abstractors at times use sentences from the source documents nearly verbatim in their own summaries, justifying this approach to some extent (Kupiec et al., 1995). Extrinsic evaluations have also shown that, while extractive summaries may be less coherent than human abstracts, users still find them to be valuable tools for browsing documents (He et al., 1999; McKeown et al., 2005; Murray et al., 2008).

However, these same evaluations also indicate that concise abstracts are generally preferred by users and lead to higher objective task scores. The limitation of a cut-and-paste summary is that the end-user does not know *why* the selected sentences are important; this can often only be discerned by exploring the context in which each sentence originally appeared. One possible improvement is to create *structured extracts* that represent an increased level of abstraction, where selected sentences are grouped according to phenomena such as *decisions*, *action items* and *problems*, thereby giving the user more information on why the sentences are being highlighted. For example, the sentence *Let's go with a simple chip* represents a decision. An even higher level of abstraction can be provided by generating new text that synthesizes or extrapolates on the information contained in the structured summary. For example, the sentence *Sandra and Sue expressed negative opinions about the remote control design* can be coupled with extracted sentences containing these negative opinions, forming a *hybrid summary*. Our summarization system ultimately performs both types of abstraction, grouping sentences according to various sentence-level phenomena, and generating novel text that describes this content at a higher level.

In this work we describe the first two components of our abstractive summarization system. In the *interpretation* stage, sentences are mapped to nodes in a conversation ontology by utilizing classifiers relating to a variety of sentence-level phenomena such as *decisions*, *action items* and *subjective sentences*. These classifiers achieve high accuracy by using a very large feature set integrating conversation structure, lexical patterns, part-of-speech (POS) tags and character n-grams. In the *transformation* stage, we select the most informative sentences by maximizing a function based on the derived ontology mapping and the coverage of weighted entities mentioned in the conversation. This transformation component utilizes integer linear programming (ILP) and we compare its performance with several greedy selection algorithms.

We do not discuss the generation component of our summarization system in this paper. The transformation component is still ex-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 894–902,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

tractive in nature, but the sentences that are selected in the transformation stage correspond to objects in the ontology and the properties linking them. Specifically, these are triples of the form $< participant, relation, entity >$ where a $participant$ is a person in the conversation, an $entity$ is an item under discussion, and a $relation$ such as *positive opinion* or *action item* links the two. This intermediate output enables us to create structured extracts as described above, with the triples also acting as input to the downstream NLG component.

We have tested our approach in summarization experiments on both meeting and email conversations, where the quality of a sentence is measured by how effectively it conveys information in a model abstract summary according to human annotators. On meetings the ILP approach consistently outperforms several greedy summarization methods. A key finding is that emails exhibit markedly varying conversation structures, and the email threads yielding the best summarization results are those that are structured similarly to meetings. Other email conversation structures are less amenable to the current treatment and require further investigation and possibly domain adaptation.

2 Related Research

The view that summarization consists of stages of *interpretation*, *transformation* and *generation* was laid out by Sparck-Jones (1999). Popular approaches to text extraction essentially collapse interpretation and transformation into one step, with generation either being ignored or consisting of post-processing techniques such as sentence compression (Knight and Marcu, 2000; Clarke and Lapata, 2006) or sentence merging (Barzilay and McKeown, 2005). In contrast, in this work we clearly separate interpretation from transformation.

The most relevant research to ours is by Kleinbauer et al. (2007), similarly focused on meeting abstraction. They create an ontology for the AMI scenario meeting corpus (Carletta et al., 2005), described in Section 5.1. The system uses topic segments and topic labels, and for each topic segment in the meeting a sentence is generated that describes the most frequently mentioned content items in that topic. Our systems differ in two major respects: their summarization process uses human gold-standard annotations of topic segments, topic labels and content items from the ontology, while our summarizer is fully automatic; and the ontology used by Kleinbauer et al. is specific not just to meetings but to the AMI scenario meetings, while our ontology applies to conversations in general.

While the work by Kleinbauer et al. is among the earliest research on abstracting multi-party dialogues, much attention in recent years has been paid to extractive summarization of such conversations, including meetings (Galley, 2006), emails (Rambow et al., 2004; Carenini et al., 2007), telephone conversations (Zhu and Penn, 2006) and internet relay chats (Zhou and Hovy, 2005).

Recent research has addressed the challenges of detecting decisions (Hsueh et al., 2007), action items (Purver et al., 2007; Murray and Renals, 2008) and subjective sentences (Raaijmakers et al., 2008). In our work we perform all of these tasks but rely on general conversational features without recourse to meeting-specific or email-specific features.

Our approach to transformation is an adaptation of an ILP sentence selection algorithm described by Xie et al. (2009). We describe both ILP approaches in Section 4.

3 Interpretation - Ontology Mapping

Source document interpretation in our system relies on a simple conversation ontology. The ontology is written in OWL/RDF and contains two core upper-level classes: Participant and Entity. When additional information is available about participant roles in a given domain, Participant subclasses such as ProjectManager can be utilized. The ontology also contains six properties that express relations between the participants and the entities. For example, the following snippet of the ontology indicates that *hasActionItem* is a relationship between a meeting participant (the property domain) and a discussed entity (the property range).

```
<owl:ObjectProperty rdf:ID="hasActionItem">
  <rdfs:domain rdf:resource="#Participant"/>
  <rdfs:range rdf:resource="#Entity"/>
</owl:ObjectProperty>
```

Similar properties exist for decisions, actions, problems, positive-subjective sentences, negative-subjective sentences and general extractive sentences (important sentences that may not match the other categories), all connecting conversation participants and entities. The goal is to populate the ontology with participant and entity instances from a given conversation and determine their relationships. This involves identifying the important entities and classifying the sentences in which they occur as being decision sentences, action item sentences, etc.

Our current definition of entity is simple. The entities in a conversation are noun phrases with mid-range document frequency. This is similar to the definition of concept as defined by Xie et al. (Xie et al., 2009), where n-grams are weighted by *tf.idf* scores, except that we use noun phrases rather than any n-grams because we want to refer to the entities in the generated text. We use mid-range document frequency instead of *idf* (Church and Gale, 1995), where the entities occur in between 10% and 90% of the documents in the collection. In Section 4 we describe how we use the entity's term frequency to detect the most informative entities. We do not currently attempt coreference resolution for entities; recent work has investigated coreference resolution for multi-party dialogues (Muller, 2007; Gupta et al., 2007), but the challenge of resolution on such noisy data is highlighted by low accuracy (e.g. F-measure of 21.21) compared with using well-formed text (e.g. monologues).

We map sentences to our ontology's object properties by building numerous supervised classifiers trained on labeled decision sentences, action sentences, etc. A general extractive classifier is also trained on sentences simply labeled as important. After predicting these sentence-level properties, we consider a participant to be linked to an entity if the participant mentioned the entity in a sentence in which one of these properties is predicted. We give a specific example of the ontology mapping using this excerpt from the AMI corpus:

1. A: And you two are going to work together on a *prototype* using *modelling clay*.
2. A: You'll get *specific instructions* from your *personal coach*.
3. C: Cool.
4. A: Um did we decide on a *chip*?
5. A: Let's go with a *simple chip*.

Example entities are italicized. Sentences 1 and 2 are classified as action items. Sentence 3 is classified as positive-subjective, but because it contains no entities, no $< participant, relation, entity >$ triple can be added to the ontology. Sentence 4 is classified as a decision sentence, and Sentence 5 is both a decision sentence and a positive-subjective sentence (because the participant is advocating a particular position). The ontology is populated by adding all of the sentence entities as instances of the Entity class, all of the participants as instances of the Participant class, and adding $< participant, relation, entity >$ triples for Sentences 1, 2, 4 and 5. For example, Sentence 5 results in the following two triples being added to the ontology:

```
<ProjectManager rdf:ID="participant-A">
<hasDecision rdf:resource="#simple-chip"/>
</ProjectManager>
```

```
<ProjectManager rdf:ID="participant-A">
<hasPos rdf:resource="#simple-chip"/>
</ProjectManager>
```

Elements in the ontology are associated with linguistic annotations used by the generation component of our system; since we do not discuss the generation task here, we presently skip the details of this aspect of the ontology. In the following section we describe the features used for the ontology mapping.

3.1 Feature Set

The interpretation component uses general features that are applicable to any conversation domain. The first set of features we use for ontology mapping are features relating to conversational structure. These are listed and briefly described in Table 1. The $Sprob$ and $Tprob$ features measure how terms cluster between conversation participants and conversation turns. There are simple features measuring sentence length (SLEN, SLEN2) and position (TLOC, CLOC). Pause-style features indicate how much time transpires between the previous turn, the current turn and the subsequent turn (PPAU, SPAU). For email conversations, pause features are based on the timestamps between consecutive emails. Lexical features capture cohesion (CWS) and cosine similarity between the sentence and the conversation (CENT1, CENT2). All structural features are normalized by document length.

Feature ID	Description
MXS	max *Sprob* score
MNS	mean *Sprob* score
SMS	sum of *Sprob* scores
MXT	max *Tprob* score
MNT	mean *Tprob* score
SMT	sum of *Tprob* scores
TLOC	position in turn
CLOC	position in conv.
SLEN	word count, globally normalized
SLEN2	word count, locally normalized
TPOS1	time from beg. of conv. to turn
TPOS2	time from turn to end of conv.
DOM	participant dominance in words
COS1	cos. of conv. splits, w/ *Sprob*
COS2	cos. of conv. splits, w/ *Tprob*
PENT	entro. of conv. up to sentence
SENT	entro. of conv. after the sentence
THISENT	entropy of current sentence
PPAU	time btwn. current and prior turn
SPAU	time btwn. current and next turn
BEGAUTH	is first participant (0/1)
CWS	rough ClueWordScore
CENT1	cos. of sentence & conv., w/ *Sprob*
CENT2	cos. of sentence & conv., w/ *Tprob*

Table 1: Features Key

While these features have been found to work well for generic extractive summarization, we use additional features for capturing the more specific sentence-level phenomena of this research.

- **Character trigrams** We derive all of the character trigrams in the collected corpora and include features indicating the presence or absence of each trigram in a given sentence.
- **Word bigrams** We similarly derive all of the word bigrams in the collected corpora.
- **POS bigrams** We similarly derive all of the POS-tag bigrams in the collected corpora.
- **Word pairs** We consider w_1, w_2 to be a word pair if they occur in the same sentence and w_1 precedes w_2. We derive all of the word pairs in the collected corpora and includes features indicating the presence or absence of each word pair in the given sentence. This is essentially a skip bigram where any amount of intervening material is allowed as long as the words occur in the same sentence.
- **POS pairs** We calculate POS pairs in the same manner as word pairs, above. These are essentially skip bigrams for POS tags.
- **Varying instantiation ngrams** We derive a simplified set of VIN features for these experiments. For each word bigram w_1, w_2, we further represent the bigram as p_1, w_2 and w_1, p_2 so that each pattern consists of a word and a POS tag. We include a feature indicating the presence or absence of each of these varying instantiation bigrams.

After removing features that occur fewer than five times, we end up with 218,957 total features.

4 Transformation - ILP Content Selection

In the previous section we described how we identify sentences that link participants and entities through a variety of sentence-level phenomena. Having populated our ontology with these triples to form a source representation, we now turn to the task of transforming the source representation to a summary representation, identifying the $< participant, relation, entity >$ triples for which we want to generate text. We adapt a method proposed by Xie et al. (2009) for extractive sentence selection. They propose an ILP approach that creates a summary by maximizing a global objective function:

$$maximize\ (1-\lambda) * \sum_i w_i c_i + \lambda * \sum_j u_j s_j \quad (1)$$

$$subject\ to\ \sum_j l_j s_j < L \quad (2)$$

where w_i is the *tf.idf* score for concept i, u_j is the weight for sentence j using the cosine similarity to the entire document, c_i is a binary variable indicating whether concept i is selected (with the concept represented by a unique weighted n-gram), s_j is a binary variable indicating whether sentence j is selected, l_j is the length of sentence j and L is the desired summary length. The λ term is used to balance concept and sentence weights. This method selects sentences that are weighted strongly and which cover as many important concepts as possible. As described by Gillick et al. (2009), concepts and sentences are tied together by two additional constraints:

$$\sum_j s_j o_{ij} \geq c_i\ \forall_i \quad (3)$$

$$s_j o_{ij} \leq c_i\ \forall_{i,j} \quad (4)$$

where o_{ij} is the occurence of concept i in sentence j. These constraints state that a concept can only be selected if it occurs in a sentence that is selected, and that a sentence can only be selected if all of its concepts have been selected.

We adapt their method in several ways. As mentioned in the previous section, we use weighted noun phrases as our entities instead of n-grams. In our version of Equation 1, w_i is the *tf* score of entity i (the *idf* was already used to identify entities as described previously). More importantly, our sentence weight u_j is the sum of all the posterior probabilities for sentence j derived from the various sentence-level classifiers. In other words, sentences are weighted highly if they correspond to multiple object properties in the ontology. To continue the example from Section 3, the sentence *Let's go with the simple chip* may be selected because it represents both a decision and a positive-subjective opinion, as well as containing the entity *simple chip* which is mentioned frequently in the conversation.

We include constraint 3 but not 4; it is possible for a sentence to be extracted even if not all of its entities are. We know that all the sentences under consideration will contain at least one entity because sentences with no entities would not have been mapped to the ontology in the form of $< participant, relation, entity >$ triples in the first place. To begin with, we set the λ term at 0.75 as we are mostly concerned with identifying important sentences containing multiple links to the ontology. In our case L is 20% of the total document word count.

5 Experimental Setup

In this section we describe our conversation corpora, the statistical classifiers used, and the evaluation metrics employed.

5.1 Corpora

These experiments are conducted on both meeting and email conversations, which we describe in turn.

5.1.1 The AMI Meetings Corpus

For our meeting summarization experiments, we use the *scenario* portion of the AMI corpus (Carletta et al., 2005), where groups of four participants take part in a series of four meetings and play roles within a fictitious company. There are 140 of these meetings in total, including a 20 meeting test set containing multiple human summary annotations per meeting (the others are annotated by a single individual). We report results on both manual and ASR transcripts. The word error rate for the ASR transcripts is 38.9%.

For the *summary annotation*, annotators wrote abstract summaries of each meeting and extracted sentences that best conveyed or supported the information in the abstracts. The human-authored abstracts each contain a general abstract summary and three subsections for "decisions," "actions" and "problems" from the meeting. A many-to-many mapping between transcript sentences and sentences from the human abstract was obtained for each annotator. Approximately 13% of the total transcript sentences are ultimately labeled as extracted sentences. A sentence is considered a decision item if it is linked to the decision portion of the abstract, and action and problem sentences are derived similarly.

For the *subjectivity annotation*, we use annotations of positive-subjective and negative-subjective utterances on a subset of 20 AMI meetings (Wilson, 2008). Such subjective utterances involve the expression of a private state, such as a positive/negative opinion, positive/negative argument, and agreement/disagreement. Of the roughly 20,000 total sentences in the 20 AMI meetings, nearly 4000 are labeled as *positive-subjective* and nearly 1300 as *negative-subjective*.

5.1.2 The BC3 Email Corpus

While our main experiments focus on the AMI meeting corpus, we follow these up with an investigation into applying our abstractive techniques to email data. The BC3 corpus (Ulrich et al., 2008) contains email threads from the World Wide Web Consortium (W3C) mailing list. The threads feature a variety of topics such as web accessibility and planning face-to-face meetings. The annotated portion of the mailing list consists of 40 threads. The threads are annotated in the same manner as the AMI corpus, with three human annotators per thread first authoring abstracts and then linking email thread sentences to the abstract sentences. The corpus also contains speech act annotations. Unlike the AMI corpus, however, there are no annotations for decisions, actions and problems, an issue addressed later.

5.2 Classifiers

For these experiments we use a maximum entropy classifier using the *liblinear* toolkit[1] (Fan et al., 2008). For each of the AMI and BC3 corpora, we perform 10-fold cross-validation on the data. In all experiments we apply a 20% compression rate in terms of the total document word count.

5.3 Evaluation

We evaluate the various classifiers described in Section 3 using the ROC curve and the area under the curve (AUROC), where a baseline AUROC is 0.5 and an ideal classifier approaches 1.

To evaluate the content selection in the transformation stage, we use weighted recall.This evaluation metric is based on the links between extracted sentences and the human gold-standard abstracts, with the underlying motivation being that sentences with more links to the human abstract are generally more informative, as they provide the content on which an effective abstract summary should be built. If M is the number of sentences selected in the transformation step, O is the total number of sentences in the document, and N is the number of annotators, then Weighted Recall is given by

$$recall = \frac{\sum_{i=1}^{M}\sum_{j=1}^{N} L(s_i, a_j)}{\sum_{i=1}^{O}\sum_{j=1}^{N} L(s_i, a_j)}$$

where $L(s_i, a_j)$ is the number of links for a sentence s_i according to annotator a_j. We can compare machine performance with human performance in the following way. For each annotator, we rank their sentences from most-linked to least-linked and select the best sentences until we reach the same word count as our selections. We then calculate their weighted recall score by using the other N-1 annotations, and then average over all N annotators to get an average human performance. We report all transformation scores normalized by human performance for that dataset.

6 Results

In this section we present results for our interpretation and transformation components.

6.1 Interpretation: Meetings

Figure 1 shows the ROC curves for the sentence-level classifiers applied to manual transcripts. On both manual and ASR transcripts, the classifiers with the largest AUROCs are the action item and general extractive classifiers. Action item sentences can be detected very well with this feature set, with the classifier having an AUROC of 0.92 on manual transcripts and 0.93 on ASR, a result comparable to previous findings of 0.91 and 0.93 (Murray and Renals, 2008) obtained using a speech-specific feature set. General extractive classification is also similar to other state-of-the-art extraction approaches on spoken data using speech features (Zhu and Penn, 2006)[2] with an AUROC of 0.87 on manual and 0.85 on ASR. Decision sentences can also be detected quite well, with AUROCs of 0.81 and 0.77. Positive-subjective, negative-subjective and problem sentences are the most difficult to detect, but the classifiers still give credible performance with AUROCs of approximately 0.76 for manual and 0.70-0.72 for ASR.

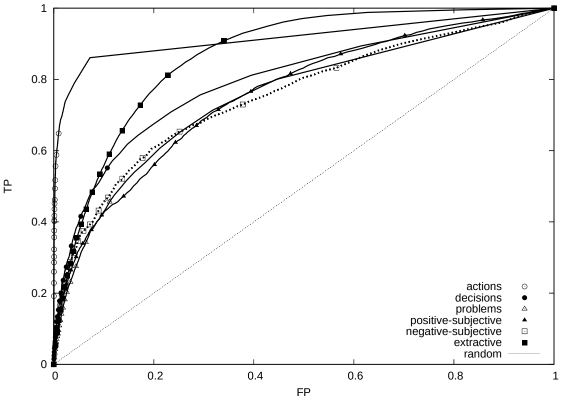

Figure 1: ROC Curves for Ontology Mapping Classifiers (Manual Transcripts)

6.2 Transformation: Meetings

In this section we present the weighted recall scores for the sentences selected using the ILP method described in Section 4. Remember, weighted recall measures how useful these sentences would be in generating sentences for an abstract summary. We also assess the performance of three baseline summarizers operating at the same compression level.

[1] http://www.csie.ntu.edu.tw/ cjlin/liblinear/

[2] Based on visual inspection of their reported best ROC curve

The simplest baseline (GREEDY) selects sentences by ranking the posterior probabilites output by the general extractive classifier. The second baseline (CLASS COMBO) averages the posterior probabilites output by *all* the classifiers and ranks sentences from best to worst. The third baseline (RETRAIN) uses the posterior probability outputs of all the classifiers (except for the extractive classifier) as new feature inputs for the general extractive classifier.

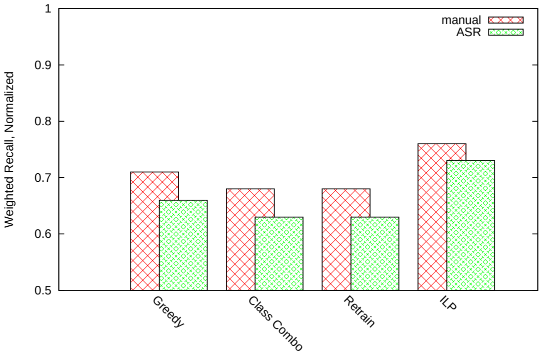

Figure 2: Weighted Recall Scores for AMI Meetings

Figure 2 shows the weighted recall scores, normalized by human performance, for all approaches on both manual and ASR transcripts. On manual transcripts, the ILP approach (0.76) is better than GREEDY (0.71) with a marginally significant difference (p=0.07) and is significantly better than CLASS COMBO and RETRAIN (both 0.68) according to t-test ($p < 0.05$) . For ASR transcripts, the ILP approach is significantly better than all other approaches ($p < 0.05$). Xie et al. (2009) reported ROUGE-1 F-measures on a different meeting corpus, and our ROUGE-1 scores are in the same range of 0.64-0.69 (they used 18% compression ratio).

6.3 Interpretation: Emails

We applied the same summarization method to the 40 BC3 email threads, with contrasting results. Because the BC3 corpus does not currently contain annotations for decisions, actions and problems, we simply ran the AMI-trained models over the data for those three phenomena. We can assess the performance of the extractive, positive-subjective and negative-subjective classifiers by examining the ROC curves displayed in Figure 3. Both the general extractive and negative-subjective classifiers have AUROCs of around 0.75. The positive-subjective classifier initially has the worst performance with an AUROC of 0.66, but we found that positive-subjective performance increased dramatically to an AUROC of 0.77 when we used only conversational features and not word bigrams, character trigrams or POS tags.

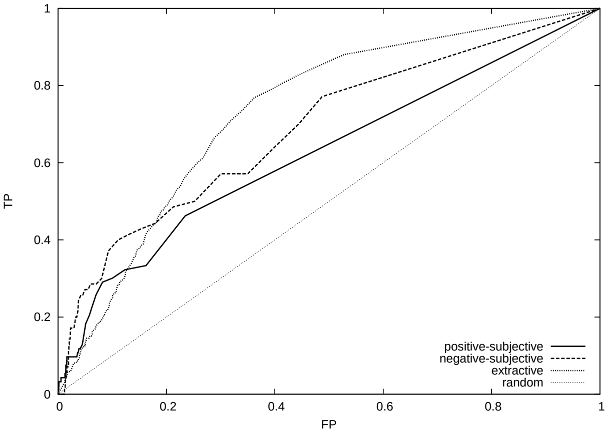

Figure 3: ROC Curves for Ontology Mapping Classifiers (BC3 Corpus)

6.4 Transformation: Emails

If we examine the weighted recall scores in Figure 4 we see that the ILP approach is worse than the greedy summarizers on the BC3 dataset. However, the differences are not significant between ILP and COMBO CLASS (p=0.15) and only marginally significant compared with RETRAIN and GREEDY (both p=0.08). The performance of the ILP approach varies greatly across email threads. The top 15 threads (out of 40) yield ILP weighted recall scores that are on par with human performance, while the worst 15 are half that.

6.4.1 Email Corpus Analysis

Due to the large discrepancy in performance on BC3 emails, we conducted additional experiments for error analysis. We first explored whether we could build a classifier that could discriminate the best 15 emails from the worst 15 emails in terms of weighted recall scores with the ILP approach, to determine whether there are certain features that correlate with good performance. Using the same fea-

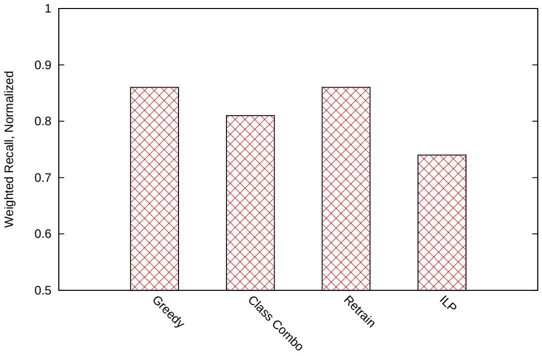

Figure 4: Weighted Recall Scores for BC3 Threads

Metric	Worst 15	Best 15
Weighted Recall	0.49	1.05
# Turns	6.27	6.73
# Participants	4.67	5.4
PPAU	0.18	0.12
BEGAUTH	0.31	0.18

Table 2: Selected Email Features, Averaged

tures described in Section 3.1, we built a logistic regression classifier on the two classes and found that they can be discriminated quite well (80% accuracy on an approximately balanced dataset) and that the conversation structure features are the most useful for discerning them. Table 2 shows the weighted recall scores and several conversation features that were weighted most highly by the logistic regression model. In particular, we found that the email threads that yielded good performance tended to feature more active participants (# Participants), were not dominated by a single individual (BEGAUTH), and featured a higher number of turns (# Turns) that followed each other in quick succession without long pauses (PPAU, pause as percentage of conversation length). In other words, these emails were structured more similarly to meetings. Note that since we normalize weighted recall by human performance, it is possible to have a weighted recall score higher than 1. On the 15 best threads, our system achieves human-level performance. Because we used AMI-trained models for detecting decisions, actions and problems in the BC3 data, it is not surprising that performance was better on those emails structured similarly to meetings. All of this indicates that there are many different types of emails and that we will have to focus on improving performance on emails that differ markedly in structure.

7 Conclusion

We have presented two components of an abstractive conversation summarization system. The *interpretation* component is used to populate a simple conversation ontology where conversation participants and entities are linked by object properties such as decisions, actions and subjective opinions. For this step we show that highly accurate classifiers can be built using a large set of features not specific to any conversation modality.

In the *transformation* step, a summary is created by maximizing a function relating sentence weights and entity weights, with the sentence weights determined by the sentence-ontology mapping. Our evaluation shows that the sentences we select are highly informative to generate abstract summaries, and that our content selection method outperforms several greedy selection approaches. The system described thus far may appear extractive in nature, as the transformation step is identifying informative sentences in the conversation. However, these selected sentences correspond to $< participant, relation, entity >$ triples in the ontology, for which we can subsequently generate novel text by creating linguistic annotations of the conversation ontology (Galanis and Androutsopolous, 2007). Even without the generation step, the approach described above allows us to create structured extracts by grouping sentences according to specific phenomena such as action items and decisions. The knowledge represented by the ontology enables us to significantly improve sentence selection according to intrinsic measures and to generate structured output that we hypothesize will be more useful to an end user compared with a generic unstructured extract.

Future work will focus on the generation component and on applying the summarization system to conversations in other modalities such as blogs and instant messages. Based on the email error analysis, we plan to pursue domain adaptation techniques to improve performance on different types of emails.

Abstract

This paper analyzes the topic identification stage of single-document automatic text summarization across four different domains, consisting of newswire, literary, scientific and legal documents. We present a study that explores the summary space of each domain via an exhaustive search strategy, and finds the probability density function (pdf) of the ROUGE score distributions for each domain. We then use this pdf to calculate the percentile rank of extractive summarization systems. Our results introduce a new way to judge the success of automatic summarization systems and bring quantified explanations to questions such as why it was so hard for the systems to date to have a statistically significant improvement over the lead baseline in the news domain.

1 Introduction

Topic identification is the first stage of the generally accepted three-phase model in automatic text summarization, in which the goal is to identify the most important units in a document, i.e., phrases, sentences, or paragraphs (Hovy and Lin, 1999; Lin, 1999; Sparck-Jones, 1999). This stage is followed by the topic interpretation and summary generation steps where the identified units are further processed to bring the summary into a coherent, human readable abstract form. The extractive summarization systems, however, only employ the topic identification stage, and simply output a ranked list of the units according to a compression ratio criterion. In general, for most systems sentences are the preferred units in this stage, as they are the smallest grammatical units that can express a statement.

Since the sentences in a document are reproduced verbatim in extractive summaries, it is theoretically possible to explore the search space of this problem through an enumeration of all possible extracts for a document. Such an exploration would not only allow us to see how far we can go with extractive summarization, but we would also be able to judge the difficulty of the problem by looking at the distribution of the evaluation scores for the generated extracts. Moreover, the high scoring extracts could also be used to train a machine learning algorithm.

However, such an enumeration strategy has an exponential complexity as it requires all possible sentence combinations of a document to be generated, constrained by a given word or sentence length. Thus the problem quickly becomes impractical as the number of sentences in a document increases and the compression ratio decreases. In this work, we try to overcome this bottleneck by using a large cluster of computers, and decomposing the task into smaller problems by using the given section boundaries or a linear text segmentation method. As a result of this exploration, we generate a probability density function (pdf) of the ROUGE score (Lin, 2004) distributions for four different domains, which shows the distribution of the evaluation scores for the generated extracts, and allows us to assess the difficulty of each domain for extractive summarization.

Furthermore, using these pdfs, we introduce a new success measure for extractive summarization systems. Namely, given a system's average score over a data set, we show how to calculate the per-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 903–911,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

centile rank of this system from the corresponding pdf of the data set. This allows us to see the true improvement a system achieves over another, such as a baseline, and provides a standardized scoring scheme for systems performing on the same data set.

2 Related Work

Despite the large amount of work in automatic text summarization, there are only a few studies in the literature that employ an exhaustive search strategy to create extracts, which is mainly due to the prohibitively large search space of the problem. Furthermore, the research regarding the alignment of abstracts to original documents has shown great variations across domains (Kupiec et al., 1995; Teufel and Moens, 1997; Marcu, 1999; Jing, 2002; Ceylan and Mihalcea, 2009), which indicates that the extractive summarization techniques are not applicable to all domains at the same level.

In order to automate the process of corpus construction for automatic summarization systems, (Marcu, 1999) used exhaustive search to generate the best *Extract* from a given *(Abstract, Text)* tuple, where the best *Extract* contains a set of clauses from *Text* that have the highest similarity to the given *Abstract*.

In addition, (Donaway et al., 2000) used exhaustive search to create all the sentence extracts of length three starting with 15 TREC Documents, in order to judge the performance of several summary evaluation measures suggested in their paper.

Finally, the study most similar to ours was done by (Lin and Hovy, 2003), who used the articles with less than 30 sentences from the DUC 2001 data set to find *oracle extracts* of 100 and 150 (± 5) words. These extracts were compared against one summary source, selected as the one that gave the highest inter-human agreement. Although it was concluded that a 10% improvement was possible for extractive summarization systems, which typically score around the lead baseline, there was no report on how difficult it would be to achieve this improvement, which is the main objective of our paper.

3 Description of the Data Set

Our data set is composed of four different domains: newswire, literary, scientific and legal. For all the domains we used 50 documents and only one summary for each document, except for newswire where we used two summaries per document. For the newswire domain, we selected the articles and their summaries from the DUC 2002 data set,[1]. For the literary domain, we obtained 10 novels that are literature classics, and available online in text format. Further, we collected the corresponding summaries for these novels from various websites such as CliffsNotes (www.cliffsnotes.com) and SparkNotes (www.sparknotes.com), which make available human generated abstracts for literary works. These sources give a summary for each chapter of the novel, so each chapter can be treated as a separate document. Thus we evaluate 50 chapters in total. For the scientific domain, we selected the articles from the medical journal *Autoimmunity Reviews*[2] were selected, and their abstracts are used as summaries. Finally, for the legal domain, we gathered 50 law documents and their corresponding summaries from the European Legislation Website,[3] which comprises four types of laws - *Council Directives*, *Acts*, *Communications*, and *Decisions* over several topics, such as society, environment, education, economics and employment.

Domain	μ_{Dw}	μ_{Sw}	μ_R	μ_C	μ_{Cw}

Legal	3469	865	75%	18	192

Table 1: Statistical properties of the data set. μ_{Dw}, and μ_{Sw} represent the average number of words for each document and summary respectively; μ_R indicates the average compression ratio; and μ_C and μ_{Cw} represent the average number of sections for each document, and the average number of words for each section respectively.

Although all the summaries are human generated abstracts for all the domains, it is worth mentioning that the documents and their corresponding summaries exhibit a specific writing style for each domain, in terms of the vocabulary used and the length of the sentences. We list some of the statistical properties of each domain in Table 1.

4 Experimental Setup

As mentioned in Section 1, an exhaustive search algorithm requires generating all possible sentence combinations from a document, and evaluating each one individually. For example, using the values from Table 1, and assuming 20 words per sentence, we find that the search space for the news domain contains approximately $\binom{32}{5} \times 50 = 10,068,800$ summaries. The same calculation method for the scientific domain gives us $\binom{99}{8} \times 50 = 8.56 \times 10^{12}$ summaries. Obviously the search space gets much bigger for the legal and literary domains due to their larger text size.

In order to be able to cope with such a huge search space, the first thing we did was to modify the ROUGE 1.5.5[4] Perl script by fixing the parameters to those used in the DUC experiments,[5] and also by modifying the way it handles the input and output to make it suitable for streaming on the cluster.

The resulting script evaluates around 25-30 summaries per second on an Intel 2.33 GHz processor. Next, we streamed the resulting ROUGE script for each (document, summary) pair on a large cluster of computers running on an Hadoop Map-Reduce framework.[6] Based on the size of the search space for a (document, summary) pair, the number of computers allocated in the cluster ranged from just a few to more than one thousand.

Although the combination of a large cluster and a faster ROUGE is enough to handle most of the documents in the news domain in just a few hours, a simple calculation shows that the problem is still impractical for the other domains. Hence for the scientific, legal, and literary domains, rather than considering each document as a whole, we divide them into sections, and create extracts for each section such that the length of the extract is proportional to the length of the section in the original document. For the legal and scientific domains, we use the given section boundaries (without considering the subsections for scientific documents). For the novels, we treat each chapter as a single document (since each chapter has its own summary), which is further divided into sections using a publicly available linear text segmentation algorithm by (Utiyama and Isahara, 2001).[7] In all cases, we let the algorithm pick the number of segments automatically.

To evaluate the sections, we modified ROUGE further so that it applies the length constraint to the extracts only, not to the model summaries. This is due to the fact that we evaluate the extracts of each section individually against the whole model summary, which is larger than the extract. This way, we can get an overall ROUGE recall score for a document extract, simply by summing up the recall scores of each section extracts. The precision score for the entire document can also be found by adding the weighted precision scores for each section, where the weight is proportional to the length of the section in the original document. In our study, however, we only use recall scores.

Note that, since for the legal, scientific, and literary domains we consider each section of a document independently, we are not performing a true exhaustive search for these domains, but rather solving a suboptimal problem, as we divide the number of words in the model summary to each section proportional to the section's length. However, we believe that this is a fair assumption, as it has been shown repeatedly in the past that text segmentation helps improving the performance of text summarization systems (yen Kan et al., 1998; Nakao, 2000; Mihalcea and Ceylan, 2007).

5 Exhaustive Search Algorithm

Let $E_{i_k} = S_{i_1}, S_{i_2}, ..., S_{i_k}$ be the i^{th} extract that has k sentences, and generated from a document D with n sentences $D = S_1, S_2, \ldots, S_n$. Further, let $len(S_j)$ give the number of words in sentence S_j. We enforce that E_{i_k} satisfies the following constraints:

$$\begin{aligned} len(E_{i_k}) &= len(S_{i_1}) + \ldots + len(S_{i_k}) \geq L \\ len(E_{i_{k-1}}) &= len(S_{i_1}) + \ldots + len(S_{i_{k-1}}) < L \end{aligned}$$

where L is the length constraint on all the extracts of document D. We note that for any E_{i_k}, the order of the sentences in $E_{i_{k-1}}$ does not affect the ROUGE scores, since only the last sentence may be

[4] http://berouge.com

[5] -n 2 -x -m -2 4 -u -c 95 -r 1000 -f A -p 0.5 -t 0

[6] http://hadoop.apache.org/

[7] http://mastarpj.nict.go.jp/ mutiyama/software/textseg/textseg-1.211.tar.gz

chopped off due to the length constraint.[8] Hence, we start generating sentence combinations $\binom{n}{r}$ in *lexicographic order*, for $r = 1...n$, and for each combination $E_{i_k} = S_{i_1}, S_{i_2}, ..., S_{i_k}$ where $k > 1$, we generate additional extracts E'_{i_k} by successfully swapping S_{i_j} with S_{i_k} for $j = 1, ..., k-1$ and checking to see if the above constraints are still satisfied. Therefore from a combination with k sentences that satisfies the constraints, we might generate up to $k-1$ additional extracts. Finally, we stop the process either when $r = n$ and the last combination is generated, or we cannot find any extract that satisfies the constraints for r.

6 Generating pdfs

Once the extracts for a document are generated and evaluated, we go through each result and assign its recall score to a range, which we refer to as a bin. We use $1,000$ equally spaced bins between 0 and 1. As an example, a recall score of 0.46873 would be assigned to the bin $[0.468, 0.469]$. By keeping a count for each bin, we are in fact building a histogram of scores for the document. Let this histogram be h, and $h[j]$ be the value in the j^{th} bin of the histogram. We then define the normalized histogram $\widehat{h}$ as:

$$\widehat{h}[j] = \frac{N}{\sum_{i=1}^{N} h[j]} \, h[j] \tag{1}$$

where $N = 1,000$ is the number of bins in the histogram. Note that since the *width* of each bin is $\frac{1}{N}$, the Riemann sum of the normalized histogram $\widehat{h}$ is equal to 1, so $\widehat{h}$ can be used as an approximation to the underlying pdf. As an example, we show the histogram $\widehat{h}$ for the newswire document AP890323-0218 in Figure 1.

We combine the normalized histograms of all the documents in a domain in order to find the pdf for that domain. This requires multiplying the value of each bin in a document's histogram, with all the other possible combinations of bin values taken from each of the remaining histograms, and assigning the result to the average bin for each combination. This can be done iteratively by keeping a moving average. We illustrate this procedure in Algorithm 1, where K represents the number of documents in a domain.

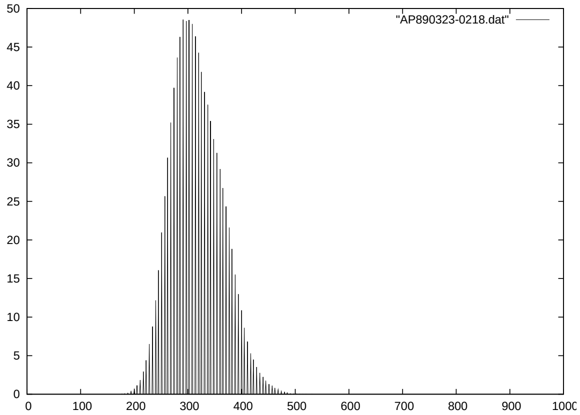

Figure 1: The normalized histogram $\widehat{h}$ of ROUGE-1 recall scores for the newswire document AP890323-0218.

Algorithm 1 Combine $\widehat{h}^i$'s for $i = 1, \ldots, K$ to create h_d, the histogram for domain d.

```
 1: $h_d := \{\}$
 2: for $i = 1$ to $N$ do
 3:     $h_d[i] := \widehat{h}^1[i]$
 4: end for
 5: for $i = 2$ to $K$ do
 6:     $h_t = \{\}$
 7:     for $j = 1$ to $N$ do
 8:         for $k = 1$ to $N$ do
 9:             $a = round(((k * (i-1)) + j)/i)$
10:             $h_t[a] = h_t[a] + (h_d[k] * \widehat{h}^i[j])$
11:         end for
12:     end for
13:     $h_d := h_t$
14: end for
```

The resulting histogram h_d, when normalized using Equation 1, is an approximation to the pdf for domain d. Furthermore, we used the $round()$ function in line 9, which rounds a number to the nearest integer, as the bins are indexed by integers. Note that this rounding introduces an error, which is distributed uniformly due to the nature of the $round()$ function. It is also possible to lower the affect of this error with higher resolutions (i.e. larger number of bins). In Figure 2, we show a sample h_d, obtained by combining 10 documents from the newswire do-

[8] Note that we do not take the coherence of extracts into account, i.e. the sentences in an extract do not need to be sorted in order of their appearance in the original document. We also do not change the position of the words in a sentence.

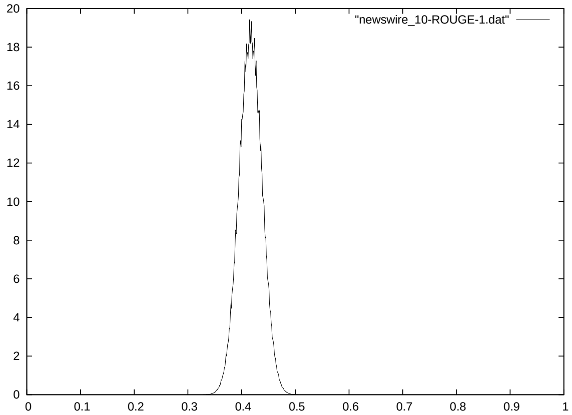

Figure 2: An example pdf obtained by combining 10 document histograms of ROUGE-1 recall scores from the newswire domain. The x-axis is normalized to [0,1].

main.

Recall from Section 4 that the documents in the literary, legal, and scientific domains are divided into sections either by using the given section boundaries or by applying a text segmentation algorithm, and the extracts of each section are then evaluated individually. Hence for these domains, we first calculate the histogram of each section individually, and then combine them to find the histogram of a document. The combination procedure for the section histograms is similar to Algorithm 1, except that in this case we do not keep a moving average, but rather sum up the bins of the sections. Note that when bin i and j are added, the resulting values should be expected to be half the times in bin $i+j$, and half the times in $i+j-1$.

7 Calculating Percentile Ranks

Given a pdf for a domain, the success of a system having a ROUGE recall score of S could be simply measured by finding the area bounded by S. This gives us the percentile rank of the system in the overall distribution. Assuming $0 \leq S \leq 1$, let $\widehat{S} = \lfloor N \times S \rfloor$, then the formula to calculate the percentile rank can be simply given as:

$$PR(S) = \frac{100}{N} \sum_{i=1}^{\widehat{S}} \widehat{h_d}[i] \tag{2}$$

8 Results

The ensemble distributions of ROUGE-1 recall scores per document are shown in Figure 3. The ensemble distributions tell us that the performance of the extracts, especially for the news and the scientific domains, are mostly uniform for each document. This is due to the fact that documents in these domains, and their corresponding summaries, are written with a certain conventional style. There is however a little scattering in the distributions of the literary and the legal domains. This is an expected result for the literary domain, as there is no specific summarization style for these documents, but somehow surprising for the legal domain, where the effect is probably due to the different types of legal documents in the data set.

The pdf plots resulting from the ROUGE-1 recall scores are shown in Figure 4.[9] In order to analyze the pdf plots, and better understand their differences, Table 2 lists the mean (μ) and the standard deviation (σ) measures of the pdfs, as well as the average minimum and maximum scores that an extractive summarization system can get for each domain.

By looking at the pdf plots and the minimum and maximum columns from Table 2, we notice that for

[9] Similar pdfs are obtained for ROUGE-2 and ROUGE-SU4, even if at a different scale.

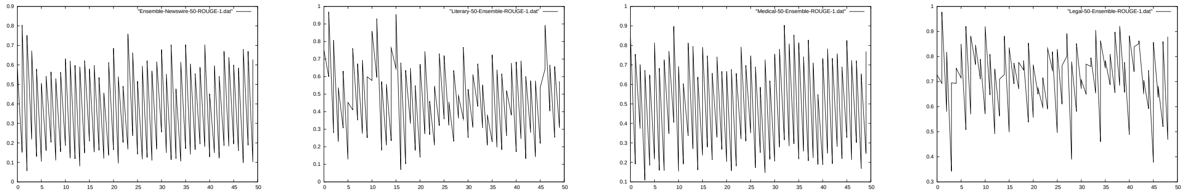

Figure 3: ROUGE-1 recall score distributions per document for Newswire, Literary, Scientific and Legal Domains, respectively from left to right.

all the domains, the pdfs are long-tailed distributions. This immediately implies that most of the extracts in a summary space are clustered around the mean, which means that for automatic summarization systems, it is very easy to get scores around this range. Furthermore, we can judge the hardness of each domain by looking at the standard deviation values. A lower standard deviation indicates a steeper curve, which implies that improving a system would be harder. From the table, we can infer that the legal domain is the hardest while the newswire is the easiest.

Comparing Table 2 with the values in Table 1, we also notice that the compression ratio affects the performance differently for each domain. For example, although the scientific domain has the highest compression ratio, it has a higher mean than the literary and the newswire domains for ROUGE-1 and ROUGE-SU4 recall scores. This implies that although the abstracts of the medical journals are highly compressed, they have a high overlap with the document, probably caused by their writing style. This was in fact confirmed earlier by the experiments in (Kupiec et al., 1995), where it was found out that for a data set of 188 scientific articles, 79% of the sentences in the abstracts could be perfectly matched with the sentences in the corresponding documents.

Next, we confirm our experiments by testing three different extractive summarization systems on our data set. The first system that we implement is called *Random*, and gives a random score between 1 and 100 to each sentence in a document, and then selects the top scoring sentences. The second system, *Lead*, implements the lead baseline method which takes the first k sentences of a document until the length limit is reached. Finally, the last system that we implement is *TextRank*, which uses a variation of the PageRank graph centrality algorithm in order to identify the most important sentences in a document (Page et al., 1999; Erkan and Radev, 2004; Mihalcea and Tarau, 2004). We selected TextRank as it has a performance competitive with the top systems participating in DUC ’02 (Mihalcea and Tarau, 2004). We would also like to mention that for the literary, scientific, and legal domains, the systems apply the algorithms for each section and each section is evaluated independently, and their resulting recall scores are summed up. This is needed in order to be consistent with our exhaustive search experiments.

The ROUGE recall scores of the three systems are shown in Table 3. As expected, for the literary and legal domains, the *Random*, and the *Lead* systems score around the mean. This is due to the fact that the leading sentences for these two domains do not indicate any significance, hence the *Lead* system just behaves like *Random*. However for the scientific and newswire domains, the leading sentences do have

Table 4: Percentile rankings of the Lead baseline, TextRank, and Random sentence selector across domains

importance so the *Lead* system consistently outperforms *Random*. Furthermore, although *TextRank* is the best system for the literary, scientific, and legal domains, it gets outperformed by the *Lead* system on the newswire domain. This is also an expected result as none of the single-document summarization systems were able to achieve a statistically significant improvement over the lead baseline in the previous Document Understanding Conferences (DUC).

The ROUGE scoring scheme does not tell us how much improvement a system achieved over another, or how far it is from the upper bound. Since we now have access to the pdf of each domain in our data set, we can find this information simply by calculating the percentile rank of each system using the formula given in Equation 2.

The percentile ranks of all three systems for each domain are shown in Table 4. Notice how different the gap is between the scores of each system this time, compared to the scores in Table 3. For example, we see in Table 3 that *TextRank* on scientific domain has only a 3.51 ROUGE-1 score improvement over a system that randomly selects sentences to include in the extract. However, Table 4 tells us that this improvement is in fact 57.57%.

From Table 4, we see that both *TextRank* and the *Lead* system are in the 99.99% percentile of the newswire domain although the systems have 1.20, 1.61, and 1.12 difference in their ROUGE-1, ROUGE-2, and ROUGE-SU4 scores respectively. The high percentile for the *Lead* system explains why it was so hard to improve over these baseline in previous evaluations on newswire data (e.g., see the evaluations from the Document Understanding Conferences). Furthermore, we see from Table 2 that the upper bounds corresponding to these scores are 65.7, 37.4, and 38.1 respectively, which are well above both the *TextRank* and the *Lead* systems. Therefore, the percentile rankings of the *Lead* and the *TextRank* systems for this domain do not seem to give us clues about how the two systems compare to each other, nor about their actual distance from the upper bounds. There are two reasons for this: First, as we mentioned earlier, most of the summary space consists of *easy* extracts, which make the distribution long-tailed.[10] Therefore even though we have quite a bit of systems achieving high scores, their number is negligible compared to the millions of extracts that are clustered around the mean. Secondly, we need a higher resolution (i.e. larger number of bins) in constructing the pdfs in order to be able to

[10] This also accounts for the fact that even though we might have two very close ROUGE scores that are not statistically significant, their percentile rankings might differ quite a bit.

see the difference more clearly between the two systems. Finally, when comparing two successful systems using percentile ranks, we believe the use of error reduction would be more beneficial.

As a final note, we also randomly sampled extracts from documents in the scientific and legal domains, but this time without considering the section boundaries and without performing any segmentation. We kept the number of samples for each document equal to the number of extracts we generated from the same document using a divide-and-conquer approach. We evaluated the samples using ROUGE-1 recall scores, and obtained pdfs for each domain using the same strategy discussed earlier in the paper. The resulting pdfs, although they exhibit similar characteristics, they have mean values (μ) around 10% lower than the ones we listed in Table 2, which supports the findings from earlier research that segmentation is useful for text summarization.

9 Conclusions and Future Work

In this paper, we described a study that explores the search space of extractive summaries across four different domains. For the news domain we generated all possible extracts of the given documents, and for the literary, scientific, and legal domains we followed a divide-and-conquer approach by chunking the documents into sections, handled each section independently, and combined the resulting scores at the end. We then used the distributions of the evaluations scores to generate the probability density functions (pdfs) for each domain. Various statistical properties of these pdfs helped us asses the difficulty of each domain. Finally, we introduced a new scoring scheme for automatic text summarization systems that can be derived from the pdfs. The new scheme calculates a percentile rank of the ROUGE-1 recall score of a system, which gives scores in the range [0-100]. This lets us see how far each system is from the upper bound, and thus make a better comparison among the systems. The new scoring system showed us that while there is a 20.1% gap between the upper bound and the lead baseline for the news domain, closing this gap is difficult, as the percentile rank of the lead baseline system, 99.99%, indicates that the system is already very close to the upper bound.

Furthermore, except for the literary domain, the percentile rank of the *TextRank* system is also very close to the upperbound. This result does not suggest that additional improvements cannot be made in these domains, but that making further improvements using only extractive summarization will be considerably difficult. Moreover, in order to see these future improvements, a higher resolution (i.e. larger number of bins) will be needed when constructing the pdfs.

In all our experiments we used the ROUGE (Lin, 2004) evaluation package and its ROUGE-1, ROUGE-2, and ROUGE-SU4 recall scores. We would like to note that since ROUGE performs its evaluations based on the n-gram overlap between the peer and the model summary, it does not take other summary quality metrics such as coherence and cohesion into account. However, our goal in this paper was to analyze the topic-identification stage only, which concentrates on selecting the right content from the document to include in the summary, and the ROUGE scores were found to correlate well with the human judgments on assessing the content overlap of summaries.

In the future, we would like to apply a similar exhaustive search strategy, but this time with different compression ratios, in order to see the impact of compression ratios on the pdf of each domain. Furthermore, we would also like to analyze the high scoring extracts found by the exhaustive search, in terms of coherence, position and other features. Such an analysis would allow us to see whether these extracts exhibit certain properties which could be used in training machine learning systems.

Abstract

We treat the text summarization problem as maximizing a submodular function under a budget constraint. We show, both theoretically and empirically, a modified greedy algorithm can efficiently solve the budgeted submodular maximization problem near-optimally, and we derive new approximation bounds in doing so. Experiments on DUC'04 task show that our approach is superior to the best-performing method from the DUC'04 evaluation on ROUGE-1 scores.

1 Introduction

Automatically generating summaries from large text corpora has long been studied in both information retrieval and natural language processing. There are several types of text summarization tasks. For example, if an input query is given, the generated summary can be query-specific, and otherwise it is generic. Also, the number of documents to be summarized can vary from one to many. The constituent sentences of a summary, moreover, might be formed in a variety of different ways — summarization can be conducted using either *extraction* or *abstraction*, the former selects only sentences from the original document set, whereas the latter involves natural language generation. In this paper, we address the problem of generic extractive summaries from clusters of related documents, commonly known as *multi-document summarization*.

In extractive text summarization, textual units (e.g., sentences) from a document set are extracted to form a summary, where grammaticality is assured at the local level. Finding the optimal summary can be viewed as a combinatorial optimization problem which is NP-hard to solve (McDonald, 2007). One of the standard methods for this problem is called *Maximum Marginal Relevance* (MMR) (Dang, 2005)(Carbonell and Goldstein, 1998), where a greedy algorithm selects the most relevant sentences, and at the same time avoids redundancy by removing sentences that are too similar to already selected ones. One major problem of MMR is that it is non-optimal because the decision is made based on the scores at the current iteration. McDonald (2007) proposed to replace the greedy search of MMR with a globally optimal formulation, where the basic MMR framework can be expressed as a knapsack packing problem, and an integer linear program (ILP) solver can be used to maximize the resulting objective function. ILP Algorithms, however, can sometimes either be expensive for large scale problems or themselves might only be heuristic without associated theoretical approximation guarantees.

In this paper, we study graph-based approaches for multi-document summarization. Indeed, several graph-based methods have been proposed for extractive summarization in the past. Erkan and Radev (2004) introduced a stochastic graph-based method, *LexRank*, for computing the relative importance of textual units for multi-document summarization. In LexRank the importance of sentences is computed based on the concept of eigenvector centrality in the graph representation of sentences. Mihalcea and Tarau also proposed an eigenvector centrality algorithm on weighted graphs for document summarization (Mihalcea and Tarau, 2004). Mihalcea et al. later applied Google's *PageRank* (Brin and Page, 1998) to natural language processing tasks ranging

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 912–920,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

from automatic keyphrase extraction and word sense disambiguation, to extractive summarization (Mihalcea et al., 2004; Mihalcea, 2004). Recent work in (Lin et al., 2009) presents a graph-based approach where an undirected weighted graph is built for the document to be summarized, and vertices represent the candidate sentences and edge weights represent the similarity between sentences. The summary extraction procedure is done by maximizing a submodular set function under a cardinality constraint.

Inspired by (Lin et al., 2009), we perform summarization by maximizing submodular functions under a *budget* constraint. A budget constraint is natural in summarization task as the length of the summary is often restricted. The length (byte budget) limitation represents the real world scenario where summaries are displayed using only limited computer screen real estate. In practice, the candidate textual/linguistic units might not have identical costs (e.g., sentence lengths vary). Since a cardinality constraint is a special case (a budget constraint with unity costs), our approach is more general than (Lin et al., 2009). Moreover, we propose a modified greedy algorithm (Section 4) and both theoretically (Section 4.1) and empirically (Section 5.1) show that the algorithm solves the problem near-optimally, thanks to submodularity. Regarding summarization performance, experiments on DUC'04 task show that our approach is superior to the best-performing method in DUC'04 evaluation on ROUGE-1 scores (Section 5).

2 Background on Submodularity

Consider a set function $f : 2^V \rightarrow \mathbb{R}$, which maps subsets $S \subseteq V$ of a finite ground set V to real numbers. $f(\cdot)$ is called normalized if $f(\emptyset) = 0$, and is *monotone* if $f(S) \leq f(T)$ whenever $S \subseteq T$. $f(\cdot)$ is called *submodular* (Lovasz, 1983) if for any $S, T \subseteq V$, we have

$$f(S \cup T) + f(S \cap T) \leq f(S) + f(T). \quad (1)$$

An equivalent definition of submodularity is the property of *diminishing returns*, well-known in the field of economics. That is, $f(\cdot)$ is submodular if for any $R \subseteq S \subseteq V$ and $s \in V \setminus S$,

$$f(S \cup \{s\}) - f(S) \leq f(R \cup \{s\}) - f(R). \quad (2)$$

Eqn. 2 states that the "value" of s never increases in the contexts of ever larger sets, exactly the property of diminishing returns. This phenomenon arises naturally in many other contexts as well. For example, the Shannon entropy function is submodular in the set of random variables. Submodularity, moreover, is a discrete analog of convexity (Lovasz, 1983). As convexity makes continuous functions more amenable to optimization, submodularity plays an essential role in combinatorial optimization.

Many combinatorial optimization problems can be solved optimally or near-optimally in polynomial time only when the underlying function is submodular. It has been shown that any submodular function can be *minimized* in polynomial time (Schrijver, 2000)(Iwata et al., 2001). Maximization of submodular functions, however, is an NP-complete optimization problem but fortunately, some submodular maximization problems can be solved near-optimally. A famous result is that the maximization of a monotone submodular function under a cardinality constraint can be solved using a greedy algorithm (Nemhauser et al., 1978) within a constant factor (0.63) of being optimal. A constant-factor approximation algorithm has also been obtained for maximizing monotone submodular function with a knapsack constraint (see Section 4.2). Feige et.al. (2007) studied unconstrained maximization of a arbitrary submodular functions (not necessarily monotone). Kawahara et.al. (2009) proposed a cutting-plane method for optimally maximizing a submodular set function under a cardinality constraint, and Lee et.al. (2009) studied non-monotone submodular maximization under matroid and knapsack constraints.

3 Problem Setup

In this paper, we study the problem of maximizing a submodular function under budget constraint, stated formally below:

$$\max_{S \subseteq V} \left\{ f(S) : \sum_{i \in S} c_i \leq \mathcal{B} \right\} \quad (3)$$

where V is the ground set of all linguistic units (e.g., sentences) in the document, S is the extracted summary (a subset of V), c_i is the non-negative cost of selecting unit i and $\mathcal{B}$ is our budget, and submodular function $f(\cdot)$ scores the summary quality.

The budgeted constraint arises naturally since often the summary must be length limited as mentioned above. In particular, the budget $\mathcal{B}$ could be the maximum number of words allowed in any summary, or alternatively the maximum number of bytes of any summary, where c_i would then be either number of words or the number of bytes in sentence i.

To benefit from submodular optimization, the objective function measuring the summary quality must be submodular. In general, there are two ways to apply submodular optimization to any application domain. One way is to force submodularity on an application, leading to an artificial and poorly performing objective function even if it can be optimized well. The alternative is to address applications where submodularity naturally applies. We are fortunate in that, like convexity in the continuous domain, submodularity seems to arise naturally in a variety of discrete domains, and as we will see below, extractive summarization is one of them. As mentioned in Section 1, our approach is graph-based, not only because a graph is a natural representation of the relationships and interactions between textual units, but also because many submodular functions are well defined on a graph and can naturally be used in measuring the summary quality.

Suppose certain pairs (i, j) with $i, j \in V$ are similar and the similarity of i and j is measured by a non-negative value $w_{i,j}$. We can represent the entire document with a weighted graph (V, E), with non-negative weights $w_{i,j}$ associated with each edge $e_{i,j}, e \in E$. One well-known graph-based submodular function that measures the similarity of S to the remainder $V \setminus S$ is the graph-cut function:

$$f_{\text{cut}}(S) = \sum_{i \in V \setminus S} \sum_{j \in S} w_{i,j}. \qquad (4)$$

In multi-document summarization, redundancy is a particularly important issue since textual units from different documents might convey the same information. A high quality (small and meaningful) summary should not only be informative about the remainder but also be compact (non-redundant). Typically, this goal is expressed as a combination of maximizing the information coverage and minimizing the redundancy (as used in MMR (Carbonell and Goldstein, 1998)). Inspired by this, we use the following objective by combining a λ-weighted penalty term with the graph cut function:

$$f_{\text{MMR}}(S) = \sum_{i \in V \setminus S} \sum_{j \in S} w_{i,j} - \lambda \sum_{i,j \in S : i \neq j} w_{i,j}, \lambda \geq 0.$$

Luckily, this function is still submodular as both the graph cut function and the redundancy term are submodular. Neither objective, however, is monotone, something we address in Theorem 3. Although similar to the MMR objective function, our approach is different since 1) ours is graph-based and 2) we formalize the problem as submodular function maximization under the budget constraint where a simple greedy algorithm can solve the problem guaranteed near-optimally.

4 Algorithms

Algorithm 1 Modified greedy algorithm

```
$G \leftarrow \emptyset$
$U \leftarrow V$
while $U \neq \emptyset$ do
    $k \leftarrow \arg\max_{\ell \in U} \frac{f(G \cup \{\ell\}) - f(G)}{(c_\ell)^r}$
    $G \leftarrow G \cup \{k\}$ if $\sum_{i \in G} c_i + c_k \leq B$ and $f(G \cup \{k\}) - f(G) \geq 0$
    $U \leftarrow U \setminus \{k\}$
end while
$v^* \leftarrow \arg\max_{v \in V, c_v \leq \mathcal{B}} f(\{v\})$
return $G_f = \arg\max_{S \in \{\{v^*\}, G\}} f(S)$
```

Inspired by (Khuller et al., 1999), we propose Algorithm 1 to solve Eqn. (3). The algorithm sequentially finds unit k with the largest ratio of objective function gain to scaled cost, i.e., $(f(G \cup \{\ell\}) - f(G))/c_\ell^r$, where $r > 0$ is the scaling factor. If adding k increases the objective function value while not violating the budget constraint, it is then selected and otherwise bypassed. After the sequential selection, set G is compared to the within-budget singleton with the largest objective value, and the larger of the two becomes the final output.

The essential aspect of a greedy algorithm is the design of the greedy heuristic. As discussed in (Khuller et al., 1999), a heuristic that greedily selects the k that maximizes $(f(G \cup \{k\}) - f(G))/c_k$ has an unbounded approximation factor. For example, let $V = \{a, b\}$, $f(\{a\}) = 1, f(\{b\}) = p$,

$c_a = 1, c_b = p+1$, and $\mathcal{B} = p+1$. The solution obtained by the greedy heuristic is $\{a\}$ with objective function value 1, while the true optimal objective function value is p. The approximation factor for this example is then p and therefore unbounded.

We address this issue by the following two modifications to the naive greedy algorithms. The first one is the final step (line 8 and 9) in Algorithm 1 where set G and singletons are compared. This step ensures that we could obtain a constant approximation factor for $r = 1$ (see the proof in the Appendix).

The second modification is that we introduce a scaling factor r to adjust the scale of the cost. Suppose, in the above example, we scale the cost as $c_a = 1^r, c_b = (p+1)^r$, then selecting a or b depends also on the scale r, and we might get the optimal solution using a appropriate r. Indeed, the objective function values and the costs might be uncalibrated since they might measure different units. E.g., it is hard to say if selecting a sentence of 15 words with an objective function gain of 2 is better than selecting sentence of 10 words with gain of 1. Scaling can potentially alleviate this mismatch (i.e., we can adjust r on development set). Interestingly, our theoretical analysis of the performance guarantee of the algorithm also gives us guidance about how to scale the cost for a particular problem (see Section 4.1).

4.1 Analysis of performance guarantee

Although Algorithm 1 is essentially a simple greedy strategy, we show that it solves Eqn. (3) globally and near-optimally, by exploiting the structure of submodularity. As far as we know, this is a new result for submodular optimization, not previously stated or published before.

Theorem 1. *For normalized monotone submodular function $f(\cdot)$, Algorithm 1 with $r = 1$ has a constant approximation factor as follows:*

$$f(G_f) \geq \left(1 - e^{-\frac{1}{2}}\right) f(S^*), \tag{5}$$

where S^* is an optimal solution.

Proof. See Appendix. □

Note that an α-approximation algorithm for an optimization problem is a polynomial-time algorithm that for *all* instances of the problem produces a solution whose value is within a factor of α of the value of the an optimal solution. So Theorem 1 basically states that the solution found by Algorithm 1 can be at least as good as $(1 - 1/\sqrt{e})f(S^*) \approx 0.39 f(S^*)$ even in the worst case. A constant approximation bound is good since it is true for all instances of the problem, and we always know how good the algorithm is guaranteed to be without any extra computation. For $r \neq 1$, we resort to instance-dependent bound where the approximation can be easily computed per problem instance.

Theorem 2. *With normalized monotone submodular $f(\cdot)$, for $i = 1, \ldots, |G|$, let v_i be the ith unit added into G and G_i is the set after adding v_i. When $0 \leq r \leq 1$,*

$$f(G_i) \geq \left(1 - \prod_{k=1}^{i}\left(1 - \frac{c_{v_k}^r}{\mathcal{B}^r |S^*|^{1-r}}\right)\right) f(S^*) \tag{6}$$

$$\geq \left(1 - \prod_{k=1}^{i}\left(1 - \frac{c_{v_k}^r}{\mathcal{B}^r |V|^{1-r}}\right)\right) f(S^*) \tag{7}$$

and when $r \geq 1$,

$$f(G_i) \geq \left(1 - \prod_{k=1}^{i}\left(1 - \left(\frac{c_{v_k}}{\mathcal{B}}\right)^r\right)\right) f(S^*). \tag{8}$$

Proof. See Appendix. □

Theorem 2 gives bounds for a specific instance of the problem. Eqn. (6) requires the size $|S^*|$, which is unknown, requiring us to estimate an upper bound of the cardinality of the optimal set S^*. Obviously, $|S^*| \leq |V|$, giving us Eqn. (7). A tighter upper bound is obtained, however, by sorting the costs. That is, let $c_{[1]}, c_{[2]}, \ldots, c_{[|V|]}$ be the sorted sequence of costs in nondecreasing order, giving $|S^*| < m$ where $\sum_{k=1}^{m-1} c_{[i]} \leq \mathcal{B}$ and $\sum_{k=1}^{m} c_{[i]} > \mathcal{B}$. In this case, the computation cost for the bound estimation is $O(|V| \log |V|)$, which is quite feasible.

Note that both Theorem 1 and 2 are for monotone submodular functions while our practical objective function, i.e. f_{MMR}, is not guaranteed everywhere monotone. However, our theoretical results still holds for f_{MMR} with high probability in practice. Intuitively, in summarization tasks, the summary is usually small compared to the ground set size ($|S| \ll |V|$). When $|S|$ is small, f_{MMR} is monotone and our theoretical results still hold. Precisely, assume that all edge weights are bounded: $w_{i,j} \in [0, 1]$ (which is the case for cosine similarity between non-negative vectors). Also assume that edges weights are independently identically distributed with mean μ, i.e. $\mathbb{E}(w_{i,j}) = \mu$. Given a budget $\mathcal{B}$, assume the maximum possible size of a solution is K. Let $\alpha = 2\lambda + 1$, and $\beta = 2K - 1$. Notice that $\beta \ll |V|$ for our summarization task. We have the following theorem:

Theorem 3. *Algorithm 1 solves the summarization problem near-optimally (i.e. Theorem 1 and Theorem 2 hold) with high probability of at least*

$$1 - \exp\left\{-\frac{2(|V| - (\alpha + 1)\beta)^2\mu^2}{|V| + (\alpha^2 - 1)\beta} + \ln K\right\}$$

Proof. Omitted due to space limitation. □

4.2 Related work

Algorithms for maximizing submodular function under budget constraint (Eqn. (3)) have been studied before. Krause (2005) generalized the work by Khuller et al.(1999) on budgeted maximum cover problem to the submodular framework, and showed a $\frac{1}{2}(1 - 1/e)$-approximation algorithm. The algorithm in (Krause and Guestrin, 2005) and (Khuller et al., 1999) is actually a special case of Algorithm 1 when $r = 1$, and Theorem 1 gives a better bound (i.e., $(1 - 1/\sqrt{e}) > \frac{1}{2}(1 - 1/e)$) in this case. There is also a greedy algorithm with partial enumerations (Sviridenko, 2004; Krause and Guestrin, 2005) factor $(1 - 1/e)$. This algorithm, however, is too computationally expensive and thus not practical for real world applications (the computation cost is $O(|V|^5)$ in general). When each unit has identical cost, the budget constraint reduces to cardinality constraint where a greedy algorithm is known to be a $(1-1/e)$-approximation algorithm (Nemhauser et al., 1978) which is the best that can be achieved in polynomial time (Feige, 1998) if P $\neq$ NP. Recent work (Takamura and Okumura, 2009) applied the maximum coverage problem to text summarization (without apparently being aware that their objective is submodular) and studied a similar algorithm to ours when $r = 1$ and for the non-penalized graph-cut function. This problem, however, is a special case of constrained submodular function maximization.

5 Experiments

We evaluated our approach on the data set of DUC'04 (2004) with the setting of task 2, which is a multi-document summarization task on English news articles. In this task, 50 document clusters are given, each of which consists of 10 documents. For each document cluster, a short multi-document summary is to be generated. The summary should not be longer than 665 bytes including spaces and punctuation, as required in the DUC'04 evaluation. We used DUC'03 as our development set. All documents were segmented into sentences using a script distributed by DUC. ROUGE version 1.5.5 (Lin, 2004), which is widely used in the study of summarization, was used to evaluate summarization performance in our experiments [1]. We focus on ROUGE-1 (unigram) F-measure scores since it has demonstrated strong correlation with human annotation (Lin, 2004).

The basic textual/linguistic units we consider in our experiments are sentences. For each document cluster, sentences in all the documents of this cluster forms the ground set V. We built semantic graphs for each document cluster based on cosine similarity, where cosine similarity is computed based on the TF-IDF (term frequency, inverse document frequency) vectors for the words in the sentences. The cosine similarity measures the similarity between sentences, i.e., $w_{i,j}$.

Here the IDF values were calculated using all the document clusters. The weighted graph was built by connecting vertices (corresponding to sentences) with weight $w_{i,j} > 0$. Any unconnected vertex was removed from the graph, which is equivalent to pre-excluding certain sentences from the summary.

5.1 Comparison with exact solution

In this section, we empirically show that Algorithm 1 works near-optimally in practice. To determine how much accuracy is lost due to approximations, we compared our approximation algorithms with an exact solution. The exact solutions were obtained by Integer Linear Programming (ILP). Solving arbitrary ILP is an NP-hard problem. If the size of the problem is not too large, we can sometimes find the exact solution within a manageable time

[1] Options used: -a -c 95 -b 665 -m -n 4 -w 1.2

using a branch-and-bound method. In our experiments, MOSEK was used as our ILP solver.

We formalize Eqn. (3) as an ILP by introducing indicator (binary) variables $x_{i,j}, y_{i,j}, i \neq j$ and z_i for $i, j \in V$. In particular, $z_i = 1$ indicates that unit i is selected, i.e., $i \in S$, $x_{i,j} = 1$ indicates that $i \in S$ but $j \notin S$, and $y_{i,j} = 1$ indicates both i and j are selected. Adding constraints to ensure a valid solution, we have the following ILP formulation for Eqn. (3) with objective function $f_{\text{MMR}}(S)$:

$$\max \sum_{i \neq j, i,j \in V} w_{i,j} x_{i,j} - \lambda \sum_{i \neq j, i,j \in V} w_{i,j} y_{i,j}$$

$$\text{subject to: } \sum_{i \in V} c_i z_i \leq \mathcal{B},$$

$$x_{i,j} - z_i \leq 0, x_{i,j} + z_j \leq 1, z_i - z_j - x_{i,j} \leq 0,$$

$$y_{i,j} - z_i \leq 0, y_{i,j} - z_j \leq 0, z_i + z_j - y_{i,j} \leq 1,$$

$$x_{i,j}, y_{i,j}, z_i \in \{0, 1\}, \forall i \neq j, i, j \in V$$

Note that the number of variables in the ILP formulation is $O(|V|^2)$. For a document cluster with hundreds of candidate textual units, the scale of the problem easily grows involving tens of thousands of variables, making the problem very expensive to solve. For instance, solving the ILP exactly on a document cluster with 182 sentences (as used in Figure 1) took about 17 hours while our Algorithm 1 finished in less than 0.01 seconds.

We tested both approximate and exact algorithms on DUC'03 data where 60 document clusters were used (30 TDT document clusters and 30 TREC document clusters), each of which contains 10 documents on average. The true approximation factor was computed by dividing the objective function value found by Algorithm 1 over the optimal objective function value (found by ILP). The average approximation factors over the 58 document clusters (ILP on 2 of the 60 document clusters failed to finish) are shown in Table 1, along with other statistics. On average Algorithm 1 finds a solution that is over 90% as good as the optimal solution for many different r values, which backs up our claim that the modified greedy algorithm solves the problem near-optimally, even occasionally optimally (Figure 1 shows one such example).

The higher objective function value does not always indicate higher ROUGE-1 score. Indeed, rather than directly optimizing ROUGE, we optimize a surrogate submodular function that indicates the quality of a summary. Optimality in the submodular function does not necessary indicate optimality in ROUGE score. Nevertheless, we will show that our approach outperforms several other approaches in terms of ROUGE. We note that ROUGE is itself a surrogate for true human-judged summary quality, it might possibly be that f_{MMR} is a still better surrogate — we do not consider this possibility further in this work, however.

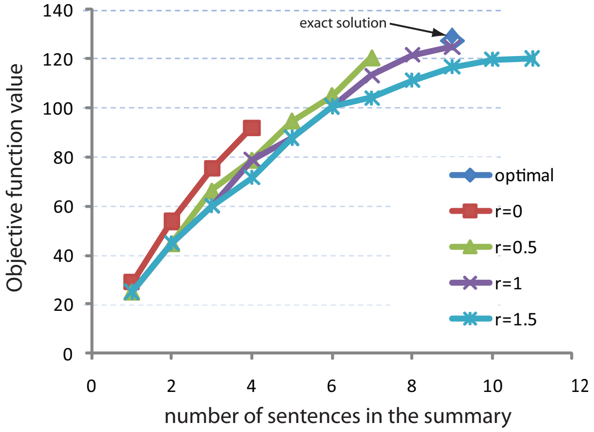

Figure 1: Application of Algorithm 1 when summarizing document cluster d30001t in the DUC'04 dataset with summary size limited to 665 bytes. The objective function was f_{MMR} with $\lambda = 2$. The plots show the achieved objective function as the number of selected sentences grows. The plots stop when in each case adding more sentences violates the budget. Algorithm 1 with $r = 1$ found the optimal solution exactly.

5.2 Summarization Results

We used DUC'03 (as above) for our development set to investigate how r and λ relate to the ROUGE-1 score. From Figure 2, the best performance is achieved with $r = 0.3, \lambda = 4$. Using these settings, we applied our approach to the DUC'04 task. The results, along with the results of other approaches, are shown in Table 2. All the results in Table 2 are presented as ROUGE-1 F-measure scores. [2]

We compared our approach to two other well-

[2] When the evaluation was done in 2004, ROUGE was still in revision 1.2.1, so we re-evaluated the DUC'04 submissions using ROUGE v1.5.5 and the numbers are slightly different from the those reported officially.

Table 1: Comparison of Algorithm 1 to exact algorithms on DUC'03 dataset. All the numbers shown in the table are the average statistics (mean/std). The "true" approximation factor is the ratio of objective function value found by Algorithm 1 over the ILP-derived true-optimal objective value, and the approximation bounds were estimated using Theorem 2.

	Approx. factor		ROUGE-1
	true	bound	(%)
exact	1.00	-	33.60/5.05
$r = 0.0$	0.65/0.15	$\geq$0.19/0.08	33.50/5.94
$r = 0.1$	0.71/0.15	$\geq$0.24/0.08	33.68/6.03
$r = 0.3$	0.88/0.11	$\geq$0.37/0.06	34.77/5.49
$r = 0.5$	0.96/0.04	$\geq$0.48/0.05	34.33/5.94
$r = 0.7$	0.98/0.02	$\geq$0.56/0.05	34.08/5.41
$r = 1.0$	0.98/0.02	$\geq$0.65/0.04	33.32/5.14
$r = 1.2$	0.97/0.02	$\geq$0.48/0.05	32.54/4.69

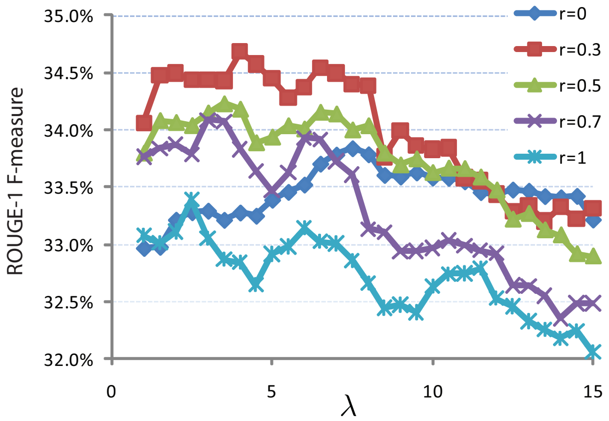

Figure 2: Different combinations of r and λ for f_{MMR} related to ROUGE-1 score on DUC'03 task 1.

known graph-based approaches, LexRank and PageRank. LexRank was one of the participating system in DUC'04, with peer code 104. For PageRank, we implemented the recursive graph-based ranking algorithm ourselves. The importance of sentences was estimated in an iterative way as in (Brin and Page, 1998)(Mihalcea et al., 2004). Sentences were then selected based on their importance rankings until the budget constraint was violated. The graphs used for PageRank were *exactly* the graphs in our submodular approaches (i.e., an undirected graph). In both cases, submodular summarization achieves better ROUGE-1 scores. The improvement is statistically significant by the Wilcoxon signed rank test at level $p < 0.05$. Our approach also outperforms the best system (Conroy et al., 2004), peer code 65 in the DUC'04 evaluation although not as significant ($p < 0.08$). The reason might be that DUC'03 is a poor representation of DUC'04 — indeed, by varying r and λ over the ranges $0 \leq r \leq 0.2$ and $5 \leq \lambda \leq 9$ respectively, the DUC'04 ROUGE-1 scores were all $> 38.8\%$ with the best DUC'04 score being 39.3%.

Table 2: ROUGE-1 F-measure results (%)

Method	ROUGE-1 score
peer65 (best system in DUC04)	37.94
peer104 (LexRank)	37.12
PageRank	35.37
Submodular ($r = 0.3, \lambda = 4$)	**38.39**

6 Appendix

We analyze the performance guarantee of Algorithm 1. We use the following notation: S^* is the optimal solution; G_f is the final solution obtained by Algorithm 1; G is the solution obtained by the greedy heuristic (line 1 to 7 in Algorithm 1); v_i is the ith unit added to G, $i = 1, \ldots, |G|$; G_i is the set obtained by greedy algorithm after adding v_i (i.e., $G_i = \cup_{k=1}^{i}\{v_k\}$, for $i = 1, \ldots, |G|$, with $G_0 = \emptyset$ and $G_{|G|} = G$); $f(\cdot) : 2^V \rightarrow \mathbb{R}$ is a monotone submodular function; and $\rho_k(S)$ is the gain of adding k to S, i.e., $f(S \cup \{k\}) - f(S)$.

Lemma 1. $\forall X, Y \subseteq V$,

$$f(X) \leq f(Y) + \sum_{k \in X \setminus Y} \rho_k(Y). \tag{9}$$

Proof. See (Nemhauser et al., 1978) □

Lemma 2. *For* $i = 1, \ldots, |G|$, *when* $0 \leq r \leq 1$,

$$f(S^*) - f(G_{i-1}) \leq \frac{\mathcal{B}^r |S^*|^{1-r}}{c^r_{v_i}} (f(G_i) - f(G_{i-1})), \tag{10}$$

and when $r \geq 1$,

$$f(S^*) - f(G_{i-1}) \leq \left(\frac{\mathcal{B}}{c_{v_i}}\right)^r (f(G_i) - f(G_{i-1})) \tag{11}$$

Proof. Based on line 4 of Algorithm 1, we have

$$\forall u \in S^* \setminus G_{i-1}, \frac{\rho_u(G_{i-1})}{c^r_u} \leq \frac{\rho_{v_i}(G_{i-1})}{c^r_{v_i}}.$$

Thus when $0 \leq r \leq 1$,

$$\begin{aligned}
\sum_{u \in S^* \setminus G_{i-1}} \rho_u(G_{i-1}) &\leq \frac{\rho_{v_i}(G_{i-1})}{c_{v_i}^r} \sum_{u \in S^* \setminus G_{i-1}} c_u^r \\
&\leq \frac{\rho_{v_i}(G_{i-1})}{c_{v_i}^r} |S^* \setminus G_{i-1}| \left(\frac{\sum_{u \in S^* \setminus G_{i-1}} c_u}{|S^* \setminus G_{i-1}|} \right)^r \\
&\leq \frac{\rho_{v_i}(G_{i-1})}{c_{v_i}^r} |S^*|^{1-r} \left(\sum_{u \in S^* \setminus G_{i-1}} c_u \right)^r \\
&\leq \frac{\rho_{v_i}(G_{i-1})}{c_{v_i}^r} |S^*|^{1-r} \mathcal{B}^r,
\end{aligned}$$

where the second inequality is due to the concavity of $g(x) = x^r, x > 0, 0 \leq r \leq 1$. The last inequality uses the fact that $\sum_{u \in S^*} c_u \leq \mathcal{B}$. Similarly, when $r \geq 1$,

$$\begin{aligned}
\sum_{u \in S^* \setminus G_{i-1}} \rho_u(G_{i-1}) &\leq \frac{\rho_{v_i}(G_{i-1})}{c_{v_i}^r} \sum_{u \in S^* \setminus G_{i-1}} c_u^r \\
&\leq \frac{\rho_{v_i}(G_{i-1})}{c_{v_i}^r} \left(\sum_{u \in S^* \setminus G_{i-1}} c_u \right)^r \\
&\leq \frac{\rho_{v_i}(G_{i-1})}{c_{v_i}^r} \mathcal{B}^r.
\end{aligned}$$

Applying Lemma 1, i.e., let $X = S^*$ and $Y = G_{i-1}$, the lemma immediately follows. □

The following is a proof of Theorem 2.

Proof. Obviously, the theorem is true when $i = 1$ by applying Lemma 2.

Assume that the theorem is true for $i-1, 2 \leq i \leq |G|$, we show that it also holds for i. When $0 \leq r \leq 1$,

$$\begin{aligned}
&f(G_i) = f(G_{i-1}) + (f(G_i) - f(G_{i-1})) \\
&\geq f(G_{i-1}) + \frac{c_{v_i}^r}{\mathcal{B}^r |S^*|^{1-r}} (f(S^*) - f(G_{i-1})) \\
&= \left(1 - \frac{c_{v_i}^r}{\mathcal{B}^r |S^*|^{1-r}}\right) f(G_{i-1}) + \frac{c_{v_i}^r}{\mathcal{B}^r |S^*|^{1-r}} f(S^*) \\
&\geq \left(1 - \frac{c_{v_i}^r}{\mathcal{B}^r |S^*|^{1-r}}\right) \left(1 - \prod_{k=1}^{i-1} \left(1 - \frac{c_{v_k}^r}{\mathcal{B}^r |S^*|^{1-r}}\right)\right) \\
&f(S^*) + \frac{c_{v_i}^r}{\mathcal{B}^r |S^*|^{1-r}} f(S^*) \\
&= \left(1 - \prod_{k=1}^{i} \left(1 - \frac{c_{v_k}^r}{\mathcal{B}^r |S^*|^{1-r}}\right)\right) f(S^*).
\end{aligned}$$

The case when $r \geq 1$ can be proven similarly. □

Now we are ready to prove Theorem 1.

Proof. Consider the following two cases:

Case 1: $\exists v \in V$ such that $f(\{v\}) > \frac{1}{2} f(S^*)$. Then it is guaranteed that $f(G_f) \geq f(\{v\})) > \frac{1}{2} f(S^*)$ due line 9 of Algorithm 1.

Case 2: $\forall v \in V$, we have $f(\{v\}) \leq \frac{1}{2} f(S^*)$. We consider the following two sub-cases, namely Case 2.1 and Case 2.2:

Case 2.1: If $\sum_{v \in G} c_v \leq \frac{1}{2}\mathcal{B}$, then we know that $\forall v \notin G, c_v > \frac{1}{2}\mathcal{B}$ since otherwise we can add a $v \notin G$ into G to increase the objective function value without violating the budget constraint. This implies that there is at most one unit in $S^* \setminus G$ since otherwise we will have $\sum_{v \in S^*} c_v > \mathcal{B}$. By assumption, we have $f(S^* \setminus G) \leq \frac{1}{2} f(S^*)$. Submodularity of $f(\cdot)$ gives us:

$$f(S^* \setminus G) + f(S^* \cap G) \geq f(S^*),$$

which implies $f(S^* \cap G) \geq \frac{1}{2} f(S^*)$. Thus we have

$$f(G_f) \geq f(G) \geq f(S^* \cap G) \geq \frac{1}{2} f(S^*),$$

where the second inequality follows from monotonicity.

Case 2.2: If $\sum_{v \in G} c_v > \frac{1}{2}\mathcal{B}$, for $0 \leq r \leq 1$, using Theorem 2, we have

$$\begin{aligned}
f(G) &\geq \left(1 - \prod_{k=1}^{|G|} \left(1 - \frac{c_{v_k}^r}{\mathcal{B}^r |S^*|^{1-r}}\right)\right) f(S^*) \\
&\geq \left(1 - \prod_{k=1}^{|G|} \left(1 - \frac{c_{v_k}^r |S^*|^{r-1}}{2^r \left(\sum_{k=1}^{|G|} c_{v_k}\right)^r}\right)\right) f(S^*) \\
&\geq \left(1 - \left(1 - \frac{|S^*|^{r-1}}{2^r |G|^r}\right)^{|G|}\right) f(S^*) \\
&\geq \left(1 - e^{-\frac{1}{2}\left(\frac{|S^*|}{2|G|}\right)^{r-1}}\right) f(S^*)
\end{aligned}$$

where the third inequality uses the fact (provable using Lagrange multipliers) that for $a_1, \ldots, a_n \in \mathbb{R}^+$ such that $\sum_{i=1}^n a_i = \alpha$, function

$$1 - \prod_{i=1}^{n} \left(1 - \frac{\beta a_i^r}{\alpha^r}\right)$$

achieves its minimum of $1 - (1 - \beta/n^r)^n$ when $a_1 = \cdots = a_n = \alpha/n$ for $\alpha, \beta > 0$. The last inequality follows from $e^{-x} \geq 1 - x$.

In all cases, we have

$$f(G_f) \geq \min\left\{\frac{1}{2}, 1 - e^{-\frac{1}{2}\left(\frac{|S^*|}{2|G|}\right)^{r-1}}\right\} f(S^*)$$

In particular, when $r = 1$, we obtain the constant approximation factor, i.e.

$$f(G_f) \geq \left(1 - e^{-\frac{1}{2}}\right) f(S^*)$$

Cross-lingual Induction of Selectional Preferences with Bilingual Vector Spaces

Abstract

We describe a cross-lingual method for the induction of selectional preferences for resource-poor languages, where no accurate monolingual models are available. The method uses bilingual vector spaces to "translate" foreign language predicate-argument structures into a resource-rich language like English. The only prerequisite for constructing the bilingual vector space is a large unparsed corpus in the resource-poor language, although the model can profit from (even noisy) syntactic knowledge. Our experiments show that the cross-lingual predictions correlate well with human ratings, clearly outperforming monolingual baseline models.

1 Introduction

Selectional preferences capture the empirical observation that not all words are equally good arguments to a given verb in a particular argument position (Wilks, 1975; Resnik, 1996). For instance, the subjects of the English verb *to shoot* are generally people, while the direct objects can be people or animals. This is reflected in speakers' intuitions. Table 1 shows that the combination *the hunter shot the deer* is judged more plausible than *the deer shot the hunter*. Selectional preferences do not only play an important role in human sentence processing (McRae et al., 1998), but are also helpful for NLP tasks like word sense disambiguation (McCarthy and Carroll, 2003) and semantic role labeling (Gildea and Jurafsky, 2002).

Computational models of selectional preferences predict such *plausibilities* for triples of a predicate p, an argument position a, and a head word h, such as (*shoot*,*object*,*hunter*). All recent models take a two-step approach: (1), they extract all triples (p, a, h) from a large corpus; (2), they apply some type of generalization to make predictions for unseen items. Clearly, the accuracy of these models relies crucially on the quality and coverage of the extracted triples, and thus on the syntactic analysis of the corpus. Unfortunately, corpora that are both large enough and have a very good syntactic analysis are only available for a handful of Western and Asian languages, which leaves all other languages without reliable selectional preference models.

Predicate	Relation	Noun	Plausibility
shoot	subject	hunter	6.9
shoot	object	hunter	2.8
shoot	subject	deer	1.0
shoot	object	deer	6.4

Table 1: Predicate-relation-noun triples with human plausibility judgments on a 7-point scale (McRae et al., 1998)

In this paper, we propose a cross-lingual knowledge transfer approach to this problem: We automatically *translate* triples (p, a, h) from resource-poor languages into English, where large and high-quality parsed corpora are available and we can compute a reliable plausibility estimate. The translations are extracted from a *bilingual semantic space*, which can be constructed via bootstrapping from large unparsed corpora in the two languages, without the need for parallel corpora or bilingual lexical resources.

Structure of the paper. Section 2 reviews models for selectional preferences. In Section 3, we describe our approach. Section 4 introduces our experimental setup, and Sections 5 and 6 present and discuss our experiments. Section 7 wraps up.

2 Selectional Preferences

The first broad-coverage model of selectional preferences was developed by Resnik (1996). To estimate the plausibility of a triple (p, a, h), Resnik first extracted all head words seen with predicate p in position a, $Seen_a(p)$, from a corpus. He then used the WordNet hierarchy to generalize over the head words and to create predictions for unseen ones. A number of studies has followed the same approach, exploring different ways of using the structure of WordNet (Abe and Li, 1996; Clark and Weir, 2002). While these approaches show good results, they can only make predictions for argument heads that are covered by WordNet. This is already a problem for English, and much more so in other languages, where comparable resources are often much smaller or entirely absent.

A promising alternative approach is to derive the generalizations from distributional information (Prescher et al., 2000; Padó et al., 2007; Bergsma et al., 2008). For example, the Padó et al. (2007) model computes vector space representations for all head words h and defines the plausibility of the triple (p, a, h) as a weighted mean of the vector space similarities between h and all h' in $Seen_a(p)$:

$$Pl(p, a, h) = \sum_{h' \in Seen_a(p)} \frac{w(h') \cdot sim(h, h')}{\sum_{h'} w(h')} \quad (1)$$

where $w(h')$ is a weight, typically frequency.

In this model, the generalization is provided by distributional similarity, which can be computed from a large corpus, without the need for additional lexical resources. Padó et al. found it to outperform Resnik's approach in an evaluation against human plausibility judgments. However, note that competitive results are only obtained by representing the head words in "syntactic" vector spaces whose dimensions consist of context words with their syntactic relation to the target rather than just context words. This is not surprising: Presumably, *hunter* and *deer* share a domain and are likely to have similar word-based context distributions, even though they differ with regard to their plausibility for particular predicate-argument positions. Only when the vector space can capture their different *syntactic* co-occurrence patterns can the model predict different plausibilities.

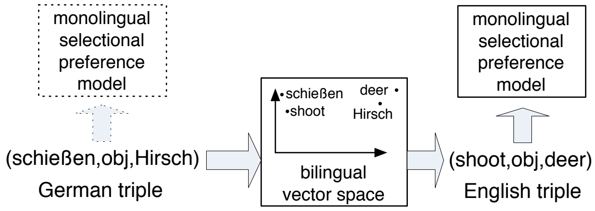

Figure 1: Predicting selectional preferences for a source language (e.g. German) by translating into a target language (e.g. English) with a bilingual vector space.

3 Cross-lingual selectional preferences

In order to compute reliable selectional preference representations, distributional models need to see at least some head words for each (p, a) combination. Manually annotated treebank corpora, which are becoming available for an increasing number of languages, are too small for this task. We therefore explore the idea of predicting the selectional preferences for such languages by taking advantage of large corpora with high-quality syntactic analyses in resource-rich languages like English. This idea falls into the general approach of *cross-lingual knowledge transfer* (see e.g. Hwa et al., 2005). The application to selectional preferences was suggested by Agirre et al. (2003), who demonstrated its feasibility by manual translation between Basque and English. We extend their experiments to an automatic model that predicts plausibility judgments in a resource-poor language (*source language*) by exploiting a model in a resource-rich language (*target language*).

Figure 1 sketches our method. We assume that there is not enough high-quality data to build a monolingual selectional preference model for the source language (shown by dotted lines). However, we can use a *bilingual vector space*, that is, a semantic space in which words of both the source and the target language are represented, to *translate* each source language word s into the target language by identifying its nearest (most similar) target word $tr(s)$:

$$tr(s) = \mathrm{argmax}_t \, sim(s, t) \quad (2)$$

Now we can use a target language selectional preference model to obtain plausibilities for source triples:

$$Pl^s(p, a, h) = Pl^t(tr(p), a, tr(h)) \quad (3)$$

where the superscript indicates the language.

Eq. (3) gives rise to three questions: (1), How can we construct the bilingual space to model *tr*? (2), Is translating actually the appropriate way of transferring selectional preferences? (3), Is it reasonable to retain the source language argument positions like *subject* or *object*? The following subsections discuss (1) and (2); we will address (3) in Sections 5 and 6.

3.1 Bilingual Vector Spaces

Bilingual vector spaces are vector spaces in which words from two languages are represented (cf. Fig. 2). The dimensions of this space are labeled with bilingual context word pairs (like *secretly/heimlich* and *rifle/Gewehr* for German–English) that are mutual translations. By treating such context word pairs as single dimensions, the vector space can represent target words from both languages, counting the target words' co-occurrences with the context words from the respective language. In other words, a source-target word pair (s, t) will be assigned similar vectors in the semantic space if the context words of s are translations of the context words of t. Cross-lingual semantic similarity between words can be measured using standard vector space similarity (Lee, 1999).

Importantly, bilingual vector spaces can be built on the basis of co-occurrences drawn from two unrelated corpora for the source and target languages. Their construction does not require resources such as parallel corpora or bilingual translation lexicons, which might not be available for resource-poor source languages. Where parallel corpora exist, they often cover specific domains (e.g., politics), while many bilingual lexicons are prone to ambiguity problems.

The main challenge in constructing bilingual vector spaces is determining the set of dimensions, i.e., bilingual word pairs, using as little knowledge as possible. Most often, such pairs are extracted from small bilingual lexicons (Fung and McKeown, 1997; Rapp, 1999; Chiao and Zweigenbaum, 2002). As mentioned above, such resources might not be available. We thus follow an alternative approach by using frequent *cognates*, words that are shared between the two languages (Markó et al., 2005). Cognates can be extracted by simple string matching between the corpora, and mostly share their meaning (Koehn and Knight, 2002). However, they account for (at most) a small percentage of all interesting translation pairs.

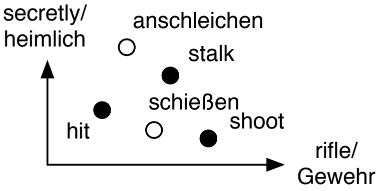

Figure 2: Sketch of a bilingual vector space for English (solid dots) and German (empty circles).

To extend the set of dimensions available for the bilingual space, we use these cognates merely as a starting point for a *bootstrapping process*: We build a bilingual vector space with the initial word pairs as dimensions, and identify nearest neighbors between the two languages in the space. These are added as dimensions of the bilingual space, and the process is repeated. Since the focus is on identifying reliable source-target word pairs rather than complete coverage as in Eq. (2), we adopt a *symmetrical* definition of translation that pairs up only mutual nearest neighbors, and allows words to remain untranslated:[1]

$$tr_{sym}(s) = t \text{ iff } tr(s) = t \text{ and } tr(t) = s \qquad (4)$$

From the second iteration onward, this process introduces dimensions that are not identical graphemes, such as *Kind–child* and *Geschwindigkeit–speed*, and is iterated until convergence. Since each word of either language can only participate in at most one dimension, dimensions acquired in later steps can correct wrong pairs from previous steps, like the "false friend" German *Kind* 'child' – English *kind*, which is part of the initial set of cognates.

3.2 Translation and Selectional Preferences

As Figure 1 shows, the easiest way of exploiting a bilingual semantic space is to identify for each source word the target language word with the highest semantic similarity. For example, in Figure 2, the best translation of German *schießen* is its English nearest neighbor, *shoot*. However, it is risky to rely on the single nearest neighbor – it might simply be wrong. Even if it is correct, *data sparsity* is an issue: The translations may be infrequent in the target language, or the two translations of p and h may form unlikely collocates for target language-internal reasons (like

[1] To avoid unreliable vectors, we also adopt only the 50% most frequent of the tr_{sym} pairs. Frequency is defined as the geometric mean of the two words' monolingual frequencies.

difference in register) that do not reflect plausibility. A third issue are monolingual semantic phenomena like *polysemy* and *idioms*: The implausible German triple *(schießen,obj,Brise)* will be judged as very plausible due to the English idiom *to shoot the breeze*.

A look at the broader neighborhood of *schießen* suggests that its second and third-best English neighbors, *hit*, and *stalk*, can be used to *smooth* plausibility estimates for *schießen*. Instead of translating source language words by their single nearest neighbor, we will take its k nearest neighbors into account. This is defensible also from a more fundamental point of view, which suggests that the cross-lingual transfer of selectional preferences does *not* require literal translation in order to work. First, ontological models like Resnik's assume that *synonymous* words behave similarly with respect to selectional preferences. Second, recent work by Chambers and Jurafsky (2009) has induced "narrative chains", i.e., likely sequences of events, by their use of similar head words. Thus, we expect that all k nearest neighbors of a source predicate s are *informative* for the selectional preferences of s (like *schießen*) as long as they are either synonyms of its literal translation (*shoot/hit*) or come from the same narrative chain (*stalk/kill/*. . .).

It is also clear that smoothing does not always equate better predictions. Closeness in a word-based vector space can also just reflect semantic association. For example, Spanish *tenista* 'tennis player' is highly associated with English *tennis*, but is a bad translation in terms of selectional preferences. We assume that this problem is more acute for nouns than for verbs: The context of verbs is dominated by their arguments, which is not true for nouns. Consequently, close nouns in vector space can differ widely in ontological type, while close verbs generally have one or more similar argument slots. In our model, we will thus consider several verb translations, but just the best head word translation. For details, see Section 5.

4 Experimental Setup

Our evaluation uses English as the target language and two source languages: German (as a very close neighbor of English) and Spanish (as a more distant one). Neither of these languages are really resource-poor, but they allow us to compare our cross-lingual model against monolingual models, to emulate different levels of "resource poorness" and to examine the model's learning curve.

Plausibility Data. For German, we used the plausibility judgments collected by Brockmann (2002). The dataset contains human judgments for ninety triples sampled from the manually annotated 1 million word TiGer corpus (Brants et al., 2002): ten verbs with three argument positions (subject [SUBJ], direct object [DOBJ], and oblique (prepositional) object [POBJ]) combined with three head words. Models are evaluated against such datasets by correlating predicted plausibilities with the (not normally distributed) human judgments using Spearman's ρ, a non-parametric rank-order correlation coefficient.

We constructed a similar 90-triple data set for Spanish by sampling triples from two Spanish corpora (see below) using Brockmann's (2002) criteria. Human judgments for the triples were collected through the Amazon Mechanical Turk (AMT) crowdsourcing platform (Snow et al., 2008). We asked native speakers of Spanish to rate the plausibility of a simple sentence with the relevant verb-argument combination on a five-point Likert scale, obtaining between 12 and 17 judgments for each triple. For each datapoint, we removed the single lowest and highest judgments and computed the mean. We assessed the reliability of our data by replicating Brockmann's experiment for German with our AMT setup. With a Spearman ρ of almost .90, our own judgments correlate very well with Brockmann's original data.

Monolingual Prior Work and Baselines. For German, Brockmann and Lapata (2003) evaluated ontology-based models trained on TiGer triples and the GermaNet ontology. The results in Table 2 show that while both models are able to predict the data significantly, neither of the models can predict all of the data. We attribute this to the small size of TiGer.[2]

To gauge the limits of monolingual knowledge-lean approaches, we constructed two monolingual distributional models for German and Spanish according to the Padó et al. (2007) model (Eq. (1)). Recall that this model performs generalization in a syntax-based vector space model. We computed vector spaces from dependency-parsed corpora for the

[2] For each of the three argument positions and "all", Brockmann and Lapata report the results for the best parametrization of the models, which explains the apparently inconsistent results.

two languages, using the 2,000 most frequent lemma-dependency relation pairs as dimensions and adopting the popular pointwise mutual information metric as co-occurrence statistic. For German, we used Schulte im Walde's verb frame resource (Schulte im Walde et al., 2001), which contains the frequency of triples calculated from probabilistic parses of 30M words from the Huge German Corpus (HGC) of newswire. For Spanish, we consulted two syntactically analyzed corpora: the AnCora (Taulé et al., 2008) and the Encarta corpus (Calvo et al., 2005). At 0.5M words, the AnCora corpus is small, but manually annotated, whereas the larger, automatically parsed Encarta corpus amounts to over 18M tokens.

Table 3 shows the results for the distributional monolingual models. For German, we get significant correlations for DOBJ and POBJ, an almost significant correlation for SUBJs, and high significance for the complete dataset ($p < 0.01$). These figures rival the performance of the ontological models (cf. Table 2), without using ontological information. For Spanish, the only significant correlation with human judgments is obtained for subjects, the most frequent argument position, with the clean AnCora data. AnCora is presumably too sparse for the other argument positions. The large Encarta corpus, in turn, is very noisy, supporting our concerns from Section 2.

	n	noun	adj	verb	all
German	7340	.61	.57	.43	.56
Spanish	4143	.62	.67	.41	.58

Table 4: First-translation accuracy for German-English and Spanish-English translation (n: size of gold standard).

Cross-lingual Selectional Preferences. Our architecture for the cross-lingual prediction of selectional preferences shown in Figure 1 consists of two components, namely the bilingual vector space and a selectional preference model in the target language.

As our English selectional preference model, we again use the Padó et al. (2007) model, trained on a version of the BNC parsed with MINIPAR (Lin, 1993). The parameters of the syntactic vector space were the same as for the monolingual baseline models. The bilingual vector spaces were constructed from three large, unparsed, comparable monolingual corpora. For German, we used the HGC described above. For Spanish, we obtained a corpus with around 100M words, consisting of 2.5 years of crawled text from two major Spanish newspapers. For English, we used the BNC.

We first constructed initial sets of bilingual labels. For German–English, we identified 1064 graphemically identical word pairs that occurred more than 4 times per million words. Due to the larger lexical distance between Spanish and English, there are fewer graphemically identical tokens for this language pair. We therefore applied a Porter stemmer and found 2104 identical stems, at a higher risk of "false friends". We then applied the bootstrapping cycle from Section 3.1. The set of dimensions converged after around five iterations.

We evaluated the (asymmetric) nearest neighbor pairs from the final spaces, $(s, tr(s))$, against two online dictionaries.[4] Table 4 shows that 55% to 60% of the pairs are listed in the dictionaries, with parallel tendencies for both language pairs. The bilingual space performs fairly well for nouns and adjectives, but badly for verbs, which is a well-known weakness of distributional models (Peirsman et al., 2008).

Even taking into account the incompleteness of dictionaries, this looks like a negative result: more

[3] Since the Encarta data consists of individual dependency relations rather than trees, we could not model the POBJ data.

[4] DE-EN: `www.dict.cc`; ES-EN: `www.freelang.net`. Pairs $(s, tr(s))$ were only evaluated if the dictionary listed s.

than half of all verb translations are incorrect. However, following up on our intuitions from Section 3.2, we performed an analysis of the "incorrect" translations. It revealed that many of the errors in Table 4 are informative, semantically related words. Nearest neighbor target language verbs in particular tend to represent the same event type and take the same kinds of arguments as the source verb. Examples are German *gefährden* 'threaten' – English *affect*, and German *Neugier* 'curiosity' – English *enthusiasm*. We concluded that literal translation quality is a misleading figure of merit for our task.

Experimental rationale. Section 3 introduced one major design decision of our model: the question of how to treat the *argument position*, which cannot be translated by the bilingual vector space, in the cross-lingual transfer. We present two experiments that investigate the model's behavior in the absence and presence of knowledge about argument positions. Experiment 1 uses no syntactic knowledge about the source language whatsoever. In this situation, the best we can do is to assume that source language argument positions like SUBJ will correspond to the same argument position in the target language. Experiment 2 attempts to identify, for each source language argument position, the "best fit" position in the target language. This results in better plausibility estimates, but also means that we need at least some syntactic information about the source language. In both experiments, we vary the number of translations we consider for each verb.

5 Exp. 1: Induction without syntactic knowledge in the source language

This experiment assumes that argument positions simply carry over between languages. While this assumption clearly simplifies linguistic reality, it has the advantage of not needing any syntactic information about the source language. We thus model German and Spanish SUBJ relations by English SUBJ relations and DOBJs by DOBJs. In the case of (lexicalized) POBJs, where we cannot assume identity, we compute plausibility scores for *all* English POBJs that account for at least 10% of the predicate's argument tokens, and select the PP with the highest plausibility estimate. The k best "translations" of the predicate p, $tr_k(p)$, are turned into a single prediction using maximization, yielding the final model:

$$Pl^s_{\text{nosyn}}(p, a, h) = \max_{p_t \in tr_k(p)} Pl^t(p_t, a, tr(h)) \quad (5)$$

Note that this model does not use any source language information, except the bilingual vector space.

The results of Experiment 1 are given in Table 5 (coverage always 100%). For German, all predictions correlate significantly with human ratings, and most even at $p < 0.01$, despite our naive assumption about the cross-lingual argument position identity. The results exceed both monolingual model types (ontological, Tab. 2, and distributional, Tab. 3), notably without the use of syntactic data. In particular, the results for the POBJs, notoriously difficult to model monolingually, are higher than for SUBJs or DOBJs. We attribute this to the cross-lingual generalization which takes all prepositional arguments into account.

The Spanish dataset is harder to model overall. We obtain significantly high correlations for SUBJ, but non-significant results for DOBJ and POBJ. This corresponds well to the patterns for the monolingual AnCora corpus (Table 3). However, we outperform AnCora on the complete dataset, where it did not achieve significance, while the cross-lingual model does at $p < 0.01$ — again, even without the use of syntactic analyses. We attribute the overall lower results compared to German to systematic syntactic differences between English and Spanish. For example, animate direct objects in Spanish are realized as POBJs headed by the preposition *a*. Estimating the plausibility of such objects by looking at English POBJs is unlikely to yield good results. The use of a larger number of verb translations yields a clear increase in correlation for the German data, but inconclusive results for Spanish.

6 Exp. 2: Induction with syntactic knowledge in the source language

As discussed in Section 3.2, verbs that are semantically similar in the bilingual vector space may very well realize their (semantic) argument positions differently in the surface syntax. For example, German *teilnehmen* is correctly translated to English *attend*, but the crucial event argument is realized differently, namely as a POBJ headed by *an* in German and as a DOBJ in English. To address this problem, we

learn a mapping function m that identifies the argument position a_t of a target language predicate p_t that corresponds best to an argument position a of a predicate p in the source language. Our simple model is in the same spirit as the cross-lingual plausibility model itself: It returns the argument position a_t of p_t for which the seen head words of (p, a) are most plausible when translated into the target language:[5]

$$m(p, a, p_t) = \operatorname*{argmax}_{a_t} \sum_{h \in Seen_a(p)} Pl^t(p_t, a_t, tr(h))$$

Parallel to Eq. (5), the cross-lingual model is now:

$$Pl^s_{\text{syn}}(p, a, h) = \max_{p_t \in tr_k(p)} Pl^t(p_t, m(p, a, p_t), tr(h)) \tag{6}$$

This model can recover English argument positions that correspond better to the original ones than the identity mapping. For example, on our data, it discovers the mapping for *teilnehmen an/attend* discussed above. A second example concerns the incorrect, but informative translation of *stagnieren* ‘stagnate’ as *boost*. Here the model recognizes that the SUBJ of *stagnieren* (the stagnating entity) corresponds to the DOBJ of *boost*.

Establishing m requires syntactic information in the source language, in order to obtain the set of seen head words $Seen_{a_s}(p_s)$. For this reason, Exp. 2 uses the parsed subset of the HGC (German), and the AnCora and Encarta corpora (Spanish). The results are shown in Table 6. We generally improve over Exp. 1. For German, every single model now correlates highly significantly with human judgments ($p < 0.01$), and the correlation for the complete dataset increases from .40 to .48. For Spanish, we see very good results for the AnCora corpus. Compared to Exp. 1, we see a slight degradation for the SUBJs; however, the correlations remain significant for all values of k. Conversely, all predictions for DOBJs are now significant,[6] and the POBJs have improved at least numerically, which validates our analysis of the problems in Exp. 1. The best correlation for the complete dataset improves from .36 to .47. The results for the Encarta corpus disappoint, though. SUBJs are significant, but worse than for AnCora, and the DOBJs remain non-significant throughout. With regard to increasing the number of verb translations, Exp. 2 shows an almost universal benefit for German, but still mixed results for Spanish, which may indicate that verb translations for Spanish are still “looser” than the German ones.

In fact, most remaining poor judgments are the result of problematic translations, which stem from three main sources. The first one is sparse data. Infrequent German and Spanish words often receive unreliable vector representations. Some examples are the

[5] To alleviate sparse data, we ignore argument positions of English verbs that represent less than 10% of its argument tokens.

[6] Note, however, that AnCora has an imperfect coverage for DOBJs (60%). This is because our Spanish dataset contains verbs sampled from Encarta that do not occur in AnCora.

German *Tau* ('dew', frequency of 180 in the HGC), translated as *alley*, and *Reifeprüfung* (German SAT, frequency 120), translated as *affiliation*. Both of these may also be due to the difference in genre between the HGC and the BNC. A second problem is formed by nearest neighbors that are ontologically dissimilar, as in the *tenista* 'tennis player'/*tennis* example from above. A final issue relates to limitations of the Padó et al. (2007) model, whose architecture is susceptible to polysemy-related problems. For instance, the Spanish combination (*excavar*, *obj*, *terreno*) was judged by speakers as very plausible, but its English equivalent (*excavate*, *obj*, *land*) is assigned a very low score by the model. This might be due to the fact that in the BNC, *land* occurs often in its political meaning, and forms an outlier among the head words for (*excavate*,*obj*).

How much syntactic information is necessary? The syntax-aware model requires syntactic information about the source language, which seems to run counter to our original motivation of developing methods for resource-poor languages. To address this point, we analyzed the behavior of the syntax-aware model for small syntactically analyzed corpora that contained only at most m occurrences for each predicate. We obtained the m occurrences by sampling from the syntactically analyzed part of the HGC; if fewer than m occurrences were present in the corpus, we simply used these. Figure 3 shows the training curve with 1 verb translation, averaged over n rounds ($n = 10$ for 5 arguments, $n = 5$ for 10 arguments, $n = 4$ for 20, 50 and 100 arguments). The general picture is clear: most of the benefit of the syntactic data is drawn form the first five occurrences for each argument position. This shows that a small amount of targeted syntactic annotation can improve the cross-lingual model substantially.

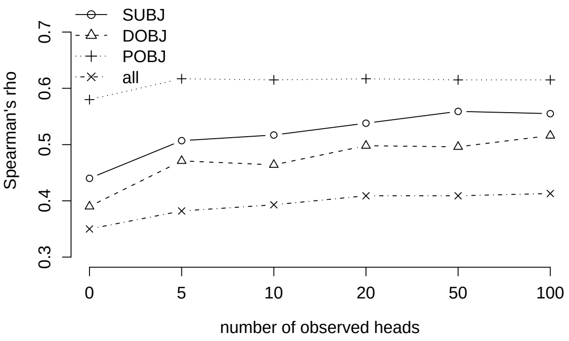

Figure 3: Training curve for the bilingual German–English model as a function of the number of observed head words per argument position in the source language.

7 Conclusions

In this article, we have presented a first unsupervised cross-lingual model of selectional preferences. Our model proceeds by automatically *translating* (predicate, argument position, head word) triples for resource-poor source languages into a resource-rich target language, where accurate selectional preference models are available. The translation is based on a bilingual vector space, which can be bootstrapped from large unparsed corpora in the two languages.

Our results indicate that bilingual methods can go a long way towards the modeling of selectional preferences in resource-poor languages, where bilingual lexicons, parallel corpora, or ontologies might not be available. Our experiments have looked at German and Spanish, where the cross-lingual models rival and even exceed monolingual methods that typically have to rely on small, clean "treebank"-style corpora or large, very noisy, automatically parsed corpora. We have also demonstrated that noisy syntactic data from the source language can be integrated in our model, where it helps improve the cross-lingual handling of argument positions. The linguistic distance between the languages can impact (1) the ability to find accurate translations and (2) the degree of syntactic overlap; nevertheless, as Agirre et al. (2003) show, the transfer is possible even for unrelated languages.

In this paper, we have instantiated the selectional preference model in the target language (English) with the distributional model by Padó et al. (2007). However, our approach is modular and can be combined with any other selectional preference model. We see two main avenues for future work: (1), The construction of properly bilingual models where source language information can also help to further improve the *target* language model (Diab and Resnik, 2002); (2), The extension of our cross-lingual mapping for the argument position to mappings that hold across multiple predicates as well as argument-dependent mappings like the Spanish direct objects, whose realization depends on their animacy.

Abstract

Datasets annotated with semantic roles are an important prerequisite to developing high-performance role labeling systems. Unfortunately, the reliance on manual annotations, which are both difficult and highly expensive to produce, presents a major obstacle to the widespread application of these systems across different languages and text genres. In this paper we describe a method for inducing the semantic roles of verbal arguments directly from unannotated text. We formulate the role induction problem as one of detecting alternations and finding a canonical syntactic form for them. Both steps are implemented in a novel probabilistic model, a latent-variable variant of the logistic classifier. Our method increases the purity of the induced role clusters by a wide margin over a strong baseline.

1 Introduction

Semantic role labeling (SRL, Gildea and Jurafsky 2002) is the task of automatically classifying the arguments of a predicate with roles such as *Agent*, *Patient* or *Location*. These labels capture aspects of the semantics of the relationship between the predicate and the argument while abstracting over surface syntactic configurations. SRL has received much attention in recent years (Surdeanu et al., 2008; Màrquez et al., 2008), partly because of its potential to improve applications that require broad coverage semantic processing. Examples include information extraction (Surdeanu et al., 2003), question answering (Shen and Lapata, 2007), summarization (Melli et al., 2005), and machine translation (Wu and Fung, 2009).

Given sentences (1-a) and (1-b) as input, an SRL system would have to identify the verb predicate (shown in boldface), its arguments (*Michael* and *sandwich*) and label them with semantic roles (*Agent* and *Patient*).

(1) a. [Michael]$_{Agent}$ **eats** [a sandwich]$_{Patient}$.
b. [A sandwich]$_{Patient}$ **is eaten** [by Michael]$_{Agent}$.

Here, sentence (1-b) is an alternation of (1-a). The verbal arguments bear the same semantic role, even though they appear in different syntactic positions: *sandwich* is the object of *eat* in sentence (1-a) and its subject in (1-b) but it is in both instances assigned the role *Patient*. The example illustrates the passive alternation. The latter is merely one type of alternation, many others exist (Levin, 1993), and their computational treatment is one of the main challenges faced by semantic role labelers.

Most SRL systems to date conceptualize semantic role labeling as a supervised learning problem and rely on role-annotated data for model training. PropBank (Palmer et al., 2005) has been widely used for the development of semantic role labelers as well as FrameNet (Fillmore et al., 2003). Under the PropBank annotation framework (which we will assume throughout this paper) each predicate is associated with a set of core roles (named $A0$, $A1$, $A2$, and so on) whose interpretations are specific to that predicate[1] and a set of adjunct roles (e.g., *Location* or *Time*) whose interpretation is common across predicates. In addition to large amounts of role-annotated data, SRL systems often make use of a parser to obtain syntactic analyses which subsequently serve as input to a pipeline of components concerned with

[1] More precisely, $A0$ and $A1$ have a common interpretation across predicates as *proto-agent* and *proto-patient* (Dowty, 1991).

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 939–947,
Los Angeles, California, June 2010.

identifying predicates and their arguments (argument identification) and labeling them with semantic roles (argument classification).

Supervised SRL methods deliver reasonably good performance (a system will recall around 81% of the arguments correctly and 95% of those will be assigned a correct semantic role; see Màrquez et al. 2008 for details). Unfortunately, the reliance on labeled training data, which is both difficult and highly expensive to produce, presents a major obstacle to the widespread application of semantic role labeling across different languages and text genres. And although corpora with semantic role annotations exist nowadays in other languages (e.g., German, Spanish, Catalan, Chinese, Korean), they tend to be smaller than their English equivalents and of limited value for modeling purposes. Moreover, the performance of supervised systems degrades considerably (by 10%) on out-of-domain data even within English, a language for which two major annotated corpora are available. Interestingly, Pradhan et al. (2008) find that the main reason for this are errors in the assignment of semantic roles, rather than the identification of argument boundaries. Therefore, a mechanism for inducing the semantic roles observed in the data without additional manual effort would enhance the robustness of existing SRL systems and enable their portability to languages for which annotations are unavailable or sparse.

In this paper we describe an unsupervised approach to argument classification or *role induction*[2] that does not make use of role-annotated data. Role induction can be naturally formalized as a clustering problem where argument instances are assigned to clusters. Ideally, each cluster should contain arguments corresponding to a specific semantic role and each role should correspond to exactly one cluster. A key insight in our approach is that many predicates are associated with a standard linking. A linking is a deterministic mapping from semantic roles onto syntactic functions such as *subject*, or *object*. Most predicates will exhibit a standard linking, i.e., they will be predominantly used with a specific mapping. Alternations occur when a different linking is used. In sentence (1-a) the predicate *eat* is used with its standard linking (the *Agent* role is mapped onto the *subject* function and the *Patient* onto the *object*), whereas in sentence (1-b) *eat* is used with its passive-linking (the *Patient* is mapped onto *subject* and the *Agent* appears as a prepositional phrase). When faced with such alternations, we will attempt to determine for each argument the syntactic function it would have had, had the standard linking been used. We will refer to this function as the arguments' *canonical function*, and use the term *canonicalization* to describe the process of inferring these canonical functions in the case of alternations. So, in sentence (1-b) the canonical functions of the arguments *by Michael* and *sandwich* are *subject* and *object*, respectively.

Since linkings are injective, i.e., no two semantic roles are mapped onto the same syntactic function, the canonical function of an argument uniquely references a specific semantic role. We define a probabilistic model for detecting non-standard linkings and for canonicalization. The model specifies a distribution $p(F)$ over the possible canonical functions F of an argument. We present an extension of the logistic classifier with the addition of latent variables which crucially allow to learn generalizations over varying syntactic configurations. Rather than using manually labeled data, we train our model on observed syntactic functions which can be obtained automatically from a parser. These training instances are admittedly noisy but readily available and as we show experimentally a useful data source for inducing semantic roles. Application of the model to a benchmark dataset yields improvements over a strong baseline.

2 Related Work

Much previous work on SRL relies on supervised learning methods for both argument identification and argument classification (see Màrquez et al. 2008 for an overview). Most systems use manually annotated resources to train separate classifiers for different SRL subtasks (e.g., Surdeanu et al. 2008). A few approaches adopt semi-supervised learning methods. The idea here is to to alleviate the data requirements for semantic role labeling by extending existing resources through the use of unlabeled data. Swier and Stevenson (2004) induce role labels with a bootstrapping scheme in which the set of labeled instances is iteratively expanded using a classifier trained on previously labeled instances. Padó and Lapata (2009) project role-semantic annotations from an annotated corpus in one language onto an unannotated corpus in another language. And Fürstenau and Lapata (2009) propose a method

[2] We use the term *role induction* rather than *argument classification* for the unsupervised setting.

in which annotations are projected from a source corpus onto a target corpus, however within the same language.

Unsupervised approaches to SRL have been few and far between. Early work on lexicon acquisition focuses on identifying verbal alternations rather than their linkings. This is often done in conjunction with hand-crafted resources such as a taxonomy of possible alternations (McCarthy and Korhonen, 1998) or WordNet (McCarthy, 2002). Lapata (1999) proposes a corpus-based method that is less reliant on taxonomic resources, however focuses only on two specific verb alternations. Other work attempts to cluster verbs into semantic classes (e.g., Levin 1993) on the basis of their alternation behavior (Schulte im Walde and Brew, 2002).

More recently, Abend et al. (2009) propose an unsupervised algorithm for argument identification that relies only on part-of-speech annotations, whereas Grenager and Manning (2006) focus on role induction which they formalize as probabilistic inference in a Bayesian network. Their model defines a joint probability distribution over the particular linking used together with a verb instance and for each verbal argument, its lemma, syntactic function as well as semantic role. Parameters in this model are estimated using the EM algorithm as the training instances include latent variables, namely the semantic roles and linkings. To make inference tractable they limit the set of linkings to a small number and do not distinguish between different types of adjuncts. Our own work also focuses on inducing the semantic roles and the linkings used by each verb. Our approach is conceptually simpler and computationally more tractable. Our model is a straightforward extension of the logistic classifier with latent variables applied to all roles not just coarse ones.

3 Problem Formulation

We treat role induction as a clustering problem. The goal is to assign argument instances (i.e., specific arguments, occurring in an input sentence) into clusters such that each cluster contains instances with the same semantic role, and each semantic role is found in exactly one cluster. As we assume PropBank-style roles (Palmer et al., 2005), our model will allocate a separate set of clusters for each predicate and assign the arguments of a specific predicate to one of the clusters associated with it.

As mentioned earlier (Section 1) a linking is a deterministic mapping from semantic roles onto syntactic functions. Table 1 shows how frequently individual semantic roles map onto certain syntactic functions. The frequencies were obtained from the CoNLL 2008 dataset (see Surdeanu et al. 2008 for details) and constitute an aggregate across predicates. As can be seen, there is a clear tendency for a semantic role to be mapped onto a single syntactic function. This is true across predicates and even more so for individual predicates. For example, A0 is commonly mapped onto subject (SBJ), whereas A1 is often realized as object (OBJ). There are two reasons for this. Firstly, a predicate is often associated with a standard linking which is most frequently used. Secondly, the alternate linkings of a given predicate often differ from the standard linking only with respect to a few roles. Importantly, we do not assume that a single standard linking is valid

Table 1: Contingency table between syntactic function and semantic role for two core roles *Agent* (A0) and *Patient* (A1) and two adjunct roles, *Time* (TMP) and *Manner* (MNR). Only syntactic functions occurring more than 1000 times are listed. Counts were obtained from the CoNLL 2008 training dataset using gold standard parses (the marginals in the bottom row also include counts of unlisted co-occurrences).

for all predicates. Rather, each predicate has its own standard linking. For example, in the standard linking for the predicate *fall*, A1 is mapped onto subject position, whereas in the standarad linking for *eat*, A1 is mapped onto object position.

When an argument is attested with a non-standard linking, we wish to determine the syntactic function it would have had if the standard linking had been used. This *canonical function* of the argument uniquely references a specific semantic role, i.e., the semantic role that is mapped onto the function under the standard linking. We can now specify an indirect method for partitioning argument instances into clusters:

1. Detect arguments that are linked in a non-standard way (detection).
2. Determine the canonical function of these arguments (canonicalization). For arguments with standard linkings, their syntactic function corresponds directly to the canonical function.
3. Assign arguments to a cluster according to their canonical function.

We distinguish between detecting non-standard linkings and canonicalization because in principle two separate models could be used. In our probabilistic formulation, both detection and canonicalization rely on an estimate of the probability distribution $p(F)$ over the canonical function F of an argument. When the most likely canonical function differs from the observed syntactic function this indicates that a non-standard linking has been used (detection). This most likely canonical function can be taken as the canonical function of the argument (canonicalization).

Arguments are assigned to clusters based on their inferred canonical function. Since we assume predicate-specific roles, we induce a separate cluster for each predicate. Given K clusters, we use the following scheme for determining the mapping from functions to clusters:

1. Order the functions by occurrence frequency.
2. For each of the $K-1$ most frequent functions allocate a separate cluster.
3. Assign all remaining functions to the K-th cluster.

4 Model

The detection of non-standard linkings and canonicalization both rely on a probabilistic model $p(F)$ which specifies the distribution over the canonical functions F of an argument. As is the case with most SRL approaches, we assume to be given a syntactic parse of the sentence from which we can extract labeled dependencies, corresponding to the syntactic functions of arguments. To train the model we exploit the fact that most observed syntactic functions will correspond to canonical functions. This enables us to use the parser's output for training even though it does not contain semantic role annotations.

Critically, the features used to determine the canonical function must be restricted so that they give no cues about possible alternations. If they would, the model could learn to predict alternations, and therefore produce output closer to the observed syntactic rather than canonical function of an argument. To avoid this pitfall we only use features at or below the node representing the argument head in the parse tree apart from the predicate lemma (see Section 5 for details).

Given these local argument features, a simple solution would be to use a standard classifier such as the logistic classifier (Berger et al., 1996) to learn the canonical function of arguments. However, this is problematic, because in our setting the training and application of the classifier happen on the same dataset. The model will over-adapt to the observed targets (i.e., the syntactic functions) and fail to learn appropriate canonical functions. Lexical sparsity is a contributing factor: the parameters associated with sparse lexical features will be unavoidably adjusted so that they are highly indicative of the syntactic function they occur with.

One way to improve generalization is to incorporate a layer of latent variables into the logistic classifier, which mediates between inputs (features defined over parse trees) and target (the canonical function). As a result, inputs and target are no longer directly connected and the information conveyed by the features about the target must be transferred via the latent layer. The model is shown in plate notation in Figure 1a. Here, X_i represents the observed input features, Y the observed target, and Z_j the latent variables. The number of latent variables influences the generalization properties of the model. With too few latent variables too little information will be transferred via the latent variables, whereas with too many latent variables generalization will degrade.

The model defines a probability distribution over the target variable Y and the latent variables Z, con-

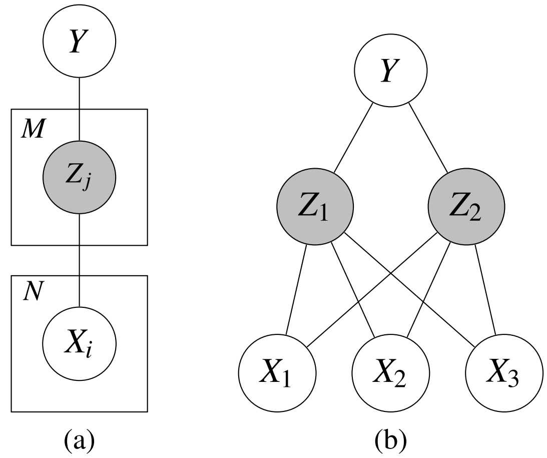

Figure 1: The logistic classifier with latent variables (shaded nodes) illustrated as a graphical model using (a) plate notation and (b) in unrolled form for $M = 2$ and $N = 3$.

ditional on the input variables X:

$$p(y,z|x,\theta) = \frac{1}{P(x,\theta)} \exp\left(\sum_k \theta_k \phi_k(x,y,z)\right) \tag{1}$$

We will assume that the latent variables Z_i are binary. Each of the feature functions ϕ_k is associated with a parameter θ_k. The partition function normalizes the distribution:

$$P(x,\theta) = \sum_y \sum_z \exp\left(\sum_k \theta_k \phi_k(x,y,z)\right) \tag{2}$$

Note that this model is a special case of a conditional random field with latent variables (Sutton and McCallum, 2007) and resembles a neural network with one hidden layer (Bishop, 2006).

Let (c,d) denote a training set of inputs and corresponding targets. The maximum-likelihood parameters can then be obtained by finding the θ maximizing:

$$\begin{aligned} l(\theta) &= \log p(d|c) \\ &= \textstyle\sum_i \log \sum_z p(d_i,z|c_i) \\ &= \textstyle\sum_i \log \frac{\sum_z \exp(\sum_k \theta_k \phi_k(c_i,d_i,z))}{P(c_i,\theta)} \end{aligned} \tag{3}$$

And the gradient is given by:

$$\begin{aligned} (\nabla l)_k &= \tfrac{\partial}{\partial \theta_k} l(\theta) \\ &= \textstyle\sum_i \sum_z p(z|d_i,c_i)\phi_k(c_i,d_i,z) \\ &\quad \textstyle -\sum_i \sum_{y,z} p(y,z|c_i)\phi_k(c_i,y,z) \end{aligned} \tag{4}$$

where the first term is the conditional expected feature count and the second term is the expected feature count.

Thus far, we have written the equations in a generic form for arbitrary conditional random fields with latent variables (Sutton and McCallum, 2007). In our model we have two types of pairwise sufficient statistics: $\beta(x,z) : \mathbb{R} \times \{0,1\} \rightarrow \mathbb{R}$, between a single input variable and a single latent variable, and $\gamma(y,z) : \mathcal{Y} \times \{0,1\} \rightarrow \mathbb{R}$, between the target and a latent variable. Then, we can more specifically write the gradient component of a parameter associated with a sufficient statistic $\beta(x_j,z_k)$ as:

$$\sum_i \sum_{z_k} p(z_k|d_i,c_i)\beta(c_{i,j},z_k) - \sum_i \sum_{z_k} p(z_k|c_i)\beta(c_{i,j},z_k) \tag{5}$$

And the gradient component of a parameter associated with a sufficient statistic $\gamma(y,z_k)$ is:

$$\sum_i \sum_{z_k} p(z_k|d_i,c_i)\gamma(d_i,z_k) - \sum_i \sum_{y,z_k} p(y,z_k|c_i)\gamma(y,z_k) \tag{6}$$

To obtain maximum-a-posteriori parameter estimates we regularize the equations. Like for the standard logistic classifier this results in an additional term of the target function and each component of the gradient (see Sutton and McCallum 2007). Computing the gradient requires computation of the marginals which can be performed efficiently using belief propagation (Yedidia et al., 2003). Note that due to the fact, that there are no edges between the latent variables, the inference graph is tree structured and therefore inference yields exact results. We use a stochastic gradient optimization method (Bottou, 2004) to optimize the target. Optimization is likely to result in a local maximum, as the likelihood function is not convex due to the latent variables.

5 Experimental Design

In this section we discuss the experimental design for assessing the performance of the model described above. We give details on the dataset, features and evaluation measures employed and present the baseline methods used for comparison with our model.

Figure 2: Dependency graph (simplified) of a sample sentence from the corpus.

Data Our experiments were carried out on the CoNLL 2008 (Surdeanu et al., 2008) training dataset which contains both verbal and nominal predicates. However, we focused solely on verbal predicates, following most previous work on semantic role labeling (Màrquez et al., 2008). The CoNLL dataset is taken form the Wall Street Journal portion of the Penn Treebank corpus (Marcus et al., 1993). Role semantic annotations are based on PropBank and have been converted from a constituent-based to a dependency-based representation (see Surdeanu et al. 2008). For each argument of a predicate only the head word is annotated with the corresponding semantic role, rather than the whole constituent. In this paper we are only concerned with role induction, not argument identification. Therefore, we identify the arguments of each predicate by consulting the gold standard.

The CoNLL dataset also supplies an automatic dependency parse of each input sentence obtained from the MaltParser (Nivre et al., 2007). The target and features used in our model are extracted from these parses. Syntactic functions occurring more than $1,000$ times in the gold standard are shown in Table 1 (for more details we refer the interested reader to Surdeanu et al. 2008). Syntactic functions were further modified to include prepositions if specified, resulting in a set of functions with which arguments can be distinguished more precisely. This was often the case with functions such as ADV, TMP, LOC, etc. Also, instead of using the preposition itself as the argument head, we used the actual content word modifying the preposition. We made no attempt to treat split arguments, namely instances where the semantic argument of a predicate has several syntactic heads. These are infrequent in the dataset, they make up for less than 1% of all arguments.

Model Setup The specific instantiation of the model used in our experiments has 10 latent variables. With 10 binary latent variables we can encode 1024 different target values, which seems reasonable for our set of syntactic functions which comprises around 350 elements.

Features representing argument instances were extracted from dependency parses like the one shown in Figure 2. We used a relatively small feature set consisting of: the predicate lemma, the argument lemma, the argument part-of-speech, the preposition involved in dependency between predicate and argument (if there is one), the lemma of left-most/right-most child of the argument, the part-of-speech of left-most/right-most child of argument, and a key formed by concatenating all syntactic functions of the argument's children. The features for the argument *maker* in Figure 2 are [*sell, maker, NN, –, the, auto, DT, NN, NMOD+NMOD*]. The target for this instance (and observed syntactic function) is SBJ.

Evaluation Evaluating the output of our model is no different from other clustering problems. We can therefore use well-known measures from the clustering literature to assess the quality of our role induction method. We first created a set of gold-standard role labeled argument instances which were obtained from the training partition of the CoNLL 2008 dataset (corresponding to sections 02–21 of PropBank). We used 10 clusters for each predicate and restricted the set of predicates to those attested with more than 20 instances. This rules out simple cases with only few instances relative to the number of clusters, which trivially yield high scores.

We compared the output of our method against the gold-standard using the following common measures. Let K denote the number of clusters, c_i the set of instances in the i-th cluster and g_j the set of instances having the j-th gold standard semantic role label. Cluster purity (PU) is defined as:

$$PU = \frac{1}{K} \sum_i \max_j |c_i \cap g_j| \qquad (7)$$

We also used cluster accuracy (CA, Equation 8),

	PU		CA		CP		CR		CF1	
	Mic	Mac	Mic	Mac	Mic	Mac	Mic	Mac	Mic	Mac
SyntFunc	73.2	75.8	82.0	80.9	67.6	65.3	55.7	50.1	61.1	56.7
LogLV	72.5	74.0	81.1	79.4	64.3	60.6	59.7	56.3	61.9	58.4
UpperBndS	94.7	96.1	96.9	97.0	97.4	97.6	90.4	100	93.7	93.8
UpperBndG	98.8	99.4	99.9	99.9	99.7	99.9	100	100	99.8	100

Table 2: Clustering results using our model (LogLV) against the baseline (SyntFunc) and upper bounds (UpperBndS and UpperBndG).

cluster precision (CP, Equation 9), and cluster recall (CR, Equation 9). Cluster F1 (CF1) is the harmonic mean of precision and recall.

$$CA = \frac{TP + TN}{TP + FP + TN + FN} \tag{8}$$

$$CP = \frac{TP}{TP + FP} \qquad CR = \frac{TP}{TP + FN} \tag{9}$$

Here TP is the number of *pairs of instances* which have the same role and are in the same cluster, TN is the number of pairs of instances which have different roles and are in different clusters, FP is the number of pairs of instances with different roles in the same cluster and FN the number of pairs of instances with the same role in different clusters.

Baselines and Upper Bound We compared our model against a baseline that assigns arguments to clusters based on their syntactic function. Here, no attempt is made to correct the roles of arguments in non-standard linkings. We would also like to compare our model against a supervised system. Unfortunately, this is not possible, as we are using the designated CoNLL training set as our test set, and any supervised system trained on this data would achieve unfairly high scores. Therefore, we approximate the performance of a supervised system by clustering instances according to their gold standard role after introducing some noise. Specifically, we randomly selected 5% of the gold standard roles and mapped them to an erroneous role. This roughly corresponds to the clustering which would be induced by a state-of-the-art supervised system with 95% precision. Finally, we also report the results of the true upper bound obtained by clustering the arguments, based on their gold standard semantic role (again using 10 clusters per verb).

6 Results

Our results are summarized in Table 2. We report cluster purity, accuracy, precision, recall, and F1 for our latent variable logistic classifier (LogLV) and a baseline that assigns arguments to clusters according to their syntactic function (SyntFunc). The table also includes the gold standard upper bound (UpperBndG) and its supervised proxy (UpperBndS). We report micro- and macro-average scores.[3]

Model scores are quite similar to the baseline, which might suggest that the model is simply replicating the observed data. However, this is not the case: canonical functions differ from observed functions for approximately 27% of the argument instances. If the baseline treated these instances correctly, we would expect it to outperform our model. The fact that it does not, indicates that the baseline error rate is higher precisely on these instances. In other words, the model can help in detecting alternate linkings and thus baseline errors.

We further analyzed our model's ability to detect alternate linkings. Specifically, if we assume a standard linking where model and observation agree and an alternate linking where they disagree, we obtain the following. The number of true positives (correctly detected alternate linkings) is 27,606, the number of false positives (incorrectly marked alternations) is 32,031, the number of true negatives (cases where the model correctly did not detect an alternate linking) is 132,556, and the number of false negatives (alternate linkings that the model should have detected but did not) is 32,516.[4]. The analysis shows that 46% of alternations (baseline errors) are detected.

[3] Micro-averages are computed over instances while macro-averages are computed over verbs.

[4] Note that the true/false positives/negatives here refer to alternate linkings, not to be confused with the true/false positives in equations (8) and (9).

	Mic	Mac	Mic	Mac	Mic	Mac	Mic	Mac	Mic	Mac
SyntFunct	73.9	77.8	82.1	81.3	68.0	66.5	55.9	50.3	61.4	57.3
LogLV	82.6	83.7	87.4	85.5	79.1	74.5	73.3	68.5	76.1	71.4

Table 3: Clustering results using our model to detect alternate linkings (LogLV) against the baseline (SyntFunc).

We can therefore increase cluster purity by clustering only those instances where the model does not indicate an alternation. The results are shown in Table 3. Using less instances while keeping the number of clusters the same will by itself tend to increase performance. To compensate for this, we also report results for the baseline on a reduced dataset. The latter was obtained from the original dataset by randomly removing the same number of instances.[5] By using the model to detect alternations, scores improve over the baseline across the board. We observe performance gains for purity which increases by 8.7% (micro-average; compare Tables 2 and 3). F1 also improves considerably by 13% (micro-average). These results are encouraging indicating that detecting alternate linkings is an important first step towards more accurate role induction.

We also conducted a more detailed error analysis to gain more insight into the behavior of our model. In most cases, alternate linkings where $A1$ occurs in subject position and $A0$ in object position are canonicalized correctly (with 96% and 97% precision, respectively). Half of the detected non-standard linkings involve adjunct roles. Here, the model has much more difficulty with canonicalization and is successful approximately 25% of the time. For example, in the phrase *occur at dawn* the model canonicalizes LOC to ADV, whereas TMP would be the correct function. About 75% of all false negatives are due to core roles and only 25% due to adjunct roles. Many false negatives are due to parser errors, which are reproduced by the model. This indicates overfitting, and indeed many of the false negatives involve infrequent lexical items (e.g., *juxtapose* or *Odyssey*).

Finally, to put our evaluation results into context, we also wanted to compare against Grenager and Manning's (2006) related system. A direct comparison is somewhat problematic due to the use of different datasets and the fact that we induce labels for *all* roles whereas they collapse adjunct roles to a single role. Nevertheless, we made a good-faith effort to evaluate our system using their evaluation setting. Specifically, we ran our system on the same test set, Section 23 of the Penn Treebank (annotated with PropBank roles), using gold standard parses with six clusters for each verb type. Our model achieves a cluster purity score of 90.3% on this dataset compared to 89.7% reported in Grenager and Manning.

7 Conclusions

In this paper we have presented a novel framework for unsupervised role induction. We conceptualized the induction problem as one of detecting alternate linkings and finding their canonical syntactic form, and formulated a novel probabilistic model that performs these tasks. The model extends the logistic classifier with latent variables and is trained on parsed output which is used as a noisy target for learning. Experimental results show promise, alternations can be successfully detected and the quality of the induced role clusters can be substantially enhanced.

We argue that the present model could be usefully employed to enhance the performance of other models. For example, it could be used in an active learning context to identify argument instances that are difficult to classify for a supervised or semi-supervised system and would presumably benefit from additional (manual) annotation. Importantly, the framework can incorporate different probabilistic models for detection and canonicalization which we intend to explore in the future. We also aim to embed and test our role induction method within a full SRL system that is also concerned with argument identification. Eventually, we also intend to replace the treebank-trained parser with a chunker.

[5] This was repeated several times to ensure that the results are stable across runs.

Abstract

This paper contributes a formalization of frame-semantic parsing as a structure prediction problem and describes an implemented parser that transforms an English sentence into a frame-semantic representation. It finds words that evoke FrameNet frames, selects frames for them, and locates the arguments for each frame. The system uses two feature-based, discriminative probabilistic (log-linear) models, one with latent variables to permit disambiguation of new predicate words. The parser is demonstrated to significantly outperform previously published results.

1 Introduction

FrameNet (Fillmore et al., 2003) is a rich linguistic resource containing considerable information about lexical and predicate-argument semantics in English. Grounded in the theory of frame semantics (Fillmore, 1982), it suggests—but does not formally define—a semantic representation that blends word-sense disambiguation and semantic role labeling.

In this paper, we present a computational and statistical model for frame-semantic parsing, the problem of extracting from text semantic predicate-argument structures such as those shown in Fig. 1. We aim to predict a frame-semantic representation as a *structure*, not as a pipeline of classifiers. We use a probabilistic framework that cleanly integrates the FrameNet lexicon and (currently very limited) available training data. Although our models often involve strong independence assumptions, the probabilistic framework we adopt is highly amenable to future extension through new features, relaxed independence assumptions, and semisupervised learning. Some novel aspects of our current approach include a latent-variable model that permits disambiguation of words not in the FrameNet lexicon, a unified model for finding and labeling arguments, and a precision-boosting constraint that forbids arguments of the same predicate to overlap. Our parser achieves the best published results to date on the SemEval'07 FrameNet task (Baker et al., 2007).

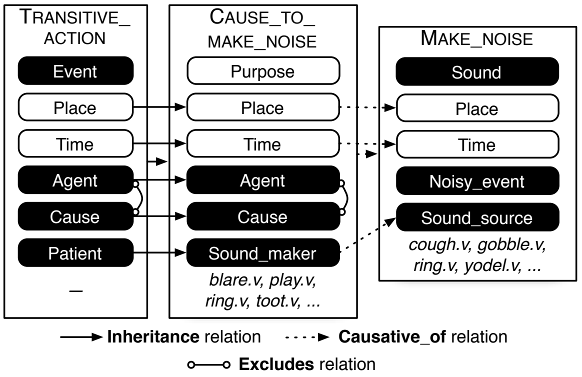

Figure 2. Partial illustration of frames, roles, and LUs related to the CAUSE_TO_MAKE_NOISE frame, from the FrameNet lexicon. "Core" roles are filled ovals. 8 additional roles of CAUSE_TO_MAKE_NOISE are not shown.

2 Resources and Task

We consider frame-semantic parsing resources.

2.1 FrameNet Lexicon

The FrameNet lexicon is a taxonomy of manually identified general-purpose **frames** for English.[1] Listed in the lexicon with each frame are several lemmas (with part of speech) that can denote the frame or some aspect of it—these are called **lexical units** (LUs). In a sentence, word or phrase tokens that evoke a frame are known as **targets**. The set of LUs listed for a frame in FrameNet may not be exhaustive; we may see a target in new data that does not correspond to an LU for the frame it evokes. Each frame definition also includes a set of frame elements, or **roles**, corresponding to different aspects of the concept represented by the frame, such as participants, props, and attributes. We use the term **ar-**

[1] Like the SemEval'07 participants, we used FrameNet v. 1.3 (http://framenet.icsi.berkeley.edu).

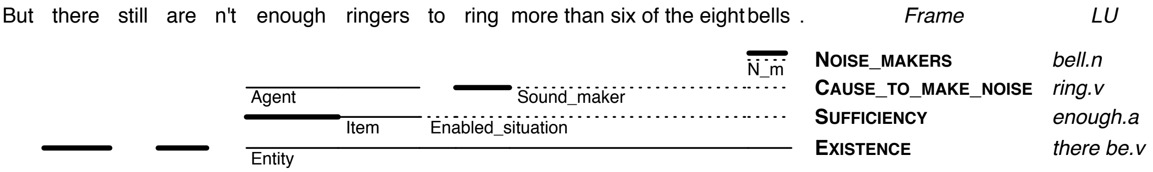

Figure 1. A sentence from PropBank and the SemEval'07 training data, and a partial depiction of gold FrameNet annotations. Each frame is a row below the sentence (ordered for readability). Thick lines indicate targets that evoke frames; thin solid/dotted lines with labels indicate arguments. "N_m" under *bells* is short for the Noise_maker role of the NOISE_MAKERS frame. The last row indicates that *there... are* is a discontinuous target. In PropBank, the verb *ring* is the only annotated predicate for this sentence, and it is not related to other predicates with similar meanings.

Table 2. Snapshot of the SemEval'07 annotated data.

gument to refer to a sequence of word tokens annotated as filling a frame role. Fig. 1 shows an example sentence from the training data with annotated targets, LUs, frames, and role-argument pairs. The FrameNet lexicon also provides information about relations between frames and between roles (e.g., INHERITANCE). Fig. 2 shows a subset of the relations between three frames and their roles.

Accompanying most frame definitions in the FrameNet lexicon is a set of lexicographic **exemplar sentences** (primarily from the British National Corpus) annotated for that frame. Typically chosen to illustrate variation in argument realization patterns for the frame in question, these sentences only contain annotations for a single frame. We found that using exemplar sentences directly to train our models hurt performance as evaluated on SemEval'07 data, even though the number of exemplar sentences is an order of magnitude larger than the number of sentences in our training set (§2.2). This is presumably because the exemplars are neither representative as a sample nor similar to the test data. Instead, we make use of these exemplars in features (§4.2).

2.2 Data

Our training, development, and test sets consist of documents annotated with frame-semantic structures for the SemEval'07 task, which we refer to collectively as the **SemEval'07 data**.[2] For the most part, the frames and roles used in annotating these documents were defined in the FrameNet lexicon, but there are some exceptions for which the annotators defined supplementary frames and roles; these are included in the possible output of our parser.

Table 2 provides a snapshot of the SemEval'07 data. We randomly selected three documents from the original SemEval training data to create a development set for tuning model hyperparameters. Notice that the test set contains more annotations per word, both in terms of frames and arguments. Moreover, there are many more out-of-lexicon frame, role, and LU types in the test set than in the training set. This inconsistency in the data results in poor recall scores for all models trained on the given data split, a problem we have not sought to address here.

[2] http://framenet.icsi.berkeley.edu/semeval/FSSE.html

Preprocessing. We preprocess sentences in our dataset with a standard set of annotations: POS tags from MXPOST (Ratnaparkhi, 1996) and dependency parses from the MST parser (McDonald et al., 2005) since manual syntactic parses are not available for most of the FrameNet-annotated documents. We used WordNet (Fellbaum, 1998) for lemmatization. We also labeled each verb in the data as having ACTIVE or PASSIVE voice, using code from the SRL system described by Johansson and Nugues (2008).

2.3 Task and Evaluation

Automatic annotations of frame-semantic structure can be broken into three parts: (1) *targets*, the words or phrases that evoke frames; (2) the *frame type*, defined in the lexicon, evoked by each target; and (3) the *arguments*, or spans of words that serve to fill roles defined by each evoked frame. These correspond to the three subtasks in our parser, each described and evaluated in turn: target identification (§3), frame identification (§4, not unlike word-sense disambiguation), and argument identification (§5, not unlike semantic role labeling).

The standard evaluation script from the SemEval'07 shared task calculates precision, recall, and F_1-measure for frames and arguments; it also provides a score that gives partial credit for hypothesizing a frame related to the correct one. We present precision, recall, and F_1-measure microaveraged across the test documents, report *labels-only* matching scores (spans must match exactly), and do not use named entity labels. More details can be found in Baker et al. (2007). For our experiments, statistical significance is measured using a reimplementation of Dan Bikel's randomized parsing evaluation comparator.[3]

2.4 Baseline

A strong baseline for frame-semantic parsing is the system presented by Johansson and Nugues (2007, hereafter J&N'07), the best system in the SemEval'07 shared task. For frame identification, they used an SVM classifier to disambiguate frames for known frame-evoking words. They used WordNet synsets to extend the vocabulary of frame-evoking words to cover unknown words, and then used a collection of separate SVM classifiers—one for each frame—to predict a single evoked frame for each occurrence of a word in the extended set.

TARGET IDENTIFICATION	P	R	F_1
Our technique (§3)	**89.92**	**70.79**	**79.21**
Baseline: J&N'07	*87.87*	*67.11*	*76.10*

Table 3. Target identification results for our system and the baseline. Scores in bold denote significant improvements over the baseline ($p < 0.05$).

J&N'07 modeled the argument identification problem by dividing it into two tasks: first, they classified candidate spans as to whether they were arguments or not; then they assigned roles to those that were identified as arguments. Both phases used SVMs. Thus, their formulation of the problem involves a multitude of classifiers—whereas ours uses two log-linear models, each with a single set of weights, to find a full frame-semantic parse.

3 Target Identification

Target identification is the problem of deciding which word tokens (or word token sequences) evoke frames in a given sentence. In other semantic role labeling schemes (e.g. PropBank), simple part-of-speech criteria typically distinguish predicates from non-predicates. But in frame semantics, verbs, nouns, adjectives, and even prepositions can evoke frames under certain conditions. One complication is that semantically-impoverished **support predicates** (such as *make* in *make a request*) do not evoke frames in the context of a frame-evoking, syntactially-dependent noun (*request*). Furthermore, only temporal, locative, and directional senses of prepositions evoke frames.

We found that, because the test set is more completely annotated—that is, it boasts far more frames per token than the training data (see Table 2)—learned models did not generalize well and achieved poor test recall. Instead, we followed J&N'07 in using a small set of rules to identify targets.

For a span to be a candidate target, it must appear (up to morphological variation) as a target in the training data or the lexicon. We consider multiword targets,[4] unlike J&N'07 (though we do not consider

[3] `http://www.cis.upenn.edu/~dbikel/software.html#comparator`

[4] There are 629 multiword LUs in the lexicon, and they correspond to 4.8% of the targets in the training set; among them are *screw up*.V, *shoot the breeze*.V, and *weapon of mass de-*

discontinuous targets). Using rules from §3.1.1 of J&N'07, we further prune the list, with two modifications: we prune *all* prepositions, including locative, temporal, and directional ones, but do not prune support verbs. This is a conservative approach; our automatic target identifier will never propose a target that was not seen in the training data or FrameNet.

Results. Table 3 shows results on target identification; our system gains 3 F_1 points over the baseline.

4 Frame Identification

Given targets, the parser next identifies their frames.

4.1 Lexical units

FrameNet specifies a great deal of structural information both within and among frames. For frame identification we make use of frame-evoking **lexical units**, the (lemmatized and POS-tagged) words and phrases listed in the lexicon as referring to specific frames. For example, listed with the BRAGGING frame are 10 LUs, including *boast*.N, *boast*.V, *boastful*.A, *brag*.V, and *braggart*.N. Of course, due to polysemy and homonymy, the same LU may be associated with multiple frames; for example, *gobble*.V is listed under both the INGESTION and MAKE_NOISE frames. All targets in the exemplar sentences, and most in our training and test data, correspond to known LUs (see Table 2).

To incorporate frame-evoking expressions found in the training data but not the lexicon—and to avoid the possibility of lemmatization errors—our frame identification model will incorporate, via a latent variable, features based directly on exemplar and training **targets** rather than LUs. Let $\mathcal{L}$ be the set of (unlemmatized and automatically POS-tagged) targets found in the exemplar sentences of the lexicon and/or the sentences in our training set. Let $\mathcal{L}_f \subseteq \mathcal{L}$ be the subset of these targets annotated as evoking a particular frame f. Let $\mathcal{L}^l$ and $\mathcal{L}^l_f$ denote the lemmatized versions of $\mathcal{L}$ and $\mathcal{L}_f$ respectively. Then, we write *boasted*.VBD $\in \mathcal{L}_{\text{BRAGGING}}$ and *boast*.VBD $\in \mathcal{L}^l_{\text{BRAGGING}}$ to indicate that this inflected verb *boasted* and its lemma *boast* have been seen to evoke the BRAGGING frame. Significantly, however, another target, such as *toot your own horn*, might be used in other data to evoke this frame. We thus face the additional hurdle of predicting frames for unknown words.

The SemEval annotators created 47 new frames not present in the lexicon, out of which 14 belonged to our training set. We considered these with the 795 frames in the lexicon when parsing new data. Predicting new frames is a challenge not yet attempted to our knowledge (including here). Note that the scoring metric (§2.3) gives partial credit for *related* frames (e.g., a more general frame from the lexicon).

4.2 Model

For a given sentence $\mathbf{x}$ with frame-evoking targets $\mathbf{t}$, let t_i denote the ith target (a word sequence). Let t^l_i denote its lemma. We seek a list $\mathbf{f} = \langle f_1, \ldots, f_m \rangle$ of frames, one per target. In our model, the set of candidate frames for t_i is defined to include every frame f such that $t^l_i \in \mathcal{L}^l_f$—or if $t^l_i \not\in \mathcal{L}^l$, then every known frame (the latter condition applies for 4.7% of the gold targets in the development set). In both cases, we let $\mathcal{F}_i$ be the set of candidate frames for the ith target in $\mathbf{x}$.

To allow frame identification for targets whose lemmas were seen in neither the exemplars nor the training data, our model includes an additional variable, ℓ_i. This variable ranges over the seen targets in $\mathcal{L}_{f_i}$, which can be thought of as **prototypes** for the expression of the frame. Importantly, frames are *predicted*, but prototypes are summed over via the latent variable. The prediction rule requires a probabilistic model over frames for a target:

$$f_i \leftarrow \operatorname{argmax}_{f \in \mathcal{F}_i} \textstyle\sum_{\ell \in \mathcal{L}_f} p(f, \ell \mid t_i, \mathbf{x}) \tag{1}$$

struction.N. In the SemEval'07 training data, there are just 99 discontinuous multiword targets (1% of all targets).

We adopt a conditional log-linear model: for $f \in \mathcal{F}_i$ and $\ell \in \mathcal{L}_f$, $p_{\boldsymbol{\theta}}(f, \ell \mid t_i, \mathbf{x}) =$

$$\frac{\exp \boldsymbol{\theta}^\top \mathbf{g}(f, \ell, t_i, \mathbf{x})}{\sum_{f' \in \mathcal{F}_i} \sum_{\ell' \in \mathcal{L}_{f'}} \exp \boldsymbol{\theta}^\top \mathbf{g}(f', \ell', t_i, \mathbf{x})} \quad (2)$$

where $\boldsymbol{\theta}$ are the model weights, and $\mathbf{g}$ is a vector-valued feature function. This discriminative formulation is very flexible, allowing for a variety of (possibly overlapping) features; e.g., a feature might relate a frame type to a prototype, represent a lexical-semantic relationship between a prototype and a target, or encode part of the syntax of the sentence.

Previous work has exploited WordNet for better coverage during frame identification (Johansson and Nugues, 2007; Burchardt et al., 2005, e.g., by expanding the set of targets using synsets), and others have sought to extend the lexicon itself (see §6). We differ in our use of a latent variable to incorporate lexical-semantic *features* in a discriminative model, relating known lexical units to unknown words that may evoke frames. Here we are able to take advantage of the large inventory of partially-annotated exemplar sentences.

Note that this model makes a strong independence assumption: each frame is predicted independently of all others in the document. In this way the model is similar to J&N'07. However, ours is a single conditional model that shares features and weights across all targets, frames, and prototypes, whereas the approach of J&N'07 consists of many separately trained models. Moreover, our model is unique in that it uses a latent variable to smooth over frames for unknown or ambiguous LUs.

Frame identification features depend on the preprocessed sentence $\mathbf{x}$, the prototype ℓ and its WordNet lexical-semantic relationship with the target t_i, and of course the frame f. Our model instantiates 662,020 binary features; see Das et al. (2010).

4.3 Training

Given the training subset of the SemEval'07 data, which is of the form $\left\langle \langle \mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{f}^{(j)}, \mathcal{A}^{(j)} \rangle \right\rangle_{j=1}^{N}$ ($N = 1663$ is the number of sentences), we discriminatively train the frame identification model by maximizing the following log-likelihood:[5]

$$\max_{\boldsymbol{\theta}} \sum_{j=1}^{N} \sum_{i=1}^{m_j} \log \sum_{\ell \in \mathcal{L}_{f_i^{(j)}}} p_{\boldsymbol{\theta}}(f_i^{(j)}, \ell \mid t_i^{(j)}, \mathbf{x}^{(j)}) \quad (3)$$

Note that the training problem is non-convex because of the summed-out prototype latent variable ℓ for each frame. To calculate the objective function, we need to cope with a sum over frames and prototypes for each target (see Eq. 2), often an expensive operation. We locally optimize the function using a distributed implementation of L-BFGS. This is the most expensive model that we train: with 100 CPUs, training takes several hours. (Decoding takes only a few minutes on one CPU for the test set.)

4.4 Results

We evaluate the performance of our frame identification model given gold-standard targets and automatically identified targets (§3); see Table 4.

Given gold-standard targets, our model is able to predict frames for lemmas not seen in training, of which there are 210. The partial-match evaluation gives our model some credit for 190 of these, 4 of which are exactly correct. The hidden variable model, then, is finding related (but rarely exact) frames for unknown target words. The net effect of our conservative target identifier on F_1 is actually positive: the frame identifier is far more precise for targets seen explicitly in training. Together, our target and frame identification outperform the baseline by 4 F_1 points. To compare the frame identification stage in isolation with that of J&N'07, we ran our frame identification model with the targets identified by their system as input. With partial matching, our model achieves a relative improvement of 0.6% F_1 over J&N'07 (though this is not significant).

While our frame identification model thus performs on par with the current state of the art for this task, it improves upon J&N's formulation of the problem because it requires only a single model, learns lexical-semantic features as part of that model rather than requiring a preprocessing step to expand the vocabulary of frame-evoking words, and is probabilistic, which can facilitate global reasoning.

5 Argument Identification

Given a sentence $\mathbf{x} = \langle x_1, \ldots, x_n \rangle$, the set of targets $\mathbf{t} = \langle t_1, \ldots, t_m \rangle$, and a list of evoked frames

[5] We found no benefit on development data from using an L_2 regularizer (zero-mean Gaussian prior).

$\mathbf{f} = \langle f_1, \ldots, f_m \rangle$ corresponding to each target, argument identification is the task of choosing which of each f_i's roles are filled, and by which parts of $\mathbf{x}$. This task is most similar to the problem of semantic role labeling, but uses frame-specific labels that are richer than the PropBank annotations.

5.1 Model

Let $\mathcal{R}_{f_i} = \{r_1, \ldots, r_{|\mathcal{R}_{f_i}|}\}$ denote frame f_i's **roles** (named frame element types) observed in an exemplar sentence and/or our training set. A subset of each frame's roles are marked as **core** roles; these roles are conceptually and/or syntactically necessary for any given use of the frame, though they need not be overt in every sentence involving the frame. These are roughly analogous to the core arguments A0–A5 and AA in PropBank. Non-core roles—analogous to the various AMs in PropBank—loosely correspond to syntactic adjuncts, and carry broadly-applicable information such as the time, place, or purpose of an event. The lexicon imposes some additional structure on roles, including relations to other roles in the same or related frames, and semantic types with respect to a small ontology (marking, for instance, that the entity filling the protagonist role must be sentient for frames of cognition). Fig. 2 illustrates some of the structural elements comprising the frame lexicon by considering the CAUSE_TO_MAKE_NOISE frame.

We identify a set $\mathcal{S}$ of spans that are candidates for filling any role $r \in \mathcal{R}_{f_i}$. In principle, $\mathcal{S}$ could contain any subsequence of $\mathbf{x}$, but in this work we only consider the set of contiguous spans that (a) contain a single word or (b) comprise a valid subtree of a word and all its descendants in the dependency parse produced by the MST parser. This covers 81% of arguments in the development data. The empty span is also included in $\mathcal{S}$, since some roles are not explicitly filled; in the development data, the average number of roles an evoked frame defines is 6.7, but the average number of overt arguments is only 1.7.[6] In training, if a labeled argument is not a valid subtree of the dependency parse, we add its span to $\mathcal{S}$.

Let $\mathcal{A}_i$ denote the mapping of roles in $\mathcal{R}_{f_i}$ to spans in $\mathcal{S}$. Our model makes a prediction for each $\mathcal{A}_i(r_k)$ (for all roles $r_k \in \mathcal{R}_{f_i}$) using:

$$\mathcal{A}_i(r_k) \leftarrow \text{argmax}_{s \in \mathcal{S}}\, p(s \mid r_k, f_i, t_i, \mathbf{x}) \tag{4}$$

We use a conditional log-linear model over spans for each role of each evoked frame:

$$p_{\boldsymbol{\psi}}(\mathcal{A}_i(r_k) = s \mid f_i, t_i, \mathbf{x}) = \frac{\exp \boldsymbol{\psi}^\top \mathbf{h}(s, r_k, f_i, t_i, \mathbf{x})}{\sum_{s' \in \mathcal{S}} \exp \boldsymbol{\psi}^\top \mathbf{h}(s', r_k, f_i, t_i, \mathbf{x})} \tag{5}$$

Note that our model chooses the span for each role separately from the other roles and ignores all frames except the frame the role belongs to. Our model departs from the traditional SRL literature by modeling the argument identification problem in a single stage, rather than first classifying token spans as arguments and then labeling them. A constraint implicit in our formulation restricts each role to have at most one overt argument, which is consistent with 96.5% of the role instances in the training data.

Out of the overt argument spans in the training data, 12% are duplicates, having been used by some previous frame in the sentence (supposing some arbitrary ordering of frames). Our role-filling model, unlike a sentence-global argument detection-and-classification approach,[7] permits this sort of argument sharing among frames. The incidence of span *overlap* among frames is much higher; Fig. 1 illustrates a case with a high degree of overlap. Word tokens belong to an average of 1.6 argument spans each, including the quarter of words that do not belong to any argument.

Features for our log-linear model (Eq. 5) depend on the preprocessed sentence $\mathbf{x}$; the target t; a role r of frame f; and a candidate argument span $s \in \mathcal{S}$. Our model includes lexicalized and unlexicalized features considering aspects of the syntactic parse (most notably the dependency path in the parse from the target to the argument); voice; word ordering/overlap/distance of the argument with respect to the target; and POS tags within and around the argument. Many features have a version specific to the frame and role, plus a smoothed version incorporating the role name, but not the frame. These features

[6] In the annotated data, each core role is filled with one of three types of *null instantiations* indicating how the role is conveyed implicitly. E.g., the imperative construction implicitly designates a role as filled by the addressee, and the corresponding filler is thus CNI (constructional null instantiation). In this work we do not distinguish different types of null instantiations.

[7] J&N'07, like us, identify arguments for each target.

are fully enumerated in (Das et al., 2010); instantiating them for our data yields 1,297,857 parameters.

5.2 Training

We train the argument identification model by:

$$\max_{\boldsymbol{\psi}} \sum_{j=1}^{N} \sum_{i=1}^{m_j} \sum_{k=1}^{|\mathcal{R}_{f_i^{(j)}}|} \log p_{\boldsymbol{\psi}}(\mathcal{A}_i^{(j)}(r_k) \mid f_i^{(j)}, t_i^{(j)}, \mathbf{x}^{(j)}) \tag{6}$$

This objective function is concave, and we globally optimize it using stochastic gradient ascent (Bottou, 2004). We train this model until the argument identification F_1 score stops increasing on the development data. Best results on this dataset were obtained with a batch size of 2 and 23 passes through the data.

5.3 Approximate Joint Decoding

Naïve prediction of roles using Eq. 4 may result in overlap among arguments filling different roles of a frame, since the argument identification model fills each role independently of the others. We want to enforce the constraint that two roles of a single frame cannot be filled by overlapping spans. We disallow illegal overlap using a 10000-hypothesis beam search; the algorithm is given in (Das et al., 2010).

5.4 Results

Performance of the argument identification model is presented in Table 5. The table shows how performance varies given different types of perfect input: correct targets, correct frames, and the set of correct spans; correct targets and frames, with the heuristically-constructed set of candidate spans; correct targets only, with model frames; and ultimately, no oracle input (the full frame parsing scenario).

The first four rows of results isolate the argument identification task from the frame identification task. Given gold targets and frames and an oracle set of argument spans, our local model achieves about 87% precision and 75% recall. Beam search decoding to eliminate illegal argument assignments within a frame (§5.3) further improves precision by about 1.6%, with negligible harm to recall. Note that 96.5% recall is possible under the constraint that roles are not multiply-filled (§5.1); there is thus considerable room for improvement with this constraint in place. Joint prediction of each frame's arguments is worth exploring to capture correlations not encoded in our local models or joint decoding scheme.

The 15-point drop in recall when the heuristically-built candidate argument set replaces the set of true argument spans is unsurprising: an estimated 19% of correct arguments are excluded because they are neither single words nor complete subtrees (see §5.1). Qualitatively, the problem of candidate span recall seems to be largely due to syntactic parse errors.[8] Still, the 10-point decrease in precision when using the syntactic parse to determine candidate spans suggests that the model has trouble discriminating between good and bad arguments, and that additional feature engineering or jointly decoding arguments of a sentence's frames may be beneficial in this regard.

The fifth and sixth rows show the effect of automatic frame identification on overall frame parsing performance. There is a 22% decrease in F_1 (18% when partial credit is given for related frames), suggesting that improved frame identification or joint prediction of frames and arguments is likely to have a sizeable impact on overall performance.

The final two rows of the table compare our full model (target, frame, and argument identification) with the baseline, showing significant improvement of more than 4.4 F_1 points for both exact and partial frame matching. As with frame identification, we compared the argument identification stage with that of J&N'07 in isolation, using the automatically identified targets and frames from the latter as input to our model. With partial frame matching, this gave us an F_1 score of 48.1% on the test set—significantly better ($p < 0.05$) than 45.6%, the full parsing result from J&N'07. This indicates that our argument identification model—which uses a single discriminative model with a large number of features for role filling (rather than argument labeling)—is more powerful than the previous state of the art.

6 Related work

Since Gildea and Jurafsky (2002) pioneered statistical semantic role labeling, a great deal of com-

[8] Note that, because of our labels-only evaluation scheme (§2.3), arguments missing a word or containing an extra word receive no credit. In fact, of the frame roles correctly predicted as having an overt span, the correct span was predicted 66% of the time, while 10% of the time the predicted starting and ending boundaries of the span were off by a total of 1 or 2 words.

putational work has investigated predicate-argument structures for semantics. Briefly, we highlight some relevant work, particularly research that has made use of FrameNet. (Note that much related research has focused on PropBank (Kingsbury and Palmer, 2002), a set of shallow predicate-argument annotations for *Wall Street Journal* articles from the Penn Treebank (Marcus et al., 1993); a recent issue of *CL* (Màrquez et al., 2008) was devoted to the subject.)

Most work on frame-semantic role labeling has made use of the exemplar sentences in the FrameNet corpus (see §2.1), each of which is annotated for a single frame and its arguments. On the probabilistic modeling front, Gildea and Jurafsky (2002) presented a discriminative model for arguments given the frame; Thompson et al. (2003) used a generative model for both the frame and its arguments; and Fleischman et al. (2003) first used maximum entropy models to find and label arguments given the frame. Shi and Mihalcea (2004) developed a rule-based system to predict frames and their arguments in text, and Erk and Padó (2006) introduced the Shalmaneser tool, which employs Naïve Bayes classifiers to do the same. Other FrameNet SRL systems (Giuglea and Moschitti, 2006, for instance) have used SVMs. Most of this work was done on an older, smaller version of FrameNet.

Recent work on frame-semantic *parsing*—in which sentences may contain multiple frames to be recognized along with their arguments—has used the SemEval'07 data (Baker et al., 2007). The LTH system of Johansson and Nugues (2007), our baseline (§2.4), performed the best in the SemEval'07 task. Matsubayashi et al. (2009) trained a log-linear model on the SemEval'07 data to evaluate argument identification features exploiting various types of taxonomic relations to generalize over roles. A line of work has sought to extend the coverage of FrameNet by exploiting VerbNet, WordNet, and Wikipedia (Shi and Mihalcea, 2005; Giuglea and Moschitti, 2006; Pennacchiotti et al., 2008; Tonelli and Giuliano, 2009), and projecting entries and annotations within and across languages (Boas, 2002; Fung and Chen, 2004; Padó and Lapata, 2005; Fürstenau and Lapata, 2009). Others have applied frame-semantic structures to question answering, paraphrase/entailment recognition, and information extraction (Narayanan and Harabagiu, 2004; Shen and Lapata, 2007; Padó and Erk, 2005; Burchardt, 2006; Moschitti et al., 2003; Surdeanu et al., 2003).

7 Conclusion

We have provided a supervised model for rich frame-semantic parsing, based on a combination of knowledge from FrameNet, two probabilistic models trained on SemEval'07 data, and expedient heuristics. Our system achieves improvements over the state of the art at each stage of processing and collectively, and is amenable to future extension. Our parser is available for download at `http://www.ark.cs.cmu.edu/SEMAFOR`.

Abstract

This paper presents efficient algorithms for expected similarity maximization, which coincides with minimum Bayes decoding for a similarity-based loss function. Our algorithms are designed for similarity functions that are sequence kernels in a general class of positive definite symmetric kernels. We discuss both a general algorithm and a more efficient algorithm applicable in a common unambiguous scenario. We also describe the application of our algorithms to machine translation and report the results of experiments with several translation data sets which demonstrate a substantial speed-up. In particular, our results show a speed-up by two orders of magnitude with respect to the original method of Tromble et al. (2008) and by a factor of 3 or more even with respect to an approximate algorithm specifically designed for that task. These results open the path for the exploration of more appropriate or optimal kernels for the specific tasks considered.

1 Introduction

The output of many complex natural language processing systems such as information extraction, speech recognition, or machine translation systems is a probabilistic automaton. Exploiting the full information provided by this probabilistic automaton can lead to more accurate results than just using the one-best sequence.

Different techniques have been explored in the past to take advantage of the full lattice, some based on the use of a more complex model applied to the automaton as in rescoring, others using additional data or information for reranking the hypotheses represented by the automaton. One method for using these probabilistic automata that has been successful in large-vocabulary speech recognition (Goel and Byrne, 2000) and machine translation (Kumar and Byrne, 2004; Tromble et al., 2008) applications and that requires no additional data or other complex models is the minimum Bayes risk (MBR) decoding technique. This returns that sequence of the automaton having the minimum expected loss with respect to all sequences accepted by the automaton (Bickel and Doksum, 2001). Often, minimizing the loss function L can be equivalently viewed as maximizing a similarity function K between sequences, which corresponds to a kernel function when it is positive definite symmetric (Berg et al., 1984). The technique can then be thought of as an *expected sequence similarity maximization*.

This paper considers this expected similarity maximization view. Since different similarity functions can be used within this framework, one may wish to select the one that is the most appropriate or relevant to the task considered. However, a crucial requirement for this choice to be realistic is to ensure that for the family of similarity functions considered the expected similarity maximization is efficiently computable. Thus, we primarily focus on this algorithmic problem in this paper, leaving it to future work to study the question of determining how to select the similarity function and report on the benefits of this choice.

A general family of sequence kernels including the sequence kernels used in computational biology, text categorization, spoken-dialog classification, and many other tasks is that of *rational kernels* (Cortes et al., 2004). We show how the expected similarity maximization can be efficiently computed for these kernels. In section 3, we describe more specifically the framework of expected similarity maximization in the case of rational kernels and the corresponding algorithmic problem. In Section 4, we describe both a general method for the computation of the expected similarity maximization, and a more efficient method that can be used with a broad sub-family of rational kernels that verify a condition of non-ambiguity. This latter family includes the class of n-gram kernels which have been previously used to

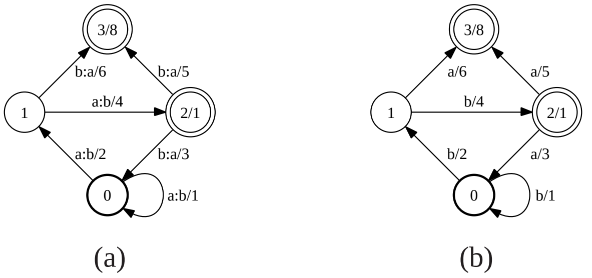
apply MBR to machine translation (Tromble et al., 2008). We examine in more detail the use and application of our algorithms to machine translation in Section 5. Section 6 reports the results of experiments applying our algorithms in several large data sets in machine translation. These experiments demonstrate the efficiency of our algorithm which is shown empirically to be two orders of magnitude faster than Tromble et al. (2008) and more than 3 times faster than even an approximation algorithm specifically designed for this problem (Kumar et al., 2009). We start with some preliminary definitions and algorithms related to weighted automata and transducers, following the definitions and terminology of Cortes et al. (2004).



(a) (b)

Figure 1: (a) Example of weighted transducer T over the real semiring $(\mathbb{R}_+, +, \times, 0, 1)$. (b) Example of weighted automaton A. A can be obtained from T by projection on the output and $T(aab, bba) = A(bba) = 1 \times 2 \times 6 \times 8 + 2 \times 4 \times 5 \times 8$.

2 Preliminaries

Weighted transducers are finite-state transducers in which each transition carries some weight in addition to the input and output labels. The weight set has the structure of a semiring.

A *semiring* $(\mathbb{K}, \oplus, \otimes, \overline{0}, \overline{1})$ verifies all the axioms of a ring except from the existence of a negative element $-x$ for each $x \in \mathbb{K}$, which it may verify or not. Thus, roughly speaking, a semiring is a ring that may lack negation. It is specified by a set of values $\mathbb{K}$, two binary operations $\oplus$ and $\otimes$, and two designated values $\overline{0}$ and $\overline{1}$. When $\otimes$ is commutative, the semiring is said to be *commutative*.

The *real semiring* $(\mathbb{R}_+, +, \times, 0, 1)$ is used when the weights represent probabilities. The *log semiring* $(\mathbb{R} \cup \{-\infty, +\infty\}, \oplus_{\log}, +, \infty, 0)$ is isomorphic to the real semiring via the negative-$\log$ mapping and is often used in practice for numerical stability. The *tropical semiring* $(\mathbb{R}\cup, \{-\infty, +\infty\}, \min, +, \infty, 0)$ is derived from the log semiring via the *Viterbi approximation* and is often used in shortest-path applications.

Figure 1(a) shows an example of a weighted finite-state transducer over the real semiring $(\mathbb{R}_+, +, \times, 0, 1)$. In this figure, the input and output labels of a transition are separated by a colon delimiter and the weight is indicated after the slash separator. A weighted transducer has a set of initial states represented in the figure by a bold circle and a set of final states, represented by double circles. A path from an initial state to a final state is an accepting path.

The weight of an accepting path is obtained by first $\otimes$-multiplying the weights of its constituent transitions and $\otimes$-multiplying this product on the left by the weight of the initial state of the path (which equals $\overline{1}$ in our work) and on the right by the weight of the final state of the path (displayed after the slash in the figure). The weight associated by a weighted transducer T to a pair of strings $(x, y) \in \Sigma^* \times \Sigma^*$ is denoted by $T(x, y)$ and is obtained by $\oplus$-summing the weights of all accepting paths with input label x and output label y.

For any transducer T, T^{-1} denotes its *inverse*, that is the transducer obtained from T by swapping the input and output labels of each transition. For all $x, y \in \Sigma^*$, we have $T^{-1}(x, y) = T(y, x)$.

The *composition* of two weighted transducers T_1 and T_2 with matching input and output alphabets Σ, is a weighted transducer denoted by $T_1 \circ T_2$ when the semiring is commutative and the sum:

$$(T_1 \circ T_2)(x, y) = \sum_{z \in \Sigma^*} T_1(x, z) \otimes T_2(z, y) \quad (1)$$

is well-defined and in $\mathbb{K}$ for all x, y (Salomaa and Soittola, 1978).

Weighted automata can be defined as weighted transducers A with identical input and output labels, for any transition. Since only pairs of the form (x, x) can have a non-zero weight associated to them by A, we denote the weight associated by A to (x, x) by $A(x)$ and call it the *weight associated by A to x*. Similarly, in the graph representation of weighted automata, the output (or input) label is omitted. Figure 1(b) shows an example of a weighted automaton. When A and B are weighted automata, $A \circ B$ is called the *intersection* of A and B. Omitting the input labels of a weighted transducer T results in a weighted automaton which is said to be the *output projection of* T.

3 General Framework

Let X be a probabilistic automaton representing the output of a complex model for a specific query input. The model may be for example a speech recognition system, an information extraction system, or a machine translation system (which originally motivated our study). For machine translation, the sequences accepted by X are the potential translations of the input sentence, each with some probability given by X.

Let Σ be the alphabet for the task considered, e.g., words of the target language in machine translation, and let $L\colon \Sigma^* \times \Sigma^* \to \mathbb{R}$ denote a loss function defined over the sequences on that alphabet. Given a reference or hypothesis set $H \subseteq \Sigma^*$, minimum Bayes risk (MBR) decoding consists of selecting a hypothesis $x \in H$ with minimum expected loss with respect to the probability distribution X (Bickel and Doksum, 2001; Tromble et al., 2008):

$$\widehat{x} = \operatorname*{argmin}_{x \in H} \operatorname*{E}_{x' \sim X}[L(x, x')]. \tag{2}$$

Here, we shall consider the case, frequent in practice, where minimizing the loss L is equivalent to maximizing a similarity measure $K\colon \Sigma^* \times \Sigma^* \to \mathbb{R}$. When K is a sequence kernel that can be represented by weighted transducers, it is a *rational kernel* (Cortes et al., 2004). The problem is then equivalent to the following *expected similarity maximization*:

$$\widehat{x} = \operatorname*{argmax}_{x \in H} \operatorname*{E}_{x' \sim X}[K(x, x')]. \tag{3}$$

When K is a positive definite symmetric rational kernel, it can often be rewritten as $K(x, y) = (T \circ T^{-1})(x, y)$, where T is a weighted transducer over the semiring $(\mathbb{R}_+ \cup \{+\infty\}, +, \times, 0, 1)$. Equation (3) can then be rewritten as

$$\widehat{x} = \operatorname*{argmax}_{x \in H} \operatorname*{E}_{x' \sim X}[(T \circ T^{-1})(x, x')] \tag{4}$$

$$= \operatorname*{argmax}_{x \in H} \|A(x) \circ T \circ T^{-1} \circ X\|, \tag{5}$$

where we denote by $A(x)$ an automaton accepting (only) the string x and by $\|\cdot\|$ the sum of the weights of all accepted paths of a transducer.

4 Algorithms

4.1 General method

Equation (5) could suggest computing $A(x) \circ T \circ T^{-1} \circ X$ for each possible $x \in H$. Instead, we can compute a composition based on an automaton accepting all sequences in H, $A(H)$. This leads to a straightforward method for determining the sequence maximizing the expected similarity having the following steps:

1. compute the composition $X \circ T$, project on the output and optimize (epsilon-remove, determinize, minimize (Mohri, 2009)) and let Y_2 be the result;[1]
2. compute the composition $Y_1 = A(H) \circ T$;
3. compute $Y_1 \circ Y_2$ and project on the input, let Z be the result;[2]
4. determinize Z;
5. find the maximum weight path with the label of that path giving $\widehat{x}$.

While this method can be efficient in various scenarios, in some instances the weighted determinization yielding Z can be both space- and time-consuming, even though the input is acyclic. The next two sections describe more efficient algorithms.

Note that in practice, for numerical stability, all of these computations are done in the log semiring which is isomorphic to $(\mathbb{R}_+ \cup \{+\infty\}, +, \times, 0, 1)$. In particular, the maximum weight path in the last step is then obtained by using a standard single-source shortest-path algorithm.

4.2 Efficient method for n-gram kernels

A common family of rational kernels is the family of n-gram kernels. These kernels are widely use as a similarity measure in natural language processing and computational biology applications, see (Leslie et al., 2002; Lodhi et al., 2002) for instance.

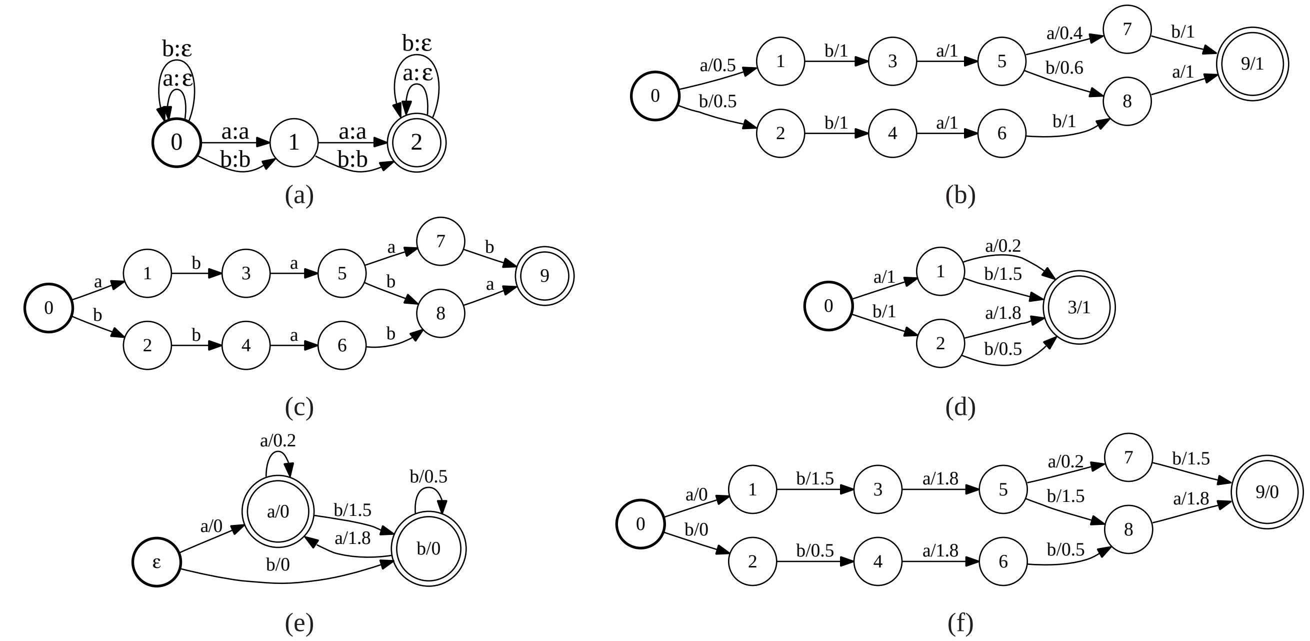
The n-gram kernel K_n of order n is defined as

$$K_n(x, y) = \sum_{|z|=n} c_x(z) c_y(z), \tag{6}$$

where $c_x(z)$ is the number of occurrences of z in x. K_n is a positive definite symmetric rational kernel since it corresponds to the weighted transducer $T_n \circ T_n^{-1}$ where the transducer T_n is defined such that $T_n(x, z) = c_x(z)$ for all $x, z \in \Sigma^*$ with $|z| = n$.

[1] Equivalent to computing $T^{-1} \circ X$ and projecting on the input.

[2] Z is then the projection on the input of $A(H) \circ T \circ T^{-1} \circ X$.



(a) (b) (c) (d) (e) (f)

Figure 2: Efficient method for bigram kernel: (a) Counting transducer T_2 for $\Sigma = \{a, b\}$ (over the real semiring). (b) Probabilistic automaton X (over the real semiring). (c) The hypothesis automaton $A(H)$ (unweighted). (d) Automaton Y_2 representing the expected bigram counts in X (over the real semiring). (e) Automaton Y_1: the context dependency model derived from Y_2 (over the tropical semiring). (f) The composition $A(H) \circ Y_1$ (over the tropical semiring).

The transducer T_2 for $\Sigma = \{a, b\}$ is shown in Figure 2(a).

Taking advantage of the special structure of n-gram kernels and of the fact that $A(H)$ is an unweighted automaton, we can devise a new and significantly more efficient method for computing $\widehat{x}$ based on the following steps.

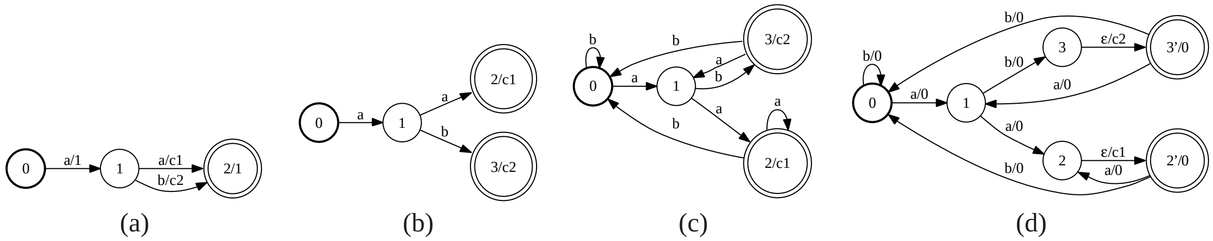
1. *Compute the expected n-gram counts in X:* We compute the composition $X \circ T$, project on output and optimize (epsilon-remove, determinize, minimize) and let Y_2 be the result. Observe that the weighted automaton Y_2 is a compact representation of the expected n-gram counts in X, i.e. for an n-gram w (i.e. $|w| = n$):
$$\begin{aligned} Y_2(w) &= \sum_{x \in \Sigma^*} X(x) c_x(w) \\ &= \mathop{\mathrm{E}}_{x \sim X}[c_x(w)] = c_X(w). \end{aligned} \tag{7}$$

2. *Construct a context-dependency model:* We compute the weighted automaton Y_1 over the tropical semiring as follow: the set of states is $Q = \{w \in \Sigma^* | \, |w| \le n$ and w occurs in $X\}$, the initial state being ϵ and every state being final; the set of transitions E contains all 4-tuple (origin, label, weight, destination) of the form:
   - $(w, a, 0, wa)$ with $wa \in Q$ and $|w| \le n - 2$ and
   - $(aw, b, Y_2(awb), wb)$ with $Y_2(awb) \neq 0$ and $|w| = n - 2$

   where $a, b \in \Sigma$ and $w \in \Sigma^*$. Observe that $w \in Q$ when $wa \in Q$ and that $aw, wb \in Q$ when $Y_2(awb) \neq 0$. Given a string x, we have
$$Y_1(x) = \sum_{|w|=n} c_X(w) c_x(w). \tag{8}$$
   Observe that Y_1 is a deterministic automaton, hence $Y_1(x)$ can be computed in $O(|x|)$ time.

3. *Compute $\widehat{x}$:* We compute the composition $A(H) \circ Y_1$. $\widehat{x}$ is then the label of the accepting path with the largest weight in this transducer and can be obtained by applying a shortest-path algorithm to $-A(H) \circ Y_1$ in the tropical semiring.

The main computational advantage of this method is that it avoids the determinization of Z in the



(a) (b) (c) (d)

Figure 3: Illustration of the construction of Y_1 in the unambiguous case. (a) Weighted automaton Y_2 (over the real semiring). (b) Deterministic tree automaton Y_2' accepting $\{aa, ab\}$ (over the tropical semiring). (c) Result of determinization of $\Sigma^* Y_2'$ (over the tropical semiring). (d) Weighted automaton Y_1 (over the tropical semiring).

$(+, \times)$ semiring, which can sometimes be costly. The method has also been shown empirically to be significantly faster than the one described in the previous section.

The algorithm is illustrated in Figure 2. The alphabet is $\Sigma = \{a, b\}$ and the counting transducer corresponding to the bigram kernel is given in Figure 2(a). The evidence probabilistic automaton X is given in Figure 2(b) and we use as hypothesis set the set of strings that were assigned a non-zero probability by X; this set is represented by the deterministic finite automaton $A(H)$ given in Figure 2(c). The result of step 1 of the algorithm is the weighted automaton Y_2 over the real semiring given in Figure 2(d). The result of step 2 is the weighted automaton Y_1 over the tropical semiring is given in Figure 2(e). Finally, the result of the composition $A(H) \circ Y_1$ (step 3) is the weighted automaton over the tropical semiring given in Figure 2(f). The result of the expected similarity maximization is the string $\widehat{x} = ababa$, which is obtained by applying a shortest-path algorithm to $-A(H) \circ Y_1$. Observe that the string $\overline{x}$ with the largest probability in X is $\overline{x} = bbaba$ and is hence different from $\widehat{x} = ababa$ in this example.

4.3 Efficient method for the unambiguous case

The algorithm presented in the previous section for n-gram kernels can be generalized to handle a wide variety of rational kernels.

Let K be an arbitrary rational kernel defined by a weighted transducer T. Let X_T denote the regular language of the strings output by T. We shall assume that X_T is a finite language, though the results of this section generalize to the infinite case. Let $\overline{\Sigma}$ denote a new alphabet defined by $\overline{\Sigma} = \{\#_x : x \in X_T\}$ and consider the simple grammar G of context-dependent batch rules:

$$\epsilon \rightarrow \#_x / x \_ \epsilon. \tag{9}$$

Each such rule inserts the symbol $\#_x$ immediately after an occurrence x in the input string. For batch context-dependent rules, the context of the application for all rules is determined at once before their application (Kaplan and Kay, 1994). Assume that this grammar is *unambiguous* for a parallel application of the rules. This condition means that there is a unique way of parsing an input string using the strings of X_T. The assumption holds for n-gram sequences, for example, since the rules applicable are uniquely determined by the n-grams (making the previous section a special case).

Given an acyclic weighted automaton Y_2 over the tropical semiring accepting a subset of X_T, we can construct a deterministic weighted automaton Y_1 for $\Sigma^* L(Y_2)$ when this grammar is unambiguous. The weight assigned by Y_1 to an input string is then the sum of the weights of the substrings accepted by Y_2. This can be achieved using weighted determinization.

This suggests a new method for generalizing Step 2 of the algorithm described in the previous section as follows (see illustration in Figure 3):

(i) use Y_2 to construct a deterministic weighted tree Y_2' defined on the tropical semiring accepting the same strings as Y_2 with the same weights, with the final weights equal to the total weight given by Y_2 to the string ending at that leaf;

(ii) let Y_1 be the weighted automaton obtained by first adding self-loops labeled with all elements of Σ at the initial state of Y_2' and then determinizing it, and then inserting new transitions leaving final states as described in (Mohri and Sproat, 1996).

Step (ii) consists of computing a deterministic weighted automaton for $\Sigma^* Y'_2$. This step corresponds to the Aho-Corasick construction (Aho and Corasick, 1975) and can be done in time linear in the size of Y'_2.

This approach assumes that the grammar G of batch context-dependent rules inferred by X_T is unambiguous. This can be tested by constructing the finite automaton corresponding to all rules in G. The grammar G is unambiguous iff the resulting automaton is unambiguous (which can be tested using a classical algorithm). An alternative and more efficient test consists of checking the presence of a *failure* or *default* transition to a final state during the Aho-Corasick construction, which occurs if and only if there is ambiguity.

5 Application to Machine Translation

In machine translation, the BLEU score (Papineni et al., 2001) is typically used as an evaluation metric. In (Tromble et al., 2008), a Minimum Bayes-Risk decoding approach for MT lattices was introduced.[3] The loss function used in that approach was an approximation of the log-BLEU score by a linear function of n-gram matches and candidate length. This loss function corresponds to the following similarity measure:

$$K_{LB}(x, x') = \theta_0 |x'| + \sum_{|w| \leq n} \theta_{|w|} c_x(w) 1_{x'}(w). \tag{10}$$

where $1_x(w)$ is 1 if w occurs in x and 0 otherwise.

(Tromble et al., 2008) implements the MBR decoder using weighted automata operations. First, the set of n-grams is extracted from the lattice. Next, the posterior probability $p(w|X)$ of each n-gram is computed. Starting with the unweighted lattice $A(H)$, the contribution of each n-gram w to (10) is applied by iteratively composing with the weighted automaton corresponding to $\overline{w}(w/(\theta_{|w|} p(w|X))\overline{w})^*$ where $\overline{w} = \Sigma^* \setminus (\Sigma^* w \Sigma^*)$. Finally, the MBR hypothesis is extracted as the best path in the automaton. The above steps are carried out one n-gram at a time. For a moderately large lattice, there can be several thousands of n-grams and the procedure becomes expensive. This leads us to investigate methods that do not require processing the n-grams one at a time in order to achieve greater efficiency.

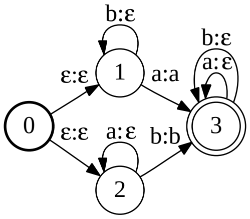


Figure 4: Transducer $\overline{T}_1$ over the real semiring for the alphabet $\{a, b\}$.

The first idea is to approximate the K_{LB} similarity measure using a weighted sum of n-gram kernels. This corresponds to approximating $1_{x'}(w)$ by $c_{x'}(w)$ in (10). This leads us to the following similarity measure:

$$\begin{aligned} K_{NG}(x, x') &= \theta_0 |x'| + \sum_{|w| \leq n} \theta_{|w|} c_x(w) c_{x'}(w) \\ &= \theta_0 |x'| + \sum_{1 \leq i \leq n} \theta_i K_i(x, x') \end{aligned} \tag{11}$$

Intuitively, the larger the length of w the less likely it is that $c_x(w) \neq 1_x(w)$, which suggests computing the contribution to $K_{LB}(x, x')$ of lower-order n-grams ($|w| \leq k$) exactly, but using the approximation by n-gram kernels for the higher-order n-grams ($|w| > k$). This gives the following similarity measure:

$$\begin{aligned} K^k_{NG}(x, x') = \theta_0 |x'| + &\sum_{1 \leq |w| \leq k} \theta_{|w|} c_x(w) 1_{x'}(w) \\ + &\sum_{k < |w| \leq n} \theta_{|w|} c_x(w) c_{x'}(w) \end{aligned} \tag{12}$$

Observe that $K^0_{NG} = K_{NG}$ and $K^n_{NG} = K_{LB}$.

All these similarity measures can still be computed using the framework described in Section 4. Indeed, there exists a transducer $\overline{T}_n$ over the real semiring such that $\overline{T}_n(x, z) = 1_x(z)$ for all $x \in \Sigma^*$ and $z \in \Sigma^n$. The transducer $\overline{T}_1$ for $\Sigma = \{a, b\}$ is given by Figure 4. Let us define the similarity measure $\overline{K}_n$ as:

$$\overline{K}_n(x, x') = (T_n \circ \overline{T}_n^{-1})(x, x') = \sum_{|w| = n} c_x(w) 1_{x'}(w). \tag{13}$$

Observe that the framework described in Section 4 can still be applied even though $\overline{K}_n$ is not symmetric. The similarity measures K_{LB}, K_{NG} and K^k_{NG}

[3] Related approaches were presented in (DeNero et al., 2009; Kumar et al., 2009; Li et al., 2009).

6 Experimental Results

Lattices were generated using a phrase-based MT system similar to the alignment template system described in (Och and Ney, 2004). Given a source sentence, the system produces a word lattice A that is a compact representation of a very large N-best list of translation hypotheses for that source sentence and their likelihoods. The lattice A is converted into a lattice X that represents a probability distribution (i.e. the posterior probability distribution given the source sentence) following:

$$X(x) = \frac{\exp(\alpha A(x))}{\sum_{y \in \Sigma^*} \exp(\alpha A(y))} \qquad (14)$$

where the scaling factor $\alpha \in [0, \infty)$ flattens the distribution when $\alpha < 1$ and sharpens it when $\alpha > 1$. We then applied the methods described in Section 5 to the lattice X using as hypothesis set H the unweighted lattice obtained from X.

The following parameters for the n-gram factors were used:

$$\theta_0 = \frac{-1}{T} \text{ and } \theta_n = \frac{1}{4Tpr^{n-1}} \text{ for } n \geq 1. \qquad (15)$$

Experiments were conducted on two language pairs Arabic-English (aren) and Chinese-English (zhen) and for a variety of datasets from the NIST Open Machine Translation (OpenMT) Evaluation.[4] The values of α, p and r used for each pair are given in Table 3. We used the IBM implementation of the BLEU score (Papineni et al., 2001).

	α	p	r
aren	0.2	0.85	0.72
zhen	0.1	0.80	0.62

Table 3: Parameters used for performing MBR.

We implemented the following methods using the OpenFst library (Allauzen et al., 2007):

- *exact*: uses the similarity measure K_{LB} based on the linearized log-BLEU, implemented as described in (Tromble et al., 2008);
- *approx*: uses the approximation to K_{LB} from (Kumar et al., 2009) and described in the appendix;
- *ngram*: uses the similarity measure K_{NG} implemented using the algorithm of Section 4.2;
- *ngram1*: uses the similarity measure K^1_{NG} also implemented using the algorithm of Section 4.2.

The results from Tables 1-2 show that *ngram1* performs as well as *exact* on all datasets[5] while being two orders of magnitude faster than *exact* and overall more than 3 times faster than *approx*.

7 Conclusion

We showed that for broad families of transducers T and thus rational kernels, the expected similar-

[4] http://www.nist.gov/speech/tests/mt

[5] We consider BLEU score differences of less than 0.4% not significant (Koehn, 2004).

ity maximization problem can be solved efficiently. This opens up the option of seeking the most appropriate rational kernel or transducer T for the specific task considered. In particular, the kernel K used in our machine translation applications might not be optimal. One may well imagine for example that some n-grams should be further emphasized and others de-emphasized in the definition of the similarity. This can be easily accommodated in the framework of rational kernels by modifying the transition weights of T. But, ideally, one would wish to select those weights in an optimal fashion. As mentioned earlier, we leave this question to future work. However, we can offer a brief look at how one could tackle this question. One method for determining an optimal kernel for the expected similarity maximization problem consists of solving a problem similar to that of learning kernels in classification or regression. Let $X_1, \ldots, X_m$ be m lattices with $\mathrm{Ref}(X_1), \ldots, \mathrm{Ref}(X_m)$ the associated references and let $\widehat{x}(K, X_i)$ be the solution of the expected similarity maximization for lattice X_i when using kernel K. Then, the kernel learning optimization problem can be formulated as follows:

$$\min_{K \in \mathcal{K}} \frac{1}{m} \sum_{i=1}^{m} L(\widehat{x}(K, X_i), \mathrm{Ref}(X_i))$$
$$\text{s. t. } K = T \circ T^{-1} \wedge \mathrm{Tr}[K] \leq C,$$

where $\mathcal{K}$ is a convex family of rational kernels and $\mathrm{Tr}[K]$ denotes the trace of the kernel matrix. In particular, we could choose $\mathcal{K}$ as a family of linear combinations of base rational kernels. Techniques and ideas similar to those discussed by Cortes et al. (2008) for learning sequence kernels could be directly relevant to this problem.

A Appendix

We describe here the approximation of the K_{LB} similarity measure from Kumar et al. (2009). We assume in this section that the lattice X is deterministic in order to simplify the notations. The posterior probability of n-gram w in the lattice X can be formulated as:

$$p(w|X) = \sum_{x \in \Sigma^*} 1_x(w) P(x|s) = \sum_{x \in \Sigma^*} 1_x(w) X(x) \tag{16}$$

where s denotes the source sentence. When using the similarity measure K_{LB} defined Equation (10), Equation (3) can then be reformulated as:

$$\widehat{x} = \operatorname*{argmax}_{x' \in H} \theta_0 |x'| + \sum_w \theta_{|w|} c_{x'}(w) p(w|X). \tag{17}$$

The key idea behind this new approximation algorithm is to rewrite the n-gram posterior probability (Equation 16) as follows:

$$p(w|X) = \sum_{x \in \Sigma^*} \sum_{e \in E_X} f(e, w, \pi_x) X(x) \tag{18}$$

where E_X is the set of transitions of X, π_x is the unique accepting path labeled by x in X and $f(e, w, \pi)$ is a score assigned to transition e on path π containing n-gram w:

$$f(e, w, \pi) = \begin{cases} 1 & \text{if } w \in e, p(e|X) > p(e'|X), \\ & \text{and } e' \text{ precedes } e \text{ on } \pi \\ 0 & \text{otherwise.} \end{cases} \tag{19}$$

In other words, for each path π, we count the transition that contributes n-gram w and has the highest transition posterior probability relative to its predecessors on the path π; there is exactly one such transition on each lattice path π.

We note that $f(e, w, \pi)$ relies on the full path π which means that it cannot be computed based on local statistics. We therefore approximate the quantity $f(e, w, \pi)$ with $f^*(e, w, X)$ that counts the transition e with n-gram w that has the highest arc posterior probability relative to predecessors in the entire lattice X. $f^*(e, w, X)$ can be computed locally, and the n-gram posterior probability based on f^* can be determined as follows:

$$\begin{aligned} p(w|\mathcal{G}) &= \sum_{x \in \Sigma^*} \sum_{e \in E_X} f^*(e, w, X) X(x) \\ &= \sum_{e \in E_x} 1_{w \in e} f^*(e, w, X) \sum_{x \in \Sigma^*} 1_{\pi_x}(e) X(x) \\ &= \sum_{e \in E_X} 1_{w \in e} f^*(e, w, X) P(e|X), \end{aligned} \tag{20}$$

where $P(e|X)$ is the posterior probability of a lattice transition $e \in E_X$. The algorithm to perform Lattice MBR is given in Algorithm 1. For each state t in the lattice, we maintain a quantity $\mathrm{Score}(w, t)$ for each n-gram w that lies on a path from the initial state to t. $\mathrm{Score}(w, t)$ is the highest posterior probability among all transitions on the paths that terminate on t and contain n-gram w. The forward pass requires computing the n-grams introduced by each transition; to do this, we propagate n-grams (up to maximum order -1) terminating on each state.

Accurate Non-Hierarchical Phrase-Based Translation

Michel Galley and **Christopher D. Manning**
Computer Science Department
Stanford University
Stanford, CA 94305
{mgalley,manning}@cs.stanford.edu

Abstract

A principal weakness of conventional (i.e., non-hierarchical) phrase-based statistical machine translation is that it can only exploit continuous phrases. In this paper, we extend phrase-based decoding to allow both source and target phrasal discontinuities, which provide better generalization on unseen data and yield significant improvements to a standard phrase-based system (Moses). More interestingly, our discontinuous phrase-based system also outperforms a state-of-the-art hierarchical system (Joshua) by a very significant margin (+1.03 BLEU on average on five Chinese-English NIST test sets), even though both Joshua and our system support discontinuous phrases. Since the key difference between these two systems is that ours is not hierarchical—i.e., our system uses a string-based decoder instead of CKY, and it imposes no hard hierarchical reordering constraints during training and decoding—this paper sets out to challenge the commonly held belief that the tree-based parameterization of systems such as Hiero and Joshua is crucial to their good performance against Moses.

1 Introduction

Phrase-based machine translation models (Och and Ney, 2004) advanced the state of the art by extending the basic translation unit from words to phrases. By conditioning translations on more than a single word, a statistical machine translation (SMT) system benefits from the larger context of a phrase pair to properly handle multi-word units and local reorderings. Experimentally, it was found that longer phrases yield better MT output (Koehn et al., 2003). However, while it is computationally feasible at training time to extract phrase pairs of nearly unbounded size (Zhang and Vogel, 2005; Callison-Burch et al., 2005), phrase pairs applicable at test time tend to be fairly short. Indeed, data sparsity often forces conventional phrase-based systems to segment test sentences into small phrases, and therefore to translate dependent words (e.g., the French *ne . . . pas*) separately instead of jointly.

We present a solution to this sparsity problem by going beyond using only *continuous phrases*, and instead define our translation unit as any subset of words of a sentence, i.e., a *discontinuous phrase*. We generalize conventional multi-beam string-based decoding (Koehn, 2004) to allow variable-size discontinuities in both source and target phrases. Since each sentence pair can be more flexibly decomposed into translation units, it is possible to exploit the rich context of longer (possibly discontinuous) phrases to improve translation quality. Our decoder provides two extensions to Moses (Koehn et al., 2007): (a) to cope with source gaps, we follow (Lopez, 2007) to efficiently find all discontinuous phrases in the training data that also appear in the input sentence; (b) to enable target discontinuities, we augment translation hypotheses to not only record the current partial translation, but also a set of subphrases that may be appended to the partial translation at some later stages of decoding. With these enhancements, our best discontinuous system outperforms Moses with lexicalized reordering by 0.77 BLEU and 1.53 TER points on average.

We also show that our approach compares favorably to binary synchronous context-free grammar (2-SCFG) systems such as Hiero (Chiang, 2007), even though 2-SCFG systems also allow phrasal discontinuities. Part of this difference may be due to a difference of expressiveness, since 2-SCFG models impose hard hierarchical constraints that our models do not impose. Recent work (Wellington et al., 2006; Søgaard and Kuhn, 2009; Søgaard and

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 966–974,
Los Angeles, California, June 2010.

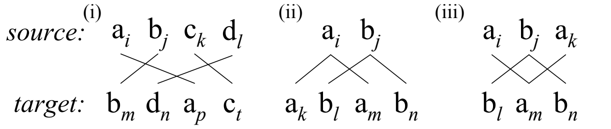

Figure 1: 2-SCFG systems such as Hiero are unable to independently generate translation units **a**, **b**, **c**, and **d** with the following types of alignments: (i) inside-out (Wu, 1997); (ii) cross-serial DTU (Søgaard and Kuhn, 2009); (iii) “bonbon” (Simard et al., 2005). Standard phrase-based decoders cope with (i), but not (ii) and (iii). Our phrase-based decoder handles all three cases.

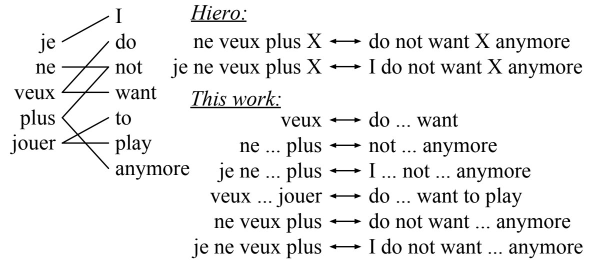
Wu, 2009) has questioned the empirical adequacy of 2-SCFG systems, which are unable to perform any of the transformations shown in Fig. 1. For instance, using manually-aligned bitexts for 12 European languages pairs, Søgaard and Kuhn found that inside-out and cross-serial discontinuous translation units (DTU) account for 1.6% (Danish-English) to 18.6% (French-English) of all translation units. The empirical adequacy of 2-SCFG models would presumably be lower with automatically-aligned texts and if the study also included non-European languages. In contrast, phrase-based systems can properly handle inside-out alignments when used with a reasonably large distortion limit, and all configurations in Fig. 1 are accounted for in our system. In our experiments, we show that our discontinuous phrase-based system outperforms Joshua (Li et al., 2009), a reimplementation of Hiero, by 1.03 BLEU points and 1.19 TER points on average. A final compelling advantage of our decoder is that it preserves the computational efficiency of Moses (i.e., time complexity is linear when a distortion limit is used), while SCFG decoders have a running time that is at least cubic (Huang et al., 2005).

2 Discontinuous Phrase Extraction

In this section, we introduce the extraction of discontinuous phrases for phrase-based MT. We will describe a decoder that can handle such phrases in the next section. Formally, we define the discontinuous phrase-based translation problem as follows. We are given a source sentence $\mathbf{f} = f_1^J = f_1, \ldots, f_j, \ldots, f_J$, which is to be translated into a target sentence $\mathbf{e} = e_1^I = e_1, \ldots, e_i, \ldots, f_I$. Unlike (Och and Ney, 2004), in this work, a sentence pair may be segmented into phrases that are not continuous, so each phrase is characterized by a coverage set, i.e., a set of word indices. Assuming that the sentence pair $(\mathbf{f}, \mathbf{e})$ is decomposed into K discontinuous phrases, we use $\mathbf{s} = (s_1, \ldots, s_K)$ and $\mathbf{t} = (t_1, \ldots, t_K)$ to respectively represent the decomposition of the source and target sentence into K word subsets that are complementary and non-overlapping. A pair of coverage sets (s_k, t_k) is said to be *consistent* with the word alignment A if the following condition holds:

$$\forall (i,j) \in A : i \in s_k \longleftrightarrow j \in t_k \qquad (1)$$



je
ne
veux
plus
jouer
I
do
not
want
to
play
anymore
Hiero:
ne veux plus X ⟷ do not want X anymore
je ne veux plus X ⟷ I do not want X anymore
This work:
veux ⟷ do ... want
ne ... plus ⟷ not ... anymore
je ne ... plus ⟷ I ... not ... anymore
veux ... jouer ⟷ do ... want to play
ne veux plus ⟷ do not want ... anymore
je ne veux plus ⟷ I do not want ... anymore

Figure 2: Due to hierarchical constraints, Hiero only extracts two discontinuous phrases from the alignment on the left, but our system extracts 11 (only 6 are shown).

For continuous phrases, finding all phrase pairs that satisfy this condition can be done in $O(nm^3)$ time (Och and Ney, 2004), where n is the length of the sentence and m is the maximum phrase length. The set of discontinuous phrases is exponential in the maximum span length, so phrase extraction must be tailored to a specific text (e.g., a given test sentence) for relatively large m values. Lopez (2007) presents an efficient solution using suffix arrays for finding all discontinuous phrases of the training data that are relevant to a given test sentence or test set. A complete overview of this technique is beyond the scope of this paper, though we will mention that it solves a phrase collocation problem by efficiently identifying collocated continuous phrases of the training data that also happen to be collocated in the test sentence. While this technique was primarily designed for extracting *hierarchical phrases* for Hiero (Chiang, 2007), it can readily be applied to the problem of finding all discontinuous phrases for our phrase-based system. Indeed, the suffix-array technique gives us for each input sentence a list of relevant source coverage sets. For each such s_k, we can easily enumerate each t_k satisfying Eq. 1. The

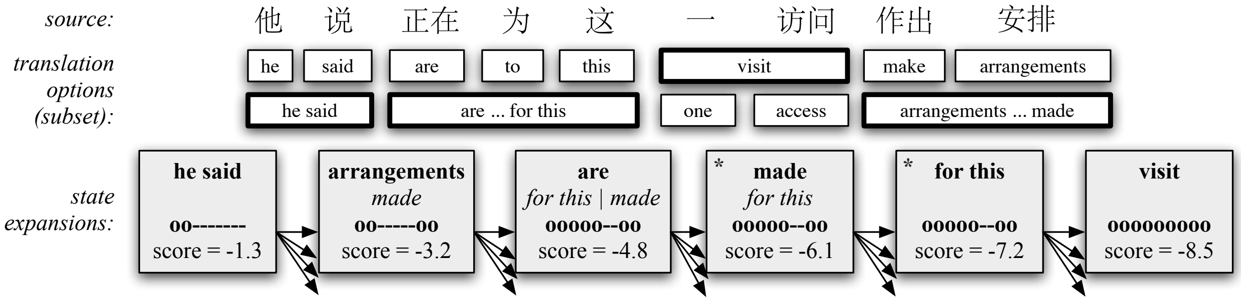


Figure 3: A particular decoder search path for the input shown at the top. Note that this example contains a cross-serial DTU (which interleaves *arrangements ... made* with *are ... for this*), a structure Hiero can't handle.

key difference between Hiero-style extraction and our work is that Eq. 1 is the *only* constraint.[1] Since our decoder doesn't impose hierarchical constraints, we exploit *all* discontinuous phrase pairs consistent with the word alignment, which often includes sound translations not captured by Hiero (e.g., *ne* ... *plus* translating to *not* ... *anymore* in Fig. 2).

3 Decoder

The core engine of our phrase-based system, Phrasal (Cer et al., 2010), is a multi-stack decoder similar to Moses (Koehn, 2004), which we extended to support variable-size gaps in the source and the target. In Moses, partial translation hypotheses are arranged into different stacks according to the total number of input words they cover. At every translation step, stacks are pruned using partial translation cost and a lower bound on the estimated future cost. Pruning is implemented using both threshold and histogram pruning, and Moses allows for hypothesis recombination between hypotheses that are indistinguishable according to the underlying models.

The key difference between Moses and our system is that, in order to account for target discontinuities, phrases that contains gaps in the target are appended to a partial translation hypothesis in multiple steps. Specifically, each translation hypothesis in our decoder is not only represented as a translation prefix and a coverage set as in Moses, but it also contains a set of isolated phrases (shown in italic in Fig. 3) that must be added to the translation at some later time. For instance, the figure shows how the phrase pair (作出安排, *arrangements ... made*) is being added to a partial translation. The prefix (*arrangements*) is immediately appended to form the hypothesis (*he said arrangements*), and the isolated phrase (*made*) is stored for later use.

Beam search algorithm.

```
1  create initial hypothesis $H_\emptyset$; add it to $S^g_0$

12         for each $(s_k, t_k)$ in translation_options$(m)$
13           if source $s_k$ does not overlap $H_{old}$ then
14             $H_{new} :=$combine$(H_{old}, s_k, t_k)$
15             add $H_{new}$ to $S^c_{j+l}$, where $l = |s_k|$
16 return $\arg\max(S^g_J)$
```

Table 1: Discontinuous phrase-based MT.

A beam search algorithm for discontinuous phrase-based MT is shown in Table 1. Pruning is done implicitly in the table to avoid cluttering the pseudo-code. The algorithm handles $2J + 1$ stacks $S^g_0, S^g_1, \ldots, S^g_J$ and $S^c_1, \ldots, S^c_J$, where each stack may contain up to N hypotheses $H_{j1}, \ldots, H_{jN}$. The main loop of the algorithm alternates two stages: grow (lines 7–15) and consolidate (lines 3–6).[2] The grow stage is similar to standard phrase-

[1] In order to keep the number of phrases manageable, we additionally require that each (maximal) contiguous substring of s_k and t_k be connected with at least one word alignment.

[2] The distinction between S^g_i and S^c_i stacks ensures that the consolidate operation does not read and write hypotheses on the same stack. While it may seem effective to store hypotheses in

based MT: we take a hypothesis H^g_{jn} from S^g_j and combine it with a translation option (s_k, t_k), which yields a new hypothesis that is added to stack S^c_{j+l} (where $l = |s_k|$). The second stage, consolidate, lets the decoder select any number of isolated phrases (not necessarily all, and possibly zero) and append them in any order at the end of the current translation.[3] Consolidation operations are marked with stars in the figure (for simplicity, the figure does not display consolidations that keep hypotheses unchanged). We limit the number of isolated phrases to 4, which is generally enough to account for most transformations seen in the data. Any hypothesis in the last beam S^g_J is automatically discarded if it contains any isolated phrase.

One last difference with standard decoders is that we also handle source discontinuities. This problem is a known instance of MT by pattern matching (Lopez, 2007), which we already mentioned in the previous section. The function translation_options(m) of Table 1 returns the set of options applicable at position m using this pattern matching algorithm. Since this function is invoked a large number of times, it is important to precompute its return values for each m prior to decoding.

4 Features

Our system incorporates the same eight baseline features of Moses: two relative-frequency phrase translation probabilities $p(e|f)$ and $p(f|e)$, two lexically-weighted phrase translation probabilities (Koehn et al., 2003) $lex(e|f)$ and $lex(f|e)$, a language model probability, word penalty, phrase penalty, and linear distortion, and we optionally add 6 lexicalized reordering features as computed in Moses.

Our computation of linear distortion is different from the one in Moses, since we need to account for discontinuous phrases. We found that it is crucial to penalize discontinuous phrases that have relatively long gaps. Hence, in our computation of linear distortion, we treat continuous subphrases of each discontinuous phrase as if they were continuous phrases on their own. Specifically, let $\bar{\mathbf{s}} = (\bar{s}_1, \ldots, \bar{s}_L)$ be the list of L (maximal) continuous subphrases of the K source phrases ($L \geq K$) selected for a given translation hypothesis. Subphrases in $\bar{\mathbf{s}}$ are enumerated according to their order in the target language, which may be different from the source-side ordering. We then compute the linear distortion between pair of successive elements $(\bar{s}_i, \bar{s}_{i+1})$ as follows:

$$d(\bar{\mathbf{s}}) = \bar{s}_1^{first} + \sum_{i=2}^{L} \left| \bar{s}_{i-1}^{last} + 1 - \bar{s}_i^{first} \right|$$

where the superscripts $first$ and $last$ respectively refer to source position of the first and last word of a given subphrase. Fig. 4 shows an example of how distortion is computed for phrases (s_1, s_2, s_3), including the discontinuous phrase s_2 split into three continuous subphrases. In practice, we compute intra-phrase (shown with thin arrows in the figure) and inter-phrase linear distortion separately in order to produce two distinct features, since translation tends to improves when the intra-phrase cost has a lower feature weight.

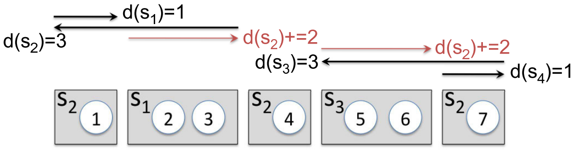

Figure 4: Linear distortion computed using both continuous and discontinuous phrase.

Finally, we add two features that are not present in Moses. First, we penalize target discontinuities by including a feature that is the sum of the lengths of all target gaps. The second feature is the count of discontinuous phrases that are in configurations (cross-serial DTU (Søgaard and Kuhn, 2009) and "bonbon" (Simard et al., 2005)) that can't be handled by 2-SCFG systems. The advantage of such features is two-fold. First, similarly to hierarchical systems, they prevent many distorted reorderings that are unlikely to correspond to quality translations. Second, it imposes soft rather than hard constraints, which means that the decoder is entirely free to violate hierarchical constraints when these violations are supported by other features.

different stacks depending on the number of isolated phrases, we have not found various implementations of this idea to work better than the algorithm described here.

[3] We let isolated phrases be reordered freely, with only three constraints: (1) the internal word order must be preserved, i.e., a phrase may not be split or reordered. (2) isolated phrases drawn from the same discontinuous phrase must appear in the specified order (i.e., the phrase *A* ... *B* ... *C* may not yield the translation *A* ... *C* ... *B*). (3) Empty gaps are forbidden.

5 Experimental Setup

Three systems are evaluated in this paper: Moses (Koehn et al., 2007), Joshua (Li et al., 2009) – a reimplementation of Hiero, and our phrase-based system. We made our best attempts to make our system comparable to Moses. That is, when no discontinuous phrases are provided to our system, it generates an output that is almost identical to Moses (only about 1% of translations differ on average). In both systems, we use the default settings of Moses, i.e., we set the beam size to 200, the distortion limit to 6, we limit to 20 the number of target phrases that are loaded for each source phrase, and we use the same default eight features of Moses. We use version 1.3 of Joshua with its default settings. Both Moses and our system are evaluated with and without lexicalized reordering (Tillmann, 2004).[4] We believe it to be fair to compare Joshua against phrase-based systems that exploit lexicalized reordering, since Hiero's hierarchical rules are also lexically sensitive.[5]

The language pair for our experiments is Chinese-to-English. The training data consists of about 28 million English words and 23.3 million Chinese words drawn from various news parallel corpora distributed by the Linguistic Data Consortium (LDC). In order to provide experiments comparable to previous work, we used the same corpora as (Wang et al., 2007). We performed word alignment using a cross-EM word aligner (Liang et al., 2006). For this, we ran two iterations of IBM Model 1 and two HMM iterations. Finally, we generated a symmetric word alignment from cross-EM Viterbi alignment using the Moses grow-diag heuristic in the case Moses and our system. In the case of Joshua, we used the grow-diag-final heuristic since this gave better results.

In order to train a competitive baseline given our computational resources, we built a large 5-gram language model using the Xinhua and AFP sections of the Gigaword corpus (LDC2007T40) in addition to the target side of the parallel data. This data represents a total of about 700 million words. We manually removed documents of Gigaword that were released during periods that overlap with those of our development and test sets. The language model was smoothed with the modified Kneser-Ney algorithm as implemented in SRILM (Stolcke, 2002), and we only kept 4-grams and 5-grams that occurred at least three times in the training data.

For tuning and testing, we use the official NIST MT evaluation data for Chinese from 2003 to 2008 (MT03 to MT08), which all have four English references for each input sentence. We used the 1664 sentences of MT06 for tuning and development and all other sets for testing. Parameter tuning was done with minimum error rate training (Och, 2003), which was used to maximize IBM BLEU-4 (Papineni et al., 2001). Since MERT is prone to search errors, especially with large numbers of parameters, we ran each tuning experiment four times with different initial conditions. We used n-best lists of size 200. In the final evaluations, we report results using both TER version 0.7.25 (Snover et al., 2006) and BLEU-4 (both uncased).

6 Results

We start by comparing some translations generated by the best configurations of Joshua, Moses, and our phrase-based decoder, systems we will empirically evaluate later in this section. Fig. 5 shows translations of our development set MT06, which were selected because our system makes a crucial use of discontinuous phrases. In the first example, the Chinese input contains 当 ... 时, which typically translates as *when*. Lacking an entry for the input phrase 当生命权被剥夺时 in its phrase table, Moses is unable to translate this segment appropriately, and must instead split this phrase to generate the translation *when the right was deprived of*, where 时 is translated into *of*. This is evidently a poor translation. Conversely, our system uses a discontinuous phrase to translate 当 ... 时, and translates the intervening words separately.

The remaining three translations all contain cross-serial DTUs (Søgaard and Kuhn, 2009) and thus would be difficult to generate using 2-SCFG systems. The second example motivates the idea

[4] We use Moses' default orientations: monotone, swap, and discontinuous. As far as this reordering model is concerned, we treat discontinuous phrases as continuous, i.e., we simply ignore what lies within gaps to determine phrase orientation.

[5] (Tillmann, 2004) learns for each phrase a tendency to either remain monotone or to swap with other phrases. As noted in (Lopez, 2008), Hiero can represent the same information with hierarchical rules of the form uX, Xu, and XuX. Hiero actually models lexicalized reordering patterns that (Tillmann, 2004) does not account for, e.g., a transformation from X_1uX_2v to $X_2u'v'X_1$.

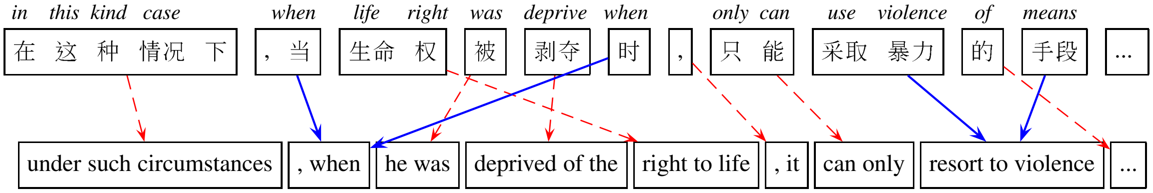
MT06 — segment 1589

Reference: Under such circumstances, when the right of existence was deprived, the only way remaining was to overthrow the existing dynasty by force and try to replace it.

Joshua: Under such circumstances, when life be deprived, can only resort to violence to overthrow the current dynasty, trying to replace,

Moses: Under such circumstances, when the right was deprived of, can only adopt the means of violence, in an attempt to overthrow the present dynasty replaced,

This work: Under such circumstances, when he was deprived of the right to life, it can only resort to violence in an attempt to overthrow the current dynasty replaced,



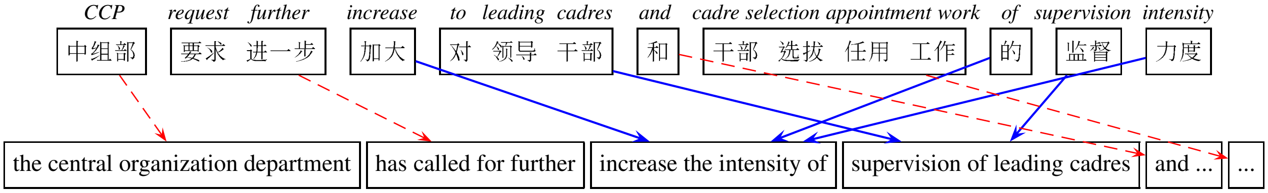
MT06 — segment 1044

Reference: CCP organization ministry demands to further enlarge strength of supervision of leading cadres and cadre selection and appointment

Joshua: Department demands further intensify supervision over the work of selecting and appointing leading cadres, and intensify

Moses: The central organization department, called on leading cadres, further increase the intensity of supervision over work of selecting and appointing cadres.

This work: The central organization department has called for further increase the intensity of supervision of leading cadres and the work of selecting and appointing cadres.



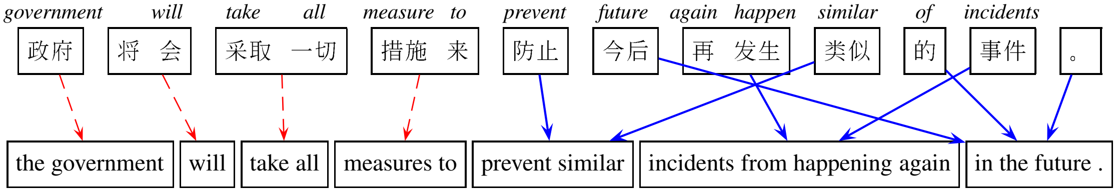
MT06 — segment 559

Reference: The government will take all possible measures to prevent similar incidents from happening in the future.

Joshua: Government will take all measures to prevent the re-occurrence of similar incidents in the future.

Moses: The government will take all measures to prevent the occurrence of similar incidents in the future.

This work: The government will take all measures to prevent similar incidents from happening again in the future.



MT06 — segment 769

Reference: He also said that the arrangements are being made now for the visits.

Joshua: He also said that now is making arrangements for this visit.

Moses: He also said that the current visit is to make arrangements.

This work: He also said that the current arrangements are made for the visit.

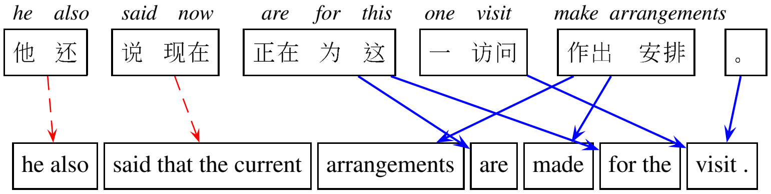


Figure 5: Actual translations produced by Joshua, Moses, and our system. For our system, we also display phrase alignments, including discontinuous phrase alignments. Results for these three systems here are displayed in rows 2, 4, and 8 of Table 2. The thick blue arrows represent alignments between discontinuous phrases, while red segmented arrows align continuous phrases.

Table 2: Our system compared again conventional and hierarchical phrase-based MT (Moses and Joshua). using uncased BLEUr4n4[%] and TER[%]. LexR indicates whether lexicalized reordering is enabled or not. We use randomization tests (Riezler and Maxwell, 2005) to determine significance of our best results (row 8) against Joshua (row 2) and Moses (row 4): differences marked in bold are significant at the $p \leq .01$ level.

that larger translation units, including discontinuous phrases, lead to better translations. The reference includes the translation *enlarge strength of supervision of leading cadres*, and our system is able to produce a translation that is almost identical (*increase the intensity of supervision of leading cadres*) using only two phrases, pulling together input words that are fairly far apart in the sentence. The third Chinese sentence has a word order quite different from English, but our decoder flexibly reorders it in a manner that can't be handled with SCFG decoders to give a word order (*prevent similar events from happening*) that matches the one in the reference. The last Chinese sentence includes the topicalization word 为 (*for*), which indicates the input sentence has no subject. One way to properly handle this translation is to turn the sentence into a passive in English (as in the reference), a transformation our system does, thanks to its support for complex reorderings.

Our main results are displayed in Table 2. First, Joshua systematically outperforms the Moses baseline (+0.82 BLEU point and −0.92 TER point on average), but performance of the two is about the same when Moses incorporates lexicalized reordering. This finding is consistent with previous work (Lopez, 2008). The results of our system displayed in rows 5–8 demonstrate that our system consistently outperforms Moses, whether they both use lexicalized reordering or not. The performance of our best system—i.e., with lexicalized reordering and both source and target gaps—is significantly better than the best Moses system (+0.77 BLEU and −1.53 TER). While the performance of our system without lexicalized reordering is close to that of Joshua, our system with lexicalized reordering significantly outperforms Joshua ($p \leq .01$) in 9 out of 10 evaluations. The single experiment where our improvement over Hiero is insignificant (i.e., BLEU on MT08) is mainly affected by a discrepancy of length (our brevity penalty on MT08 is 0.92).

It is interesting to notice that our system allowing phrasal discontinuities only on the source (row 5) performs almost as well as the system that allows them on both sides (row 7). For instance, while source discontinuities improve performance by 0.7 BLEU point on MT06, further enabling target discontinuities only raises performance by a mere 0.09 BLEU point. This naturally raises the question of whether our support for target gaps is ineffective, or whether target-discontinuous phrases are somewhat superfluous to the MT task. While it is certainly difficult to either confirm or deny the latter hypothesis, we can at least compare our handling of target-discontinuous phrases with hierarchical systems. In one additional set of experiments, we removed target-discontinuous phrases in Joshua prior to MERT and test time. Specifically, we removed all hierarchical phrases whose target side has the form uXv, $uXvX$, $XuXv$, and $uXvXw$, and only allowed rules whose target side has the form uX, Xu, XuX, XXu, or uXX. After this filtering, we found that target-discontinuous phrases in Joshua are also not crucial to its performance, since their removal only caused a drop of 0.2 BLEU point (row 1) and almost no change in terms of TER. We speculate that using target discontinuous phrases is more diffi-

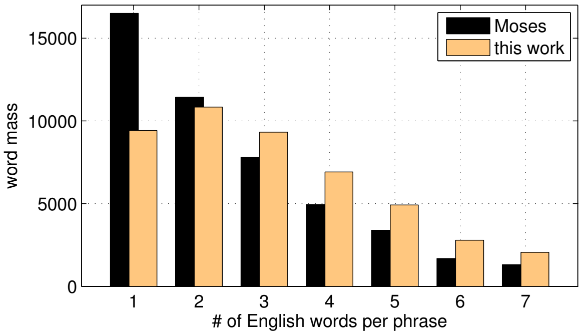

Figure 6: Phrase length histogram for MT06.

cult, since it represents a generation rather than just a matching problem.

In this paper, we have also argued that a main benefit of discontinuous phrases—and particularly source-discontinuous phrases—is that the decoder is allowed to use larger translation units than when restricted to continuous phrases. This claim is confirmed in Fig. 6. We find that our decoder makes effective use of the extended set of translation options at its disposal: While the Moses baseline translates MT06 with an average 1.73 words per phrase, adding support for discontinuities increases this average to 2.16, and reduces by 43% the use of single word phrases. On MT06, 53% of the translated sentences produced by our best system use at least one source-discontinuous phrase, and 9% of them exploit one or more target-discontinuous phrases.

7 Related Work

The main goal of this paper is to show that discontinuous phrases can greatly improve the performance of phrase-based systems. While some of the most recent phrase-based systems (Chiang, 2007; Watanabe et al., 2006) exploit context-free decoding algorithms (CKY, Earley, etc.) to cope with discontinuities, our system preserves the simplicity and speed of conventional phrase-based decoders, and in particular does not build any intermediate tree structure, does not impose any hard reordering constraints other than the distortion limit, and still achieves translation performance that is superior to that of a state-of-the-art hierarchical system.

A few previous non-hierarchical systems have also exploited phrasal discontinuities. The most notable previous attempt to incorporate gaps is described in (Simard et al., 2005). Simard et al. presents an extension to Moses that allows gaps in both source and target phrases, though each of their gap symbols must span exactly one word. This fact makes decoding simpler, since the position of all target words in a translation hypothesis is known as soon as the hypothesis is laid down, but fixed-size discontinuous phrases are less general and increase sparsity. By comparison, our gaps may span any number of words, so we have an increased ability to flexibly match the input sentence effectively. (Crego and Yvon, 2009) also handles gaps, though this work is applicable to an n-gram-based SMT framework (Mariòo et al., 2006), which is fairly different from the phrase-based framework.

8 Conclusions

In this paper, we presented a generalization of conventional phrase-based decoding to handle discontinuities in both source and target phrases. Our system significantly outperforms Moses and Joshua, two standard implementations of conventional and hierarchical phrase-based decoding. We found that allowing discontinuities in the source is more useful than target discontinuities in our system, though we found that this turns out to also be the case with the hierarchical phrases of Joshua. In future work, we plan to extend the parameterization of phrase-based lexicalized reordering models to be sensitive to these discontinuities, and we will also consider adding syntactic features to our models to penalize discontinuities that are not syntactically motivated (Marton and Resnik, 2008; Chiang et al., 2009). The discontinuous phrase-based MT system described in this work is part of Phrasal, an open-source phrase-based system available for download at http://nlp.stanford.edu/software/phrasal.

Abstract

Machine translation benefits from two types of decoding techniques: consensus decoding over multiple hypotheses under a single model and system combination over hypotheses from different models. We present *model combination*, a method that integrates consensus decoding and system combination into a unified, forest-based technique. Our approach makes few assumptions about the underlying component models, enabling us to combine systems with heterogenous structure. Unlike most system combination techniques, we reuse the search space of component models, which entirely avoids the need to align translation hypotheses. Despite its relative simplicity, model combination improves translation quality over a pipelined approach of first applying consensus decoding to individual systems, and then applying system combination to their output. We demonstrate BLEU improvements across data sets and language pairs in large-scale experiments.

1 Introduction

Once statistical translation models are trained, a decoding approach determines what translations are finally selected. Two parallel lines of research have shown consistent improvements over the standard max-derivation decoding objective, which selects the highest probability derivation. *Consensus decoding* procedures select translations for a single system by optimizing for model predictions about n-grams, motivated either as minimizing Bayes risk (Kumar and Byrne, 2004), maximizing sentence similarity (DeNero et al., 2009), or approximating a max-translation objective (Li et al., 2009b). *System combination* procedures, on the other hand, generate translations from the output of multiple component systems (Frederking and Nirenburg, 1994). In this paper, we present *model combination*, a technique that unifies these two approaches by learning a consensus model over the n-gram features of multiple underlying component models.

Model combination operates over the component models' posterior distributions over translation derivations, encoded as a forest of derivations.[1] We combine these components by constructing a linear consensus model that includes features from each component. We then optimize this consensus model over the space of all translation derivations in the support of all component models' posterior distributions. By reusing the components' search spaces, we entirely avoid the hypothesis alignment problem that is central to standard system combination approaches (Rosti et al., 2007).

Forest-based consensus decoding techniques differ in whether they capture model predictions through n-gram posteriors (Tromble et al., 2008; Kumar et al., 2009) or expected n-gram counts (DeNero et al., 2009; Li et al., 2009b). We evaluate both in controlled experiments, demonstrating their empirical similarity. We also describe algorithms for expanding translation forests to ensure that n-grams are local to a forest's hyperedges, and for exactly computing n-gram posteriors efficiently.

Model combination assumes only that each translation model can produce expectations of n-gram features; the latent derivation structures of component systems can differ arbitrarily. This flexibility allows us to combine phrase-based, hierarchical, and syntax-augmented translation models. We evaluate by combining three large-scale systems on Chinese-English and Arabic-English NIST data sets, demonstrating improvements of up to 1.4 BLEU over the

[1] In this paper, we use the terms *translation forest* and *hypergraph* interchangeably.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 975–983,
Los Angeles, California, June 2010.

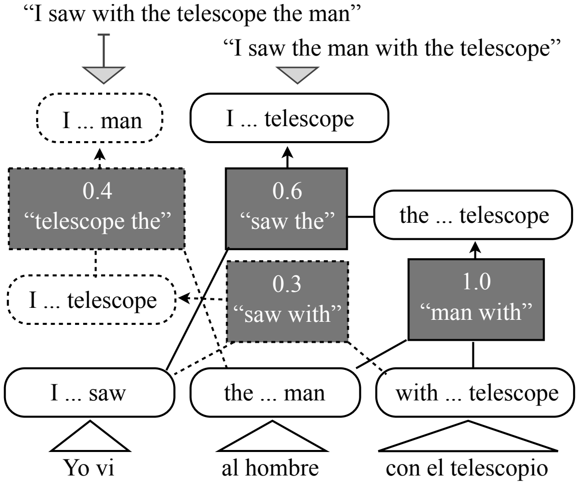

Figure 1: An example translation forest encoding two synchronous derivations for a Spanish sentence: one solid and one dotted. Nodes are annotated with their left and right unigram contexts, and hyperedges are annotated with scores $\theta \cdot \phi(r)$ and the bigrams they introduce.

best single system max-derivation baseline, and consistent improvements over a more complex multi-system pipeline that includes independent consensus decoding and system combination.

2 Model Combination

Model combination is a model-based approach to selecting translations using information from multiple component systems. Each system provides its posterior distributions over derivations $P_i(d|f)$, encoded as a weighted translation forest (i.e., translation hypergraph) in which hyperedges correspond to translation rule applications r.[2] The conditional distribution over derivations takes the form:

$$P_i(d|f) = \frac{\exp\left[\sum_{r \in d} \theta_i \cdot \phi_i(r)\right]}{\sum_{d' \in \mathcal{D}(f)} \exp\left[\sum_{r \in d'} \theta_i \cdot \phi_i(r)\right]}$$

where $\mathcal{D}(f)$ is the set of synchronous derivations encoded in the forest, r iterates over rule applications in d, and θ_i is the parameter vector for system i. The feature vector ϕ_i is system specific and includes both translation model and language model features. Figure 1 depicts an example forest.

Model combination includes four steps, described below. The entire sequence is illustrated in Figure 2.

2.1 Computing Combination Features

The first step in model combination is to compute n-gram expectations from component system posteriors—the same quantities found in MBR, consensus, and variational decoding techniques. For an n-gram g and system i, the expectation

$$v_i^n(g) = \mathbb{E}_{P_i(d|f)}\left[h(d,g)\right]$$

can be either an n-gram expected count, if $h(d,g)$ is the count of g in d, or the posterior probability that d contains g, if $h(d,g)$ is an indicator function. Section 3 describes how to compute these features efficiently.

2.2 Constructing a Search Space

The second step in model combination constructs a hypothesis space of translation derivations, which includes all derivations present in the forests contributed by each component system. This search space D is also a translation forest, and consists of the conjoined union of the component forests. Let R_i be the root node of component hypergraph D_i. For all i, we include all of D_i in D, along with an edge from R_i to R, the root of D. D may contain derivations from different types of translation systems. However, D only contains derivations (and therefore translations) that appeared in the hypothesis space of some component system. We do not intermingle the component search spaces in any way.

2.3 Features for the Combination Model

The third step defines a new combination model over all of the derivations in the search space D, and then annotates D with features that allow for efficient model inference. We use a linear model over four types of feature functions of a derivation:

1. Combination feature functions on n-grams $v_i^n(d) = \sum_{g \in \text{Ngrams}(d)} v_i^n(g)$ score a derivation according to the n-grams it contains.
2. Model score feature function b gives the model score $\theta_i \cdot \phi_i(d)$ of a derivation d under the system i that d is from.
3. A length feature ℓ computes the word length of the target-side yield of a derivation.
4. A system indicator feature α_i is 1 if the derivation came from system i, and 0 otherwise.

[2] Phrase-based systems produce phrase lattices, which are instances of forests with arity 1.

All of these features are local to rule applications (hyperedges) in D. The combination features provide information sharing across the derivations of different systems, but are functions of n-grams, and so can be scored on any translation forest. Model score features are already local to rule applications. The length feature is scored in the standard way. System indicator features are scored only on the hyperedges from R_i to R that link each component forest to the common root.

Scoring the joint search space D with these features involves annotating each rule application r (i.e. hyperedge) with the value of each feature.

2.4 Model Training and Inference

We have defined the following combination model $s_w(d)$ with weights w over derivations d from I different component models:

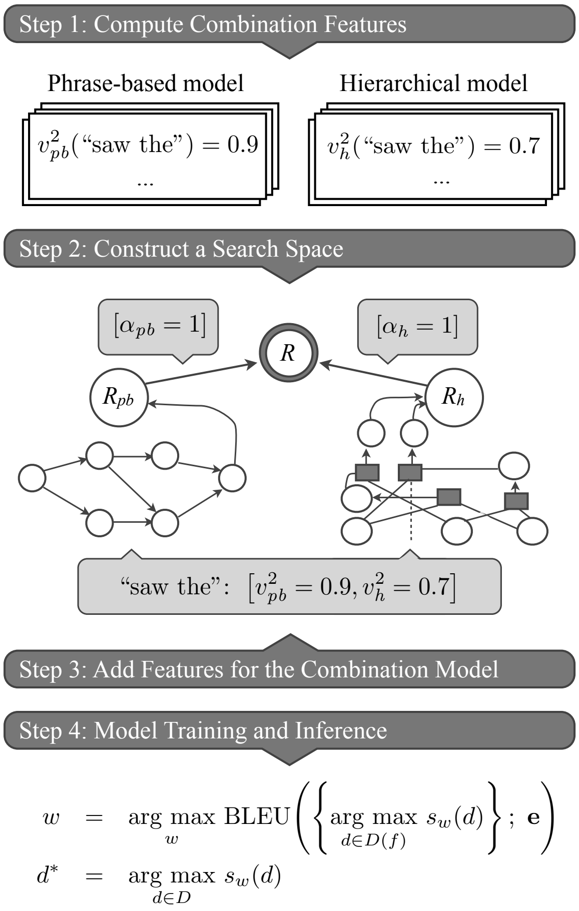
$$\sum_{i=1}^{I} \left[\sum_{n=1}^{4} w_i^n v_i^n(d) + w_i^\alpha \alpha_i(d) \right] + w^b \cdot b(d) + w^\ell \cdot \ell(d)$$

Because we have assessed all of these features on local rule applications, we can find the highest scoring derivation $d^* = \arg\max_{d \in D} s_w(d)$ using standard max-sum (Viterbi) inference over D.

We learn the weights of this consensus model using hypergraph-based minimum-error-rate training (Kumar et al., 2009). This procedure maximizes the translation quality of d^* on a held-out set, according to a corpus-level evaluation metric $B(\cdot; \mathbf{e})$ that compares to a reference set $\mathbf{e}$. We used BLEU, choosing w to maximize the BLEU score of the set of translations predicted by the combination model.

3 Computing Combination Features

The combination features $v_i^n(d)$ score derivations from each model with the n-gram predictions of the others. These predictions sum over all derivations under a single component model to compute a posterior belief about each n-gram. In this paper, we compare two kinds of combination features, posterior probabilities and expected counts.[3]



Step 1: Compute Combination Features
Phrase-based model
Hierarchical model
$v_{pb}^2(\text{“saw the”}) = 0.9$
...
$v_h^2(\text{“saw the”}) = 0.7$
...
Step 2: Construct a Search Space
$[\alpha_{pb} = 1]$
$[\alpha_h = 1]$
R
R_{pb}
R_h
“saw the”: $[v_{pb}^2 = 0.9, v_h^2 = 0.7]$
Step 3: Add Features for the Combination Model
Step 4: Model Training and Inference
$w = \arg\max_w \text{BLEU}\left(\left\{\arg\max_{d \in D(f)} s_w(d)\right\}; \mathbf{e}\right)$
$d^* = \arg\max_{d \in D} s_w(d)$

Figure 2: Model combination applied to a phrase-based (pb) and a hierarchical model (h) includes four steps. (1) shows an excerpt of the bigram feature function for each component, (2) depicts the result of conjoining a phrase lattice with a hierarchical forest, (3) shows example hyperedge features of the combination model, including bigram features v_i^n and system indicators α_i, and (4) gives training and decoding objectives.

Posterior probabilities represent a model's belief that the translation will contain a particular n-gram at least once. They can be expressed as $\mathbb{E}_{P(d|f)}[\delta(d, g)]$ for an indicator function $\delta(d, g)$ that is 1 if n-gram g appears in derivation d. These quantities arise in approximating BLEU for lattice-based and hypergraph-based minimum Bayes risk decoding (Tromble et al., 2008; Kumar et al., 2009). Expected n-gram counts $\mathbb{E}_{P(d|f)}[c(d, g)]$ represent the model's belief of how many times an n-gram g will appear in the translation. These quantities appear in forest-based consensus decoding (DeNero et al., 2009) and variational decoding (Li et al., 2009b).

[3] The model combination framework could incorporate arbitrary features on the common output space of the models, but we focus on features that have previously proven useful for consensus decoding.

Methods for computing both of these quantities appear in the literature. However, we address two outstanding issues below. In Section 5, we also compare the two quantities experimentally.

3.1 Computing N-gram Posteriors Exactly

Kumar et al. (2009) describes an efficient *approximate* algorithm for computing n-gram posterior probabilities. Algorithm 1 is an *exact* algorithm that computes all n-gram posteriors from a forest in a single inside pass. The algorithm tracks two quantities at each node n: regular inside scores $\beta(n)$ and n-gram inside scores $\hat{\beta}(n, g)$ that sum the scores of all derivations rooted at n that contain n-gram g.

For each hyperedge, we compute $\bar{b}(g)$, the sum of scores for derivations that *do not* contain g (Lines 8-11). We then use that quantity to compute the score of derivations that *do* contain g (Line 17).

Algorithm 1 Computing n-gram posteriors

```
1:  for $n \in N$ in topological order do
2:      $\beta(n) \leftarrow 0$
3:      $\hat{\beta}(n,g) \leftarrow 0, \ \forall g \in \text{Ngrams}(n)$
4:      for $r \in \text{Rules}(n)$ do
5:          $w \leftarrow \exp\left[\theta \cdot \phi(r)\right]$
6:          $b \leftarrow w$
7:          $\bar{b}(g) \leftarrow w, \ \forall g \in \text{Ngrams}(n)$
8:          for $\ell \in \text{Leaves}(r)$ do
9:              $b \leftarrow b \times \beta(\ell)$
10:             for $g \in \text{Ngrams}(n)$ do
11:                 $\bar{b}(g) \leftarrow \bar{b}(g) \times \Big(\beta(\ell) - \hat{\beta}(\ell, g)\Big)$
12:         $\beta(n) \leftarrow \beta(n) + b$
13:         for $g \in \text{Ngrams}(n)$ do
14:             if $g \in \text{Ngrams}(r)$ then
15:                 $\hat{\beta}(n,g) \leftarrow \hat{\beta}(n,g) + b$
16:             else
17:                 $\hat{\beta}(n,g) \leftarrow \hat{\beta}(n,g) + b - \bar{b}(g)$
18: for $g \in \text{Ngrams}(\text{root})$ (all $g$ in the HG) do
19:     $P(g|f) \leftarrow \frac{\hat{\beta}(\text{root}, g)}{\beta(\text{root})}$
```

This algorithm can in principle compute the posterior probability of any indicator function on local features of a derivation. More generally, this algorithm demonstrates how vector-backed inside passes can compute quantities beyond expectations of local features (Li and Eisner, 2009).[4] Chelba and Mahajan (2009) developed a similar algorithm for lattices.

3.2 Ensuring N-gram Locality

DeNero et al. (2009) describes an efficient algorithm for computing n-gram expected counts from a translation forest. This method assumes *n-gram locality* of the forest, the property that any n-gram introduced by a hyperedge appears in *all* derivations that include the hyperedge. However, decoders may recombine forest nodes whenever the language model does not distinguish between n-grams due to backoff (Li and Khudanpur, 2008). In this case, a forest encoding of a posterior distribution may not exhibit n-gram locality in all regions of the search space. Figure 3 shows a hypergraph which contains non-local trigrams, along with its local expansion.

Algorithm 2 expands a forest to ensure n-gram locality while preserving the encoded distribution over derivations. Let a forest (N, R) consist of nodes N and hyperedges R, which correspond to rule applications. Let $\text{Rules}(n)$ be the subset of R rooted by n, and $\text{Leaves}(r)$ be the leaf nodes of rule application r. The expanded forest (N_e, R_e) is constructed by a function $\text{Reapply}(r, L)$ that applies the rule of r to a new set of leaves $L \subset N_e$, forming a pair (r', n') consisting of a new rule application r' rooted by n'. P is a map from nodes in N to subsets of N_e which tracks how N projects to N_e. Two nodes in N_e are identical if they have the same $(n-1)$-gram left and right contexts and are projections of the same node in N. The symbol $\bigotimes$ denotes a set cross-product.

Algorithm 2 Expanding for n-gram locality

```
$N_e \leftarrow \{\}; R_e \leftarrow \{\}$
for $n \in N$ in topological order do
    $P(n) \leftarrow \{\}$
    for $r \in \text{Rules}(n)$ do
        for $L \in \bigotimes_{\ell \in \text{Leaves}(r)} [P(\ell)]$ do
            $r', n' \leftarrow \text{Reapply}(r, L)$
            $P(n) \leftarrow P(n) \cup \{n'\}$
            $N_e \leftarrow N_e \cup \{n'\}$
            $R_e \leftarrow R_e \cup \{r'\}$
```

This transformation preserves the original distribution over derivations by splitting states, but maintaining continuations from those split states by duplicating rule applications. The process is analogous

[4] Indicator functions on derivations are not locally additive over the rules of a derivation, even if the features they indicate are local. Therefore, Algorithm 1 is not an instance of an expectation semiring computation.

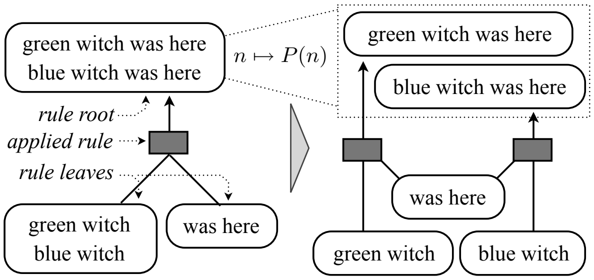


Figure 3: Hypergraph expansion ensures n-gram locality without affecting the distribution over derivations. In the left example, trigrams "green witch was" and "blue witch was" are non-local due to language model back-off. On the right, states are split to enforce trigram locality.

to expanding bigram lattices to encode a trigram history at each lattice node (Weng et al., 1998).

4 Relationship to Prior Work

Model combination is a multi-system generalization of consensus or minimum Bayes risk decoding. When only one component system is included, model combination is identical to minimum Bayes risk decoding over hypergraphs, as described in Kumar et al. (2009).[5]

4.1 System Combination

System combination techniques in machine translation take as input the outputs $\{e_1, \cdots, e_k\}$ of k translation systems, where e_i is a structured translation object (or k-best lists thereof), typically viewed as a sequence of words. The dominant approach in the field chooses a primary translation e_p as a *backbone*, then finds an alignment a_i to the backbone for each e_i. A new search space is constructed from these backbone-aligned outputs, and then a voting procedure or feature-based model predicts a final consensus translation (Rosti et al., 2007). Model combination entirely avoids this alignment problem by viewing hypotheses as n-gram occurrence vectors rather than word sequences.

Model combination also requires less total computation than applying system combination to consensus-decoded outputs. The best consensus decoding methods for individual systems already require the computation-intensive steps of model combination: producing lattices or forests, computing n-gram feature expectations, and re-decoding to maximize a secondary consensus objective. Hence, to maximize the performance of system combination, these steps must be performed for *each* system, whereas model combination requires only one forest rescoring pass over all systems.

Model combination also leverages aggregate statistics from the components' posteriors, whereas system combiners typically do not. Zhao and He (2009) showed that n-gram posterior features are useful in the context of a system combination model, even when computed from k-best lists.

Despite these advantages, system combination may be more appropriate in some settings. In particular, model combination is designed primarily for statistical systems that generate hypergraph outputs. Model combination can in principle integrate a non-statistical system that generates either a single hypothesis or an unweighted forest.[6] Likewise, the procedure could be applied to statistical systems that only generate k-best lists. However, we would not expect the same strong performance from model combination in these constrained settings.

4.2 Joint Decoding and Collaborative Decoding

Liu et al. (2009) describes two techniques for combining multiple synchronous grammars, which the authors characterize as joint decoding. Joint decoding does not involve a consensus or minimum-Bayes-risk decoding objective; indeed, their best results come from standard max-derivation decoding (with a multi-system grammar). More importantly, their computations rely on a correspondence between nodes in the hypergraph outputs of different systems, and so they can only joint decode over models with similar search strategies. We combine a phrase-based model that uses left-to-right decoding with two hierarchical systems that use bottom-up decoding — a scenario to which joint decoding is not applicable. Though Liu et al. (2009) rightly point out that most models can be decoded either left-to-

[5] We do not refer to model combination as a minimum Bayes risk decoding procedure despite this similarity because *risk* implies a belief distribution over outputs, and we now have multiple output distributions that are not necessarily calibrated. Moreover, our generalized, multi-model objective (Section 2.4) is motivated by BLEU, but not a direct approximation to it.

[6] A single hypothesis can be represented as a forest, while an unweighted forest could be assigned a uniform distribution.

right or bottom-up, such changes can have substantial implications for search efficiency and search error. We prefer to maintain the flexibility of using different search strategies in each component system.

Li et al. (2009a) is another related technique for combining translation systems by leveraging model predictions of n-gram features. K-best lists of partial translations are iteratively reranked using n-gram features from the predictions of other models (which are also iteratively updated). Our technique differs in that we use no k-best approximations, have fewer parameters to learn (one consensus weight vector rather than one for each collaborating decoder) and produce only one output, avoiding an additional system combination step at the end.

5 Experiments

We report results on the constrained data track of the NIST 2008 Arabic-to-English (ar-en) and Chinese-to-English (zh-en) translation tasks.[7] We train on all parallel and monolingual data allowed in the track. We use the NIST 2004 eval set (*dev*) for optimizing parameters in model combination and test on the NIST 2008 evaluation set. We report results using the IBM implementation of the BLEU score which computes the brevity penalty using the closest reference translation for each segment (Papineni et al., 2002). We measure statistical significance using 95% confidence intervals computed using paired bootstrap resampling. In all table cells (except for Table 3) systems without statistically significant differences are marked with the same superscript.

5.1 Base Systems

We combine outputs from three systems. Our phrase-based system is similar to the alignment template system described by Och and Ney (2004). Translation is performed using a standard left-to-right beam-search decoder. Our hierarchical systems consist of a syntax-augmented system (SAMT) that includes target-language syntactic categories (Zollmann and Venugopal, 2006) and a Hiero-style system with a single non-terminal (Chiang, 2007). Each base system yields state-of-the-art translation performance, summarized in Table 1.

Table 2: Performance from the best single system for each language pair without consensus decoding (*Best MAX system*), the best system with minimum Bayes risk decoding (*Best MBR system*), and model combination across three systems.

For each system, we report the performance of max-derivation decoding (MAX), hypergraph-based MBR (Kumar et al., 2009), and a linear version of forest-based consensus decoding (CON) (DeNero et al., 2009). MBR and CON differ only in that the first uses n-gram posteriors, while the second uses expected n-gram counts. The two consensus decoding approaches yield comparable performance. Hence, we report performance for hypergraph-based MBR in our comparison to model combination below.

5.2 Experimental Results

Table 2 compares model combination (MC) to the best MAX and MBR systems. Model combination uses a conjoined search space wherein each hyperedge is annotated with 21 features: 12 n-gram posterior features v_i^n computed from the PB/Hiero/SAMT forests for $n \leq 4$; 4 n-gram posterior features v^n computed from the conjoined forest; 1 length feature ℓ; 1 feature b for the score assigned by the base model; and 3 system indicator (SI) features α_i that select which base system a derivation came from. We refer to this model combination approach as MC

Table 3: Model Combination experiments.

Conjoin/SI. Model combination improves over the single best MAX system by 1.4 BLEU in ar-en and 0.6 BLEU in zh-en, and always improves over MBR.

This improvement could arise due to multiple reasons: a bigger search space, the consensus features from constituent systems, or the system indicator features. Table 3 teases apart these contributions.

We first perform MBR on the conjoined hypergraph (MBR-Conjoin). In this case, each edge is tagged with 4 conjoined n-gram features v^n, along with length and base model features. MBR-Conjoin is worse than MBR on the hypergraph from the single best system. This could imply that either the larger search space introduces poor hypotheses or that the n-gram posteriors obtained are weaker. When we now restrict the n-gram features to those from the best system (MBR Conjoin/feats-best), BLEU scores increase relative to MBR-Conjoin. This implies that the n-gram features computed over the conjoined hypergraph are weaker than the corresponding features from the best system.

Adding system indicator features (MBR Conjoin+SI) helps the MBR-Conjoin system considerably; the resulting system is better than the best MBR system. This could mean that the SI features guide search towards stronger parts of the larger search space. In addition, these features provide a normalization of scores across systems.

We next do several model-combination experiments. We perform model combination using the search space of only the best MBR system (MC 1best HG). Here, the hypergraph is annotated with n-gram features from the 3 base systems, as well as length and base model features. A total of $3 \times 4 + 1 + 1 = 14$ features are added to each edge. Surprisingly, n-gram features from the additional systems did not help select a better hypothesis within the search space of a single system.

MC-conjoin-SI		**53.5**	**45.3**	**41.6**	**29.0**$^{+}$

Table 4: BLEU performance for different system and model combination approaches. Sentence-level and word-level system combination operate over the sentence output of the base systems, which are either decoded to maximize derivation score (MAX) or to minimize Bayes risk (MBR).

When we expand the search space to the conjoined hypergraph (MC Conjoin), it performs worse relative to MC 1-best. Since these two systems are identical in their feature set, we hypothesize that the larger search space has introduced erroneous hypotheses. This is similar to the scenario where MBR Conjoin is worse than MBR 1-best. As in the MBR case, adding system indicator features helps (MC Conjoin/base/SI). The result is comparable to MBR on the conjoined hypergraph with SI features.

We finally add extra n-gram features which are computed from the conjoined hypergraph (MC Conjoin + SI). This gives the best performance although the gains over MC Conjoin/base/SI are quite small. Note that these added features are the same n-gram features used in MBR Conjoin. Although they are not strong by themselves, they provide additional discriminative power by providing a consensus score across all 3 base systems.

5.3 Comparison to System Combination

Table 4 compares model combination to two system combination algorithms. The first, which we call *sentence-level* combination, chooses among the base systems' three translations the sentence that has the highest consensus score. The second, *word-level* combination, builds a "word sausage" from the outputs of the three systems and chooses a path through the sausage with the highest score under a similar model (Macherey and Och, 2007). Nei-

ther system combination technique provides much benefit, presumably because the underlying systems all share the same data, pre-processing, language model, alignments, and code base.

Comparing system combination when no consensus (i.e., minimum Bayes risk) decoding is utilized at all, we find that model combination improves upon the result by up to 1.1 BLEU points. Model combination also performs slightly better relative to system combination over MBR-decoded systems. In the latter case, system combination actually requires more computation compared to model combination; consensus decoding is performed for *each* system rather than only once for model combination. This experiment validates our approach. Model combination outperforms system combination while avoiding the challenge of aligning translation hypotheses.

5.4 Algorithmic Improvements

Section 3 describes two improvements to computing n-gram posteriors: hypergraph expansion for n-gram locality and exact posterior computation. Table 5 shows MBR decoding with and without expansion (Algorithm 2) in a decoder that collapses nodes due to language model back-off. These results show that while expansion is necessary for correctness, it does not affect performance.

Table 6 compares exact n-gram posterior computation (Algorithm 1) to the approximation described by Kumar et al. (2009). Both methods yield identical results. Again, while the exact method guarantees correctness of the computation, the approximation suffices in practice.

6 Conclusion

Model combination is a consensus decoding strategy over a collection of forests produced by multiple machine translation systems. These systems can have varied decoding strategies; we only require that each system produce a forest (or a lattice) of translations. This flexibility allows the technique to be applied quite broadly. For instance, de Gispert et al. (2009) describe combining systems based on multiple source representations using minimum Bayes risk decoding—likewise, they could be combined via model combination.

Model combination has two significant advantages over current approaches to system combination. First, it does not rely on hypothesis alignment between outputs of individual systems. Aligning translation hypotheses accurately can be challenging, and has a substantial effect on combination performance (He et al., 2008). Instead of aligning hypotheses, we compute expectations of local features of n-grams. This is analogous to how BLEU score is computed, which also views sentences as vectors of n-gram counts (Papineni et al., 2002) . Second, we do not need to pick a backbone system for combination. Choosing a backbone system can also be challenging, and also affects system combination performance (He and Toutanova, 2009). Model combination sidesteps this issue by working with the conjoined forest produced by the union of the component forests, and allows the consensus model to express system preferences via weights on system indicator features.

Despite its simplicity, model combination provides strong performance by leveraging existing consensus, search, and training techniques. The technique outperforms MBR and consensus decoding on each of the component systems. In addition, it performs better than standard sentence-based or word-based system combination techniques applied to either max-derivation or MBR outputs of the individual systems. In sum, it is a natural and effective model-based approach to multi-system decoding.

Abstract

Automatically finding email messages that contain requests for action can provide valuable assistance to users who otherwise struggle to give appropriate attention to the actionable tasks in their inbox. As a speech act classification task, however, automatically recognising requests in free text is particularly challenging. The problem is compounded by the fact that typical emails contain extraneous material that makes it difficult to isolate the content that is directed to the recipient of the email message. In this paper, we report on an email classification system which identifies messages containing requests; we then show how, by segmenting the content of email messages into different functional zones and then considering only content in a small number of message zones when detecting requests, we can improve the accuracy of message-level automated request classification to 83.76%, a relative increase of 15.9%. This represents an error reduction of 41% compared with the same request classifier deployed without email zoning.

1 Introduction

The variety of linguistic forms that can be used to express requests, and in particular the frequency with which indirect speech acts are used in email, is a major source of difficulty in determining whether an email message contains one or more requests. Another significant problem arises from the fact that whether or not a request is directed at the recipient of the email message depends on where in the message the request is found. Most obviously, if the request is part of a replied-to message that is contained within the current message, then it is perhaps more likely that this request was directed at the sender of the current message. However, separating out content intended for the recipient from other extraneous content is not as simple as it might appear. Segmenting email messages into their different functional parts is hampered by the lack of standard syntax used by different email clients to indicate different message parts, and by the *ad hoc* ways in which people vary the structure and layout of messages.

In this paper, we present our results in classifying messages according to whether or not they contain requests, and then show how a separate classifier that aims to determine the nature of the zones that make up an email message can improve upon these results. Section 2 contains some context and motivation for this work before we briefly review relevant related work in Section 3. Then, in Section 4, we describe a first experiment in request classification using data gathered from a manual annotation experiment. In analysing the errors made by this classifier, we found that a significant number of errors seemed to arise from the inclusion of content in parts of a message (e.g., quoted reply content) that were not authored by the current sender, and thus were not relevant other than as context for interpreting the current message content. Based on this analysis, we hypothesised that segmenting messages into their different functional parts, which we call **email zones**, and then using this information to consider only content from certain parts of a message for request classification, would improve request classifi-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 984–992,

cation performance.

To test this hypothesis, we developed an SVM-based automated email zone classifier configured with graphic, orthographic and lexical features; this is described in more detail in (Lampert et al., 2009). Section 5 describes how we improve request classification performance using this email zone classifier. Section 6 summarises the performance of our request classifiers, with and without automated email zoning, along with an analysis of the contribution of lexical features to request classification, discussion of request classification learning curves, and a detailed error analysis that explores the sources of request classification errors. Finally, in Section 7, we offer pointers to future work and some concluding remarks.

2 Background and Motivation

Previous research has established that users routinely use email for managing requests in the workplace — e.g., (Mackay, 1988; Ducheneaut and Bellotti, 2001). Such studies have highlighted how managing multiple ongoing tasks through email leads to information overload (Whittaker and Sidner, 1996; Bellotti et al., 2003), especially in the face of an ever-increasing volume of email. The result is that many users have difficulty giving appropriate attention to requests hidden in their email which require action or response. A particularly lucid summary of the requirements placed on email users comes from work by Murray (1991), whose ethnographic research into the use of electronic messaging at IBM highlighted that:

> [Managers] would like to be able to track outstanding promises they have made, promises made to them, requests they've made that have not been met and requests made of them that they have not fulfilled.

This electronic exchange of requests and commitments has previously been identified as a fundamental basis of the way work is delegated and completed within organisations. Winograd and Flores were among the first to recognise and attempt to exploit this with their Coordinator system (Winograd and Flores, 1986). Their research into organisational communication concluded that "Organisations exist as networks of directives and commissives". It is on this basis that our research explores the use of requests (directive speech acts) and commitments (commissive speech acts) in email. In this paper, we focus on requests; feedback from users of the request and commitment classifier plug-in for Microsoft Outlook that we have under development suggests that, at least within the business context of our current users, requests are the more important of the two phenomena.

Our aim is to create tools that assist email users to identify and manage requests contained in incoming and outgoing email. We define a request as an utterance that places an obligation on an email recipient to schedule an action; perform (or not perform) an action; or to respond with some speech act. A simple example might be *Please call when you have a chance*. A more complicated request is *David will send you the latest version if there have been any updates*. If David (perhaps cc'ed) is a recipient of an email containing this second utterance, the utterance functions as a (conditional) request for him, even though it is addressed as a commitment to a third-party. In real-world email, requests are frequently expressed in such subtle ways, as we discuss in Section 4.

A distinction can be drawn between **message-level identification**—i.e., the task of determining *whether* an email message contains a request — and **utterance-level identification**—i.e., determining precisely where and how the request is expressed. In this paper, we focus on the task of message-level identification, since utterance-level identification is a significantly more problematic task: it is often the case that, while we might agree that a message contains a request or commitment, it is much harder to determine the precise extent of the text that conveys this request (see (Lampert et al., 2008b) for a detailed discussion of some of the issues here).

3 Related Work

Our request classification work builds on influential ideas proposed by Winograd and Flores (1986) in taking a language/action perspective and identifying speech acts in email. While this differs from the approach of most currently-used email systems, which routinely treat the content of email messages as homogeneous bags-of-words, there is a growing body of research applying ideas from Speech Act Theory (Austin, 1962; Searle, 1969) to analyse and enhance email communication.

Khosravi and Wilks (1999) were among the first to automate message-level request classification in email. They used cue-phrase based rules to classify three classes of requests: Request-Action, Request-Information and Request-Permission. Unfortunately, their approach was quite brittle, with the rules being very specific to the computer support domain from which their email data was drawn.

Cohen, Carvalho and Mitchell (2004) developed machine learning-based classifiers for a number of email speech acts. They performed manual email zoning, but didn't explore the contribution this made to the performance of their various speech act classifiers. For requests, they report peak F-measure of 0.69 against a majority class baseline accuracy of approximately 66%. Cohen, Carvalho and Mitchell found that unweighted bigrams were particularly useful features in their experiments, out-performing other features applied. They later applied a series of text normalisations and n-gram feature selection algorithms to improve performance (Carvalho and Cohen, 2006). We apply similar normalisations in our work. While difficult to compare due to the use of a different email corpus that may or may not exclude annotation disagreements, our request classifier performance exceeds that of the enhanced classifier reported in (Carvalho and Cohen, 2006).

Goldstein and Sabin (2006) have also worked on related email classification tasks. They use verb classes, along with a series of hand-crafted form- and phrase-based features, for classifying what they term **email genre**, a task which overlaps significantly with email speech act classification. Their results are difficult to compare since they include a mix of form-based classifications like **response** with more intent-based classes such as **request**. For requests, the results are rather poor, with precision of only 0.43 on a small set of personal mail.

The SmartMail system (Corston-Oliver et al., 2004) is probably the most mature previous work on utterance-level request classification. SmartMail attempted to automatically extract and reformulate action items from email messages for the purpose of adding them to a user's to-do list. The system employed a series of deep linguistic features, including phrase structure and semantic features, along with word and part-of-speech n-gram features. The authors found that word n-grams were highly predictive for their classification task, and that there was little difference in performance when the more expensive deep linguistic features were added. Based on this insight, our own system does not employ deeper linguistic features. Unfortunately, the results reported reveal only the aggregate performance across all classes, which involves a mix of both form-based classes (such as signature content address lines and URL lines), and intent-based classes (such as requests and promises). It is thus very difficult to directly compare the results with our system. Additionally, the experiments were performed over a large corpus of messages that are not available for use by other researchers. In contrast, we use messages from the widely-available Enron email corpus (Klimt and Yang, 2004) for our own experiments.

While several of the above systems involve manual processes for removing particular parts of message bodies, none employ a comprehensive, automated approach to email zoning.

We focus on the combination of email zoning and request classification tasks and provide details of how email zoning improves request classification — a task not previously explored. To do so, we require an automated email zone classifier. We experimented with using the Jangada system (Carvalho and Cohen, 2004), but found similar shortcomings to those noted by Estival et al. (2007). In particular, Jangada did not accurately identify forwarded or reply content in email messages from the email Enron corpus that we use. We achieved much better performance with our own Zebra zone classifier (Lampert et al., 2009); it is this system that we use for email zoning throughout this paper.

4 Email Request Classification

Identifying requests requires interpretation of the intent that lies behind the language used. Given this, it is natural to approach the problem as one of **speech act identification**. In Speech Act Theory, speech acts are categories like **assertion** and **request** that capture the intentions underlying surface utterances, providing abstractions across the wide variety of different ways in which instances of those categories might be realised in linguistic form. In this paper we focus on the speech acts that represent requests, where people are placing obligations upon others via actionable content within email messages.

The task of building automated classifiers is difficult since the function of conveying a request does not neatly map to a particular set of language forms; requests often involve what are referred to as **indirect speech acts**. While investigating particular surface forms of language is relatively unproblematic, it is widely recognised that "investigating a collection of forms that represent, for example, a particular speech act leads to the problem of establishing which forms constitute that collection" (Archer et al., 2008). Email offers particular challenges as it has been shown to exhibit a higher frequency of indirect speech acts than other media (Hassell and Christensen, 1996). We approach the problem by gathering judgments from human annotators and using this data to train supervised machine learning algorithms.

Our request classifier works at the message-level, marking emails as requests if they contain one or more request utterances. As noted earlier, we define a request as an utterance from the email sender that places an obligation on a recipient to schedule an action (e.g., add to a calendar or task list), perform an action, or respond. Requests may be conditional or unconditional in terms of the obligation they impose on the recipient. Conditional requests require action only if a stated condition is satisfied. Previous annotation experiments have shown that conditional requests are an important phenomena and occur frequently in email (Scerri et al., 2008; Lampert et al., 2008a). Requests may also be phrased as either a direct or indirect speech act.

Although some linguists distinguish between speech acts that require a physical response and those that require a verbal or information response, e.g., (Sinclair and Coulthard, 1975), we follow Searle's approach and make no such distinction. We thus consider questions requiring an informational response to be requests, since they place an obligation on the recipient to answer.[1]

Additionally, there are some classes of request which have been the source of systematic human disagreement in our previous annotation experiments. One such class consists of **requests for inaction**. Requests for inaction, sometimes called **prohibitives** (Sadock and Zwicky, 1985), prohibit action or request negated action. An example is: *Please don't let anyone else use the computer in the office*. As they impose an obligation on the sender, we consider requests for inaction to be requests. Similarly, we consider that meeting announcements (e.g., *Today's Prebid Meeting will take place in EB32c2 at 3pm*) and requests to read, open or otherwise act on documents attached to email messages (e.g., *See attached*) are also requests.

Several complex classes of requests are particularly sensitive to the context for their interpretation. Reported requests are one such class. Some reported requests, such as *Paul asked if you could put together a summary of your accomplishments in an email*, clearly function as a request. Others do not impose an obligation on the recipient, e.g., *Sorry for the delay; Paul requested your prize to be sent out late December*. The surrounding context must be used to determine the intent of utterances like reported requests. Such distinctions are often difficult to automate.

Other complex requests include instructions. Sometimes instructions are of the kind that one might 'file for later use'. These tend to not be marked as requests. Other instructions, such as *Your user id and password have been set up. Please follow the steps below to access the new environment*, are intended to be executed more promptly. Temporal distance between receipt of the instruction and expected action is an important factor to distinguish between requests and non-requests. Another influencing property is the likelihood of the trigger event that would lead to execution of the described action. While the example instructions above are likely to be executed, instructions for how to handle suspected anthrax-infected mail are (for most people) unlikely to be actioned.

Further detail and discussion of these and other

[1] Note, however, that not all questions are requests. Rhetorical questions are perhaps the most obvious class of non-request questions.

challenges in defining and interpreting requests in email can be found in (Lampert et al., 2008b). In particular, that paper includes analysis of a series of complex edge cases that make even human agreement in identifying requests difficult to achieve.

4.1 An Email Request Classifier

Our request classifier is based around an SVM classifier, implemented using Weka (Witten and Frank, 2005). Given an email message as input, complete with header information, our binary request classifier predicts the presence or absence of request utterances within the message.

For training our request classifier, we use email from the database dump of the Enron email corpus released by Andrew Fiore and Jeff Heer.[2] This version of the corpus has been processed to remove duplicate messages and to normalise sender and recipient names, resulting in just over 250,000 email messages. No attachments are included.

Our request classifier training data is drawn from a collection of 664 messages that were selected at random from the Enron corpus. Each message was annotated by three annotators, with overall kappa agreement of 0.681. From the full dataset of 664 messages, we remove all messages where annotators disagreed for training and evaluating our request classifier, in order to mitigate the effects of annotation noise, as discussed in (Beigman and Klebanov, 2009). The unanimously agreed data set used for training consists of 505 email messages.

4.2 Request Classification Features

The features we use in our request classifier are:

- message length in characters and words;
- number and percentage of capitalised words;
- number of non alpha-numeric characters;
- whether the subject line contains markers of email replies or forwards (e.g. `Re:`, `Fw:`);
- the presence of sender or recipient names;
- the presence of sentences that begin with a modal verb (e.g., *might*, *may*, *should*, *would*);
- the presence of sentences that begin with a question word (e.g, *who*, *what*, *where*, *when*, *why*, *which*, *how*);
- whether the message contains any sentences that end with a question mark; and
- binary word unigram and word bigram features for n-grams that occur at least three times across the training set.

Before generating n-gram features, we normalise the message text as shown in Table 1, in a manner similar to Carvalho and Cohen (2006). We also add tokens marking the start and end of sentences, detected using a modified version of Scott Piao's sentence splitter (Piao et al., 2002), and tokens marking the start and end of the message.

Symbol Used	Pattern
numbers	Any sequence of digits
day	Day names or abbreviations
pronoun-object	Objective pronouns: *me*, *her*, *him*, *us*, *them*
pronoun-subject	Subjective pronouns: *I*, *we*, *you*, *he*, *she*, *they*
filetype	.doc, .pdf, .ppt, .txt, .xls, .rtf
multi-dash	3 or more sequential '−' characters
multi-underscore	3 or more sequential '_' characters

Table 1: Normalisation applied to n-gram features

Our initial request classifier achieves an accuracy of 72.28%. Table 2 shows accuracy, precision, recall and F-measure results, calculated using stratified 10-fold cross-validation, compared against a majority class baseline. Given the well-balanced nature of our training data (52.08% of messages contain a request), this is a reasonable basis for comparison.

	Majority Baseline		No Zoning Classifier	
	Request	Non-Request	Request	Non-Request
Accuracy	52.08%		72.28%	
Precision	0.521	0.000	0.729	0.716
Recall	1.000	0.000	0.745	0.698
F-Measure	0.685	0.000	0.737	0.707

Table 2: Request classifier results without email zoning

An error analysis of the predictions from our initial request classifier uncovered a series of classification errors that appeared to be due to request-like signals being picked up from parts of messages such as email signatures and quoted reply content. It seemed likely that our request classifier would benefit from an email zone classifier that could identify and ignore such message parts.

[2] http://bailando.sims.berkeley.edu/enron/enron.sql.gz

5 Improving Request Classification with Email Zoning

Requests in email do not occur uniformly across the zones that make up the email message. There are specific zones of a message in which requests are likely to occur.

Unfortunately, accurate classification of email zones is difficult, hampered by the lack of standard syntax used by different email clients to indicate different message parts, and by the *ad hoc* ways in which people vary the structure and layout of their messages. For example, different email clients indicate quoted material in a variety of ways. Some prefix every line of the quoted message with a character such as '>' or '|', while others indent the quoted content or insert the quoted message unmodified, prefixed by a message header. Sometimes the new content is above the quoted content (a style known as **top-posting**); in other cases, the new content may appear after the quoted content (**bottom-posting**) or interleaved with the quoted content (**inline replying**). Confounding the issue further is that users are able to configure their email client to suit their individual tastes, and can change both the syntax of quoting and their quoting style (top, bottom or inline replying) on a per message basis.

Despite the likelihood of some noise being introduced through mis-classification of email zones, our hypothesis was that even imperfect information about the functional parts of a message should improve the performance of our request classifier.

Based on this hypothesis, we integrated Zebra (Lampert et al., 2009), our SVM-based email zone classifier, to identify the different functional parts of email messages. Using features that capture graphic, orthographic and lexical information, Zebra classifies and segments the body text into nine different email zones: author content (written by the current sender), greetings, signoffs, quoted reply content, forwarded content, email signatures, advertising, disclaimers, and automated attachment references. Zebra has two modes of operation, classifying either message fragments — whitespace separated sets of contiguous lines — or individual lines. We configure Zebra for line-based zone classification, and use it to extract only lines classified as author, greeting and signoff text. We remove the content of all other zones before we evaluate features for request classification.

6 Results and Discussion

Classifying the zones in email messages and applying our request classifier to only relevant message parts significantly increases the performance of the request classifier. As noted above, without zoning, our request classifier achieves accuracy of 72.28% and a weighted F-measure (weighted between the F-measure for requests and non-requests based on the relative frequency of each class) of 0.723. Adding the zone classifier, we increase the accuracy to 83.76% and the weighted F-measure to 0.838. This corresponds to a relative increase in both accuracy and weighted F-measure of 15.9%, which in turn corresponds to an error reduction of more than 41%. Table 3 shows a comparison of the results of the non-zoning and zoning request classifiers, generated using stratified 10-fold cross-validation. In a two-tailed paired t-test, run over ten iterations of stratified 10-fold cross-validation, the increase in accuracy, precision, recall and f-measure were all significant at p=0.01.

	No Zoning		With Zoning	
	Request	Non-Request	Request	Non-Request
Accuracy	72.28%		83.76%*	
Precision	0.729	0.716	0.849*	0.825*
Recall	0.745	0.698	0.837*	0.839*
F-Measure	0.737	0.707	0.843*	0.832*

Table 3: Request classifier results with and without email zoning (* indicates a statistically significant difference at p=0.01)

6.1 Lexical Feature Contribution

As expected, lexical information is crucial to request classification. When we experimented with removing all lexical (n-gram) features, the non-zoning request classifier accuracy dropped to 57.62% and the zoning request classifier accuracy dropped to 61.78%. In contrast, when we apply *only* n-gram features, we achieve accuracy of 71.49% for the non-zoning classifier and 83.36% for the zoning classifier. Clearly, lexical information is critical for accurate request classification, regardless of whether email messages are zoned.

Using Information Gain, we ranked the n-gram features in terms of their usefulness. Table 4 shows the top-10 unigrams and bigrams for our non-zoning request classifier. Using these top-10 n-grams (plus our non-n-gram features), we achieve only 66.34% accuracy. These top-10 n-grams do not seem to align well with linguistic intuitions, illustrating how the noise from irrelevant message parts hampers performance. In particular, there were several similar, apparently automated messages that were annotated (as non-requests) which appear to be the source of several of the top-10 n-grams. This strongly suggests that without zoning, the classifier is not learning features from the training set at a useful level of generality.

Word Unigrams	Word Bigrams	
	Word 1	Word 2
pronoun-object	let	*pronoun-object*
please	*pronoun-object*	know
iso	*start-sentence*	no
pronoun-subject	start	date
hourahead	hour	:
attached	;	hourahead
let	hourahead	hour
westdesk	*start-sentence*	start
parsing	westdesk	/
if	iso	final

Table 4: Top 10 useful n-grams for our request classifier without zoning, ranked by Information Gain

In contrast, once we add the zoning classifier, the top-10 unigrams and bigrams appear to correspond much better with linguistic intuitions about the language of requests. These are shown in Table 5. Using these top-10 n-grams (plus our non-n-gram features), we achieve 80% accuracy. This suggests that, even with our relatively small amount of training data, the zone classifier helps the request classifier to extract fairly general n-gram features.

Interestingly, although lexical features are very important, the top three features ranked by Information Gain are non-lexical: message length in words, the number of non-alpha-numeric characters in the message and the number of capitalised words in the message.

Word Unigrams	Word Bigrams	
	Word 1	Word 2
please	?	*end-sentence*
?	*pronoun-object*	know
pronoun-object	let	*pronoun-object*
if	*start-sentence*	please
pronoun-subject	if	*pronoun-subject*
let	*start-sentence*	thanks
to	please	let
know	*pronoun-subject*	have
thanks	thanks	*comma*
do	start	date

Table 5: Top 10 useful n-grams for our request classifier with zoning, ranked by Information Gain

6.2 Learning Curves

Figure 1 shows a plot of accuracy, precision and recall versus the number of training instances used to build the request classifier. These results are calculated over zoned email bodies, using the average across ten iterations of stratified 10-fold cross-validation for each different sized set of training instances, implemented via the `FilteredClassifier` with the `Resample` filter in Weka. Given our pool of 505 agreed message annotations, we plot the recall and precision for training instance sets of size 50 to 505 messages.

There is a clear trend of increasing performance as the training set size grows. It seems reasonable to assume that more data should continue to facilitate better request classifier performance. To this end, we are annotating more data as part of our current and future work.

6.3 Error Analysis

To explore the errors made by our request classifier, we examined the output of our zoning request classifier using our full feature set, including all word n-grams.

Approximately 20% of errors relate to requests that are implicit, and thus more difficult to detect from surface features. Another 10% of errors are due to attempts to classify requests in inappropriate genres of email messages. In particular, both marketing messages and spam frequently include request-like, directive utterances which our annotators all agreed would not be useful to mark as re-

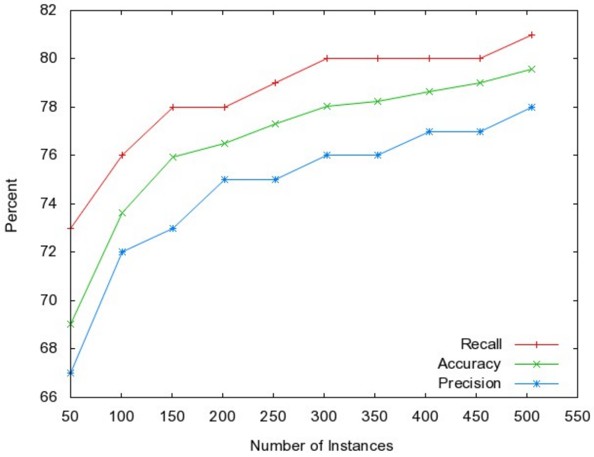

Figure 1: Learning curve showing recall, accuracy and precision versus the number of training instances

quests for an email user. Not unreasonably, our classifier is sometimes confused by the content of these messages, mistakenly marking requests where our annotators did not. We intend to resolve these classification errors by filtering out such messages before we apply the request classifier.

Another 5% of errors are due to request content occurring in zones that we ignore. The most common case is content in a forwarded zone. Sometimes email senders forward a message as a form of task delegation; because we ignore forwarded content, our request classifier misses such requests. We did experiment with including content from forwarded zones (in addition to the author, greeting and signoff zones), but found that this reduced the performance of our request classifier, presumably due to the additional noise from irrelevant content in other forwarded material. Forwarded messages are thus somewhat difficult to deal with. One possible approach would be to build sender-specific profiles that might allow us to deal with forwarded content (and potentially content from other zones) differently for different users, essentially learning to adapt to the different styles of different email users.

A further 5% of errors involve errors in the zone classifier, which leads to incorrect zone labels being applied to zone content that we would wish to include for our request classifier. Examples include author content being mistakenly identified as signature content. In such cases, we incorrectly remove relevant content from the body text that is passed to our request classifier. Improvements to the zone classifier would resolve these issues.

As part of our annotation task, we also asked coders to mark the presence of **pleasantries**. We define a pleasantry as an utterance that could be a request in some other context, but that does not function as a request in the context of use under consideration. Pleasantries are frequently formulaic, and do not place any significant obligation on the recipient to act or respond. Variations on the phrase *Let me know if you have any questions* are particularly common in email messages. The context of the entire email message needs to be considered to distinguish between when such an utterance functions as a request and when it should be marked as a pleasantry. Of the errors made by our request classifier, approximately 5% involve marking messages containing only pleasantries as containing a request.

The remaining errors are somewhat diverse. Close to 5% involve errors interpreting requests associated with attached files. The balance of almost 50% of errors involve a wide range of issues, from misspellings of key words such as *please* to a lack of punctuation cues such as question marks.

7 Conclusion

Request classification, like any form of automated speech act recognition, is a difficult task. Despite this inherent difficulty, the automatic request classifier we describe in this paper correctly labels requests at the message level in 83.76% of email messages from our annotated dataset. Unlike previous work that has attempted to automate the classification of requests in email, we zone the messages without manual intervention. This improves accuracy by 15.9% relative to the performance of the same request classifier without the assistance of an email zone classifier to focus on relevant message parts. Although some zone classification errors are made, error analysis reveals that only 5% of errors are due to zone misclassification of message parts. This suggests that, although zone classifier performance could be further improved, it is likely that focusing on improving the request classifier using the existing zone classifier performance will lead to greater performance gains.

Evaluating Hierarchical Discourse Segmentation

Lucien Carroll

lucien@ling.ucsd.edu

Abstract

Hierarchical discourse segmentation is a useful technology, but it is difficult to evaluate. I propose an error measure based on the word error rate of Beeferman et al. (1999). I then show that this new measure not only reliably distinguishes baseline segmentations from lexically-informed hierarchical segmentations and more informed segmentations from less informed segmentations, but it also offers an improvement over previous linear error measures.

1 Introduction

Discourse segmentation is the task of identifying coherent clusters of sentences and the points of transition between those groupings. Discourse segmentation can be viewed as shallow parsing of discourse structure. The segments and the relations between them are left unlabeled, focusing instead on the boundaries between the segments (i.e., the bracketing).

Discourse segmentation is thought to facilitate automatic summarization (Angheluta et al., 2002; Boguraev and Neff, 2000), information retrieval (Kaszkiel and Zobel, 1997), anaphora resolution (Walker, 1997) and question answering (Chai and Jin, 2004). Automatic discourse segmentation, as shallow annotation of discourse structure, also provides a testing grounds for linguistic theories of discourse (Passonneau and Litman, 1997) and provides a natural unit of measure in linguistic corpora (Biber et al., 2004).

1.1 The structure of discourse

Research in discourse structure theory (Hobbs, 1985; Grosz and Sidner, 1986; Mann and Thompson, 1988; Kehler, 2002; Asher and Lascarides, 2003; Webber, 2004) and discourse parsing (Marcu, 2000; Forbes et al., 2003; Polanyi et al., 2004; Baldridge et al., 2007) has variously defined discourse structure in terms of communicative intention, attention, topic/subtopic structure, coherence relations, and cohesive devices. There is much disagreement about the units and elementary relations of discourse structure, but they agree that the structures are hierarchical, most commonly trees (Marcu, 2000), while others have argued for directed acyclic graphs (Danlos, 2004), or general graphs (Wolf and Gibson, 2004). In contrast, most of the segmentation research to date has focused on linear segmentation, in which segments are non-overlapping and sequential, and it has been argued that this sequence model is sufficient for many purposes (Hearst, 1994). I focus here on tree discourse segmentation, in which larger segments are composed of sequences of subsegments. This is potentially more informative and more faithful to linguistic theory than linear discourse segmentation is, but it poses a more challenging evaluation problem.

1.2 Hierarchical segmentation

Four studies have described hierarchical discourse segmentation algorithms, but none of them rigorously evaluated the segmentation in its hierarchical form. Yaari (1997) used a hierarchical clustering algorithm for hierarchical discourse segmentation, and to evaluate it, he linearized the tree (taking all boundaries equally) and compared the result-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 993–1001,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

ing precision and recall to contemporary linear segmentation algorithms. Slaney and Ponceleon (2001) used scale-space segmentation (an image segmentation algorithm) on the discourse's trajectory in a Latent Semantic Indexing (LSI) space (Landauer et al., 1998). They evaluated the algorithm by visual comparison with the heading-subheading structure of the text. Angheluta et al. (2002) applied a linear discourse segmentation algorithm recursively, segmenting each major segment into a sequence of subsegments. They used the result in a summarization system, and they evaluated the summarization system but not the segmentation itself. Eisenstein (2009) used a Bayesian latent topic model to find a hierarchical segmentation, and he comes the closest to quantitative evaluation of the whole segmentation. He evaluated it against three recursive segmentation algorithms on a corpus that had just two levels of segment depth and considers these two levels as separate and equally important. While each of these studies offers some insight into the validity of the hierarchical segmentation, none of these evaluation methods directly and quantitatively assesses the hierarchical segmentation as a whole.

Many state-of-the-art linear discourse segmentation algorithms also use hierarchical frameworks, making them applicable to hierarchical discourse segmentation with only trivial modification. For example, the C99 algorithm (Choi, 2000) applies contrast enhancement and divisive clustering to a matrix of lexical vector cosine similarities. The CWM algorithm (Choi et al., 2001) applies the same procedure to a similarity matrix of LSI vectors. Using these algorithms for hierarchical discourse segmentation simply requires keeping record of the boundary ranking, but until now they have only been used for linear segmentation.

1.3 The Beeferman error measure

Studies of linear discourse segmentation have revealed that discourse boundaries are inherently fuzzy. Human annotators demonstrate frequent disagreement about the number of segments and exactly where the transitions between segments occur, while still demonstrating statistically significant agreement (Passonneau and Litman, 1997). Because of this, conventional precision and recall measures penalize 'near misses' when they should be treated much the same as complete matches. The crossing-bracket measure (Carbone et al., 2004) is more forgiving, but still over-penalizes near misses and favors sparse bracketings. An error measure P_k proposed by Beeferman et al. (1999) compensates for the variation in boundary locations. It considers a moving window of width k equal to half the average segment length in the reference segmentation, where distances are measured in words or sentences, depending on whether word boundaries or sentence boundaries are considered possible discourse segment boundaries. The error is the average disagreement, between the reference segmentation and the evaluated segmentation, about whether the two ends of the window are in the same segment. Formally,

$$P_k = \frac{1}{N-k} \sum_{i=1}^{N-k} \delta(\delta(r_i, r_{i+k}), \delta(h_i, h_{i+k}))$$

where N is the total number of atoms (words or sentences) in the document, and k is the window width. The arguments r_i and h_i are the indices of the segments that contain atom i in the reference and hypothesized segmentations, respectively, and δ is the discrete delta function, evaluating to 1 if its arguments are equal and to 0 otherwise. Pevzner and Hearst (2001) proposed WindowDiff, a modification of P_k that indicates the average disagreement about how many boundaries lie within the window, replacing the inner δ functions with the count of segment boundaries between the two atoms. It is as sensitive to false positives as it is to false negatives, whereas P_k is more sensitive to false negatives.

There are still a few problems with these error measures. In penalizing false negatives and false positives equally, WindowDiff actually favors sparse segmentations. Whereas P_k scores the baseline strategies of no boundaries and all possible boundaries as within a few percent of 50% error, WindowDiff scores the all-boundaries baseline at 100% error for typical reference segmentations. Furthermore, in running the summation from $i = 1$ to $i = N - k$, both error measures count boundaries near the edges of the text less than boundaries near the middle of the text. A boundary that is $j < k$ atoms from the beginning or end of the text has weight $\frac{j}{k}$ relative to boundaries in the middle of the text. Finally, because of the hierarchical structure of many texts, it is quite possible that a reference segmentation might not include legitimate but fairly unimportant boundaries that a hypothesized segmentation does include. These unimportant boundaries should not count against the hypothesized segmentation, but in the linear segmentation paradigm, they necessarily do. The ideal error measure should distinguish more-informed algorithms from less-informed algorithms, treating equally uninformed baselines the same, and it should treat boundary placement errors according to the prominence of the boundaries, and not according to their positions within the text.

Building on work in evaluating linear segmentation, this study considers the evaluation of tree segmentations. I propose an error measure, derived from Beeferman et al.'s P_k (1999), for evaluating the alignment of a tree segmentation to a reference segmentation. I first show that this error measure is advantageous even for evaluating linear segmentations, and then I evaluate four hierarchical segmentation algorithms against a gold standard derived from encyclopedia articles.

2 A hierarchical measure

The proposed error measure is based on the intuition that prominent boundaries count more than less prominent boundaries. The hierarchical atom error rate E_{P_k} is the mean of Beeferman errors calculated over all linearizations of the segmentation tree (see Fig. 1). Assume a set R of reference boundaries and a set H of hypothesized boundaries each in rank order (prominent boundaries precede less prominent ones). The error is calculated as

$$E_{P_k} = \frac{1}{|R|} \sum_i c_i P_k(R_i, H_i)$$

where

$$R_i = \{b_j : b_j \in R \wedge j \leq i\}$$

The elements of H_i are chosen such that $|H_i| = |R_i|$ and no $b_n \in H \setminus H_i$ is more prominent than any $b_j \in H_i$. If the reference boundaries are completely ordered, then $c_i = 1$ for all ranks i, but if some reference boundaries share ranks, one P_k term is calculated for each rank level in the reference segmentation, and weighted (c_i) by the number of boundaries that were at that level. In the degenerate case of linear segmentation, all segments have the same rank, and E_{P_k} reduces to the original P_k.

When hypothesized boundaries share ranks, each affected term in the summation is theoretically the average over all combinations (n boundaries at the next rank *Choose* r boundaries to complete H_i). But when the number of combinations is large, the computational complexity of the calculation can be reduced without sacrificing much accuracy by using a representative sampling of the combinations, as this closely approximates the average.

When the set of hypothesized boundaries is smaller than the set of reference boundaries, we could simply permit H_i to be smaller than R_i for large values of i, but that unnecessarily penalizes the hypothesized segmentation. The set of possible boundaries (word or sentence boundaries) which were not marked as segment boundaries can be understood to be segment boundaries of a baseline low ranking. Adding these unmarked boundaries to H, all at a single low rank, prevents incurring an undeserved penalty for false negatives.

In order to avoid undercounting boundaries near the beginning and end of the text, I consider the possibility of wrapping the window around from the beginning to the end of the text. In calculating P_k, the sum is understood to run from $i = 1$ to $i = N$, rather than stopping at $N - k$, and the atom index of the leading edge of the window $(i + k)$ generalizes to $((i + k) \bmod N)$.

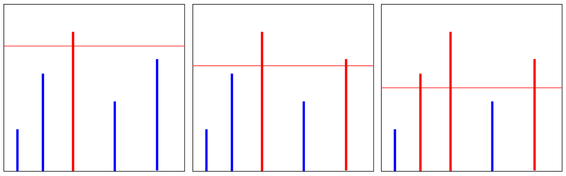

Figure 1: Sequential linearizations in computing hierarchical word error rate. The heights of the vertical lines represent the prominences of boundaries, and each horizontal line is one linearization. In the first step, only the highest boundary is used, producing just two segments. Each following step includes one more boundary.

3 Hierarchical replication of Choi et al.

As a preliminary test of the error measure, I evaluated two algorithms from Choi et al. (2001) on the standard segmentation data set that Choi (2000) compiled. Each file in that data is composed of 10 random portions of texts from the Brown Corpus (Francis and Kucera, 1979). The following results are based on the T_{3-11} subset, in which text segment lengths are uniformly distributed between 3 and 11 sentences. Since each file is composed of a sequence of text portions, the reference segmentation is linear, not hierarchical. Nevertheless, I evaluate hierarchical segmentation algorithms with the hierarchical measure, to show that treating linear segmentation as a special case of hierarchical segmentation solves the issue of unequal treatment of false positives and false negatives, and running the WindowDiff sum to N (wrapping the window around to the beginning) solves the problem of undercounting the boundaries near the text edges.

3.1 Segmentation algorithms

The C99 (Choi, 2000) and CWM (Choi et al., 2001) algorithms were evaluated. While these were designed and originally evaluated as linear segmentation algorithms, the hierarchical clustering they use makes hierarchical segmentation a trivial matter of retaining the order of the cluster splits. I refer to the hierarchical versions of these algorithms as HC99 and HCWM. The HC99 implementation used here is built directly from the C99 code which Choi released for educational use, and the HCWM implementation is based off that. The implementation uses a document-based LSI space built with Infomap-NLP[1] from the British National Corpus (Aston and Burnard, 1998), whereas the original CWM used sentence-based and paragraph-based LSI spaces derived from the Brown Corpus. Because of these differences, the implementation of HCWM reported here differs somewhat from the implementation of CWM reported by Choi et al. (2001).

The C99 and CWM algorithms include a criterion for optional automatic determination of the number of segments, but the hierarchical error measure does not penalize a segmentation for having more segments (defined by lower ranking boundaries) than the reference segmentation, so I used a constant number of segments, greater than in the reference segmentation, for the results reported here.

One baseline (BIN) was constructed by a recursive bisection of segments, and another baseline (NONE) consisted of only the implicit boundaries at the beginning and end of the discourse, and all the possible intermediate boundaries (sentence breaks) are implicitly at one unmarked lower rank.

3.2 Results and Discussion

The calculated E_{P_k} error rates are displayed in Fig. 2.[2] The error for HC99 in Fig. 2a (12.5%) matches what Choi et al. (2001) reported (12%), while the error for HCWM (12.1%) is higher than that reported for the version with a paragraph-based 500-dimension LSI space (9%) but appears comparable to their sentence-based 400-dimension LSI space. (They do not report results for the sentence-based spaces on this T_{3-11} data set, but based on the results they report for a larger data set, it would appear to be about 12% for the T_{3-11} set.) The result for BIN (43.9%) is slightly lower than what Choi et al. (2001) reported for their equal-size segment baseline (45%). Since BIN would be an equal-segment baseline if there were only 8 segments per text, BIN should be similar to Choi et al's equal-size baseline. And the result for NONE (46.1%) agrees with Choi et al. (2001)'s results for their NONE (46%) baseline.

Comparison of graphs (a) and (b) in Fig. 2 shows that continuing the sum to wrap the window around to the beginning of the text generally lowers the measured error, to the greatest extent for BIN and least for HCWM. The average segment length in the reference segmentation is 7 sentences, so the window size k is usually 3 or 4 sentences, comparable to the minimum segment length (3). As a result, a boundary very rarely falls within k sentences of the text ends, and fully including these sentences in the sum leads to a lower error for segmentations like BIN that don't hypothesize boundaries near the text ends.

The E_{WD} hierarchical error rates (calculated according to WindowDiff) are consistently higher (Fig. 2c, d) than the corresponding E_{P_k}. WindowDiff

[1] Software available at http://infomap-nlp.sourceforge.net

[2] The error rates in this section are calculated using the word-error rate for comparison with Choi's results, but since the candidate boundaries are actually the line breaks, the line-error rate would be more appropriate. Line error rates are 1% to 2% higher.

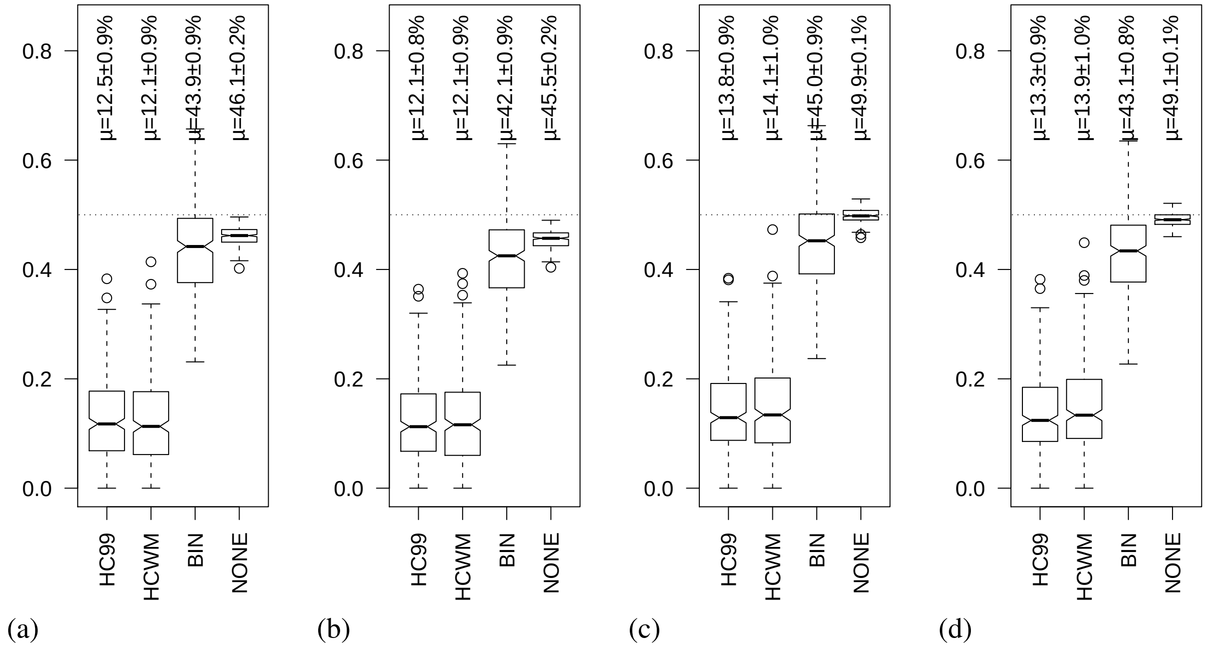

Figure 2: Distributions of E_{P_k} (a, b) and E_{WD} (c, d) for each of the hypothesized and baseline segmentation algorithms. The data in graphs (a) and (c) are calculated with sums that stop at $N-k$ (when the window reaches the end of the text), whereas (b) and (d) are calculated with sums that run to N (wrapping the window back to the beginning). The boxes indicate the quartiles, and the means with 95% confidence intervals are written above.

scores are never lower than P_k scores, because in order to count as in agreement, the two segmentations must agree about the number of boundaries within the window rather than just about whether there are boundaries within the window. But these scores are not much higher than EP_k either, even though the original linear WindowDiff measure sometimes assigns much higher scores. Under the original WindowDiff measure, with reference and hypothesized boundary sets of unequal size, the NONE baseline scores 43.8% (cf. P_k=43.5% for sum to N), while an ALL baseline scores 99.2% (cf. P_k=51.1% for sum to N). WindowDiff was designed to penalize false positives even when two boundaries are close together, a condition that P_k underpenalizes. When a hypothesized segmentation has more segments than the reference segmentation, the extra boundaries incur false positive penalties without corresponding false negative penalties, and WindowDiff assigns an error rate that is higher than the P_k error rate and sometimes even higher than the NONE baseline. But with the hierarchical E_{WD} error, extra boundaries are sampled or ignored, and so every false positive has a corresponding false negative, which limits the divergence between E_{WD} and E_{P_k} and keeps the E_{WD} error of informed segmentations below baseline errors. As with E_{P_k}, continuing the sum to N (Fig. 2d), has only a slight effect on the error, but the effect is most pronounced on BIN, reflecting the fact that BIN, like the reference segmentation systematically does not place boundaries near the text ends.

3.3 Conclusion

We have seen here that treating linear segmentations as a special case of hierarchical segmentations, having just one rank of marked boundaries but having implicit higher ranking boundaries at the text ends and implicit lower ranking boundaries at all ‘non-boundaries’, resolves the outstanding issues of unequal sensitivity that P_k and WindowDiff have. Furthermore, in sampling hypothesized boundaries to match the number of reference boundaries, the hierarchical conception of the error metric smoothly adapts to segmentations that overestimate or underestimate the number of segments. A segmentation can not do much worse than 50% (at chance) just by hypothesizing fewer or more segments than the reference segmentation 'knows' about. The major remaining strength of WindowDiff over the P_k metric is that P_k still undercounts errors when there are segments much smaller than the average size.

For these reasons, I adopt a version of E_{WD} that continues the sum to wrap the window around the end of the text. In addition, when I refer to the linear error measure in the following sections, I mean the special case of E_{WD} in which the information in the reference segmentation about the ranking of the marked boundaries is ignored, but boundary ranking information in the hypothesized segmentation (both marked and unmarked boundaries) is still used to select as many segment boundaries as are in the reference segmentation.

4 Wikipedia Evaluation

In this section, I compare the same two algorithms and baselines with two additional hierarchical segmentation algorithms, using a hierarchical reference segmentation. The reference segmentation corpus is derived from encyclopedia articles, and I use the hierarchical error measure developed in the previous sections. I also constrast the hierarchical error rates with measurements that ignore the boundary ranking information in the hypothesized or reference segmentations in order to highlight the difference between the performance on boundary position and the performance on boundary ranking.

4.1 Corpus and Algorithms

The evaluation corpus is derived from the *2006 Wikipedia CD* release.[3] The html pages were converted to flat text, removing boilerplate, navigation, info-boxes, and image captions. Heading text was replaced with a boundary marker, indicating the heading depth. The subcorpus used for this evaluation consists of articles with a heading depth of four (i.e. having html elements h2 through h5), a total of 66 articles. The texts were reformatted with an automatic sentence detector[4] to have one sentence per line, and then tokenized.[5]

In addition to the HC99 and HCWM algorithms used in the previous section, I use two algorithms described by Eisenstein (2009). The HIERBAYES algorithm (here, HBT) uses a multi-level latent topic model to perform joint inference over the locations and prominences of topic change boundaries. The GREEDY-BAYES algorithm (here, GBEM) uses a single-level latent topic model to find a linear segmentation, and recursively divides each of the segments.[6] Both algorithms internally decide the number of hypothesized boundaries, sometimes underestimating it and sometimes overestimating.[7]

4.2 Results and Discussion

The E_{WD} error rates for each of the hypothesized segmentations are presented in Fig. 3. As with the Choi data, the NONE baseline has an error rate at chance (50%), while the lexical algorithms perform better than that (highly statistically significantly ($p < .0001$) less than 50%, according to individual two-sided one-sample t-tests). However, they perform much worse than they did on the Choi data.

In spite of the relatively high error rates, the discriminating power of the evaluation measure is revealed by comparison of the fully hierarchical error rates (Fig. 3a) with the error rates that ignore the ranking information in the reference (Fig. 3b) or hypothesized (Fig. 3c) segmentations. For each of the lexical algorithms that were originally designed as linear segmentation algorithms (HC99, HCWM, and GBEM), the mean error is less in Fig. 3b against the linear standard (when reference segmentation boundary prominences are ignored) than in Fig. 3a under the fully hierarchical measure (two-tailed paired t-tests, each $p < .0001$). In contrast, HBT, designed as a hierarchical segmentation algorithm, obtains a lower error rate under the fully hierarchical E_{WD} measure (though the difference does

[3] Available from http://schools-wikipedia.org/2006/.

[4] From Ratnaparkhi's 'jmx' (ftp://ftp.cis.upenn.edu/pub/adwait/jmx/jmx.tar.gz).

[5] The evaluation code and corpus can be downloaded from http://idiom.ucsd.edu/~lucien/segmentation

[6] Both algorithms are part of the HBayesSeg package, available at http://people.csail.mit.edu/jacobe/naacl09.html

[7] Options for HBT were set to produce 3 levels of text-internal boundary prominence. Attempts to obtain more boundaries and more depth levels lead to deteriorated performance, because the search space grows geometrically with the number of levels (Eisenstein, p.c.)

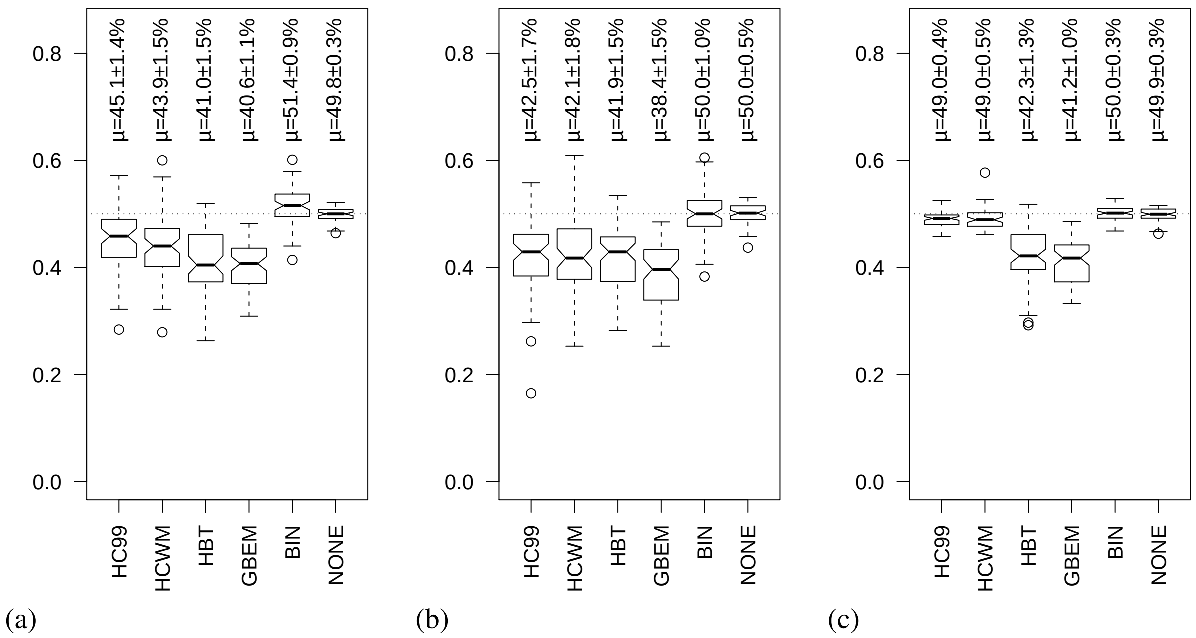

Figure 3: E_{WD} error rates for each of the segmentation algorithms. (a) Hierarchical error (b) Linear error (ignoring reference segmentation prominences) (c) Hierarchical error ignoring hypothesized segmentation prominences. Boxes show quantiles and means are written above, with 95% confidence intervals.

not reach significance: $p = 0.1$, two-tailed paired t-test). When instead the hypothesized boundary prominences are ignored (Fig. 3c), reducing them to linear segmentations but still evaluating against the hierarchical standard, the error rates of all the lexical algorithms are raised (in two-tailed paired t-tests, each $p < .0001$), but HBT and GBEM are only slightly affected, whereas HC99 and HCWM are almost raised to chance. While HBT and GBEM hypothesize about the same number of boundaries as the reference segmentation (13 and 22 text-internal boundaries on average, compared to 22 text-internal boundaries in the reference corpus), the HC99 and HCWM algorithms were made to hypothesize 54 boundaries for each text. The difference between their error rates in (Fig. 3a) and (Fig. 3c) shows that the HC99 and HCWM boundaries given the highest prominences corresponded much more closely to the reference boundaries than the hypothesized boundaries given the lowest prominences.

The mean scores for the BIN baseline are over 50% on the encyclopedia data. In contrast, the mean score for BIN on the Choi standard data (Fig. 2) was 45% for the linear measure and 43% for the hierarchical measure. Why did BIN do so poorly here when it performed well above chance on the Choi data? The difference is in the distributions of segment lengths. As seen in Fig. 4, the Choi data segment lengths are well-defined by their mean, because they were constructed with uniform distributions of segment length. On the other hand, the distribution of segment lengths in the encyclopedia data is more skewed, with many quite short segments and a few quite long segments.

The error rates for both HC99 and HCWM are much higher on the encyclopedia data than they are on the Choi data, and the error rates for HBT and GBEM are not much better. Choi's evaluation corpus was specifically designed to have obvious boundaries, whereas the boundaries in these discourse samples are much less obvious. As discussed by Kauchak and Chen (2005), even algorithms that obtain low error rates on newsfeed do not perform well on more fluid discourse, and while Ji and Zha (2003) reported quite low error on an expository text sample ($P_k = 12\%$), Kauchak and Chen (2005) report a best error rate of $P_k = 38.5\%$ on the encyclopedia corpus they used, and Malioutov and Barzi-

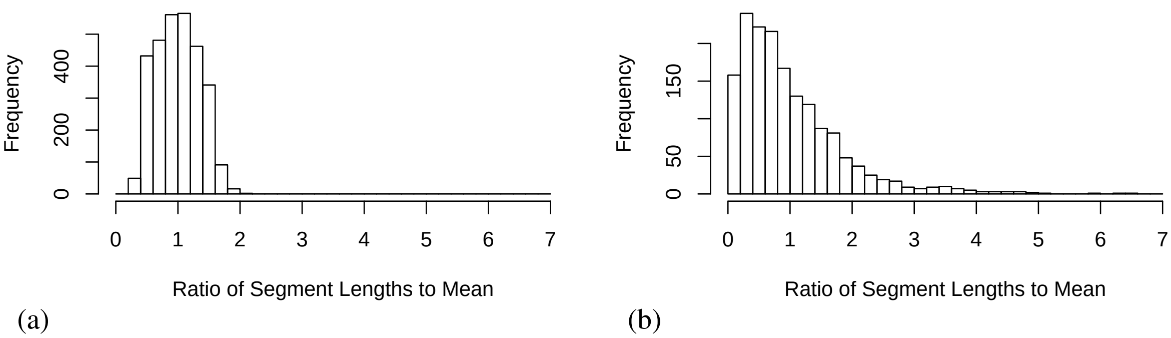

Figure 4: Distribution of sentences per segment for (a) Choi standard data (b) Wikipedia data

lay (2006) obtained P_k error rates between 30% and 40% on the lecture data they used, comparable to human annotator pairwise P_k ranging from 24% to 42%. C99 and CWM—like the other algorithms that make use of hierarchical representations of the text, such as Ji and Zha (2003) and Fragkou et al. (2004)—depend completely on lexical information. Another strand of research, including Galley et al. (2003) and Kauchak and Chen (2005), make use of a wide variety of linguistic and orthographic cues. And the discourse parsing systems take advantage of even more linguistic cues. The ideal segmentation algorithm needs to combine the advantages of each of these approaches, but the frameworks are not straightforwardly compatible. The Bayesian framework explored by Eisenstein and Barzilay (2008) is a potential route to a richer model, and they found their richer model beneficial for a meetings corpus but not for a textbook. The HBT and GBEM algorithms, which were based on that work, do not attempt to go beyond lexical cohesion, but it does provide a framework for hierarchical segmentation algorithms that take advantage of other cues.

5 Conclusions

In Section 2, I introduced a modification of the error measure developed by Beeferman et al. (1999) and Pevzner and Hearst (2001). I then showed that this modification, directed at evaluating hierarchical segmentations, also produces a more robust evaluation of linear segmentations as well. And applied to hierarchical segmentations, it successfully distinguishes lexically-informed segmentations from baseline segmentations, and it distinguishes hierarchical segmentations from segmentations composed of the same boundaries but without the boundary ranking information. As a more reliable evaluation of both linear and hierarchical segmentation algorithms, this error measure will facilitate the development of more richly informed segmentation algorithms.

Acknowledgments

In this research, I have benefited from resources at both San Diego State University and UC San Diego. This work has been enriched by the questions and advice of many people, including Eniko Csomay, Rob Malouf, Lara Taylor, Rebecca Colavin, Andy Kehler, and the NAACL anonymous reviewers. I am also grateful to Freddy Choi and Jacob Eisenstein for making their code and data available, and to Jacob for additional help running his code. All errors are my own.

Abstract

In this paper we report a behavioural experiment documenting that different lexico-syntactic formulations of the discourse relation of *causation* are deemed more or less acceptable by different categories of readers. We further report promising results for automatically selecting the formulation that is most appropriate for a given category of reader using supervised learning. This investigation is embedded within a longer term research agenda aimed at summarising scientific writing for lay readers using appropriate paraphrasing.

1 Introduction

There are many reasons why a speaker/writer would want to choose one formulation of a discourse relation over another; for example, maintaining thread of discourse, avoiding shifts in focus and issues of salience and end weight. There are also reasons to use different formulations for different audiences; for example, to account for differences in reading skills and domain knowledge. In this paper, we present a psycholinguistic experiment designed to illuminate the factors that determine the appropriateness of particular realisations of discourse relations for different audiences. The second part of this paper focuses on training a natural language generation system to predict which realisation choices are more felicitous than others for a given audience. Our paraphrases include eight different constructions. Consider 1a.–d. below:

(1) a. Tom ate **because** he was hungry.
b. Tom ate **because of** his hunger.
c. Tom's hunger **caused** him to eat.
d. The **cause** of Tom's eating was his hunger.

These differ in terms of the lexico-syntactic properties of the discourse marker (shown in bold font). Indeed the discourse markers here are conjunctions, prepositions, verbs and nouns. As a consequence the propositional content is expressed either as a clause or a noun phrase ("*he was hungry*" vs "*his hunger*", etc.). Additionally, the order of presentation of propositional content can be varied to give four more lexico-syntactic paraphrases:

(1) e. **Because** Tom was hungry, he ate.
f. **Because of** his hunger, Tom ate.
g. Tom's eating **was caused by** his hunger.
h. Tom's hunger was the **cause** of his eating.

It is clear that some formulations of this propositional content are more felicitous than others; for example, 1a. seems preferable to 1d., but for a different propositional content, other formulations might be more felicitous (for instance, example 4, section 3.1, where the passive seems in fact preferable). While discourse level choices based on information ordering play a role in choosing a formulation, it is of particular interest to us that some decontextualised information orderings within a sentence are deemed unacceptable. Any summarisation task that considers discourse coherence should not introduce sentence-level unacceptability.

We now summarise our main research questions:

1. Are some formulations of a discourse relation more felicitous than others, given the same propositional content?
2. Does the reader's level of domain expertise affect their preferred formulation?
3. What linguistic features determine which formulations are acceptable?
4. How well can a natural language generator be trained to predict the most appropriate formulation for a given category of reader?

In this paper, we focus on causal relations because these are pervasive in science writing and are integral to how humans conceptualise the world. The 8 formulations selected are 2 information orderings

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 1002–1010,
Los Angeles, California, June 2010.

of 4 different syntactic constructs; thus we explore a fairly broad range of constructions.

With regard to genre, we have a particular interest in scientific writing, specifically biomedical texts. Reformulating such texts for lay audiences is a highly relevant task today and many news agencies perform this service; e.g., Reuters Health summarises medical literature for lay audiences and BBC online has a Science/Nature section that reports on science. These services rely either on press releases by scientists and universities or on specialist scientific reporters, thus limiting coverage of a growing volume of scientific literature in a digital economy. Thus, reformulating technical writing for lay audiences is a research area of direct relevance to information retrieval, information access and summarisation systems.

At the same time, while there are numerous studies about the effect of text reformulation on people with different literacy levels or language deficits (see section 2), the issue of expert vs lay audiences has received less attention. Further, most studies focus on narrative texts such as news or history. However, as Linderholm et al. (2000) note, results from studies of causality in narrative texts might not carry over to scientific writing, because inferences are made more spontaneously during the reading of narrative than expository texts. Thus comparing expert vs lay readers on the comprehension of causal relations in scientific writing is a most timely investigation.

In section 2, we relate our research to the existing linguistic, psycholinguistic and computational literature. Then in section 3, we describe our psycholinguistic experiment that addresses our first two research questions and in section 4 we present a computational approach to learning felicitous paraphrases that addresses the final two questions.

2 Background and related work

2.1 Expressing causation

Linguists generally consider five different components of meaning (Wolff et al., 2005) in causal expressions: (a) occurrence of change in patient, (b) specification of endstate, (c) tendency and concordance, (d) directness and (e) mechanism. The expressions we consider in this paper, “because” (**conjunction**), “because of” (**preposition**) and “cause” as noun or verb (**periphrastic causatives**) express (a), (b) and in some instances, (c). This is in contrast to **affect verbs** that only express (a), **link verbs** that express (a–b), **lexical causatives** that express (a–d) and **resultatives** that express (a–e). These distinctions are illustrated by the sentences in example 2:

(2) a. Sara **kicked** the door. (affect verb – end state not specified)

b. The door’s **breaking** was linked to Sara. (link verb – end state specified, but unclear that door has a tendency to break)

c. Sara **caused** the door to break. / The door broke **because of** Sara. (periphrastic / preposition – indirect; the door might have a tendency to break)

d. Sara **broke** the door. (lexical causative – directness of action is specified)

e. Sara **broke** the door **open**. (resultative – end state is “open”)

There is much literature on how people prefer one type of causative over the other based on these five components of meaning (e.g. see Wolff et al. (2005)). What is less understood is how one selects between various expressions that carry similar semantic content. In this paper we consider four constructs “because of”, “because”, and “cause” as a verb and a noun. These express the components of meaning (a–c) using different syntactic structures. By considering only these four lexically similar constructs, we can focus on the role of the lexis and of syntax in determining the most felicitous expression of causation for a given propositional content.

2.2 Discourse connectives and comprehension

Previous work has shown that when texts have been manually rewritten to make discourse relations such as *causation* explicit, reading comprehension is significantly improved in middle/high school students (Beck et al., 1991). Further, connectives that permit pre-posed adverbial clauses have been found to be difficult for third to fifth grade readers, even when the order of mention coincides with the causal (and temporal) order; for instance, 3b. is more accessible than 3a. (e.g. from Anderson and Davison (1988)).

(3) a. **Because** Mexico allowed slavery, many Americans and their slaves moved to Mexico during that time.

b. Many Americans and their slaves moved to Mexico during that time, **because** Mexico allowed slavery.

Such studies show that comprehension can be improved by reformulating text; e.g., making causal relations explicit had a facilitatory effect for readers with low reading skills (Linderholm et al., 2000; Beck et al., 1991) and for readers with low levels of domain expertise (Noordman and Vonk, 1992). Further, specific information orderings were found to be facilitatory by Anderson and Davison (1988).

However, it has not been investigated whether readers with different levels of domain expertise are facilitated by any specific lexico-syntactic formulation among the many possible explicit realisations of a relation. This is a novel question in the linguistics literature, and we address it in section 3.

2.3 Connectives and automatic (re)generation

Much of the work regarding (re)generation of text based on discourse connectives aims to simplify text in certain ways, to make it more accessible to particular classes of readers. The PSET project (Carroll et al., 1998) considered simplifying news reports for aphasics. The PSET project focused mainly on lexical simplification (replacing difficult words with easier ones), but more recently, there has been work on syntactic simplification and, in particular, the way syntactic rewrites interact with discourse structure and text cohesion (Siddharthan, 2006). Elsewhere, there has been renewed interest in *paraphrasing*, including the replacement of words (especially verbs) with their dictionary definitions (Kaji et al., 2002) and the replacement of idiomatic or otherwise troublesome expressions with simpler ones. The current research emphasis is on automatically learning paraphrases from comparable or aligned corpora (Barzilay and Lee, 2003; Ibrahim et al., 2003). The text simplification and paraphrasing literature does not address paraphrasing that requires syntactic alterations such as those in example 1 or the question of appropriateness of different formulations of a discourse relation.

Some natural language generation systems incorporate results from psycholinguistic studies to make principled choices between alternative formulations. For example, SkillSum (Williams and Reiter, 2008) and ICONOCLAST (Power et al., 2003) are two contemporary generation systems that allow for specifying aspects of style such as choice of discourse marker, clause order, repetition and sentence and paragraph lengths in the form of constraints that can be optimised. However, to date, these systems do not consider syntactic reformulations of the type we are interested in. Our research is directly relevant to such generation systems as it can help such systems make decisions in a principled manner.

2.4 Corpus studies and treebanking

There are two major corpora that mark up discourse relations – the RST Discourse Treebank based on Rhetorical Structure Theory (Mann and Thompson, 1988), and the Penn Discourse Treebank (Webber et al., 2005). Neither is suitable for studies on the felicity of specific formulations of a discourse relation. As part of this research, we have created a corpus of 144 real text examples, reformulated in 8 ways, giving 1152 sentences in total.

There have been numerous corpus studies of discourse connectives, such as studies on the discourse-role disambiguation of individual cue-phrases in spoken and written corpora (e.g., Hirschberg and Litman (1993)), the substitutability of discourse connectives (e.g., Hutchinson (2005)), and indeed corpus studies as a means of informing the choice of discourse relations to consider in a theory (e.g., Knott and Dale (1994); Knott (1996)). A distinguishing feature of our approach relative to previous ones is an in-depth study of syntactic variations; in contrast, for example, Knott's taxonomy of discourse relations is based on the use of a substitution text that precludes variants of the same relation having different syntax.

3 Linguistic acceptability study

3.1 Dataset creation

We have constructed a dataset that can be used to gain insights into differences between different realisations of discourse relations. In the following, we will illustrate such rewriting situations using an example from a medical article. As mentioned previously, we are particularly interested in complex syntactic reformulations; in example 4 below, a. is from the original text and b.–h. are reformulations. There are two examples each of formulations using "*because*", "*because of*", the verb "*cause*" and the noun "*cause*" with different ordering of propositional content. This provides us with 8 formulations per example sentence; for example:

(4) a. Fructose-induced hypertension **is caused by** increased salt absorption by the intestine and kidney. **[cause_p]**

b. Increased salt absorption by the intestine and kidney **causes** fructose-induced hypertension. **[cause_a]**

c. Fructose-induced hypertension occurs **because of** increased salt absorption by the intestine and kidney. **[a_becof_b]**

d. **Because of** increased salt absorption by the intestine and kidney, fructose-induced hypertension occurs. **[becof_ba]**

e. Fructose-induced hypertension occurs **because** there is increased salt absorption by the intestine and kidney. **[a_bec_b]**

f. **Because** there is increased salt absorption by the intestine and kidney, fructose-induced hypertension occurs. **[bec_ba]**

g. Increased salt absorption by the intestine and kidney is the **cause of** fructose-induced hypertension. **[b_causeof_a]**

h. The **cause of** fructose-induced hypertension is increased salt absorption by the intestine and kidney. **[causeof_ab]**

Our corpus contains 144 such examples from three genres (see below), giving 1152 sentences in total. These 144 examples contain equal numbers of original sentences (18) of each of the 8 types. The manual reformulation is formulaic, and it is part of our broader research effort to automate the process using transfer rules and a bi-directional grammar. The example above is indicative of the process. To make a clause out of a noun phrase (examples 4c.–f.), we introduce either the copula or the verb "occur", based on a subjective judgement of whether this is an event or a continuous phenomenon. Conversely, to create a noun phrase from a clause, we use a possessive and a gerund; for example (simplified for illustration):

(5) a. Irwin had triumphed because he was so good a man.

b. The cause of Irwin's having triumphed was his being so good a man.

Clearly, there are many different possibilities for this reformulation; for example:

(5) b'. The cause of Irwin's *triumph* was his being so good a man.

b". The cause of Irwin's *triumph* was his *exceptional goodness as* a man.

As part of our wider research agenda, we are exploring automatic reformulation using transfer rules and a bi-directional grammar. In this context, given our immediate interest is in the discourse markers, we restrict our reformulation method to only generate sentences such as 5b. This not only makes automation easier, but also standardises data for our experiment by removing an aspect of subjectivity from the manual reformulation.

We used equal numbers of sentences from three different genres[1]:

- **PubMed Abstracts**: Technical writing from the Biomedical domain
- **BNC World**: Article from the British National Corpus tagged as World News
- **BNC Natural Science**: Article from the British National Corpus tagged as Natural Science. This covers popular science writing in the mainstream media

There were 48 example sentences chosen randomly from each genre, such that there were 6 examples of each of the 8 types of formulation)

3.2 Experimental setup

Human judgements for acceptability for each of the 1152 sentences in our corpus were obtained using the WebExp package (Keller et al., 2008 to appear).[2] We investigated acceptability because it is a measure which reflects both ease of comprehension and surface well-formedness.

The propositional content of 144 sentences was presented in 8 formulations. Eight participant groups (A–H) consisting of 6 people each were presented with exactly one of the eight formulations of each of 144 different sentences, as per a Latin square design. Thus, while each participant read an equal number of sentences in each formulation type, they never read more than one formulation of the same propositional content. Each group saw 18 original and 126 reformulated sentences in total, 48 from each genre. This experimental design allows all statistical comparisons between the eight types of causal formulations to be within-participants.

Acceptability judgements were elicited on the sentences without presenting the preceding context

[1] PubMed URL: http://www.ncbi.nlm.nih.gov/pubmed/
The British National Corpus, version 3 (BNC XML Edition). 2007. Distributed by Oxford University Computing Services on behalf of the BNC Consortium. http://www.natcorp.ox.ac.uk

[2] Note that the reformulations are, strictly speaking, grammatical according to the authors' judgement. We are testing violations of acceptability, rather than grammaticality per se.

from the original text. The participants were University of Cambridge students (all native English speakers with different academic backgrounds). Post experimentally we divided participants in two groups based on having a Science or a non-Science background[3]. Rather than giving participants a fixed scale (e.g. 1–7), we used the magnitude estimation paradigm, which is more suitable to capture robust or subtle differences between the relative strength of acceptability or grammaticality violations (see Bard et al. (1996); Cowart (1997); Keller (2000)).

3.3 Magnitude estimation

Participants were asked to score how acceptable a modulus sentence was, using any positive number. They were then asked to score other sentences relative to this modulus, using any positive number, even decimals, so that higher scores were assigned to more acceptable sentences. The advantage of Magnitude estimation is that the researcher does not make any assumptions about the number of linguistic distinctions allowed. Each subject makes as many distinctions as they feel comfortable. Scores were normalised to allow comparison across participants, following standard practice in the literature by using the z-score: For each participant, each sentence score was normalised so that the mean score is 0 and the standard deviation is 1:

$$z_{ih} = \frac{x_{ih} - \mu_h}{\sigma_h}$$

where z_{ih} is participant h's z-score for the sentence i when participant h gave a magnitude estimation score of x_{ih} to that sentence. μ_h is the mean and σ_h the standard deviation of the set of magnitude estimation scores for user h.

3.4 Results

42 out of 48 participants (19 science students and 23 non-science students) completed the experiment, giving us 3–6 ratings for each of the 1152 sentences. Figure 1 shows the average z-scores with standard error bars for Science and non-Science students for each of the three genres. The first six columns show the scores for only the 144 Original Sentences. Note that science students find PubMed sentences most acceptable (significantly more than BNC Natural Science; t-test, $p < .005$), while among non-science students there is a numerical tendency to find the world news sentences most acceptable. Both categories of participants disprefer sentences from the popular science genre. Columns 7–12 show the average z-scores for the 1008 reformulated sentences. Let us note that these are significantly lower than for the originals (t-test, $p < .001$).

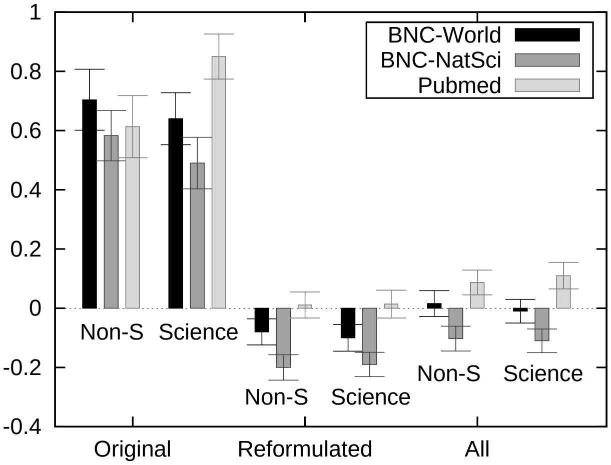

Figure 1: Preferences by Field of Study – **Science** or **Non-S**cience.

Some of these results are as expected. With regard to genre preferences, scientists might find the style of technical writing acceptable because of familiarity with that style of writing. Second, with regard to the average score for original and reformulated sentences, some reformulations just don't work for a given propositional content. This pulls the average for reformulated sentences down. However, on average 2 out of 7 reformulations score quite high.

It is interesting that the popular science genre is least preferred by both groups. This suggests that reformulating technical writing for lay readers is not a trivial endeavour, even for journalists.

Now consider Figure 2, which shows the average z-scores for only PubMed sentences for science and non-science students as a function of sentence type. For non-science students reading PubMed sentences, three formulations are strongly dispreferred – "a is caused by b", "because b, a" and "b is the

[3] Participants provided subject of study prior to participation in the experiment. Our classification of Science consists of Life Sciences(Genetics/Biology/etc), Chemistry, Environmental Science, Engineering, Geology, Physics, Medicine, Pharmacology, Veterinary Science and Zoology. Non-Science consists of Archaeology, Business, Classics, Education, Literature&Languages, International Relations, Linguistics, Maths, Music, Politics and Theology.

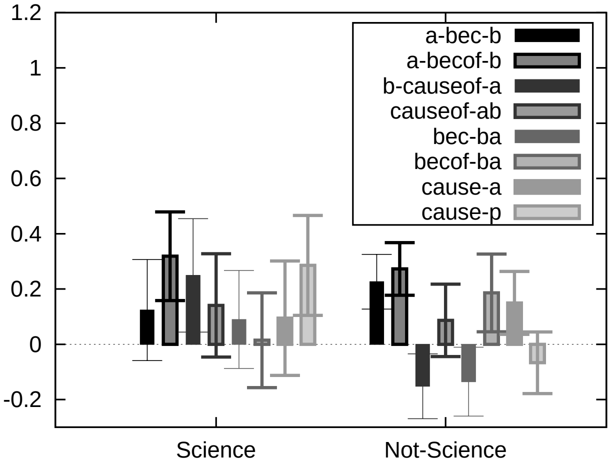

Figure 2: PubMed type preferences

cause of a". The last two are significantly lower than "a because b", "a because of b" and "because of b, a" (t-test, $.005 < p < .01$). On the contrary, there are no strong preferences among the science students and all the error bars overlap. Let us now look at some specific differences between science and non-science students:

1. Science students prefer sentences in the passive voice, while these are strongly dispreferred by non-science students. While active voice is the canonical form in English, much of science is written in the passive by convention. This difference can thus be explained by different levels of exposure.

2. Non-science students disprefer the use of "cause" as a noun while science students don't (columns 3–4 and 11–12).

3. Non-science students prefer "because of b, a" to "because b, a" while science students show the opposite preference.

The lack of strongly dispreferred formulations in the Science students is most likely due to two factors: (a) the group's familiarity with this genre and (b) their expert knowledge compensates for acceptability even for relatively odd formulations. In the absence of exposure and background knowledge, the non-Science students display clear preferences.[4]

Note that these preferences are not surprising. The preference for canonical constructs such as active voice and conjunction in infix position are well documented. Our claim however, is that blindly rewriting all instances of globally dispreferred constructs with globally preferred constructs is counterproductive because not all formulations are acceptable for any given propositional content. This claim is easily verified. Table 1 shows the average z-scores of non-science students when one formulation of each of the PubMed sentences is selected based only on the global preferences in Figure 2. Such rewriting invariably makes matters worse. In the next section we present a more intelligent approach.

Selection Method	Av. z
Always select original sentence	.61
Replace cause-p, b-causeof-a and causeof-ab with cause-a & bec-ba with a-bec-b	.48
Replace cause-p with cause-a, b-causeof-a with causeof-ab & bec-ba with a-bec-b	.47
Always select most preferred type (a-becof-b)	.27

Table 1: Selecting a formulation of PubMed sentences for non-science students using their global preferences.

4 Machine learning experiment

The first question we address is: for a given propositional content, which formulations are acceptable and which are not? This is a useful question for multiple reasons. In this paper, our interest stems from our desire to selectively rewrite causation based on the properties of the sentence as well as global preferences of categories of users. More generally, this information is important for summarisation tasks, where sentences might appear in different contexts and different information orderings might be desirable for reasons of coherence. Knowing which formulations are acceptable in isolation for a given propositional content is thus important.

Since Magnitude estimation scores are freescale, we first need to determine how high a score needs to be for that formulation to be considered acceptable. Our solution is to (a) treat the original formulation as acceptable and (b) treat any reformulations with a higher average z-score than the original as also acceptable. We find that roughly 3 formulations (the original and another two) out of 8 are acceptable on average. Our data is summarised below:

- 1152 Sentences in total (144 originals, 1008 reformulations)
  - 361 labelled as acceptable (31%; 144 originals, 217 reformulations)

[4] While we only show the averages for all sentences, the distributions for original and reformulated sentences look remarkably similar.

- 791 labelled as unacceptable (69%; 791 reformulations)

4.1 Features

We use shallow features derived from the sentence, as well as the textual genre. Sentences were parsed using the RASP parser (Briscoe and Carroll, 2002). The features we extract are as follows:

1. Type (8 values: cause_a, cause_p, a_bec_b, bec_ba, a_becof_b, becof_ba, a_causeof_b, causeof_ba)
2. Genre (3 values: pubmed, bnc-world, bnc-natsci)
3. Complexity: As an indication of the complexity of the propositional content, we use the following:
   (a) Length Features
      - length (in words) of the sentence and each clause
      - length (as proportion of total length) of each clause

   (b) Whether the causative is embedded in a relative clause or other construct

   (c) The presence or absence of copula in each clause (e.g., "because there is...")

   (d) Whether the causation is quantified (e.g., "a major cause of...")

The only feature that varies between the eight formulations of the same sentence is the "type" feature; the "genre" and "complexity" features are constant across reformulations. The reason for using 3(c–d) as features is that expressions such as "because there is" might be better formulated as "because of" and that it is hard to find an exact reformulation when quantifiers are present (e.g., "a major cause of" is not equivalent to "often because of").

Machine performance on this task is not very good (First Run, Table 2). The problem is that some propositional content is harder to formulate than others. Therefore good formulations of some propositional content might have much lower scores than even mediocre formulations of other propositional content. This makes it hard to learn a function that distinguishes good from bad formulations for any particular propositional content. To overcome this, we run the classifier twice. Given 8 formulations of 144 sentences $S_{i=1..144,j=1..8}$, the first run gives us 1152 probabilities $p_{weka1}(S_{ij})$ for the acceptability of each sentence, independent of propositional content (these are test-set probabilities using 10-fold cross-validation). We then run the machine learner again, with this new feature $relative$:

- The ratio of the test-set probability (from the first run) to the highest of the 8 test-set probabilities for the different formulations of that sentence:

$$relative_{i=a,j=b} = \frac{p_{weka1}(S_{i=a,j=b})}{max_{i=a,j=1..8}(p_{weka1}(S_{i=a,j}))}$$

Thus probabilities for acceptability are normalised such that the best score for a given propositional content is 1 and the other 7 formulations score less than or equal to 1. The second classifier uses these relative probabilities as an extra feature.

Classifier	Accuracy	Kappa
Baseline	.69	0
First Run	.72	.23
Second Run	.85	.65
Only PubMed	.89	.73

Table 2: Accuracy and Agreement of classifier relative to human judgement.

Genre	Class	P	R	F
All Genres	Good	.72	.78	.75
	Bad	.91	.89	.90
Only PubMed	Good	.89	.89	.89
	Bad	.89	.97	.92

Table 3: Precision, Recall and F-measure of classifier (second run) relative to human judgement.

4.2 Results

Our results are summarised in Table 2 (accuracy and agreement) and Table 3 (f-measure). We experimented with the Weka toolkit (Witten and Frank, 2000) and report results using "weka.classifiers.trees.J48 -C 0.3 -M 3" and 10-fold cross-validation for both runs.[5]

Table 2 shows that the first run performs at around baseline levels, but the second run performs significantly better (using z-test, p=0.01 on % Accuracy), with acceptable agreement of $\kappa = 0.65$[6]. This increases to 89% ($\kappa = .73$) when we only consider technical writing (PubMed genre). Table 3 shows that precision, recall and f-measure are also around .90 for PubMed sentences.

[5] J48 outperformed other Weka classifiers for this task.

[6] Following Carletta (1996), we measure agreement in κ, which follows the formula $K = \frac{P(A)-P(E)}{1-P(E)}$ where P(A) is observed, and P(E) expected agreement. κ ranges between -1 and 1. κ=0 means agreement is only as expected by chance. Generally, κ of 0.8 are considered stable, and κ of 0.69 as marginally stable, according to the strictest scheme applied in the field.

Table 4: Accuracy and Kappa of classifier when complexity features are left out.

All our context features proved useful for the classification task, with the length features being the most useful. Table 4 shows the performance of the classifier when we leave out individual features.

It thus appears that we can determine the acceptable formulations of a sentence with high accuracy. The next question is how this information might be used to benefit a text regeneration system. To evaluate this, we combined our predictions with the user preferences visible in figure 2 as follows:

- We calculate a prior $prior_j$ for each formulation of type j using the z-score distribution for non-science students in Figure 2.
- We calculate $prior_{j=b}.p_{weka2}(S_{i=a,j=b})$ for each formulation $S_{i=a,j=b}$ of sentence a and type b, where $p_{weka2}(S_{i=a,j=b})$ is the probability returned by the classifier (second run) for formulation b of sentence a.
- **Selectively Reformulate:** We reformulate only the four dispreferred constructs (cause_p, bec_ba, causeof_ab, b_causeof_a) using the formulation for which the prior times the classifier probability is the maximum; i.e, for sentence a, we select $max_{i=a,j=1..8}(prior_j.p_{weka2}(S_{i=a,j}))$.

Table 5 shows the impact this reformulation has on the acceptability of the sentences. Our algorithm selects one formulation of each PubMed sentence based on our prior knowledge of the preferences of non-science students, and the Weka-probabilities for acceptability of each formulation of a sentence. Our selective reformulation increases the average z-score from .613 to .713. This is now comparable with the acceptability ratings of non-scientists for sentences from the world news genre. Note that reformulation only using priors resulted in worse results (Table 1).

However there remains scope for improvement. If we had an oracle that selected the best formulation of each sentence (as scored by non-scientists), this would result in an average score of 1.04.

Genre	Version	z-score
PubMed	Randomly Selected	–.17
PubMed	Original Sentences	.61
PubMed	Selectively Reformulate	.71
PubMed	Selected by Oracle	1.04
BNC World	Original Sentences	.70

Table 5: Average z-scores for non-science students. Selective reformulation increases the acceptability scores of sentences drawn from technical writing to levels comparable to acceptability scores of sentences drawn from news reports on world news (their most preferred genre).

5 Conclusions and future work

In this investigation we report that science and non-science university students have different global preferences regarding which formulations of causation are acceptable. Using surface features that reflect propositional complexity, a machine classifier can learn which of 8 formulations of a discourse relation are acceptable (with Accuracy $= .89$ and Kappa $= .73$ for sentences from the PubMed genre). Using the global preferences of non-science students as priors, and combining these with machine classifier predictions of acceptability, we have demonstrated that it is possible to selectively rewrite sentences from PubMed in a manner that is personalised for non-science students. This boosts the average z-score for acceptability from .613 to .713 on PubMed sentences, a level similar to scores of non-scientists for sentences from their most preferred World News genre. We have thus shown that there is potential for reformulating technical writing for a lay audience – differences in preferences for expressing a discourse relation do exist between lay and expert audiences, and these can be learnt.

While in this paper we focus on the discourse relation of causation, other discourse relations commonly used in scientific writing can also be realised using markers with different syntactic properties; for instance, *contrast* can be expressed using markers such as “while”, “unlike”, “but”, “compared to”, “in contrast to” or “the difference between”. As part of our wider goals, we are in the process of extending the number of discourse relations considered. We are also in the process of developing a framework within which we can use transfer rules and a bi-directional grammar to automate such complex syntactic reformulation.

Tree Edit Models for Recognizing Textual Entailments, Paraphrases, and Answers to Questions

Abstract

We describe tree edit models for representing sequences of tree transformations involving complex reordering phenomena and demonstrate that they offer a simple, intuitive, and effective method for modeling pairs of semantically related sentences. To efficiently extract sequences of edits, we employ a tree kernel as a heuristic in a greedy search routine. We describe a logistic regression model that uses 33 syntactic features of edit sequences to classify the sentence pairs. The approach leads to competitive performance in recognizing textual entailment, paraphrase identification, and answer selection for question answering.

1 Introduction

Many NLP tasks involve modeling relations between pairs of sentences or short texts in the same language. Examples include recognizing textual entailment, paraphrase identification, and question answering. Generic approaches are, of course, desirable; we believe such approaches are also feasible because these tasks exhibit some similar semantic relationships between sentences.

A popular method for such tasks is Tree Edit Distance (TED), which models sentence pairs by finding a low or minimal cost sequence of editing operations to transform a tree representation of one sentence (e.g., a dependency or phrase structure parse tree) into a tree for the other. Unlike grammar-based models and shallow-feature discriminative approaches, TED provides an intuitive story for tree pairs where one tree is derived from the other by a sequence of simple transformations.

The available operations in standard TED are the following: insertion of a node, relabeling (i.e., renaming) of a node, and deletion (i.e., removal) of a node. While the restriction to these three operations permits efficient dynamic programming solutions for finding a minimum-cost edit sequence (Klein, 1989; Zhang and Shasha, 1989), certain interesting and prevalent phenomena involving reordering and movement cannot be elegantly captured. For example, consider the following sentence pair, which is a simplified version of a true entailment (i.e., the premise entails the hypothesis) in the development data for the RTE-3 task.

Premise: *Pierce built the home for his daughter off Rossville Blvd, as he lives nearby.*

Hypothesis: *Pierce lives near Rossville Blvd.*

In a plausible dependency tree representation of the premise, *live* and *Rossville Blvd* would be in separate subtrees under *built*. In the hypothesis tree, however, the corresponding nodes would be in a grandparent-child relationship as part of the same phrase, *lives near Rossville Blvd*. In general, one would expect that short transformation sequences to provide good evidence of true entailments. However, to account for the grandparent-child relationship in the hypothesis, TED would produce a fairly long sequence, relabeling *nearby* to be *near*, deleting the two nodes for *Rossville Blvd*, and then reinserting those nodes under *near*.

We describe a tree edit approach that allows for more effective modeling of such complex reordering phenomena. Our approach can find a shorter and more intuitive edit sequence, relabeling *nearby* to be *near*, and then moving the whole subtree *Rossville Blvd* to be a child of *near*, as shown in Figure 1.

A model should also be able to consider characteristics of the tree edit sequence other than its overall length (e.g., how many proper nouns were deleted). Using a classifier with a small number of syntactic

features, our approach allows us to learn—from labeled examples—how different types of edits should affect the model's decisions (e.g., about whether two sentences are paraphrases).

The structure of this paper is as follows. §2 introduces our model and describes the edit operations that were implemented for our experiments. §3 details the search-based procedure for extracting edit sequences for pairs of sentences. §4 describes the classifier for sentence pairs based on features of their corresponding edit sequences. §5 describes and presents the results of experiments involving recognizing textual entailment (Giampiccolo et al., 2007), paraphrase identification (Dolan et al., 2004), and an answer selection task for question answering (Wang et al., 2007). §6 addresses related work, and §7 provides concluding remarks.

2 Extended Tree Edit Sequences

This section defines a tree edit sequence and describes the operations used in our experiments.

We begin with some conventions. We use dependency trees as the structure upon which the tree edits will operate. The child nodes for a given parent are represented in a head-outward fashion such that the left and right children are separate lists, with the left- and right-most elements as the last members of their respective lists, as in most generative dependency models (Eisner, 1996). Each node consists of a lemmatized word token as its main label (hereafter, lemma), a part of speech tag (POS), and a syntactic relation label for the edge to its parent. We assume the root node has a special dummy edge label ROOT.

Let T_c be a "current tree" that is being transformed and let T_t be a "target tree" into which T_c will ultimately be transformed. Let $T(i)$ be a node with an index i into the tree T, where the indices are arbitrary (e.g., they could be word positions).

2.1 Definition

We define a tree edit sequence to be a series of edit operations that transform a source tree (the initial T_c) into a target tree T_t.[1] While TED permits only insert, relabel, and delete operations, edit sequences may contain more complex operations, such as moving entire subtrees and re-ordering child nodes.

2.2 Implemented Operations

For our experiments, we used the types of edit operations listed in Table 1.[2] The first six operations are straightforward extensions of the insert, relabel and delete operations allowed in TED. The final three operations, MOVE-SUBTREE, NEW-ROOT, and MOVE-SIBLING, enable succinct edit sequences for complex transformations. For a given current tree, there may be many instantiations of each operation (e.g., DELETE-LEAF could be invoked to delete any of a number of leaf nodes). Note that any tree can be transformed into any other simply by deleting all nodes from the one tree and inserting all the nodes in the other. However, our set of tree edit operations permits more concise and intuitive edit sequences.

3 Searching for Tree Edit Sequences

To model sentence pairs effectively, we seek a short sequence of tree edits that transforms one tree into another. The space of possible edit sequences, as with TED and many other methods involving trees,

[1] Such a sequence is sometimes called a "script" for TED.

[2] We leave for future work the exploration of other operations (e.g., swapping parent and child nodes).

Operation	Arguments	Description
INSERT-CHILD	node index j, new lemma l, POS p, edge label e, side $s \in \{\mathit{left}, \mathit{right}\}$	Insert a node with lemma l, POS p, and edge label e as the last child (i.e., farthest from parent) on side s of $T(j)$.
INSERT-PARENT	non-root node index j, new lemma l, new POS p, edge label e, side $s \in \{\mathit{left}, \mathit{right}\}$	Create a node with lemma l, POS p, and edge label e. Make $T(j)$ a child of the new node on side s. Insert the new node as a child of the former parent of $T(j)$ in the same position.
DELETE-LEAF	leaf node index j	Remove the leaf node $T(j)$.
DELETE-&-MERGE	node index j (s.t. $T(j)$ has exactly 1 child)	Remove $T(j)$. Insert its child as a child of $T(j)$'s former parent in the same position.
RELABEL-NODE	node index j, new lemma l, new POS p	Set the lemma of $T(j)$ to be l and its POS to be p.
RELABEL-EDGE	node index j, new edge label e	Set the edge label of $T(j)$ to be e.
MOVE-SUBTREE	node index j, node index k (s.t. $T(k)$ is not a descendant of $T(j)$), side $s \in \{\mathit{left}, \mathit{right}\}$	Move $T(j)$ to be the last child on the s side of $T(k)$.
NEW-ROOT	non-root node index j, side $s \in \{\mathit{left}, \mathit{right}\}$	Make $T(j)$ the new root node of the tree. Insert the former root as the last child on the s side of $T(j)$.
MOVE-SIBLING	non-root node index j, side $s \in \{\mathit{left}, \mathit{right}\}$, position $r \in \{\mathit{first}, \mathit{last}\}$	Move $T(j)$ to be the r child on the s side of its parent.

Table 1: Possible operations in our extended tree edit implementation. All are described as operations to tree T.

is exponentially large in the size of the trees. However, while dynamic programming solutions exist for TED (Klein, 1989; Zhang and Shasha, 1989), it is unlikely that such efficient algorithms are available for our problem because of the lack of locality restrictions on edit operations.[3]

3.1 Algorithm for Extracting Sequences

Rather than dynamic programming, we use greedy best-first search (Pearl, 1984) to efficiently find sensible (if not minimal) edit sequences. The distinguishing characteristic of greedy best-first search is that its function for evaluating search states is simply a heuristic function that estimates the remaining cost, rather than a heuristic function plus the cost so far (e.g., number of edits), as in other types of search.

Here, the initial search state is the source tree, the current state is T_c, and the goal state is T_t. The function for generating the successors for a given state returns returns trees for all possible specifications of operations on T_c (§2.2), subject to the minimal constraints to be described in §3.3. The enumeration order of the edits in the search procedure (i.e., the order in which states are explored) follows the order of their presentation in Table 1. In preliminary experiments, varying this order had no effect on the extracted transformations.

3.2 Tree Kernel Heuristic

In our greedy search approach, the evaluation function's value for a state depends only on the heuristic function's estimate of how different the current tree at that state is from the target tree. Using this function, at each step, the search routine chooses the next state (i.e., edit) so as to minimize the difference between the current and target trees.

We use a tree kernel to define the heuristic function. A kernel is a special kind of symmetric function from a pair of objects to a real number. It can be interpreted as the inner product of those objects represented in some real-valued feature space (Schölkopf and Smola, 2001). A tree kernel, as proposed by Collins and Duffy (2001), is a convolution kernel[4] whose input is a pair of trees and whose output is a positive number indicating the similarity of the sets of all their subtrees.

The dimensionality of the feature vector associated with a tree kernel is thus unbounded in general, and larger trees generally lead to larger kernel values. Direct use as a search heuristic would lead to the exploration of states for larger and larger trees, even ones larger than the target tree. Thus, as in

[3] Gildea (2003) proposes a dynamic programming algorithm for a related tree alignment problem, but it is still exponential in the maximum number of children for a node.

[4] Haussler (1999) provides a proof, which can be extended for our kernel, that tree kernels are valid kernel functions.

Equation 1, the search heuristic H "normalizes" the kernel K of the current tree T_c and target tree T_t to unit range by dividing by the geometric mean of the kernels comparing the individual trees to themselves.[5] Also, the normalized value is subtracted from 1 so as to make it a difference rather than a similarity. The search routine will thus reach the goal state when the heuristic reaches 0, indicating that the current and target trees are identical.

$$H(T_c) = 1 - \frac{K(T_c, T_t)}{\sqrt{K(T_c, T_c) \times K(T_t, T_t)}} \qquad (1)$$

Kernels are most commonly used in the efficient construction of margin-based classifiers in the implied representation space (e.g., Zelenko et al., 2003). Here, however, the kernel helps to find a representation (i.e., an edit sequence) for subsequent modeling steps.

We are effectively mapping the source, current, and target trees to points on the surface of a high-dimensional unit sphere associated with the normalized kernel. In this geometric interpretation, the search heuristic in Equation 1 leads the search algorithm to explore reachable trees along the surface of this sphere, always choosing the one whose angle with the target tree is smallest, until the angle is 0. The path on the sphere corresponds to an edit sequence, from which we will derive edit features in §4 for classification.

Our kernel is based on the partial tree kernel (PTK) proposed by Moschitti (2006). It considers matches between ordered subsequences of children in addition to the full sequences of children as in Collins and Duffy (2001). This permits a very fine-grained measure of tree pair similarity. Importantly, if two nodes differ only by the presence or position of a single child, they will still lead to a large kernel function value. We also sum over the similarities between all pairs of nodes, similar to (Collins and Duffy, 2001).

Since the PTK considers non-contiguous subsequences, it is very computationally expensive. We therefore restrict our kernel to consider only contiguous subsequences, as in the contiguous tree kernel (CTK) (Zelenko et al., 2003).

To define our kernel, we begin with a similarity function for pairs of nodes n_1 and n_2 that depends on their lemmas, POS tags, edge labels, and sides with respect to their parents:[6]

$$\begin{aligned} s(n_1, n_2) = &\delta(l(n_1), l(n_2)) \\ &\times \sum_{f \in \{l,e,p,s\}} \delta(f(n_1), f(n_2)) \end{aligned} \qquad (2)$$

where δ returns 1 if its arguments are equivalent, 0 otherwise. l, e, p, and s are used here as functions to select the lemma, edge label, POS, and side of a node. Equation 2 encodes the linguistic intuition that the primary indicator of node similarity should be a lexical match between lemmas. If the lemmas match, then edge labels, POS, and the locations (sides) relative to their parents are also considered.

The kernel is defined recursively (starting from the roots), where n_i is a node in the set of nodes N_{T_i} in tree T_i:

$$K(T_1, T_2) = \sum_{n_1 \in \{N_{T_1}\}} \sum_{n_2 \in \{N_{T_2}\}} \Delta(n_1, n_2) \qquad (3)$$

$$\begin{aligned} \Delta(n_1, n_2) = \mu \Bigg(&\lambda^2 s(n_1, n_2) + \qquad (4) \\ &\sum_{J_1, J_2, |J_1| = |J_2|} \prod_{i=1}^{l(J_1)} \Delta(c_{n_1}[J_{1i}], c_{n_2}[J_{2i}]) \Bigg) \end{aligned}$$

$J_1 = \langle J_{11}, J_{12}, J_{13}, \ldots \rangle$ is an index sequence associated with any *contiguous* ordered sequence of children c_{n_1} of node n_1 (likewise for J_2). J_{1i} and J_{2i} point to the ith children in the two sequences. $|\cdot|$ returns the length of a sequence.

The kernel includes two decay factors: λ for the length of child subsequences, as in Zelenko et al. (2003) and Moschitti (2006); and μ for the height of the subtree, as in Collins and Duffy (2001) and Moschitti (2006). We set both to 0.25 in our experiments to encourage the search to consider edits leading to smaller matches (e.g., of individual parent-child dependencies) before larger ones.[7]

[5] This normalized function is also guaranteed to be a kernel function (Schölkopf and Smola, 2001).

[6] The side of a node relative to its parent in a dependency tree is important: two parent nodes with the same children should not be considered exact matches if children are on different sides (e.g., *defeated the insurgents* and *the insurgents defeated*).

[7] From experiments with the paraphrase training set (§5.2), performance does not appear sensitive to the decay parameters. Settings of 0.1, 0.2, 0.3, and 0.4 led to 10-fold cross-validation

The main difference between our kernel and the CTK is that we sum over all pairs of subtrees (Equation 3). In contrast, the CTK only considers only one pair of subtrees. When the CTK is applied to relation extraction by Culotta and Sorensen (2004), each subtree is the smallest common subtree that includes the entities between which a relation may exist (e.g., the subtree for *Texas-based energy company Exxon Mobil* when extracting ORGANIZATION-LOCATION relations).

3.3 Constraints on the Search Space

For computational efficiency, we impose the following three constraints to simplify the search space. Note that the first two simply prune away obviously unhelpful search states.

1. For INSERT-CHILD, INSERT-PARENT, and RELABEL-NODE edits, the lemma and POS of the node to insert must occur in the target tree. Also, the pair consisting of the lemma for the node to insert and the lemma for its prospective parent must not appear more times in the resulting tree than in the target tree.
2. For MOVE-SUBTREE edits, the pair consisting of the lemma for the node to move and the lemma for its prospective parent must exist in the target tree.
3. For INSERT-CHILD and INSERT-PARENT edits, the edge labels attaching the newly inserted nodes to their parents are always the most frequent edge label for the given POS.[8] Further edits can modify these edge labels.

3.4 Search Error and Failure

The search does not always find optimal edit sequences, but most sequences seem reasonable upon inspection. However, for some cases, the search does not find a sequence in a reasonable number of iterations. We therefore set an upper limit of $maxIters = 200$ on the number of iterations.[9] In practice, this constraint is enforced a small fraction of the time (e.g., less than 0.1% of the time for the answer selection training data). If no goal state is found after $maxIters$ iterations, a special unknown sequence feature is recorded.

4 Classification of Sequences

Given a training set of labeled sentence pairs, after extracting edit sequences, we train a logistic regression (LR) classification model (Hastie et al., 2001) on the labels and features of the extracted sequences.[10] We optimize with a variant of Newton's method (le Cessie and van Houwelingen, 1997).

The tree edit models use a set of 33 features of edit sequences to classify sentence pairs. We used the training data for the paraphrase task (§5.2) to develop this set. All features are integer-valued, and most are counts of different types of edits. Five are counts of the nodes in the source tree that were not edited directly by any operations (though their ancestors or descendants may have been). Table 2 describes the features in detail.

5 Experiments

Experiments were conducted to evaluate tree edit models for three tasks: recognizing textual entailment (Giampiccolo et al., 2007), paraphrase identification (Dolan et al., 2004), and an answer selection task (Wang et al., 2007) for question answering (Voorhees, 2004). The feature set and first tree edit model were developed for paraphrase, and then applied to the other tasks with very few modifications (all explained below) and no further tuning.[11]

5.1 Recognizing Textual Entailment

A tree edit model was trained for recognizing textual entailment (RTE). Here, an instance consists of

accuracy values that were not significantly different from each other. However, we did observe that increased search failure (§3.4) resulted from settings above 0.5.

[8] Edge label frequencies for each POS were computed from the training data for the MST parser (McDonald et al., 2005).

[9] $maxIters = 400$ for the textual entailment experiments to account for multi-sentence premises. For all tasks, extracting sequences took about 5 seconds on average per sentence pair with 1 GB of RAM on a 3.0 GHz machine.

[10] In cross-validation experiments with the training data, we found that unregularized LR outperformed SVMs (Vapnik, 1995) and ℓ_2-regularized LR, perhaps due to the small number of features in our models.

[11] All datasets were POS-tagged using Ratnaparkhi's (1996) tagger and parsed for dependencies using the MST Parser (McDonald et al., 2005). Features were computed from POS and edge label information in the dependency parses. The WordNet API (Miller et al., 1990) was used for lemmatization only. An appendix with further experimental details is available at http://www.ark.cs.cmu.edu/mheilman/tree-edit-appendix/.

Feature	Description
`totalEdits`	# of edits in the sequence.
X`Edits`	#s of X edits (where X is one of the nine edit types in Table 1).

`relabelSamePOS,`
`relabelSameLemma,`
`relablePronoun,`
`relabelProper,`
`relabelNum`
	#s of `RELABEL-NODE` edits that: preserve POS, preserve lemmas, convert between nouns and pronouns, change proper nouns, change numeric values by more than 5% (to allow rounding), respectively.

`insertVorN,`
`insertProper`
	#s of `INSERT-CHILD` or `INSERT-PARENT` edits that: insert nouns or verbs, insert proper nouns, respectively.

`removeVorN,`
`removeProper,`
`removeSubj,`
`removeObj,`
`removeVC,`
`removeRoot`
	#s of `REMOVE-LEAF` or `REMOVE-&-MERGE` edits that: remove nouns or verbs, remove proper nouns, remove nodes with subject edge labels, remove nodes with object edge labels, remove nodes with verb complement edge labels, remove nodes with root edge labels (which may occur after `NEW-ROOT` edits), respectively.

`relabelEdgeSubj,`
`relabeledgeObj,`
`relabelEdgeVC,`
`relabelEdgeRoot`
	#s of `RELABEL-EDGE` edits that: change to or from subject edge labels, change to or from object edge labels, change to or from verb complement edge labels, change to or from root edge labels, respectively.

`uneditedNodes,`
`uneditedNum,`
`uneditedVerbs,`
`uneditedNouns,`
`uneditedProper`
	#s of unedited nodes: in total, that are numeric values, that are verbs, that are nouns, that are proper nouns, respectively.

`unknownSeq`	1 if no edit sequence was found and 0 otherwise (§3.4).

Table 2: Tree edit sequence classification features.

System	Acc. %	Prec. %	Rec. %
Harmeling, 2007	59.5	-	-
de Marneffe et al., 2006	60.5	61.8	60.2
M&M, 2007 (NL)	59.4	**70.1**	36.1
M&M, 2007 (Hybrid)	**64.3**	65.5	63.9
Tree Edit Model	62.8	61.9	**71.2**

Table 3: Results for recognizing textual entailments. Precision and recall values are for the true entailment class. Results for de Marneffe et al. (2006) were reported by MacCartney and Manning (2008). Harmeling (2007) only reported accuracy.

a “premise,” which is a sentence or paragraph about a particular topic or event, and a “hypothesis,” which is a single, usually short, sentence that may or may not follow from the premise. The task is to decide whether or not the hypothesis is entailed by the premise (Giampiccolo et al., 2007).

Tree edit sequences were extracted in one direction, from premise to hypothesis.[12] Since premises may consist of multiple sentences, we attach sentences as children of dummy root nodes, for both the premise and hypothesis. The model was trained on the development set (i.e., training data) for RTE-3 along with all the data from the RTE-1 and RTE-2 tasks. It was then evaluated on the RTE-3 test set. We report precision and recall for true entailments, and overall accuracy (i.e., percentage correct).

We compare to four systems that use syntactic dependencies and lexical semantic information.[13] De Marneffe et al. (2006) described an RTE system that finds word alignments and then classifies sentence pairs based on those alignments. MacCartney and Manning (2008) used an inference procedure based on Natural Logic, leading to a relatively high-precision, low-recall system. MacCartney and Manning (2008) also tested a hybrid of the natural logic system and the complementary system of de Marneffe et al. (2006) to improve coverage. Harmeling (2007) took an approach similar to ours involving classification based on transformation sequences, but with less general operations and a more complex, heuristic procedure for finding sequences.

Table 3 presents RTE results, showing that the tree edit model performs competitively. While it does not outperform state-of-the-art RTE systems, the tree edit model is simpler and less tailored to this task than many other RTE systems based on similar linguistic information.

[12] It is counter-intuitive to model *adding* information through extensive insertions, for both entailment and answer selection.

[13] The top-performing RTE systems often involve significant manual engineering for the RTE task. Also, many employ techniques that make them not very comparable to our approach (e.g., theorem proving). We also note that Kouylekov and Magnini (2005) report 55% accuracy for RTE-2 using TED. See Giampiccolo et al. (2007) for more RTE-3 results.

Table 5: Results for the task of answer selection for question answering. +WN denotes use of WordNet features.

5.2 Paraphrase Identification

A tree edit model was trained and tested for paraphrase identification using the the Microsoft Research Paraphrase Corpus (Dolan et al., 2004). The task is to identify whether two sentences convey essentially the same meaning.

The standard training set was used to train the tree edit classification model to distinguish between true and false paraphrases. Since there is no predefined direction for paraphrase pairs, we extracted two sequences for each pair (one in each direction) and summed the feature values. The model was evaluated with the standard test set.

We report accuracy, positive class precision (i.e., percentage of predicted positive paraphrases that had positive gold-standard labels), and positive class recall (i.e., percentage of positive gold-standard labels that were predicted to be positive paraphrases).

We compare to two of the best performance approaches to paraphrase. One approach, by Wan et al. (2006), uses an SVM classifier with features based on syntactic dependencies, TED, unigram overlap, and BLEU scores (Papineni et al., 2002). The other system, by Das and Smith (2009), is based on a quasi-synchronous grammar (QG; Smith and Eisner, 2006), a probabilistic model that allows loose alignments between trees but prefers tree isomorphism. In addition to syntactic dependencies, the QG model utilizes entity labels from BBN Identifinder (Bikel et al., 1999) and lexical semantics knowledge from WordNet. Das and Smith (2009) also use a product of experts (PoE) (Hinton, 1999) to combine the QG model with lexical overlap features.

Table 4 shows the test set results for all of the systems. While the tree edit model did not outperform the other systems, it produced competitive results. Moreover, the tree edit model does not make use of BLEU scores (Wan et al., 2006), entity labeling components, lexical semantics knowledge sources such as WordNet (beyond lemmatization), or system combination techniques (Das and Smith, 2009).

5.3 Answer Selection for Question Answering

A tree edit model was trained for answer selection in question answering (QA). In this task, an instance consists of a short factual question (e.g., *Who wrote the 'Tale of Genji'?*) and a candidate answer sentence retrieved by the information retrieval component of a question answering system. For a positive instance, the text will correctly answer the question—though perhaps indirectly. It may also contain various extraneous information (e.g., *Kano script made possible the development of a secular Japanese literature, beginning with such Late Heian classics as Lady Murasaki's "Tales of Genji."*). For a given set of questions, the task here is to *rank* candidate answers (Wang et al., 2007).

The experimental setup is the same as in Wang et al. (2007). We trained the tree edit model on the manually judged positive and negative QA pairs from previous QA tracks at the Text REtrieval Conference (TREC-8 through TREC-12). The goal of the task is to rank answer candidates rather than classify them; therefore, after training a logistic regression classifier, we rank the answer candidates for a given question by their posterior probabilities of correctness according to the model.

We tested our model with QA pairs from TREC-13. We report Mean Average Precision (MAP) and Mean Reciprocal Rank (MRR), which are information retrieval measures for ranked lists.

Tree edit sequences were extracted only in one direction, from answer to question. We compare our tree edit model to three other systems as they are reported by Wang et al. (2007). Wang et al. use a QG model, incorporating information from dependency trees, entity labels from BBN Identifinder (Bikel et al., 1999), and lexical semantics knowledge from WordNet (Miller et al., 1990). Cui et al. (2005) developed an information theoretic measure based on dependency trees. Punyakanok et al. (2004) used a generalization of TED to model the QA pairs. For their experiments, Wang et al. also extended both of the latter models to utilize WordNet.

Table 5 displays answer selection results, including test set results for the baseline systems with and without lexical semantic information from WordNet. The tree edit model, which does not use lexical semantics knowledge, produced the best result reported to date. The results for the tree edit model are statistically significantly different (sign test, $p < 0.01$) from the results for all except the Wang et al. (2007) system with WordNet ($p > 0.05$).

5.4 Discussion

The parameter settings learned for the features in Table 2 were broadly similar for the three tasks. For example, operations involving changes to subjects and proper nouns tended to be associated with non-paraphrases, false entailments, and incorrect answers. We did not observe any interesting differences in the parameter values.

While the tree edit models perform competitively in multiple tasks by capturing relevant syntactic phenomena, it is clear that syntax alone cannot solve these semantic tasks. Fortunately, this approach is amenable to extensions, facilitated by the separation of the representation extraction and classification steps. Richer edits could be included; lexical semantics could be integrated into the classifier or the search heuristic; or edit sequences might be found for other types of trees, such as semantic parses.

6 Related Work

TED is a widely studied technique with many applications (Klein, 1989; Zhang and Shasha, 1989; Punyakanok et al., 2004; Schilder and McInnes, 2006). See Bille (2005) for a review. Chawathe and Garcia-Molina (1997) describe a tree edit algorithm for detecting changes in structured documents that incorporates edits for moving subtrees and reordering children. However, they make assumptions unsuitable for natural language, such as the absence of recursive syntactic rewrite rules. Bernard et al. (2008) use EM to learn the costs for simple insert, relabel, and delete edits, but they only discuss experiments for digit recognition and a task using artificial data.

Much research has focused on modeling word reordering phenomena and syntactic alignments (e.g., Gildea, 2003; Smith and Eisner, 2006; *inter alia*), and such methods have been applied successfully to semantic tasks (de Marneffe et al., 2006; Wang et al., 2007; Das and Smith, 2009). While we not describe connections to such approaches in detail due to space limitations, we note that theoretical connections are possible between transformations and alignments (Chawathe and Garcia-Molina, 1997).

Tree kernels have been applied to a variety of natural language tasks (Collins and Duffy, 2001; Zelenko et al., 2003; Culotta and Sorensen, 2004). Of particular interest, Zanzotto and Moschitti (2006) describe a kernel for RTE that takes tree pairs, rather than single trees, as input. To our knowledge, our use of a tree kernel as a search heuristic is novel.

7 Conclusion

We described tree edit models that generalize TED by allowing operations that better account for complex reordering phenomena and by learning from data how different edits should affect the models decisions about output variables of interest (e.g., the correctness of answers). They offer an intuitive and effective method for modeling sentence pairs. They led to competitive performance for three tasks: paraphrase identification, recognizing textual entailment, and answer selection for question answering.

Abstract

In this paper, we describe an approach based on off-the-shelf parsers and semantic resources for the Recognizing Textual Entailment (RTE) challenge that can be generally applied to any domain. Syntax is exploited by means of tree kernels whereas lexical semantics is derived from heterogeneous resources, e.g. WordNet or distributional semantics through Wikipedia. The joint syntactic/semantic model is realized by means of tree kernels, which can exploit lexical relatedness to match syntactically similar structures, i.e. whose lexical compounds are related. The comparative experiments across different RTE challenges and traditional systems show that our approach consistently and meaningfully achieves high accuracy, without requiring any adaptation or tuning.

1 Introduction

Recognizing Textual Entailment (RTE) is rather challenging as effectively modeling syntactic and semantic for this task is difficult. Early deep semantic models (e.g., (Norvig, 1987)) as well as more recent ones (e.g., (Tatu and Moldovan, 2005; Bos and Markert, 2005; Roth and Sammons, 2007)) rely on specific world knowledge encoded in rules for drawing decisions. Shallower models exploit matching methods between syntactic/semantic graphs of texts and hypotheses (Haghighi et al., 2005). The matching step is carried out after the application of some lexical-syntactic rules that are used to transform the text T or the hypothesis H (Bar-Haim et al., 2009) at surface form level. For all these methods, the effective use of syntactic and semantic information depends on the coverage and the quality of the specific rules. Lexical-syntactic rules can be automatically extracted from plain corpora (e.g., (Lin and Pantel, 2001; Szpektor and Dagan, 2008)) but the quality (also in terms of little noise) and the coverage is low. In contrast, rules written at the semantic level are more accurate but their automatic design is difficult and so they are typically hand-coded for the specific phenomena.

In this paper, we propose models for effectively using syntactic and semantic information in RTE, without requiring either large automatic rule acquisition or hand-coding. These models exploit lexical similarities to generalize lexical-syntactic rules automatically derived by supervised learning methods. In more detail, syntax is encoded in the form of parse trees whereas similarities are defined by means of WordNet simlilarity measures or Latent Semantic Analysis (LSA) applied to Wikipedia or to the British National Corpus (BNC). The joint syntactic/semantic model is realized by means of novel tree kernels, which can match subtrees whose leaves are lexically similar (so not just identical).

To assess the benefit of our approach, we carried out comparative experiments with previous work: especially with the method described in (Zanzotto and Moschitti, 2006; Zanzotto et al., 2009). This constitutes our strong baseline as, although it can only exploit lexical-syntactic rules, it has achieved top accuracy in all RTE challenges. The results, across different RTE challenges, show that our approach constantly and significantly improves the

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 1020–1028,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

baseline model. Moreover, our approach does not require any adaptation or tuning and uses a computation for the similarity function based on Wikipedia which is faster than the computation of tools based on WordNet or other resources (Basili et al., 2006).

The remainder of the paper is organized as follows: Section 2 critically reviews the previous work by highlighting the need of generalizing lexico-syntactic rules. Section 3 describes lexical similarity approaches, which can serve the generalization purpose. Section 4 describes how to integrate lexical similarity in syntactic structures using syntactic/semantic tree kernels (SSTK) whereas Section 5 shows how to use SSTK in a kernel-based RTE system. Section 6 describes the experiments and results. Section 7 discusses the efficiency and accuracy of our system compared with other RTE systems. Finally, we draw the conclusions in Section 8.

2 Related work

Lexical-syntactic rules are largely used in textual entailment recognition systems (e.g., (Bar-Haim et al., 2007; Dinu and Wang, 2009)) as they conveniently encode world knowledge into linguistic structures. For example, to decide whether the simple sentences are in the entailment relation:

$T_2 \Rightarrow ?H_2$

T_2	*"In 1980 Chapman killed Lennon."*
H_2	*"John Lennon died in 1980."*

we need a lexical-syntactic rule such as:

$$\rho_3 = \; \boxed{X}\, killed \boxed{Y} \;\rightarrow\; \boxed{Y} died$$

along with such rules, the temporal information should be taken into consideration.

Given the importance of lexical-syntactic rules in RTE, many methods have been proposed for their extraction from large corpora (e.g., (Lin and Pantel, 2001; Szpektor and Dagan, 2008)). Unfortunately, these unsupervised methods in general produce rules that can hardly be used: noise and coverage are the most critical issues.

Supervised approaches were experimented in (Zanzotto and Moschitti, 2006; Zanzotto et al., 2009), where lexical-syntactic rules were derived from examples in terms of complex relational features. This approach can easily miss some useful information and rules. For example, given the pair $\langle T_2, H_2\rangle$, to derive the entailment value of the following case:

$T_4 \Rightarrow ?H_4$

T_4	*"In 1963 Lee Harvey Oswald murdered JFK"*
H_4	*"JFK died in 1963"*

we can only rely on this relatively interesting lexical-syntactic rule (i.e. which is in common between the two examples):

$$\rho_5 = \;\; (VP(VBZ)(NP\boxed{X})) \;\rightarrow\; (S(NP\boxed{X})(VP(VBZ \quad died)))$$

Unfortunately, this can be extremely misleading since it also derives similar decisions for the following example:

$T_6 \Rightarrow ?H_6$

T_6	*"In 1956 JFK met Marilyn Monroe"*
H_6	*"Marilyn Monroe died in 1956"*

The problem is that the pairs $\langle T_2, H_2\rangle$ and $\langle T_4, H_4\rangle$ share more meaningful features than the rule ρ_5, which should make the difference with respect to the relation between the pairs $\langle T_2, H_2\rangle$ and $\langle T_6, H_6\rangle$. Indeed, the word "*kill*" is more semantically related to "*murdered*" than to "*meet*". Using this information, it is possible to derive more effective rules from training examples.

There are several solutions for taking this information into account, e.g. by using FrameNet semantics (e.g., like in (Burchardt et al., 2007)), it is possible to encode a lexical-syntactic rule using the KILLING and the DEATH frames, i.e.:

$$\rho_7 = \begin{array}{l} KILLING(Killer: \boxed{X}, \\ Victim: \boxed{Y}) \end{array} \;\rightarrow\; \begin{array}{l} DEATH(\\ Protagonist: \boxed{Y}) \end{array}$$

However, to use this model, specific rules and a semantic role labeler on the specific corpora are needed.

3 Lexical similarities

Previous research in computational linguistics has produced many effective lexical similarity measures based on many different resources or corpora. For example, WordNet similarities (Pedersen et al., 2004) or Latent Semantic Analysis over a large corpus are widely used in many applications and for the definition of kernel functions, e.g. (Basili et al., 2006; Basili et al., 2005; Bloehdorn et al., 2006).

In this section we present the main component of our new kernel, i.e. a lexical similarity derived from different resources. This is used inside the syntactic/semantic tree kernel defined in (Bloehdorn and Moschitti, 2007a; Bloehdorn and Moschitti, 2007b) to enhance the basic tree kernel functions.

3.1 WordNet Similarities

WordNet similarities have been heavily used in previous NLP work (Chan and Ng, 2005; Agirre et al., 2009). All WordNet similarities apply to pairs of synonymy sets (synsets) and return a value indicating their semantic relatedness. For example, the following measures, that we use in this study, are based on path lengths between concepts in the Wordnet Hierarchy:

Path the measure is equal to the inverse of the shortest path length ($path\_length$) between two synsets c_1 and c_2 in WordNet

$$Sim_{Path} = \frac{1}{path\_length(c_1, c_2)} \tag{1}$$

WUP the Wu and Palmer (Wu and Palmer, 1994) similarity metric is based on the depth of two given synsets c_1 and c_2 in the WordNet taxonomy, and the depth of their least common subsumer (lcs). These are combined into a similarity score:

$$Sim_{WUP} = \frac{2 \times depth(lcs)}{depth(c_1) + depth(c_2)} \tag{2}$$

Wordnet similarity measures on synsets can be extended to similarity measures between words as follows:

$$\kappa_{\mathcal{S}}(w_1, w_2) = max_{(c_1,c_2) \in C_1 \times C_2} Sim_{\mathcal{S}}(c_1, c_2) \tag{3}$$

where $\mathcal{S}$ is Path or WUP and C_i is the set of the synsets related to the word w_i.

3.2 Distributional Semantic Similarity

Latent Semantic Analysis (LSA) is one of the corpus-based measure of distributional semantic similarity, proposed by (Landauer et al., 1998). Words $\vec{w_i}$ are represented in a document space. Each feauture is a document and its value is the frequency of the word in the document. The similarity is generally computed as a cosine similarity:

$$\kappa_{LSI}(w_1, w_2) = \frac{\vec{w_1}\vec{w_2}}{||\vec{w_1}|| \times ||\vec{w_2}||} \tag{4}$$

In our approach we define a proximity matrix P where $p_{i,j}$ represents $\kappa_{LSI}(w_i, w_j)$ The core of our approach lies on LSI (Latent Semantic Indexing) over a large corpus. We used singular value decomposition (SVD) to build the proximity matrix $P = DD^T$ from a large corpus, represented by its word-by-document matrix D.

SVD decomposes D (weighted matrix of term frequencies in a collection of text) into three matrices $U\Sigma V^T$, where U (matrix of term vectors) and V (matrix of document vectors) are orthogonal matrices whose columns are the eigenvectors of DD^T and D^TD respectively, and Σ is the diagonal matrix containing the singular value of D.

Given such decomposition, P can be obtained as $U_k\Sigma_k^2 U_k^T$, where U_k is the matrix containing the first k columns of U and k is the dimensionality of the latent semantic space. This is efficiently used to reduce the memory requirements while retaining the information. Finally we computed the term similarity using the cosine measure in the vector space model (VSM).

Generally, LSA can be observed as a way to overcome some of the drawbacks of the standard vector space model, such as sparseness and dimensionality. In other words, the LSA similarity is computed in a lower dimensional space, in which second-order relations among words and documents are exploited (Mihalcea et al., 2006).

It is worth mentioning that the LSA similarity measure depends on the selected corpus but it benefits from a higher computation speed in comparison to the construction of the similarity matrix based on the WordNet Similarity package (Pedersen et al., 2004).

4 Lexical similarity in Syntactic Tree Kernels

Section 2 has shown that the role of the syntax is important in extracting generalized rules for RTE but it is not enough. Therefore, the lexical similarity described in the previous section should be taken into

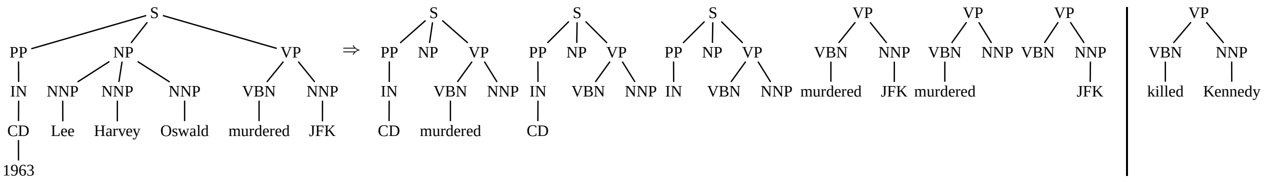

Figure 1: A syntactic parse tree (on the left) along with some of its fragments. After the bar there is an important fragment from a semantically similar sentence, which cannot be matched by STK but it is matched by SSTK.

account in the model definition. Since tree kernels have been shown to be very effective for exploiting syntactic information in natural language tasks, a promising idea is to merge together the two different approaches, i.e. tree kernels and semantic similarities.

4.1 Syntactic Tree Kernel (STK)

Tree kernels compute the number of common substructures between two trees T_1 and T_2 without explicitly considering the whole fragment space. The standard definition of the STK, given in (Collins and Duffy, 2002), allows for any set of nodes linked by one or more entire production rules to be valid substructures. The formal characterization is given in (Collins and Duffy, 2002) and is reported hereafter:

Let $\mathcal{F} = \{f_1, f_2, \ldots, f_{|\mathcal{F}|}\}$ be the set of tree fragments and $\chi_i(n)$ be an indicator function, equal to 1 if the target f_i is rooted at node n and equal to 0 otherwise. A tree kernel function over T_1 and T_2 is defined as $TK(T_1, T_2) = \sum_{n_1 \in N_{T_1}} \sum_{n_2 \in N_{T_2}} \Delta(n_1, n_2)$, where N_{T_1} and N_{T_2} are the sets of nodes in T_1 and T_2, respectively and $\Delta(n_1, n_2) = \sum_{i=1}^{|\mathcal{F}|} \chi_i(n_1)\chi_i(n_2)$.

Δ function counts the number of subtrees rooted in n_1 and n_2 and can be evaluated as follows:

1. if the productions at n_1 and n_2 are different then $\Delta(n_1, n_2) = 0$;

2. if the productions at n_1 and n_2 are the same, and n_1 and n_2 have only leaf children (i.e. they are pre-terminal symbols) then $\Delta(n_1, n_2) = \lambda$;

3. if the productions at n_1 and n_2 are the same, and n_1 and n_2 are not pre-terminals then $\Delta(n_1, n_2) = \lambda \prod_{j=1}^{l(n_1)} (1 + \Delta(c_{n_1}(j), c_{n_2}(j)))$, where $l(n_1)$ is the number of children of n_1, $c_n(j)$ is the j-th child of node n and λ is a decay factor penalizing larger structures.

Figure 1 shows some fragments (out of the overall 472) of the syntactic parse tree on the left, which is derived from the text T4. These fragments satisfy the constraint that grammatical rules cannot be broken. For example, *(VP (VBN (murdered) NNP (JFK)))* is a valid fragment whereas *(VP (VBN (murdered))* is not. One drawback of such kernel is that two sentences expressing similar semantics but with different lexicals produce structures which will not be matched. For example, after the vertical bar there is a fragment, extracted from the parse tree of a semantically identical sentences: `In 1963 Oswald killed Kennedy`. In this case, much less matches will be counted by the kernel function applied to such parse trees and the one of T4. In particular, the complete VP subtree will not be matched.

To tackle this problem the Syntactic Semantic Tree Kernel (SSTK) was defined in (Bloehdorn and Moschitti, 2007a); hereafter, we report its definition.

4.2 Syntactic Semantic Tree kernels (SSTK)

An SSTK produces all the matches of STK. Moreover, the fragments, which are identical but for their lexical nodes, produce a match proportional to the product of the similarity between their corresponding words. This is a sound definition. Indeed, since the structures are the same, each word in position i of the first fragment can be associated with a word located in the same position i of the second fragment. More formally, the fast evaluation of Δ for STK can be used for computing the semantic Δ for SSTK by simply adding the following step

0. if n_1 and n_2 are pre-terminals and $label(n_1) = label(n_2)$ then $\Delta(n_1, n_2) = \lambda\kappa_{\mathcal{S}}(ch^1_{n_1}, ch^1_{n_2})$,

where $label(n_i)$ is the label of node n_i and $\kappa_{\mathcal{S}}$ is a term similarity kernel, e.g. based on Wikipedia, Wordnet or BNC, defined in Section 3. Note that: (a) since n_1 and n_2 are pre-terminals of a parse tree they can have only one child (i.e. $ch^1_{n_1}$ and $ch^1_{n_2}$) and such children are words and (b) Step 2 of the original Δ evaluation is no longer necessary.

For example, the fragments: *(VP (VBN (murdered) NNP (JFK)))* has a match with *(VP (VBN (killed) NNP (Kennedy)))* equal to $\kappa_{\mathcal{S}}(murdered, kill) \times \kappa_{\mathcal{S}}(JFK, Kennedy)$.

Beside the novelty of taking into account tree fragments that are not identical it should be noted that the lexical semantic similarity is constrained in syntactic structures, which limit errors/noise due to incorrect (or, as in our case, not provided) word sense disambiguation.

Finally, it should be noted that when a valid kernel is used in place of $\kappa_{\mathcal{S}}$, SSTK is a valid kernel for definition of convolution kernels (Haussler, 1999). Since the matrix P derived by applying LSA produces a semi-definite matrix (see (Cristianini and Holloway, 2001)) we can always use the similarity matrix derived by LSA in SSTK. In case of Wordnet, the validity of the kernel will depend of the kind of similarity used. In our experiments, we have carried out single value decomposition and we have verified that our Wordenet matrices, Path and WUP, are indeed positive semi-definite.

5 Kernels for Textual Entailment Recognition

In this section, we describe how we use the syntactic tree kernel (STK) and the semantic/syntactic tree kernel (SSTK) for modeling lexical-syntactic kernels for textual entailment recognition. We build on the kernel described in (Zanzotto and Moschitti, 2006; Zanzotto et al., 2009) that can model lexical-syntactic rules with variables (i.e., first-order rules).

5.1 Anchoring and pruning

Kernels for modeling lexical-syntactic rules with variables presuppose that words in texts T are explicitly related to words in hypotheses H. This correlation is generally called anchoring and it is implemented with placeholders that co-index the syntactic trees derived from T and H. Words and intermediate nodes are co-indexed when they are equal or similar. For example, in the pair:

$T_8 \Rightarrow ?H_8$

T_8	*"Lee Harvey Oswald was born in New Orleans, Louisiana, and was of English, German, French and Irish ancestry. In 1963*$\boxed{1}$ *Oswald murdered JFK*$\boxed{2}$*"*
H_8	*"JFK*$\boxed{2}$ *died in 1963*$\boxed{1}$*"*

Moreover, the set of anchors also allows us to prune fragments of the text T that are irrelevant for the final decision: we can discard sentences or phrases uncovered by placeholders. For example, in the pair $\langle T_8, H_8\rangle$, we can infer that "*Lee H... ancestry*" is not a relevant fragment and remove it. This allows us to focus on the critical part for determining the entailment value.

5.2 Kernels for capturing lexical-syntactic rules

Once placeholders are available in the entailment pairs, we can apply the model proposed in (Zanzotto et al., 2009). This derives the maximal similarity between pairs of T and H based on the lexico-syntactic information encoded by the syntactic parse trees of T and H enriched with placeholders. More formally, the original kernel is based on the following equation:

$$maxSTK(\langle T,H\rangle,\langle T',H'\rangle) = max_{c \in C} \qquad (5)$$
$$(STK(t(T,c),t(T',i)) + STK(t(H,c),t(H',i)),$$

where: (i) C is the set of all bijective mappings between the placeholders (i.e., the possible variables) from $\langle T,H\rangle$ into $\langle T',H'\rangle$; (ii) $c \in C$ is a substitution function, which implements such mapping; (iii) $t(\cdot, c)$ returns the syntactic tree enriched with placeholders replaced by means of the substitution c; and (iv) $STK(\tau_1, \tau_2)$ is a tree kernel function.

The new semantic-syntactic kernel for lexical-syntactic rules, maxSSTK, substitutes STK with SSTK in Eq. 5 thus enlarging the coverage of the matching between the pairs of texts and the pairs of hypotheses.

6 Experiments

The aim of the experiments is to investigate if our RTE system exploiting syntactic semantic kernels (SSTK) can effectively derive generalized lexico-syntactic rules. In more detail, first, we determine the best lexical similarity suitable for the task, i.e.

		No Semantic	Wiki	BNC	Path	WUP
RTE2	**j = 1**	63.12	63.5	62.75	62.88	**63.88**
	j = 0.9	63.38	**64.75**	62.26	63.88	64.25
RTE3	**j = 1**	66.88	**67.25**	**67.25**	66.88	66.5
	j = 0.9	67.25	**67.75**	67.5	67.12	67.38
RTE5	**j = 1**	65.5	**66.5**	65.83	66	66
	j = 0.9	65.5	**66.83**	65.67	66	66.33

Table 1: Accuracy of plain (WOK+STK+maxSTK) and Semantic Lexico-Syntactic (WOK+SSTK+maxSSTK) Kernels. The latter according to different similarities

distributional vs. Wordnet-based approaches. Second, we derive qualitative and quantitative properties, which justify the selection of one with respect to the other.

For this purpose, we tested four different version of SSTK, i.e. using Path, WUP, BNC and WIKI lexical similarities on three different RTE datasets. These correspond to the three different challenges in which the development set was provided.

6.1 Experimental Setup

We used the data from three recognizing textual entailment challenge: RTE2 (Bar-Haim et al., 2006), RTE3 (Giampiccolo et al., 2007), and RTE5, along with the standard split between training and test sets. We did not use RTE1 as it was differently built from the others and RTE4 as it does not contain the development set.

We used the following publicly available tools: the Charniak Parser (Charniak, 2000) for parsing sentences and SVM-light-TK (Moschitti, 2006; Joachims, 1999), in which we coded our new kernels for RTE. Additionally, we used the Jiang&Conrath (J&C) distance (Jiang and Conrath, 1997) computed with `wn::similarity` package (Pedersen et al., 2004) to measure the similarity between T and H. This similarity is also used to define the text-hypothesis word overlap kernel (WOK).

The distributional semantics is captured by means of LSA: we used the java Latent Semantic Indexing (jLSI) tool (Giuliano, 2007). In particular, we precomputed the word-pair matrices for RTE2, RTE3, and RTE5. We built different LSA matrices from the British National Corpus (BNC) and Wikipedia (Wiki). The British National Corpus (BNC) is a balanced synchronic text corpus containing 100 million words with morpho-syntactic annotation. For Wikipedia, we created a model from the 200,000 most visited Wikipedia articles, after cleaning the unnecessary markup tags. Articles are our documents for creating the term-by-document matrix. Wikipedia provides the largest coverage knowledge resource developed by a community, besides the noticeable coverage of named entities. This further motivates the design of a similarity measure. We also consider two typical WordNet similarities (i.e., Path and WUP, respectively) as described in Sec. 3.1.

The main RTE model that we consider is constituted by three main kernels:

- WOK, i.e. the kernel based on only the text-hypothesis lexical overlapping words (this is an intra-pair similarity);
- STK, i.e. the sum of the standard tree kernel (see Section 4.1) applied to the two text parse-trees and the two hypothesis parse trees;
- SSTK, i.e. the same as STK with the use of lexical similarities as explained in Section 4.2;
- maxSTK and maxSSTK, i.e. the kernel for RTE, illustrated in Section 5.2, where the latter exploits similarity since it uses SSTK in Eq. 5.

Note that the model presented in (Zanzotto et al., 2009), our baseline, corresponds to the combination kernel: WOK+maxSTK. In this paper, in addition to the role of lexical similarities, we also study several combinations (we just need to sum the separated kernels), i.e. WOK+STK+maxSTK, SSTK+maxSSTK, WOK+SSTK+maxSSTK and WOK+maxSSTK.

Finally, we measure the performance of our system with the standard accuracy and then we determine the statistical significance by using the model

		STK	SSTK	maxSTK	maxSSTK	STK+maxSTK	SSTK+maxSSTK	∅
RTE2	+WOK	61.5	61.12	63.88	64.12	63.12	63.50	60.62
		52.62	52.75	61.25	59.38	61.25	58.75	-
RTE3	+WOK	66.38	66.5	66.5	67.0	66.88	67.25	66.75
		53.25	54.5	62.25	64.38	63.12	63.62	-
RTE5	+WOK	62.0	62.0	64.83	64.83	65.5	66.5	60.67
		54.33	57.33	63.33	62.67	61.83	62.67	-

Table 2: Comparing different lexico-syntactic kernels with Wiki-based semantic kernels

described in (Yeh, 2000) and implemented in (Padó, 2006).

6.2 Distributional vs. WordNet-based Semantics

The first experiment compares the basic kernel, i.e. WOK+STK+maxSTK, with the new semantic kernel, i.e. WOK+SSTK+maxSSTK, where SSTK and maxSSTK encode four different kinds of similarities, BNC, WIKI, WUP and Path. The aim is twofold: understanding if semantic similarities can be effectively used to derive generalized lexico-syntactic rules and to determine the best similarity model.

Table 1 shows the results according to No Semantics, Wiki, BNC, Path and WUP. The three pairs of rows represent the results over the three different datasets, i.e., RTE2, RTE3, and RTE5. For each pair, we have two rows representing a different j parameter of SVM. An increase of j augments the weight of positive with respect to negative examples and during learning it tunes-up the Recall/Precision rate. We use two values $j = 1$ (the default value) and $j = 0.9$ (selected during a preliminary experiment on a validation set on RTE2). $j = 0.9$ was used to minimally increase the Precision, considering that the semantic model tends to improve the Recall.

The results show that:

- WIKI semantics constantly improves the basic kernel (no Semantics) for any datasets or parameter.
- The distributional semantics is almost always better than the WordNet-based one.
- In one case WUP improves WIKI, i.e. 63.88 vs 63.5 and in another case BNC reaches WIKI, i.e. 67.25 but this happens for the default values of the j parameters, i.e. $j = 1$, which was not selected by our limited parameter validation.

Finally, the difference between the accuracy of the best WIKI kernels and the No Semantic kernels are statistically significant ($p << 0.05$).

6.3 Kernel Comparisons

The previous experiments (Sec. 6.2) show that Wikipedia-based distributional semantics provides an effective similarity to generalize lexico-syntactic rules (features). As our RTE kernel is a composition of other basic kernels, we experimented with different combinations to understand the role of each component. Moreover, to obtain results independent of parameterization we used the default parameter j.

Table 2 reports the accuracy of different kernels and their combinations on different RTE datasets. Each row describes the results for each dataset and it is split in two according to the use of WOK or not in the RTE model. In the each column, the different kernels are reported. For example, the entry in the 4th column and the 2nd row refers to the accuracy of SSTK in combination with WOK, i.e. WOK+SSTK for the RTE2.

We observe that: first WOK produces a very high accuracy in RTE challenges, i.e. 60.62, 66.75 and 60.67 and it is an essential component of RTE systems since its ablation always causes a large accuracy decrease. This is reasonable as the major source of information to establish entailment between sentences is their word overlap.

Second, STK and SSTK, when added to WOK, improve it on RTE2 and RTE5 but do not improve it on RTE3. This suggests a difficulty of exploiting syntactic information for RTE3.

Third, maxSTK+WOK relevantly improves WOK on RTE2 and RTE5 but fails in RTE3. Again, the syntactic rules (with variables) which this kernel

	BNC	WN	WIKI
RTE2	0.55	0.42	0.83
RTE3	0.54	0.41	0.83
RTE5	0.45	0.34	0.82

Table 3: Coverage of the different resources for the words of the three datasets

can provide are not enough general for RTE3. In contrast, maxSSTK+WOK improves WOK on all datasets thanks to its generalization ability.

Finally, STK and SSTK added to maxSTK+WOK or to maxSSTK+WOK tend to produce an accuracy increase, although not in every condition.

7 Discussion

7.1 Coverage and efficiency

As already mentioned, the practical use of Wikipedia to design lexical similarities is motivated by a large coverage. Deriving similarities from other resources such as WordNet is more time-consuming. To prove our claim, we performed an analysis on the coverage and efficiency in computing the pair term similarity.

Table 3 shows the coverage of the content words of the three datasets. The coverage of Wikipedia is about two times more than the other resources in all experimented datasets.

Speed	Milliseconds
LSA	0.54
WN with POS	5.3
WN without POS	15.2

Table 4: The comparison in terms of speed calculated over 10000 pairs after loading the model.

Moreover, Table 4 shows that the computation of the LSA matrix on Wikipedia is faster than using the WordNet similarity software (Pedersen et al., 2004). Even if the accuracy of some WordNet models can reach the one based on Wikipedia, the latter is preferable for the smaller computational cost.

7.2 Comparison with previous work

The results of our models show that lexical semantics for building more effective lexical-syntactic rules is promising. Here, we compare our approaches with other RTE systems to show that our results are indeed state-of-the-art. Unfortunately, deriving a reasonable accuracy value to represent the state-of-the-art is extremely difficult as many factors can determine the final score. For example, the best systems in RTE2 and RTE3 (Giampiccolo et al., 2007) have an accuracy 10% higher than the others but they generally use resources that are not publicly available.

	Average Acc.	Our rank	# participants
RTE2	59.8	3rd	23
RTE3	64.5	4th	26
RTE5	61.5	4th	20

Table 5: Comparison with other approaches to RTE

Table 5 shows the average accuracy of the participant systems, the rank of our system that we propose in this paper and the number of participants. Our model accuracy is absolutely above the average and it is ranked at the top positions. We can also carry out a finer comparison with respect to RTE2 (Bar-Haim et al., 2006). Our system results are the best when compared with systems using semantic models based on FrameNet, indeed the best ranked system in this class, i.e., (Burchardt et al., 2007), scores only 62.5. Among systems using logical inference, our model is instead the 3rd out of 8 systems using logical inference that perform worse than ours. Finally, it is the 2nd among systems using supervised machine learning models.

8 Conclusion

In this paper we presented a model to effectively include semantics in lexical-syntactic features for textual entailment recognition. We have experimentally shown that LSA-derived lexical semantics embedded in syntactic structures is a promising approach. The model that we have presented is one of the best system in the RTE challenges. Additionally, in contrast to many other methods it does not require large sets of handcrafted or corpus extracted lexical-syntactic rules.

Automatic Metaphor Interpretation as a Paraphrasing Task

Ekaterina Shutova
Computer Laboratory

Ekaterina.Shutova@cl.cam.ac.uk

Abstract

We present a novel approach to metaphor interpretation and a system that produces literal paraphrases for metaphorical expressions. Such a representation is directly transferable to other applications that can benefit from a metaphor processing component. Our method is distinguished from the previous work in that it does not rely on any hand-crafted knowledge about metaphor, but in contrast employs automatically induced selectional preferences. Being the first of its kind, our system is capable of paraphrasing metaphorical expressions with a high accuracy (0.81).

1 Introduction

Metaphors arise when one concept is viewed in terms of the properties of the other. In other words it is based on *similarity* between the concepts. Similarity is a kind of association implying the presence of characteristics in common. Here are some examples of metaphor.

(1) News *travels* fast. (Lakoff and Johnson, 1980)

(2) How can I *kill* a process? (Martin, 1988)

(3) And then my heart with pleasure *fills*,
And *dances* with the daffodils.[1]

In metaphorical expressions seemingly unrelated features of one concept are associated with another concept. In the example (2) the *computational process* is viewed as something *alive* and, therefore, its forced termination is associated with the act of killing.

Metaphorical expressions represent a great variety, ranging from conventional metaphors, which we reproduce and comprehend every day, e.g. those in (1) and (2), to poetic and largely novel ones, such as (3). The use of metaphor is ubiquitous in natural language text and it is a serious bottleneck in automatic text understanding. In order to estimate the frequency of the phenomenon, we conducted a corpus study on a subset of the British National Corpus (BNC) (Burnard, 2007) representing various genres. We manually annotated metaphorical expressions in this data and found that 241 out of 761 sentences contained a metaphor or (rarely) an idiom. Due to such a high frequency of their use, a system capable of interpreting metaphorical expressions in unrestricted text would become an invaluable component of any semantics-oriented NLP application.

Automatic processing of metaphor can be clearly divided into two subtasks: *metaphor recognition* (distinguishing between literal and metaphorical language in text) and *metaphor interpretation* (identifying the intended literal meaning of a metaphorical expression). Both of them have been repeatedly addressed in NLP.

To date the most influential account of metaphor recognition has been that of Wilks (1978). According to Wilks, metaphors represent a violation of selectional restrictions in a given context. Consider the following example.

(4) My car *drinks* gasoline. (Wilks, 1978)

[1] taken from the verse "I wandered lonely as a cloud" written by William Wordsworth in 1804.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 1029–1037,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

The verb *drink* normally takes an *animate* subject and a *liquid* object. Therefore, *drink* taking a *car* as a subject is an anomaly, which may as well indicate metaphorical use of *drink*.

Most approaches to metaphor interpretation rely on task-specific hand-coded knowledge (Fass, 1991; Martin, 1990; Narayanan, 1997; Narayanan, 1999; Feldman and Narayanan, 2004; Barnden and Lee, 2002; Agerri et al., 2007) and produce interpretations in a non-textual format. However, the ultimate objective of automatic metaphor processing is a type of interpretation that can be directly embedded into other systems to enhance their performance. Thus, we define metaphor interpretation as a *paraphrasing task* and build a system that automatically derives literal paraphrases for metaphorical expressions in unrestricted text.

In summary, our system (1) produces a list of all possible paraphrases for a metaphorical expression (induced automatically from a large corpus); (2) ranks the paraphrases according to their likelihood derived from the corpus; (3) discriminates between literal and figurative paraphrases by detecting selectional preference violation and outputs the literal ones; and (4) disambiguates the sense of the paraphrases using WordNet (Fellbaum, 1998) inventory of senses.

We tested our system on a collection of metaphorical expressions representing verb-subject and verb-object constructions, where the verb is used metaphorically. To compile this dataset we manually annotated such phrases in a subset of the BNC using the metaphor identification procedure (MIP) (Pragglejaz Group, 2007). We then evaluated the quality of paraphrasing with the help of human annotators and created a gold standard for this task.

2 Experimental Data

Since we focus on single-word metaphors expressed by a verb, our annotation task can be viewed as verb classification according to whether the verbs are used metaphorically or literally. However, some verbs have weak or no potential of being a metaphor and, thus, our study is not concerned with them. We excluded the following verb classes: (1) auxiliary verbs; (2) modal verbs; (3) aspectual verbs (e.g. *begin, start, finish)*; (4) light verbs (e.g. *take, give, put, get, make*).

2.1 The Corpus

Our corpus is a subset of the BNC. We sampled texts representing various genres: literature, newspaper/journal articles, essays on politics, international relations and history, radio broadcast (transcribed speech). The corpus contains 761 sentences and 13642 words.

2.2 Annotation Scheme

The annotation scheme we use is based on the principles of the metaphor identification procedure (MIP) developed by Pragglejaz Group (2007). We adopt their definition of *basic* sense of a word and their approach to distinguishing basic senses from the metaphorical ones. MIP involves metaphor annotation at the word level as opposed to identifying metaphorical relations (between words) or source–target domain mappings (between concepts or domains). Such annotation can be viewed as a form of word sense disambiguation with an emphasis on metaphoricity.

In order to discriminate between the verbs used metaphorically and literally we use the following procedure as part of our guidelines:

1. For each verb establish its meaning in context and try to imagine a more basic meaning of this verb on other contexts. As defined in the framework of MIP (Pragglejaz Group, 2007) basic meanings normally are: (1) more concrete; (2) related to bodily action; (3) more precise (as opposed to vague); (4) historically older.

2. If you can establish the basic meaning that is distinct from the meaning of the verb in this context, the verb is likely to be used metaphorically.

Consider the following example sentence:

(5) If he asked her to post a letter or buy some razor blades from the chemist, she was transported with pleasure.

In this sentence one needs to annotate four verbs that are underlined. The first 3 verbs are used in their basic sense, i.e. literally (*ask* in the context of “a person asking another person a question or a favour”;

post in the context of "a person posting/sending a letter"; *buy* in the sense of "making a purchase"). Thus, they are tagged as literal. The verb *transport*, however, in its basic sense is used in the context of "goods being transported/carried by a vehicle". The context in this sentence involves "a person being transported by a feeling", which contrasts the basic sense in that the agent of *transporting* is an EMOTION as opposed to a VEHICLE. Thus, we can infer that the use of *transport* in this sentence is metaphorical.

2.3 Annotation Reliability

We tested reliability of this annotation scheme using multiple annotators on a subset of the corpus. The rest of the annotation was done by a single annotator.

Annotators We had three independent volunteer annotators, who were all native speakers of English and had some linguistics background.

Material and Task All of them received the same text taken from the BNC containing 142 verbs to annotate. They were asked to classify verbs as metaphorical or literal.

Guidelines and Training The annotators received written guidelines (2 pages) and were asked to do a small annotation exercise (2 sentences containing 8 verbs in total). The goal of the exercise was to ensure they were at ease with the annotation format.

Interannotator Agreement We evaluate reliability of our annotation scheme by assessing interannotator agreement in terms of κ (Siegel and Castellan, 1988). The classification was performed with the agreement of 0.64 (κ), which is considered reliable. The main source of disagreement was the high conventionality of some expressions, i.e. cases where the metaphorical etymology could be clearly traced, but the senses are highly lexicalized.

2.4 Phrase Selection

Only the phrases that were tagged as metaphorical by all of the annotators were included in the test set. Here are some examples of such phrases: *memories were slipping away; hold the truth back; stirred an unfathomable excitement; factors shape results; mending their marriage; brushed aside the accusations* etc. In order to avoid extra noise we placed some additional criteria to select the test phrases: (1) exclude phrases where subject or object referent is unknown, e.g. containing pronouns such as in *in which they [changes] operated*; (2) exclude phrases whose metaphorical meaning is realised solely in passive constructions (e.g. *sociologists have been inclined to [..]*); (3) exclude phrases where the subject or object of interest are represented by a named entity (e.g. *Then Hillary leapt into the conversation*); (4) exclude multiword metaphors (e.g. *go on pilgrimage with Raleigh or put out to sea with Tennyson*). The resulting test set contains 62 metaphorical expressions.

3 The Method

The system takes phrases containing annotated single-word metaphors (where a verb is used metaphorically, its context is used literally) as input. It generates a list of possible paraphrases that can occur in the same context and ranks them according to their likelihood derived from the corpus. Subsequently it identifies shared features of the paraphrases and the metaphorical verb using WordNet hierarchy of concepts and removes the unrelated concepts. Among the related paraphrases it then identifies the literal ones given the context relying on the automatically induced selectional preferences.

3.1 The Model for Paraphrase Ranking

We model the likelihood of a particular paraphrase as a joint probability of the following events: the interpretation (another term to replace the one used metaphorically) i co-occurring with the other lexical items from its context $w_1, ..., w_N$ in the relations $r_1, ..., r_N$ respectively.

$$L_i = P(i, (w_1, r_1), (w_2, r_2), ..., (w_N, r_N)), \quad (1)$$

where $w_1, ..., w_N$ and $r_1, ..., r_N$ represent the fixed context of the term used metaphorically in the sentence. This context will be kept as part of the paraphrase, and the term used metaphorically will be replaced.

We take each relation of the term in a phrase to be independent from the other relations of this term in this phrase. E.g. for a verb in the presence of both the subject and the object the `Verb-Subject` and `Verb-Object` relations would be considered to be independent events within the model. This yields the following approximation:

$$P(i,(w_1,r_1),(w_2,r_2),...,(w_N,r_N)) = \\ P(i)\cdot P((w_1,r_1)|i)\cdot ... \cdot P((w_N,r_N)|i). \tag{2}$$

We can calculate the probabilities using maximum likelihood estimation

$$P(i) = \frac{f(i)}{\sum_k f(i_k)}, \tag{3}$$

$$P(w_n,r_n|i) = \frac{f(w_n,r_n,i)}{f(i)}, \tag{4}$$

where $f(i)$ is the frequency of the interpretation on its own, $\sum_k f(i_k)$ is the number of times this part of speech is attested in the corpus and $f(w_n,r_n,i)$ - the frequency of the co-occurrence of the interpretation with the context word w_n in the relation r_n. By performing appropriate substitutions into (2) we obtain

$$P(i,(w_1,r_1),(w_2,r_2),...,(w_N,r_N)) = \\ \frac{f(i)}{\sum_k f(i_k)}\cdot\frac{f(w_1,r_1,i)}{f(i)}\cdot ... \cdot\frac{f(w_N,r_N,i)}{f(i)} = \\ \frac{\prod_{n=1}^{N} f(w_n,r_n,i)}{(f(i))^{N-1}\cdot\sum_k f(i_k)} \tag{5}$$

This model is then used to rank the possible replacements of the term used metaphorically in the fixed context according to the data.

3.2 Parameter Estimation

The parameters of the model were estimated from the British National Corpus that was parsed using the RASP parser of Briscoe et al. (2006). We used the grammatical relations (GRs) output of RASP for BNC created by Andersen et al. (2008). The same output of RASP was used to identify the GRs in the metaphorical expressions themselves, as the metaphor corpus from which they were extracted is a subset of the BNC. To obtain the counts for $f(w_n,r_n,i)$ we extracted all the terms appearing in the corpus in the relation r_n with w_n for each lexical item - relation pair. The initial list of replacements for the metaphorical term was constructed by taking an overlap of the lists of terms for each lexical item - relation pair.

3.3 Identifying Shared Meanings in WordNet

It should be noted that the context-based model described in 3.1 overgenerates and hence there is a need to further narrow the search space. It is acknowledged in the linguistics community that metaphor is to a great extent based on similarity between the concepts involved. We exploit this fact to refine paraphrasing. After obtaining the initial list of possible substitutes for the metaphorical term, we filter out the terms whose meaning does not share any common features with that of the metaphorical term. Consider a Computer Science metaphor *kill a process*, which stands for *terminate a process*. The basic sense of *kill* implies an *end* or *termination* of life. Thus, *termination* is the shared element of the metaphorical verb and its literal interpretation.

Such overlap of features can be identified using the hyponymy relations in the WordNet taxonomy. Within the initial list of paraphrases we select the terms that are a hypernym of the metaphorical term or share a common hypernym with it[2]. To maximize the accuracy we restrict the hypernym search to three level distance in the taxomomy. The filtered lists of metaphorical verb replacements for some of the phrases from our dataset together with their log-likelihood are demonstrated in Table 1. Selecting the highest ranked paraphrase from this list as a literal interpretation will serve as a baseline.

3.4 Filtering Based on Selectional Preferences

The obtained lists contain some irrelevant paraphrases (e.g. *contain the truth* for *hold back the truth*) and some paraphrases where the substitute is used metaphorically again (e.g. *suppress the truth*). However, the task is to identify the literal interpretation, therefore, these need to be removed.

One way of dealing with both problems at once is to take into account selectional preferences of the verbs in our list. The verbs used metaphorically are likely to demonstrate strong semantic preference for the source domain, e.g. *suppress* would select for *movements (political)* rather than *ideas*, or *truth*, (the target domain), whereas the ones used literally (e.g.,

[2] We excluded the expressions containing a term whose metaphorical sense is included in WordNet from the test set, to ensure that the system does not rely on this extra hand-coded knowledge about metaphor.

conceal) would select for *truth*. This would potentially allow us to filter out non-literalness, as well as unrelated verbs, by selecting the verbs that the noun in the metaphorical expression matches best.

We automatically acquired selectional preference distributions of the verbs in the paraphrase lists (for `Verb-Subject` and `Verb-Object` relations) from the BNC parsed by RASP. We first clustered 2000 most frequent nouns in the BNC into 200 clusters using the algorithm of Sun and Korhonen (2009). The obtained clusters formed our selectional preference classes. We adopted the association measure proposed by Resnik (1993) and successfully applied to a number of tasks in NLP including word sense disambiguation (Resnik, 1997). Resnik models selectional preference of a verb in probabilistic terms as the difference between the posterior distribution of noun classes in a particular relation with the verb and their prior distribution in that syntactic position regardless of the identity of the predicate. He quantifies this difference using the relative entropy (or Kullback-Leibler distance), defining the *selectional preference strength* as follows.

$$S_R(v) = D(P(c|v)||P(c)) = \sum_c P(c|v) \log \frac{P(c|v)}{P(c)}, \tag{6}$$

where $P(c)$ is the prior probability of the noun class, $P(c|v)$ is the posterior probability of the noun class given the verb and R is the grammatical relation in question. Selectional preference strength measures how strongly the predicate constrains its arguments. In order to quantify how well a particular argument class fits the verb, Resnik defines another measure called *selectional association*:

$$A_R(v,c) = \frac{1}{S_R(v)} P(c|v) \log \frac{P(c|v)}{P(c)}. \tag{7}$$

We use this measure to rerank the paraphrases and filter out those not well suited or used metaphorically. The new ranking is demonstrated in Table 2. The expectation is that the paraphrase in the first rank (i.e. the verb with which the noun in question has the highest association) represents the literal interpretation.

3.5 Sense Disambiguation

Another feature of our system is that having identified literal interpretations, it is capable to perform their word sense disambiguation (WSD). Disambiguated metaphorical interpretations are potentially a useful source of information for NLP applications dealing with word senses.

We adopt WordNet representation of a sense. Disambiguation is performed by selecting WordNet nodes containing those verbs that share a common hypernym with the metaphorical verb. The list of disambiguated interpretations for a random selection of phrases from our dataset is demonstrated in Table 3. However, we did not evaluate the WSD of the paraphrases at this stage.

4 Evaluation and Discussion

We evaluated the paraphrases with the help of human annotators in two different experimental settings.

Setting 1: the annotators were presented with a set of sentences containing metaphorical expressions and their rank 1 paraphrases produced by the system and by the baseline. They were asked to mark the ones that have the same meaning as the term used metaphorically and are used literally in the context of the paraphrase expression as correct.

We had 7 volunteer annotators who were all native speakers of English (one bilingual) and had no or sparse linguistic expertise. Their agreement on the task was 0.62 (κ), whereby the main source of disagreement was the presence of highly lexicalised metaphorical paraphrases. We then evaluated the system performance against their judgments in terms of *accuracy*. Accuracy measures the proportion of correct literal interpretations among the paraphrases in rank 1. The results are demonstrated in Table 4, the final systems identifies literal paraphrases with the accuracy of 0.81.

Setting 2: the annotators were presented with a set of sentences containing metaphorical expressions and asked to write down all suitable literal paraphrases for the highlighted metaphorical verbs. We had 5 volunteer subjects for this experiment (note that these were people not employed in the previous setting); they were all native speakers of English and had some linguistics background. We then compiled a gold standard by incorporating all of the annotations. E.g. the gold standard for the phrase *brushed aside the accusations* contains the verbs *rejected, ignored, disregarded, dismissed, overlooked, discarded.*

We compared the system output against the gold standard using *mean reciprocal rank* (MRR) as a measure. MRR is traditionally used to evaluate the performance of Question-Answering systems. We adapted this measure in order to be able to assess ranking quality beyond rank 1 and the recall of our system. An individual metaphorical expression receives a score equal to the reciprocal of the rank at which the first correct literal interpretation (according to the human gold standard) is found among the top five paraphrases, or 0 if none of the five paraphrases contains a correct interpretation. Once the individual reciprocal ranks of metaphorical expressions are estimated their mean is computed across the dataset. The MRR of our system equals 0.63 and that of the baseline is 0.55. However, it should be noted that given that our task is open-ended, it is hard to construct a comprehensive gold standard. For example, for the phrase *stir excitement* most annotators suggested only one paraphrase *create excitement*, which is found in rank 3. However, the top ranks of the system output are occupied by *provoke* and *stimulate*, which are more precise paraphrases, although they have not occurred to the annotators. Such examples result in the system's MRR being significantly lower than its accuracy at rank 1.

The obtained results are promising, the selectional preference-based reranking yields a considerable improvement in accuracy (26%) over the baseline. However, for one of the phrases in the dataset, *mend marriage*, the new ranking overruns the correct top suggestion of the baseline, *improve marriage*, and outputs *repair marriage* as the most likely literal interpretation. This is due to both the conventionality of some metaphorical senses (in this case *repair*) and to the fact that some verbs, e.g. *improve*, expose a moderate selectional preference strength, i.e. they are equally associated with a large number of classes. This demonstrates potential drawbacks of the selectional preference-based solutions. Another

Met. Expression	Top Int.	Its WordNet Sense
Verb-DirectObject		
stir excitement	provoke	**(arouse-1 elicit-1 enkindle-2 kindle-3 evoke-1 fire-7 raise-10 provoke-1)** - call forth (emotions, feelings, and responses): ”arouse pity”; ”raise a smile”; ”evoke sympathy”
inherit state	acquire	**(get-1 acquire-1)** - come into the possession of something concrete or abstract: ”She got a lot of paintings from her uncle”; ”They acquired a new pet”
reflect concern	manifest	**(attest-1 certify-1 manifest-1 demonstrate-3 evidence-1)** - provide evidence for; stand as proof of; show by one’s behavior, attitude, or external attributes: ”The buildings in Rome manifest a high level of architectural sophistication”; ”This decision demonstrates his sense of fairness”
brush aside accusation	reject	**(reject-1)** - refuse to accept or acknowledge: ”we reject the idea of starting a war”; ”The journal rejected the student’s paper”
Verb-Subject		
campaign *surged*	improve	**(better-3 improve-2 ameliorate-2 meliorate-2)** - to make better: ”The editor improved the manuscript with his changes”
report *leaked*	disclose	**(unwrap-2 disclose-1 let_on-1 bring_out-9 reveal-2 discover-6 expose-2 divulge-1 break-15 give_away-2 let_out-2)** - make known to the public information that was previously known only to a few people or that was meant to be kept a secret: ”The auction house would not disclose the price at which the van Gogh had sold”; ”The actress won’t reveal how old she is”
tension *mounted*	lift	**(rise-1 lift-4 arise-5 move_up-2 go_up-1 come_up-6 uprise-6)** - move upward: ”The fog lifted”; ”The smoke arose from the forest fire”; ”The mist uprose from the meadows”

Table 3: Disambiguated paraphrases produced by the system

Relation	Baseline	System
Verb-DirectObject	0.52	0.79
Verb-Subject	0.57	0.83
Average	0.55	0.81

Table 4: Accuracy with the evaluation setting 1

controvertial example was the metaphorical expression *tension mounted*, for which the system produced a paraphrase *tension lifted* with the opposite meaning. This error is likely to have been triggered by the feature similarity component, whereby one of the senses of *lift* would stem from the same node in WordNet as the metaphorical sense of *mount*.

5 Related Work

According to Conceptual Metaphor Theory (Lakoff and Johnson, 1980) metaphor can be viewed as an analogy between two distinct domains - the *target* and the *source*. Consider the following example:

(6) He *shot down* all of my arguments. (Lakoff and Johnson, 1980)

A mapping of a concept of *argument* (target) to that of *war* (source) is employed here. The idea of such interconceptual mappings has been exploited in some NLP systems.

One of the first attempts to identify and interpret metaphorical expressions in text automatically is the approach of Fass (1991). It originates in the work of Wilks (1978) and utilizes hand-coded knowledge. Fass (1991) developed a system called met*, capable of discriminating between literalness, metonymy, metaphor and anomaly. It does this in three stages. First, literalness is distinguished from non-literalness using selectional preference violation as an indicator. In the case that non-literalness is detected, the respective phrase is tested for being a metonymic relation using hand-coded patterns (such as CONTAINER-for-CONTENT). If the system fails to recognize metonymy, it proceeds to search the knowledge base for a *relevant analogy* in order to discriminate metaphorical relations from anomalous ones. E.g., the sentence in (4) would be represented in this framework as (*car,drink,gasoline*), which does not satisfy the preference (*animal,drink,liquid*), as *car* is not a hyponym of *animal*. met* then searches its knowledge base for a triple containing a hypernym of both the actual argument and the desired argument and finds (*thing,use,energy_source*), which represents the metaphorical interpretation.

Almost simultaneously with the work of Fass (1991), Martin (1990) presents a Metaphor Interpretation, Denotation and Acquisition System (MIDAS). The idea behind this work is that the more specific conventional metaphors descend from the general ones. Given an example of a metaphorical expression, MIDAS searches its database for a corresponding metaphor that would explain the anomaly. If it does not find any, it abstracts from the example to more general concepts and repeats the search. If it finds a suitable general metaphor, it creates a mapping for its descendant, a more specific metaphor, based on this example. This is also how novel metaphors are acquired. MIDAS has been integrated with the Unix Consultant (UC), the system that answers users questions about Unix.

Another cohort of approaches relies on performing inferences about entities and events in the source and target domains for metaphor interpretation. These include the KARMA system (Narayanan, 1997; Narayanan, 1999; Feldman and Narayanan, 2004) and the ATT-Meta project (Barnden and Lee, 2002; Agerri et al., 2007). Within both systems the authors developed a metaphor-based reasoning framework in accordance with the theory of conceptual metaphor. The reasoning process relies on manually coded knowledge about the world and operates mainly in the source domain. The results are then projected onto the target domain using the conceptual mapping representation. The ATT-Meta project concerns metaphorical and metonymic description of mental states and reasoning about mental states using first order logic. Their system, however, does not take natural language sentences as input, but logical expressions that are representations of small discourse fragments. KARMA in turn deals with a broad range of abstract actions and events and takes parsed text as input.

Veale and Hao (2008) derive a "fluid knowledge representation for metaphor interpretation and generation", called Talking Points. Talking Points are a set of characteristics of concepts belonging to source and target domains and related facts about the world which the authors acquire automatically from WordNet and from the web. Talking Points are then organized in *Slipnet*, a framework that allows for a number of insertions, deletions and substitutions in definitions of such characteristics in order to establish a connection between the target and the source concepts. This work builds on the idea of *slippage* in knowledge representation for understanding analogies in abstract domains (Hofstadter and Mitchell, 1994; Hofstadter, 1995). Consider the metaphor *Make-up is a Western burqa*:

Make-up =>

$\equiv$ typically worn by women

$\approx$ expected to be worn by women

$\approx$ must be worn by women

$\approx$ must be worn by Muslim women

Burqa <=

By doing insertions and substitutions the system arrives from the definition *typically worn by women* to that of *must be worn by Muslim women*, and thus establish a link between the concepts of *make-up* and *burqa*. Veale and Hao (2008), however, did not evaluate to which extent their method is useful to interpret metaphorical expressions occurring in text.

6 Conclusions

We presented a novel approach to metaphor interpretation and a system that produces literal paraphrases for metaphorical expressions. Such a representation is directly transferable to other applications that can benefit from a metaphor processing component. Our method is distinguished from the previous work in that it does not rely on any hand-crafted knowledge, other than WordNet, but in contrast employs automatically induced selectional preferences.

Our system is the first of its kind and it is capable of paraphrasing metaphorical expressions with a high accuracy (0.81). Although we reported results on a test set consisting of verb-subject and verb-object metaphors only, we are convinced that the described interpretation techniques can be similarly applied to other parts of speech and a wider range of syntactic constructions. Extending the system to deal with more types of phrases is part of our future work.

Acknowledgments

I am very grateful to Anna Korhonen, Simone Teufel, Ann Copestake and the reviewers for their helpful feedback on this work, Lin Sun for sharing his noun clustering data and the volunteer annotators. My studies and, thus, this research are funded by generosity of Cambridge Overseas Trust.
