Preface: General Chair

It is with great pleasure that I welcome you to the 2010 Human Language Technologies conference of the North American chapter of the Association for Computational Linguistics. An enormous amount of effort has gone into organizing the conference, and the result is the rich set of intellectual and social experiences that you will enjoy this week.

The NAACL HLT 2010 conference is an orchestrated production of many events. The centerpiece is the collection of carefully chosen papers, posters, and demonstrations that will be presented during the three days of the main conference. This includes the papers and posters of the Student Research Workshop, a setting that gives encouragement and opportunity for new members of our community to present their work. The main conference is preceded by a day of tutorials on topics of current interest in the field, and it is followed by a very full program of specialized workshops.

Many people have volunteered their time and energy to ensure the success of the conference. Indeed, the community as a whole has contributed by submitting papers and proposals for workshops, demos, and tutorials, by making thoughtful judgments as members of the many review committees, and for coming to participate in the events this week. These contributions are very much appreciated. The heaviest burdens have been shared by the people who agreed to lead the major subcommittees of the conference, and I want to recognize them here and explicitly thank them for their service.

To begin, I want to express my gratitude to Jill Burstein, Mary Harper, and Gerald Penn, the co-Chairs of the Program Committee. They supervised the selection of papers and scheduling for the main conference, recruiting the Area Chairs and managing the overall process. They chose the Noisy Genre theme of the conference, collaborated with the Area Chairs to select the Invited Speakers, administered the START reviewing system, and worked with the Area Chairs and the Local Arrangements Committee to assemble the final program. They also added a new feature to the program, a ”one-minute madness” session to raise awareness and excitement about the poster and demo presentations.

The Program Committee co-Chairs and Area Chairs recommended a small number of papers for further consideration by the Best Papers Committee, chaired by Aravind Joshi. Tremendous thanks go to Aravind, Eugene Charniak, Michael Collins, Diane Litman, Daniel Marcu, and Drago Radev for their work in identifying the best examples of current work in the field.

The main-conference days include some other important activities. I appreciate Kristina Toutanova’s effort to organize a second lunch-time Industry Panel, a follow-on to the successful panel at NAACL HLT 2009. I thank Carolyn Penstein Rosé, Chair of the Demonstration Committee, for soliciting candidates for the Demo Session and overseeing the rigorous process of review. For organizing the Student Research Workshop I thank Adriane Boyd, Mahesh Joshi, and Frank Rudzicz, the student co-Chairs, and also Julia Hockenmaier and Diane Litman for the assistance and guidance they provided as Faculty Advisors. Financial support for the student workshop came from a grant from the National Science Foundation.

I thank Richard Sproat and David Traum for serving as co-Chairs of the Workshop Committee. The workshop proposal and selection process was a joint activity of committees representing all three of this year’s computational linguistics conferences, the ACL conference in Uppsala, Coling in Beijing, and NAACL HLT. Their challenge was to honor the location requests of the workshop proposers while arranging for each conference to have a broad and balanced collection of workshops. A full complement of 16 workshops were chosen for NAACL HLT, and Richard and David then became the interface with the organizers of the individual workshops as they put out their calls, reviewed submissions, and assembled final papers for the Publications Committee.

I am grateful to Jason Baldridge, Peter Clark, and Gokhan Tur for volunteering to co-Chair the Tutorial Committee and for attracting and selecting tutorials that introduce a range of novel techniques and address a number of theoretical and practical problems.

The Publications Committee is responsible for constructing the written Proceedings of the conference from the materials that come from the many sources. The Publications Committee, with Claudia Leacock and Richard Wicentowski as co-Chairs, comes in at the end of the preparation stage and must operate on a strict schedule if the Proceedings are to be available by the time the conference begins. This year Claudia and Richard have been the pioneers for two major departures from past procedure. ACL proceedings in the past have been produced by a stand-alone community-developed software package, ACLPUB; this year we are using a version of that package that has been integrated directly into the START conference-management system. This should simplify the publication process for future conferences, but Claudia and Richard endured a fair amount of first-user suffering. The second departure from past practices is that for the first time we are providing the proceedings only on a USB memory stick, unaccompanied by a hardcopy volume. I deeply appreciate the care and attention with which Claudia and Richard have carried out their responsibilities.

We are all very much indebted to David Chiang, Jason Riesa, Jonathan May, and Eduard Hovy, the co-Chairs of the Local Arrangements Committee, and to the other members of the committee from the USC Information Sciences Institute. They have been hard at work for the longest time, and the comfort and elegance of the conference setting is the result of the many decisions they have made. To highlight just a few, they selected the hotel, made sure that the session rooms are properly laid out and equipped, and planned for the reception and banquet. They also designed and maintained the very attractive and informative conference web site. Liang Huang served as Coordinator of the Student Volunteers, and Jillian Gerten and Kenji Sagae served as Exhibit Coordinators.

I am grateful to the sponsoring organizations listed above for their financial support of the conference, and to the members of the Sponsorship Committee for identifying and nurturing those important relationships. The Sponsorship Committee–Srinivas Bangalore, Christy Doran, Eduard Hovy, Stephen Pulman, and Frédérique Segond–raised money jointly for NAACL HLT and ACL this year.

The NAACL executive committee, chaired by Owen Rambow and Rebecca Hwa, provides overall supervision and maintains the continuity and traditions of the conference from year to year. They helped by identifying candidates for many of the committee positions, by resolving several significant issues of conference policy, and by overseeing the budgeting process.

Finally, my heartfelt thanks go to Priscilla Rasmussen, the Business Manager of the ACL office and for the ACL conferences, for her steady guidance through all the stages of conference preparation. Priscilla, as always, played a critical role as the voice of experience and the source of wise advice that kept everything moving in the right direction.

General Chair, NAACL HLT 2010

Preface: Program Chairs

Thanks for attending NAACL HLT 2010! As can be seen in the Conference Program, the NAACL HLT program contains innovative, high-quality work spanning a large array of disciplines within computational linguistics and human language technology. This year, we have included a special Noisy Genre theme to acknowledge the significant work in that area across several disciplines. We would like to thank L.Venkata Subramaniam of IBM Research-India for this suggestion.

NAACL HLT 2010 consists of oral and poster presentations of full and short papers, tutorials, application demonstrations, and workshops. A one-minute madness session has been introduced this year to highlight the poster and demo contributions. We are excited to have two very interesting and diverse keynote speakers: David Temperley, University of Rochester, whose talk is entitled, "Music, Language, and Computational Modeling: Lessons from the Key-Finding Problem", and Steve Renals, University of Edinburgh, "Recognition and Understanding of Meetings." In addition, we have a panel session Recent and Future HLT Challenges in Industry, chaired by Kristina Toutanova, which very appropriately reflects the conference theme.

This year, 291 full papers were submitted and reviewed, of which 90 papers were accepted (a 30.9% acceptance rate); 159 short papers were submitted and reviewed, of which 56 were accepted (a 35.2% acceptance rate). One of the accepted short papers was withdrawn to appear elsewhere, leaving a total of 55 short papers in the proceedings. Eighty-six full papers and 25 short papers will be presented orally. The remaining 34 accepted full and short papers will be presented as posters. We would like to thank all of the authors for submitting such remarkable papers to the conference.

Two best papers have been selected this year, and will be presented at the conference in a special awards session. The Best Full Paper, entitled Coreference Resolution in a Modular, Entity-Centered Model, was written by Aria Haghighi and Dan Klein. The Best Short Paper, entitled "cba to check the spelling": Investigating Parser Performance on Discussion Forum Posts, was written by Jennifer Foster. Congratulations to the authors! The selection process worked as follows. The Senior Program Committee (SPC) nominated an initial set of best paper candidates for the awards; the final decisions were then made by a separate committee: Aravind Joshi (chair), Eugene Charniak, Michael Collins, Diane Litman, Daniel Marcu, and Dragomir Radev. We would like to thank the committee for reading, discussing, and contributing to the final selection process. The committee was selected to handle the breadth of expertise required to review the nominated best papers. Once the camera-ready versions of the papers were submitted by the authors, the Best Paper committee chair used the following process: (a) Committee members were asked to notify the chair about conflicts of interest. Members with conflicts of interest did not rank or discuss those papers with which they were conflicted. (b) Short papers were ranked first by committee members, and additional discussions were held to make a final decision. (c) Next, long papers were ranked by members and a smaller set of top papers were identified. Discussions were then held to make the final decision. (d) The committee chair was available to break any ties.

The review process was organized as a two-tier system with 18 SPC members and 382 reviewers. The SPC members managed the review process for both the full and short paper submissions: each paper received at least three reviews. Strict conflict-of-interest policies were in place during the review process. Specifically, authors who served on the Program Committee in any capacity were removed from any responsibility related to their paper. Any such conflict-of-interest paper was handled by another committee member. In addition, the author was prohibited from participating in any discussion or decision making related to the paper. A similar policy also applied if a Program Committee member had an institutional or personal conflict with an author. All decisions on papers with these types of conflicts were made by members without conflicts. We would not have been able to produce such an interesting conference program without the dedicated SPC members who spent many weeks handling and evaluating the submission reviews, nor without the reviewers who provided such thoughtful evaluations. The full list of the SPC members and reviewers is listed elsewhere in these Proceedings. We would also like to thank the SPC members for their best paper recommendations and suggestions for the program, and Chris Dyer for his suggestions on the Machine Translation sessions.

There were, of course, a number of additional people with whom we directly interacted, and who made significant contributions to the success of this conference. So, here are some well-deserved acknowledgements. We would like to thank Rich Gerber and the START team for their help with the system that managed paper submissions and reviews, and the Local Arrangement co-chairs, David Chiang, Eduard Hovy, Jonathan May, and Jason Riesa, for their help with organizing the program, the preparation and publication of the conference handbook, handling the NAACL HLT 2010 website, and various other tasks – a list too lengthy to name here. We would also like to thank the Publication Co-chairs, Claudia Leacock and Richard Wicentowski, for forging through a number of obstacles, and doing an excellent job of handling the preparation and printing of these proceedings. We would like to thank the Workshop Co-chairs, David Traum and Richard Sproat, the Demo Chair, Carolyn Penstein Rosé, the Tutorial Co-chairs, Jason Baldridge, Peter Clark and Gokhan Tur, and the Student Research Workshop Faculty Co-chairs, Julia Hockenmeier and Diane Litman, and Student Co-chairs, Adriane Boyd, Mahesh Joshi, and Frank Rudzicz. The hard work of all of these co-chairs contributed to the quality of the entire conference program. We would also like to thank Chris Callison-Burch for handling Student Author Support, and to Liang Huang for serving as the Student Volunteer Coordinator. We are grateful to Priscilla Rasmussen for supporting the visa application process, as well as answering a variety of our questions and concerns around general conference logistics and event planning. Finally, we would like to express our deepest thanks to the General Chair, Ron Kaplan, for his continual support and patience throughout this process.

We hope that you will have a unique and enriching conference experience!

Jill Burstein, Educational Testing Service
Mary Harper, University of Maryland; Johns Hopkins HLT COE
Gerald Penn, University of Toronto

Organizers

General Chair:

Ronald Kaplan, Powerset Division of Microsoft Bing

Program Co-Chairs:

Jill Burstein (NLP), Educational Testing Service
Mary Harper (Speech), University of Maryland and The Johns Hopkins University HLTCOE
Gerald Penn (NLP), University of Toronto

Workshop Chairs:

Richard Sproat, Oregon Health & Science University
David Traum, University of Southern California, Institute for Creative Technologies

Demo Chair:

Carolyn Penstein Rosé, Carnegie Mellon University

Tutorial Chairs:

Jason Baldridge, The University of Texas at Austin
Peter Clark, The Boeing Company
Gokhan Tur, SRI International

Publications Chairs:

Claudia Leacock, Butler Hill Group
Richard Wicentowski, Swarthmore College

Student Research Workshop Chairs:

Julia Hockenmaier (Faculty Advisor), University of Illinois at Urbana-Champaign
Diane Litman (Faculty Advisor), University of Pittsburgh
Adriane Boyd (NLP Co-Chair), University of Ohio
Mahesh Joshi (NLP Co-Chair), Carnegie Mellon University
Frank Rudzicz (Speech Co-Chair), University of Toronto

Local Arrangements Chairs:

David Chiang, University of Southern California, Information Sciences Institute

Table of Contents

Conference Program

Wednesday, June 2, 2010

Plenary Session I

8:45–9:00 Opening Ceremony

9:00–10:10 Invited Talk: *Recognition and Understanding of Meetings*
Steve Renals

10:10–10:40 **Break**

Parsing I

10:40–11:05 *Chart Mining-based Lexical Acquisition with Precision Grammars*
Yi Zhang, Timothy Baldwin, Valia Kordoni, David Martinez and Jeremy Nicholson

11:05–11:30 *Products of Random Latent Variable Grammars*
Slav Petrov

11:30–11:55 *Automatic Domain Adaptation for Parsing*
David McClosky, Eugene Charniak and Mark Johnson

11:55–12:20 *Appropriately Handled Prosodic Breaks Help PCFG Parsing*
Zhongqiang Huang and Mary Harper

Noisy Genre I

10:40–11:05 *Using Confusion Networks for Speech Summarization*
Shasha Xie and Yang Liu

11:05–11:30 *Qme! : A Speech-based Question-Answering system on Mobile Devices*
Taniya Mishra and Srinivas Bangalore

11:30–11:55 *Dialogue-Oriented Review Summary Generation for Spoken Dialogue Recommendation Systems*
Jingjing Liu, Stephanie Seneff and Victor Zue

Wednesday, June 2, 2010 (continued)

11:55–12:20 *Minimally-Supervised Extraction of Entities from Text Advertisements*
Sameer Singh, Dustin Hillard and Chris Leggetter

Semantics I

10:40–11:05 *Taxonomy Learning Using Word Sense Induction*
Ioannis P. Klapaftis and Suresh Manandhar

11:05–11:30 *Visual Information in Semantic Representation*
Yansong Feng and Mirella Lapata

11:30–11:55 *Automatic Evaluation of Topic Coherence*
David Newman, Jey Han Lau, Karl Grieser and Timothy Baldwin

11:55–12:20 *Multi-Prototype Vector-Space Models of Word Meaning*
Joseph Reisinger and Raymond J. Mooney

Student Research Workshop I

Note: All student research workshop papers are located in a companion volume of the proceedings.

10:40–11:10 *Improving Syntactic Coordination Resolution using Language Modeling*
Philip Ogren

11:10–11:40 *On Automated Evaluation of Readability of Summaries: Capturing Grammaticality, Focus, Structure and Coherence*
Ravikiran Vadlapudi and Rahul Katragadda

11:40–12:10 *Detecting Novelty in the Context of Progressive Summarization*
Praveen Bysani

12:20–2:00 **Lunch**

Wednesday, June 2, 2010 (continued)

Machine Translation I

2:00–2:25 *Unsupervised Syntactic Alignment with Inversion Transduction Grammars*
Adam Pauls, Dan Klein, David Chiang and Kevin Knight

2:25–2:50 *Joint Parsing and Alignment with Weakly Synchronized Grammars*
David Burkett, John Blitzer and Dan Klein

2:50–3:15 *Learning Translation Boundaries for Phrase-Based Decoding*
Deyi Xiong, Min Zhang and Haizhou Li

3:15–3:40 *Hitting the Right Paraphrases in Good Time*
Stanley Kok and Chris Brockett

Noisy Genre II

2:00–2:25 *Training Paradigms for Correcting Errors in Grammar and Usage*
Alla Rozovskaya and Dan Roth

2:25–2:50 *Using Mostly Native Data to Correct Errors in Learners' Writing*
Michael Gamon

2:50–3:15 *Unsupervised Modeling of Twitter Conversations*
Alan Ritter, Colin Cherry and Bill Dolan

3:15–3:40 *Streaming First Story Detection with application to Twitter*
Saša Petrović, Miles Osborne and Victor Lavrenko

Wednesday, June 2, 2010 (continued)

Speech Processing

2:00–2:25 *Unsupervised Model Adaptation using Information-Theoretic Criterion*
Ariya Rastrow, Frederick Jelinek, Abhinav Sethy and Bhuvana Ramabhadran

2:25–2:50 *Formatting Time-Aligned ASR Transcripts for Readability*
Maria Shugrina

2:50–3:15 *Cheap, Fast and Good Enough: Automatic Speech Recognition with Non-Expert Transcription*
Scott Novotney and Chris Callison-Burch

3:15–3:40 *Contextual Information Improves OOV Detection in Speech*
Carolina Parada, Mark Dredze, Denis Filimonov and Frederick Jelinek

Student Research Workshop II

Note: All student research workshop papers are located in a companion volume of the proceedings.

2:00–2:30 *Extrinsic Parse Selection*
David Goss-Grubbs

2:30–3:00 *Towards a Matrix-based Distributional Model of Meaning*
Eugenie Giesbrecht

3:00–3:30 *Distinguishing Use and Mention in Natural Language*
Shomir Wilson

3:40–4:10 **Break**

Poster Plenary Session

4:10–5:30 One-Minute Madness: Poster and Demo Previews

5:30–6:30 **Break**

6:30–8:30 **Poster and Demo Session**

Posters

Improved Extraction Assessment through Better Language Models
Arun Ahuja and Doug Downey

Language Identification: The Long and the Short of the Matter
Timothy Baldwin and Marco Lui

Inducing Synchronous Grammars with Slice Sampling
Phil Blunsom and Trevor Cohn

Task-based Evaluation of Multiword Expressions: a Pilot Study in Statistical Machine Translation
Marine Carpuat and Mona Diab

Improving Semantic Role Labeling with Word Sense
Wanxiang Che, Ting Liu and Yongqiang Li

Extending the METEOR Machine Translation Evaluation Metric to the Phrase Level
Michael Denkowski and Alon Lavie

Testing a Grammar Customization System with Sahaptin
Scott Drellishak

Two monolingual parses are better than one (synchronous parse)
Chris Dyer

Fast Query for Large Treebanks
Sumukh Ghodke and Steven Bird

Wednesday, June 2, 2010 (continued)

Efficient Parsing of Well-Nested Linear Context-Free Rewriting Systems
Carlos Gómez-Rodríguez, Marco Kuhlmann and Giorgio Satta

Utility Evaluation of Cross-document Information Extraction
Heng Ji, Zheng Chen, Jonathan Feldman, Antonio Gonzalez, Ralph Grishman and Vivek Upadhyay

Evaluation Metrics for the Lexical Substitution Task
Sanaz Jabbari, Mark Hepple and Louise Guthrie

Movie Reviews and Revenues: An Experiment in Text Regression
Mahesh Joshi, Dipanjan Das, Kevin Gimpel and Noah A. Smith

Using Gaussian Mixture Models to Detect Figurative Language in Context
Linlin Li and Caroline Sporleder

Improving Phrase-Based Translation with Prototypes of Short Phrases
Frank Liberato, Behrang Mohit and Rebecca Hwa

Putting the User in the Loop: Interactive Maximal Marginal Relevance for Query-Focused Summarization
Jimmy Lin, Nitin Madnani and Bonnie Dorr

Improving Blog Polarity Classification via Topic Analysis and Adaptive Methods
Feifan Liu, Dong Wang, Bin Li and Yang Liu

Creating Local Coherence: An Empirical Assessment
Annie Louis and Ani Nenkova

Time-Efficient Creation of an Accurate Sentence Fusion Corpus
Kathleen McKeown, Sara Rosenthal, Kapil Thadani and Coleman Moore

Towards Cross-Lingual Textual Entailment
Yashar Mehdad, Matteo Negri and Marcello Federico

A Comparative Study of Word Co-occurrence for Term Clustering in Language Model-based Sentence Retrieval
Saeedeh Momtazi, Sanjeev Khudanpur and Dietrich Klakow

Wednesday, June 2, 2010 (continued)

Information Content Measures of Semantic Similarity Perform Better Without Sense-Tagged Text
Ted Pedersen

Generating Expository Dialogue from Monologue: Motivation, Corpus and Preliminary Rules
Paul Piwek and Svetlana Stoyanchev

The Simple Truth about Dependency and Phrase Structure Representations: An Opinion Piece
Owen Rambow

Word Alignment with Stochastic Bracketing Linear Inversion Transduction Grammar
Markus Saers, Joakim Nivre and Dekai Wu

Crowdsourcing the evaluation of a domain-adapted named entity recognition system
Asad B. Sayeed, Timothy J. Meyer, Hieu C. Nguyen, Olivia Buzek and Amy Weinberg

Generalizing Hierarchical Phrase-based Translation using Rules with Adjacent Nonterminals
Hendra Setiawan and Philip Resnik

The Effect of Ambiguity on the Automated Acquisition of WSD Examples
Mark Stevenson and Yikun Guo

Word Sense Subjectivity for Cross-lingual Lexical Substitution
Fangzhong Su and Katja Markert

Query Ambiguity Revisited: Clickthrough Measures for Distinguishing Informational and Ambiguous Queries
Yu Wang and Eugene Agichtein

For the sake of simplicity: Unsupervised extraction of lexical simplifications from Wikipedia
Mark Yatskar, Bo Pang, Cristian Danescu-Niculescu-Mizil and Lillian Lee

Predicting Human-Targeted Translation Edit Rate via Untrained Human Annotators
Omar F. Zaidan and Chris Callison-Burch

Recognition and Understanding of Meetings

Steve Renals
Centre for Speech Technology Research, University of Edinburgh
Informatics Forum, 10 Crichton Street, Edinburgh EH8 9AB, UK
s.renals@ed.ac.uk homepages.inf.ed.ac.uk/srenals/

Abstract

This paper is about interpreting human communication in meetings using audio, video and other signals. Automatic meeting recognition and understanding is extremely challenging, since communication in a meeting is spontaneous and conversational, and involves multiple speakers and multiple modalities. This leads to a number of significant research problems in signal processing, in speech recognition, and in discourse interpretation, taking account of both individual and group behaviours. Addressing these problems requires an interdisciplinary effort. In this paper, I discuss the capture and annotation of multimodal meeting recordings—resulting in the AMI meeting corpus—and how we have built on this to develop techniques and applications for the recognition and interpretation of meetings.

1 Introduction

On the face of it, meetings do not seem to form a compelling research area. Although many people spend a substantial fraction of their time in meetings (e.g. the 1998 3M online survey at http://www.3m.com/meetingnetwork/), for most people they are not the most enjoyable aspect of their work. However, for all the time that is spent in meetings, technological support for the meeting process is scant. Meeting records usually take the form of brief minutes, personal notes, and more recent use of collaborative web 2.0 software. Such records are labour intensive to produce—because they are manually created—and usually fail to capture much of the content of a meeting, for example the factors that led to a particular decision and the different subjective attitudes displayed by the meeting attendees. For all the time invested in meetings, very little of the wealth of information that is exchanged is explicitly preserved.

To preserve the information recorded in meetings, it is necessary to capture it. Obviously this involves recording the speech of the meeting participants. However, human communication is a multimodal activity with information being exchanged via gestures, handwritten diagrams, and numerous social signals. The creation of a rich meeting record involves the capture of data across several modalities. It is a key engineering challenge to capture such multimodal signals in a reliable, unobtrusive and flexible way, but the greater challenges arise from unlocking the multimodal recordings. If such recordings are not transcribed and indexed (at the least), then access merely corresponds to replay. And it is rare that people will have the time, or the inclination, to replay a meeting.

There is a long and interesting thread of research which is concerned to better understand the dynamics of meetings and the way that groups function (Bales, 1951; McGrath, 1991; Stasser and Taylor, 1991). The types of analyses and studies carried out by these authors is still someway beyond what we can do automatically. The first significant work on automatic processing of meetings, coupled with an exploration of how people might interact with an archive of recorded meetings, was performed in the mid 1990s (Kazman et al., 1996). This work was limited by the fact that it was not possible at

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 1–9,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

that time to transcribe meeting speech automatically. Other early work in the area concentrated on the multimodal capture and broadcast of meetings (Roy and Luz, 1999; Cutler et al., 2002; Yong et al., 2001).

Three groups further developed approaches to automatically index the content of meetings. A team at Fuji Xerox PARC used video retrieval techniques such as keyframing to automatically generate manga-style summaries of meetings (Uchihashi et al., 1999), Waibel and colleagues at CMU used speech recognition and video tracking for meetings (Waibel et al., 2001), and Morgan and colleagues at ICSI focused on audio-only capture and speech recognition (Morgan et al., 2003). Since 2003 research in the recognition and understanding of meetings has developed substantially, stimulated by evaluation campaigns such as the NIST Rich Transcription (RT)[1] and CLEAR[2] evaluations, as well as some large multidisciplinary projects such as AMI/AMIDA[3], CHIL[4] and CALO[5].

This paper is about the work we have carried out in meeting capture, recognition and interpretation within the AMI and AMIDA projects since 2004. One of the principal outputs of these projects was a multimodal corpus of meeting recordings, annotated at a number of different levels. In section 2 we discuss collection of meeting data, and the construction of the AMI corpus. The remainder of the paper discusses the automatic recognition (section 3) and interpretation (section 4) of multimodal meeting recordings, application prototypes (section 5) and issues relating to evaluation (section 6).

2 The AMI corpus

Ideally it would not be necessary to undertake a large scale data collection and annotation exercise, every time we address a new domain. However unsupervised adaptation techniques are still rather immature, and prior to the collection of the AMI corpus, there had not been a controlled collection and multilevel annotation of multiparty interactions, recorded across multiple modalities.

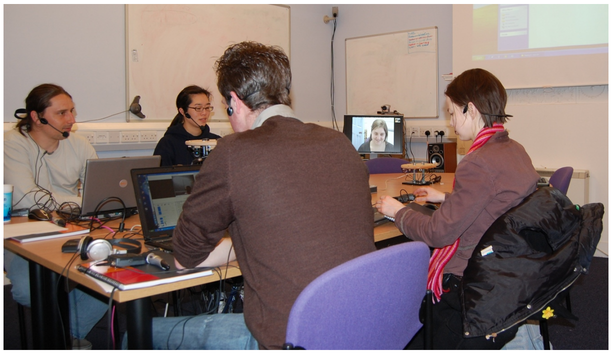

Figure 1: AMI instrumented meeting room: four co-located participants, one joined by video conference. In this case two microphone arrays and seven cameras were used.

One of our key motivations is the development of automatic approaches to recognise and interpret group interactions, using information spread across multiple modalities, but collected as unobtrusively as possible. This led to the design and construction of the AMI Instrumented Meeting Rooms (figure 1) at the University of Edinburgh, Idiap Research Institute, and TNO Human Factors. These rooms contained a set of standardised recording equipment including six or seven cameras (four of which would be used for close-up views in meeting of up to four people), an 8-element microphone array, a close-talking microphone for each participant (used to guarantee a clean audio signal for each speaker), as well capture of digital pens, whiteboards, shared laptop spaces, data projector and videoconferencing if used. A considerable amount of hardware was necessary for ensuring frame-level synchronisation. More recently we have used a lighter weight setup, that uses a high resolution spherical digital video camera system, and a single microphone array (7–20 elements, depending on meeting size) synchronised using software. We have also constructed a prototype system using a low-cost, flexible array of digital MEMS microphones (Zwyssig et al., 2010).

We used these instrumented meeting rooms to record the AMI Meeting Corpus (Carletta, 2007). This corpus contains over 100 hours of meeting recordings, with the different recording streams synchronised to a common timeline. The corpus contains a number of manually created and automatic annotations, synchronised to the same timeline. This

[5] caloproject.sri.com/

includes a high-quality manual word-level transcription of the complete corpus, as well as reference automatic speech recognition output, using the speech recognition system discussed in section 3 (using 5-fold cross-validation). In addition to word-level transcriptions, the corpus includes manual annotations that describe the behaviour of meeting participants at a number of levels. These include dialogue acts, topic segmentation, extractive and abstractive summaries, named entities, limited forms of head and hand gestures, gaze direction, movement around the room, and head pose information. Some of these annotations, in particular video annotation, are expensive to perform: about 10 hours of meetings have been completely annotated at all these levels; over 70% of the corpus has been fully annotated with the linguistic annotations. NXT—the NITE XML Toolkit[6]—an XML-based open source software infrastructure for multimodal annotation was used to carry out and manage the annotations.

About 70% of the AMI corpus consists of meetings based on a design scenario, in which four participants play roles in a design team. The scenario involves four team meetings, between which the participants had tasks to accomplish. The participant roles were stimulated in real-time by email and web content. Although the use of a scenario reduces the overall realism of the meetings, we adopted this approach for several reasons, most importantly: (1) there were some preferred design outcomes, making it possible to define some objective group outcome measures; (2) the knowledge and motivation of the participants was controlled, thus removing the serious confounding factors that would arise from the long history and context found in real organisations; and (3) allowing the meeting scenario to be replicated, thus enabling system-level evaluations (as discussed in section 6). We recorded and annotated thirty replicates of the scenario: this provides an unparalleled resource for system evaluation, but also reduces the variability of the corpus (for example in terms of the language used). The remaining 30% of the corpus contains meetings that would have occurred anyway; these are meetings with a lot less control than the scenario meetings, but with greater linguistic variability.

All the meetings in the AMI corpus are spoken in English, but over half the participants are non-native speakers. This adds realism in a European context, as well as providing an additional speech recognition challenge. The corpus is publicly available[7], and is released under a licence that is based on the Creative Commons Attribution NonCommercial ShareAlike 2.5 Licence. This includes all the signals and manual annotations, plus a number of automatic annotations (e.g. speech recognition) made available to lower the startup cost of performing research on the corpus.

3 Multimodal recognition

The predominant motivation behind the collection and annotation of the AMI corpus was to enable the development of multimodal recognisers to address issues such as speech recognition, speaker diarisartion (Wooters and Huijbregts, 2007), gesture recognition (Al-Hames et al., 2007) and focus of attention (Ba and Odobez, 2008). Although speech recognition is based on the (multichannel) audio signal, the other problems can be successfully addressed by combining modalities. (There is certainly information in other modalities that has the potential to make speech recognition more accurate, but so far we have not been able to use it consistently and robustly.)

Speech recognition: The automatic transcription of what is spoken in a meeting is an essential prerequisite to interpreting a meeting. Morgan et al (2003) described the speech recognition of meetings as an "ASR-complete" problem. Developing an accurate system for meeting recognition involves the automatic segmentation of the recording into utterances from a single talker, robustness to reverberation and competing acoustic sources, handling overlapping talkers, exploitation of multiple microphone recordings, as well as the core acoustic and language modelling problems that arise when attempting to recognise spontaneous, conversational speech.

Our initial systems for meeting recognition used audio recorded with close-talking microphones, in order to develop the core acoustic modelling techniques. More recently our focus has been on recognising speech obtained using tabletop microphone

[6] sourceforge.net/projects/nite/

[7] corpus.amiproject.org/

arrays, which are less intrusive but have a lower signal-to-noise ratio. Multiple microphone systems are based on microphone array beamforming in which the individual microphone signals are filtered and summed to enhance signals coming from a particular direction, while suppressing signals from competing locations (Wölfel and McDonough, 2009).

The core acoustic and language modelling components for meeting speech recognition correspond quite closely to the state-of-the-art systems used in other domains. Acoustic modelling techniques include vocal tract length normalisation, speaker adaptation based on maximum likelihood linear transforms, and further training using a discriminative minimum Bayes risk criterion such as minimum phone error rate (Gales and Young, 2007; Renals and Hain, 2010). In addition we have employed a number of novel acoustic parameterisations including approaches based on local posterior probability estimation (Grezl et al., 2007) and pitch adaptive features (Garau and Renals, 2008), the automatic construction of domain-specific language models using documents obtained from the web by searching with n-grams obtained from meeting transcripts (Wan and Hain, 2006; Bulyko et al., 2007), and automatic approaches to acoustic segmentation optimised for meetings (Wrigley et al., 2005; Dines et al., 2006).

A feature of the systems developed for meeting recognition is the use of multiple recognition passes, cross-adaptation and model combination (Hain et al., 2007). In particular successive passes make use of more detailed—and more diverse—acoustic and language models. Different acoustic models trained on different feature representations (e.g. standard PLP features and posterior probability-based features) are cross-adapted, and different feature representations are also combined using linear transforms such as heteroscedastic linear discriminant analysis (Kumar and Andreou, 1998).

These systems have been evaluated in successive NIST RT evaluations: the core microphone array based system has a word error rate of about 40%; after adaptation and feature combination steps, this error rate can be reduced to about 30%. The equivalent close-talking microphone system has baseline word error rate of about 35%, reduced to less than 25% after further recognition passes (Hain et al., 2007). The core system runs about five times slower than real-time, and the full system is about fourteen times slower than real-time, on current commodity hardware. We have developed a low-latency real-time system (with an error rate of about 41% for microphone array input) (Garner et al., 2009), based on an open source runtime system[8].

4 Meeting interpretation

One of the interdisciplinary joys of working on meetings is that researchers with different approaches are able to build collaborations through working on common problems and common data. The automatic interpretation of meetings is a very good example: meetings form an exciting challenge for work in things such as topic identification, summarisation, dialogue act recognition and the recognition of subjective content. Although text-based approaches (using the output of a speech recognition system) form strong baselines, it is often the case that systems can be improved through the incorporation of information characteristic of spoken communication, such as prosody and speaker turn patterns, as well video information such as head or hand movements.

Segmentation: We have explored multistream statistical models to automatically segment meeting recordings. Meetings can be usefully segmented at many different levels, for example into speech and non-speech (an essential pre-processing for speech recognition), into utterances spoken by a single talker, into dialogue acts, into topics, and into "meeting phases". The latter was the subject of our first investigations in using multimodal multistream models to segment meetings.

Meetings are group events, characterised by both individual actions and group actions. To obtain structure at the group level, we and colleagues in the M4 and AMI projects investigated segmenting a meeting into a sequence of group actions such as monologue, discussion and presentation (McCowan et al., 2005). We used a number of feature streams for this segmentation and labelling task including speaker turn dynamics, prosody, lexical information,

[8] `juicer.amiproject.org/`

and participant head and hand movements (Dielmann and Renals, 2007). Our initial experiments used an HMM to model the feature streams with a single hidden state space, and resulted in an "action error rate" of over 40% (action error rate is analogous to word error rate, but defined over meeting actions, presumed not to overlap). The HMM was then substituted by a richer DBN multistream model in which each feature stream was processed independently at a lower level of the model. These partial results were then combined at a higher level, thus providing hierarchical integration of the multimodal feature streams. This multistream approach enabled a later integration of feature streams and increased flexibility in modelling the interdependences between the different streams, enabling some accommodation for asynchrony and multiple time scales. Thus use of the richer DBN multistream model resulted in a significant lowering of the action error rate to around 13%.

We extended this approach to look at a much finer grained segmentation: dialogue acts. A dialogue act can be viewed as a segment of speech labelled so as to roughly categorise the speaker's intention. In the AMI corpus each dialogue act in a meeting is given one of 15 labels, which may be categorised as information exchange, making or eliciting suggestions or offers, commenting on the discussion, social acts, backchannels, or "other". The segmentation problem is non-trivial, since a single stretch of speech (with no pauses) from a speaker may comprise several dialogue acts—and conversely a single dialogue act may contain pauses. To address the tasks of automatically segmenting the speech into dialogue acts, and assigning a label to each segment, we employed a switching dynamic Bayesian network architecture, which modelled a set of features related to lexical content and prosody and incorporates a weighted interpolated factored language model (Dielmann and Renals, 2008). The switching DBN coordinated the recognition process by integrating all the available resources. This approach was able to leverage additional corpora of conversational data by using them as training data for a factored language model which was used in conjunction with additional task specific language models. We followed this joint generative model, with a discriminative approach, based on conditional random fields, which performed a reclassification of the segmented dialogue acts.

Our experiments on dialogue act recognition used both automatic and manual transcriptions of the AMI corpus. The degradation when moving from manual transcriptions to the output of a speech recogniser was less than 10% absolute for both dialogue act classification and segmentation. Our experiments indicated that it is possible to perform automatic segmentation into dialogue acts with a relatively low error rate. However the operations of tagging and recognition into fifteen imbalanced DA categories have a relatively high error rate, even after discriminative reclassification, indicating that this remains a challenging task.

Summarisation: The automatic generation of summaries provides a natural way to succinctly describe the content of a meeting, and can be an efficient way for users to obtain information. We have focussed on extractive techniques to construct summaries, in which the most relevant parts of a meeting are located, and concatenated together to provide a 'cut-and-paste' summary, which may be textual or multimodal.

Our approach to extractive summarisation is based on automatically extracting relevant dialogue acts (or alternatively "spurts", segments spoken by a single speaker and delimited by silence) from a meeting (Murray et al., 2006). This requires (as a minimum) the automatic speech transcription and, if spurts are not used, dialogue act segmentation. Lexical information is clearly extremely important for summarisation, but we have also found speaker features (relating to activity, dominance and overlap), structural features (the length and position of dialogue acts), prosody, and discourse cues (phrases which signal likely relevance) to be important for the development of accurate methods for extractive summarisation of meetings. Furthermore we have explored reduced dimension representations of text, based on latent semantic analysis, which we found added precision to the summarisation. Using an evaluation measure referred to as weighted precision, we discovered that it is possible to reliably extract the most relevant dialogue acts, even in the presence of speech recognition errors.

5 Application prototypes

We have incorporated these meeting recognition and interpretation components in a number of applications. Our basic approach to navigating meeting archives centres on the notion of meeting browsers, in which media files, transcripts and segmentations are synchronised to a common time line. Figure 2 (a) gives an example of such a browser, which also enables a user to pan and zoom within the captured spherical video stream.

We have explored (and, as discussed below, evaluated) a number of ways of including automatically generated summaries in meeting browsers. The browser illustrated in figure 2 (b) enables navigation by the summarised transcript or via the topic segmentation. In this case the degree of summarisation is controlled by a slider, which removes those speech segments that do no contribute to the summary. We have also explored real-time (with a few utterances latency) approaches to summarisation, to facilitate meeting "catchup" scenarios, including the generation of audio only summaries, with about 60% of the speech removed (Tucker et al., 2010). Visualisations of summaries include a comic book layout (Castronovo et al., 2008), illustrated in figure 3. This is related to "VideoManga" (Uchihashi et al., 1999), but driven by transcribed speech rather than visually identified keyframes.

(b) Summary browser

Figure 2: Two examples of meeting browsers, both include time synchronisation with a searchable ASR transcript and speaker activities. (a) is a basic web-based browser; (b) also employs extractive summarisation and topic segmentation components.

The availability of real-time meeting speech recognition, with phrase-level latency (Garner et al., 2009), enables a new class of applications. Within AMIDA we developed a software architecture referred to as "The Hub" to support real-time applications. The Hub is essentially a real-time annotation server, mediating between annotation producers, such as speech recognition, and annotation consumers, such as a real-time catchup browser. Of course many applications will be both producers and consumers: for instance topic segmentation consumes transcripts and speaker turn information and produces time aligned topic segments. A good example of an application made possible by real-time recognition components and the Hub is the AMIDA Content Linking Device (Popescu-Belis et al., 2008). Content linking is essentially a continual real-time search in which a repository is searched using a query constructed from the current conversational context. In this case the context is obtained from a speech recognition transcript of the past 30 seconds of the conversation, and a query is constructed using $tf{\cdot}idf$ or a similar measure, combined with predefined keywords or topic weightings. The repository to be searched may be the web, or a portion of the web, or it may be an organisational document repository, including transcribed, structured and indexed recordings of previous meetings. Figure 4 shows a basic interface to content linking. We have constructed live content-linking systems, driven by microphone array based real-time speech recognition, with the aim of presenting—without explicit query—potentially relevant documents to meeting participants.

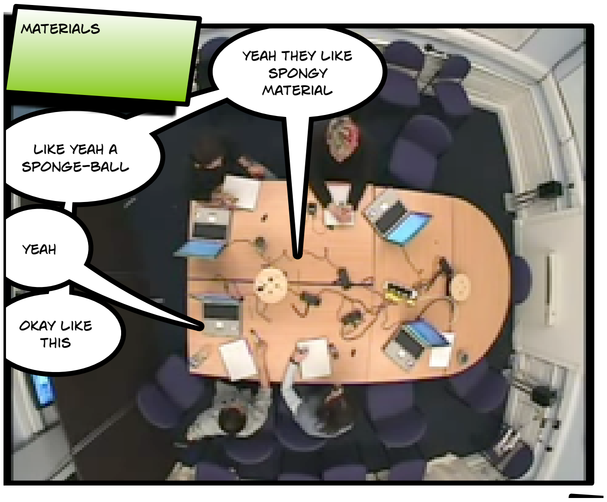

Figure 3: Comic book display of automatically generated meeting summary.

6 Evaluation

The multiple streams of data and multiple layers of annotations that make up the AMI corpus enable it to be used for evaluations of specific recognition components. The corpus has been used to evaluate many different things including voice activity detection, speaker diarisation and speech recognition (in the NIST RT evaluations), and head pose recognition (in the CLEAR evaluation). In the spoken language processing domain, the AMI corpus has been used to evaluate meeting summarisation, topic segmentation, dialogue act recognition and cross-language retrieval.

In addition to intrinsic component-level evaluations, it is valuable to evaluate complete systems, and components in a system context. In the AMI/AMIDA projects, we investigated a number of extrinsic evaluation frameworks for browsing and accessing meeting archives. The Browser Evaluation Test (BET) (Wellner et al., 2005) provides a framework for the comparison of arbitrary meeting browser setups, which may differ in terms of which content extraction or abstraction components are employed. In the BET test subjects have to answer true/false questions about a number of "observations of interest" relating to a recorded meeting, using the browser under test with a specified time limit (typically half the meeting length).

We developed of a variant of the BET to specifically evaluate different summarisation approaches. In the Decision Audit evaluation (Murray et al., 2009) the user's task is to ascertain the factors across a number of meetings that lead to a particular decision being made. A set of browsers were constructed differing in the summarisation approach employed (manual vs. ASR transcripts; extractive vs. abstractive vs. human vs. keyword-based summarisation), and the test subjects used them to perform the decision audit. Like the BET this evaluation is labour-intensive, but the results can be analysed using a battery of objective and subjective measures. Conclusions from carrying out this evaluation indicated that the task itself was quite challenging for users (even with human transcripts and summaries, most users could not find many factors involved in the decision), that automatic extractive summaries outperformed reasonably competitive baseline approaches, and that although subjects reported ASR transcripts to be unsatisfactory (due to the error rate) browsing using the ASR transcript still resulted in users' being generally able to find the relevant parts of the meeting archive.

7 Conclusions

In this paper I have given an overview of our investigations into automatic meeting recognition and interpretation. Multiparty communication is a challenging problem at many levels, from signal processing to discourse modelling. A major part of our attempt to address this problem, in an interdisciplinary way, was the collection, annotation, and distribution of the AMI meeting corpus. The AMI corpus has been at the basis of nearly all the work that we have carried out in the area, from speech recognition to summarisation. Multiparty speech recognition remains a difficult task, with a typical error rate of over 20%, however the accuracy is enough to enable various components to build on top of it. A major achievement has been the development of prototype applications that can use phrase-level latency real-time speech recognition.

Many of the automatic approaches to meeting recognition and characterisation are characterised by extensive combination at the feature stream, model and system level. In our experience, such approaches offer consistent improvements in accuracy for these complex, multimodal tasks.

Meetings serve a social function, and much of this has been ignored in our work, so far. We have focussed principally on understanding meetings in terms of their lexical content, augmented by various multimodal streams. However in many interactions, the social signals are at least as important as the propositional content of the words (Pentland, 2008); it is a major challenge to develop meeting interpretation components that can infer and take advantage of such social cues. We have made initial attempts to do this, by attempting to include aspects such as social role (Huang and Renals, 2008).

The AMI corpus involved a substantial effort from many individuals, and provides an invaluable resource. However, we do not wish to do this again, even if we are dealing with a domain that is significantly different, such as larger groups, or family "meetings". However, our recognisers rely strongly on annotated in-domain data. It is a major challenge to develop algorithms that are unsupervised and adaptive to free us from the need to collect and annotate large amount of data each time we are interested in a new domain.

Acknowledgments

This paper has arisen from a collaboration involving several laboratories. I have benefitted, in particular, from long-term collaborations with Hervé Bourlard, Jean Carletta, Thomas Hain, and Mike Lincoln, and from a number of fantastic PhD students. Abstract

In this paper, we present an innovative chart mining technique for improving parse coverage based on partial parse outputs from precision grammars. The general approach of mining features from partial analyses is applicable to a range of lexical acquisition tasks, and is particularly suited to domain-specific lexical tuning and lexical acquisition using low-coverage grammars. As an illustration of the functionality of our proposed technique, we develop a lexical acquisition model for English verb particle constructions which operates over unlexicalised features mined from a partial parsing chart. The proposed technique is shown to outperform a state-of-the-art parser over the target task, despite being based on relatively simplistic features.

1 Introduction

Parsing with precision grammars is increasingly achieving broad coverage over open-domain texts for a range of constraint-based frameworks (e.g., TAG, LFG, HPSG and CCG), and is being used in real-world applications including information extraction, question answering, grammar checking and machine translation (Uszkoreit, 2002; Oepen et al., 2004; Frank et al., 2006; Zhang and Kordoni, 2008; MacKinlay et al., 2009). In this context, a "precision grammar" is a grammar which has been engineered to model grammaticality, and contrasts with a treebank-induced grammar, for example.

Inevitably, however, such applications demand complete parsing outputs, based on the assumption that the text under investigation will be completely analysable by the grammar. As precision grammars generally make strong assumptions about complete lexical coverage and grammaticality of the input, their utility is limited over noisy or domain-specific data. This lack of complete coverage can make parsing with precision grammars less attractive than parsing with shallower methods.

One technique that has been successfully applied to improve parser and grammar coverage over a given corpus is error mining (van Noord, 2004; de Kok et al., 2009), whereby n-grams with low "parsability" are gathered from the large-scale output of a parser as an indication of parser or (precision) grammar errors. However, error mining is very much oriented towards grammar engineering: its results are a mixture of different (mistreated) linguistic phenomena together with engineering errors for the grammar engineer to work through and act upon. Additionally, it generally does not provide any insight into the cause of the parser failure, and it is difficult to identify specific language phenomena from the output.

In this paper, we instead propose a **chart mining** technique that works on intermediate parsing results from a parsing chart. In essence, the method analyses the validity of different analyses for words or constructions based on the "lifetime" and probability of each within the chart, combining the constraints of the grammar with probabilities to evaluate the plausibility of each.

For purposes of exemplification of the proposed technique, we apply chart mining to a deep lexical acquisition (DLA) task, using a maximum entropy-based prediction model trained over a seed lexicon and treebank. The experimental set up is the following: given a set of sentences containing putative instances of English verb particle constructions,

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 10–18,
Los Angeles, California, June 2010.

extract a list of non-compositional VPCs optionally with valence information. For comparison, we parse the same sentence set using a state-of-the-art statistical parser, and extract the VPCs from the parser output. Our results show that our chart mining method produces a model which is superior to the treebank parser.

To our knowledge, the only other work that has looked at partial parsing results of precision grammars as a means of linguistic error analysis is that of Kiefer et al. (1999) and Zhang et al. (2007a), where partial parsing models were proposed to select a set of passive edges that together cover the input sequence. Compared to these approaches, our proposed chart mining technique is more general and can be adapted to specific tasks and domains. While we experiment exclusively with an HPSG grammar in this paper, it is important to note that the proposed method can be applied to any grammar formalism which is compatible with chart parsing, and where it is possible to describe an unlexicalised lexical entry for the different categories of lexical item that are to be extracted (see Section 3.2 for details).

The remainder of the paper is organised as follows. Section 2 defines the task of VPC extraction. Section 3 presents the chart mining technique and the feature extraction process for the VPC extraction task. Section 4 evaluates the model performance with comparison to two competitor models over several different measures. Section 5 further discusses the general applicability of chart mining. Finally, Section 6 concludes the paper.

2 Verb Particle Constructions

The particular construction type we target for DLA in this paper is English Verb Particle Constructions (henceforth VPCs). VPCs consist of a head verb and one or more obligatory **particles**, in the form of intransitive prepositions (e.g., *hand in*), adjectives (e.g., *cut short*) or verbs (e.g., *let go*) (Villavicencio and Copestake, 2002; Huddleston and Pullum, 2002; Baldwin and Kim, 2009); for the purposes of our dataset, we assume that all particles are prepositional—by far the most common and productive of the three types—and further restrict our attention to single-particle VPCs (i.e., we ignore VPCs such as *get along together*).

One aspect of VPCs that makes them a particularly challenging target for lexical acquisition is that the verb and particle can be non-contiguous (for instance, *hand the paper in* and *battle right on*). This sets them apart from conventional collocations and terminology (cf., Manning and Schütze (1999), Smadja (1993) and McKeown and Radev (2000)) in that they cannot be captured effectively using n-grams, due to their variability in the number and type of words potentially interceding between the verb and the particle. Also, while conventional collocations generally take the form of compound nouns or adjective–noun combinations with relatively simple syntactic structure, VPCs occur with a range of valences. Furthermore, VPCs are highly productive in English and vary in use across domains, making them a prime target for lexical acquisition (Dehé, 2002; Baldwin, 2005; Baldwin and Kim, 2009).

In the VPC dataset we use, there is an additional distinction between compositional and non-compositional VPCs. With compositional VPCs, the semantics of the verb and particle both correspond to the semantics of the respective simplex words, including the possibility of the semantics being specific to the VPC construction in the case of particles. For example, *battle on* would be classified as compositional, as the semantics of *battle* is identical to that for the simplex verb, and the semantics of *on* corresponds to the continuative sense of the word as occurs productively in VPCs (cf., *walk/dance/drive/govern/... on*). With non-compositional VPCs, on the other hand, the semantics of the VPC is somehow removed from that of the parts. In the dataset we used for evaluation, we are interested in extracting exclusively non-compositional VPCs, as they require lexicalisation; compositional VPCs can be captured via lexical rules and are hence not the target of extraction.

English VPCs can occur with a number of valences, with the two most prevalent and productive valences being the simple transitive (e.g., *hand in the paper*) and intransitive (e.g., *back off*). For the purposes of our target task, we focus exclusively on these two valence types.

Given the above, we define the English VPC extraction task to be the production of triples of the form $\langle v, p, s \rangle$, where v is a verb lemma, p is a prepositional particle, and $s \in \{\mathit{intrans}, \mathit{trans}\}$ is the valence; additionally, each triple has to be semantically non-compositional. The triples are extracted relative to a set of putative token instances for each of the intransitive and transitive valences for a given VPC. That is, a given triple should be classified as positive if and only if it is associated with at least one non-compositional token instance in the provided token-level data.

The dataset used in this research is the one used in the LREC 2008 Multiword Expression Workshop Shared Task (Baldwin, 2008).[1] In the dataset, there is a single file for each of 4,090 candidate VPC triples, containing up to 50 sentences that have the given VPC taken from the British National Corpus. When the valence of the VPC is ignored, the dataset contains 440 unique VPCs among 2,898 VPC candidates. In order to be able to fairly compare our method with a state-of-the-art lexicalised parser trained over the WSJ training sections of the Penn Treebank, we remove any VPC types from the test set which are attested in the WSJ training sections. This removes 696 VPC types from the test set, and makes the task even more difficult, as the remaining testing VPC types are generally less frequent ones. At the same time, it unfortunately means that our results are not directly comparable to those for the original shared task.[2]

3 Chart Mining for Parsing with a Large Precision Grammar

3.1 The Technique

The chart mining technique we use in this paper is couched in a constituent-based bottom-up chart parsing paradigm. A parsing chart is a data structure that records all the (complete or incomplete) intermediate parsing results. Every passive edge on the parsing chart represents a complete local analysis covering a sub-string of the input, while each active edge predicts a potential local analysis. In this view, a full analysis is merely a passive edge that spans the whole input and satisfies certain *root conditions*. The bottom-up chart parser starts with edges instantiated from lexical entries corresponding to the input words. The grammar rules are used to incrementally create longer edges from smaller ones until no more edges can be added to the chart.

Standardly, the parser returns only outputs that correspond to passive edges in the parsing chart that span the full input string. For those inputs without a full-spanning edge, no output is generated, and the chart becomes the only source of parsing information.

A parsing chart takes the form of a hierarchy of edges. Where only passive edges are concerned, each non-lexical edge corresponds to exactly one grammar rule, and is connected with one or more daughter edge(s), and zero or more parent edge(s). Therefore, traversing the chart is relatively straightforward.

There are two potential challenges for the chart-mining technique. First, there is potentially a huge number of parsing edges in the chart. For instance, when parsing with a large precision grammar like the HPSG English Resource Grammar (ERG, Flickinger (2002)), it is not unusual for a 20-word sentence to receive over 10,000 passive edges. In order to achieve high efficiency in parsing (as well as generation), ambiguity packing is usually used to reduce the number of productive passive edges on the parsing chart (Tomita, 1985). For constraint-based grammar frameworks like LFG and HPSG, subsumption-based packing is used to achieve a higher packing ratio (Oepen and Carroll, 2000), but this might also potentially lead to an inconsistent packed parse forest that does not unpack successfully. For chart mining, this means that not all passive edges are directly accessible from the chart. Some of them are packed into others, and the derivatives of the packed edges are not generated. Because of the ambiguity packing, zero or more local analyses may exist for each passive edge on the chart, and the cross-combination of the packed daughter edges is not guaranteed to be compatible. As a result, expensive unification operations must be reapplied during the unpacking phase. Carroll and Oepen (2005) and Zhang et al. (2007b) have proposed efficient k-best unpacking algorithms that can selectively extract the most probable readings from the packed parse forest according to a discrimina-

[1] Downloadable from http://www.csse.unimelb.edu.au/research/lt/resources/vpc/vpc.tgz.

[2] In practice, there was only one team who participated in the original VPC task (Ramisch et al., 2008), who used a variety of web- and dictionary-based features suited more to high-frequency instances in high-density languages, so a simplistic comparison would not have been meaningful.

tive parse disambiguation model, by minimising the number of potential unifications. The algorithm can be applied to unpack any passive edges. Because of the dynamic programming used in the algorithm and the hierarchical structure of the edges, the cost of the unpacking routine is empirically linear in the number of desired readings, and $O(1)$ when invoked more than once on the same edge.

The other challenge concerns the selection of informative and representative pieces of knowledge from the massive sea of partial analyses in the parsing chart. How to effectively extract the indicative features for a specific language phenomenon is a very task-specific question, as we will show in the context of the VPC extraction task in Section 3.2. However, general strategies can be applied to generate parse ranking scores on each passive edge. The most widely used parse ranking model is the log-linear model (Abney, 1997; Johnson et al., 1999; Toutanova et al., 2002). When the model does not use non-local features, the accumulated score on a sub-tree under a certain (unpacked) passive edge can be used to approximate the probability of the partial analysis conditioned on the sub-string within that span.[3]

3.2 The Application: Acquiring Features for VPC Extraction

As stated above, the target task we use to illustrate the capabilities of our chart mining method is VPC extraction.

The grammar we apply our chart mining method to in this paper is the English Resource Grammar (ERG, Flickinger (2002)), a large-scale precision HPSG for English. Note, however, that the method is equally compatible with any grammar or grammar formalism which is compatible with chart parsing.

The lexicon of the ERG has been semi-automatically extended with VPCs extracted by Baldwin (2005). In order to show the effectiveness of chart mining in discovering "unknowns" and remove any lexical probabilities associated with pre-existing lexical entries, we block the lexical entries for the verb in the candidate VPC by substituting the input token with a DUMMY-V token, which is coupled with four candidate lexical entries of type: (1) intransitive simplex verb (*v_-_e*), (2) transitive simplex verb (*v_np_le*), (3) intransitive VPC (*v_p_le*), and (4) transitive VPC (*v_p-np_le*), respectively. These four lexical entries represent the two VPC valences we wish to distinguish between in the VPC extraction task, and the competing simplex verb candidates. Based on these lexical types, the features we extract with chart mining are summarised in Table 1. The maximal constituent (MAXCONS) of a lexical entry is defined to be the passive edge that is an ancestor of the lexical entry edge that: (i) must span over the particle, and (ii) has maximal span length. In the case of a tie, the edge with the highest disambiguation score is selected as the MAXCONS. If there is no edge found on the chart that spans over both the verb and the particle, the MAXCONS is set to be NULL, with a MAXSPAN of 0, MAXLEVEL of 0 and MAXCRANK of 4 (see Table 1). The stem of the particle is also collected as a feature.

One important characteristic of these features is that they are completely unlexicalised on the verb. This not only leads to a fair evaluation with the ERG by excluding the influence from the lexical coverage of VPCs in the grammar, but it also demonstrates that complete grammatical coverage over simplex verbs is not a prerequisite for chart mining.

To illustrate how our method works, we present the unpacked parsing chart for the candidate VPC *show off* and input sentence *The boy shows off his new toys* in Figure 1. The non-terminal edges are marked with their syntactic categories, i.e., HPSG rules (e.g., *subjh* for the subject-head-rule, *hadj* for the head-adjunct-rule, etc.), and optionally their disambiguation scores. By traversing upward through parent edges from the DUMMY-V edge, all features can be efficiently extracted (see the third column in Table 1).

It should be noted that none of these features are used to deterministically dictate the predicted VPC category. Instead, the acquired features are used as inputs to a statistical classifier for predicting the type of the VPC candidate at the token level (in the context of the given sentence). In our experiment, we used a maximum entropy-based model to do a 3-

[3] To have a consistent ranking model on any sub-analysis, one would have to retrain the disambiguation model on every passive edge. In practice, we find this to be intractable. Also, the approximation based on full-parse ranking model works reasonably well.

Feature	Description	Examples
LE:MAXCONS	A lexical entry together with the maximal constituent constructed from it	*v_-_le:subjh, v_np_le:hadj, v_p_le:subjh, v_p-np_le:subj*
LE:MAXSPAN	A lexical entry together with the length of the span of the maximal constituent constructed from the LE	*v_-_le:7, v_np_le:5, v_p_le:4, v_p-np_le:7*
LE:MAXLEVEL	A lexical entry together with the levels of projections before it reaches its maximal constituent	*v_-_le:2, v_np_le:1, v_p_le:2, v_p-np_le:3*
LE:MAXCRANK	A lexical entry together with the relative disambiguation score ranking of its maximal constituent among all MaxCons from different LEs	*v_-_le:4, v_np_le:3, v_p_le:1, v_p-np_le:2*
PARTICLE	The stem of the particle in the candidate VPC	*off*

Table 1: Chart mining features used for VPC extraction

category classification: non-VPC, transitive VPC, or intransitive VPC. For the parameter estimation of the ME model, we use the TADM open source toolkit (Malouf, 2002). The token-level predictions are then combined with a simple majority voting to derive the type-level prediction for the VPC candidate. In the case of a tie, the method backs off to the naïve baseline model described in Section 4.2, which relies on the combined probability of the verb and particle forming a VPC.

We have also experimented with other ways of deriving type-level predictions from token-level classification results. For instance, we trained a separate classifier that takes the token-level prediction as input in order to determine the type-level VPC prediction. Our results indicate no significant difference between these methods and the basic majority voting approach, so we present results exclusively for this simplistic approach in this paper.

4 Evaluation

4.1 Experiment Setup

To evaluate the proposed chart mining-based VPC extraction model, we use the dataset from the LREC 2008 Multiword Expression Workshop shared task (see Section 2). We use this dataset to perform three distinct DLA tasks, as detailed in Table 2.

The chart mining feature extraction is implemented as an extension to the PET parser (Callmeier,

Task	Description
GOLD VPC	Determine the valence for a verb–preposition combination which is known to occur as a non-compositional VPC (i.e. known VPC, with unknown valence(s))
FULL	Determine whether each verb–preposition combination is a VPC or not, and further predict its valence(s) (i.e. unknown if VPC, and unknown valence(s))
VPC	Determine whether each verb–preposition combination is a VPC or not *ignoring valence* (i.e. unknown if VPC, and don't care about valence)

Table 2: Definitions of the three DLA tasks

2001). We use a slightly modified version of the ERG in our experiments, based on the *nov-06* release. The modifications include 4 newly-added dummy lexical entries for the verb DUMMY-V and the corresponding inflectional rules, and a lexical type prediction model (Zhang and Kordoni, 2006) trained on the LOGON Treebank (Oepen et al., 2004) for unknown word handling. The parse disambiguation model we use is also trained on the LOGON Treebank. Since the parser has no access to any of the verbs under investigation (due to the DUMMY-V substitution), those VPC types attested in the LOGON Treebank do not directly impact on the model's performance. The chart mining feature extraction process took over 10 CPU days, and collected a total of 44K events for 4,090 candidate VPC triples.[4] 5-fold cross validation is used to train/test the model. As stated above (Section 2), the VPC triples attested in the WSJ training sections of the Penn Treebank are excluded in each testing fold for comparison with the Charniak parser-based model (see Section 4.2).

4.2 Baseline and Benchmark

For comparison, we first built a naïve baseline model using the combined probabilities of the verb and particle being part of a VPC. More specifically, $P(c|v)$ and $P(c|p)$ are the probabilities of a given verb v and particle p being part of a VPC candidate of type $s \in \{intrans, trans, null\}$, for transitive VPC, intransitive VPC, and non-VPC, respectively. $\tilde{P}(s|v,p) = P(s|v) \cdot P(s|p)$ is used to approximate the joint probability of verb-particle (v,p) being of type s, and the prediction type is chosen randomly based on this probabilistic distribution. Both $P(s|v)$ and $P(s|p)$ can be estimated from a list of VPC candidate types. If v is unseen, $P(s|v)$ is set to be $\frac{1}{|V|}\sum_{v_i \in V} P(s|v_i)$ estimated over all verbs $|V|$ seen in the list of VPC candidates. The naïve baseline performed poorly, mainly because there is not enough knowledge about the context of use of VPCs. This also indicates that the task of VPC extraction is non-trivial, and that context (evidence from sentences in which the VPC putatively occurs) must be incorporated in order to make more accurate predictions.

As a benchmark VPC extraction system, we use the Charniak parser (Charniak, 2000). This statistical parser induces a context-free grammar and a generative parsing model from a training set of gold standard parse trees. Traditionally, it has been trained over the WSJ component of the Penn Treebank, and for this work we decided to take the same approach and train over sections 1 to 22, and use section 23 for parameter-tuning. After parsing, we simply search for the VPC triples in each token instance with `tgrep2`,[5] and decide on the classification of the candidate by majority voting over all instances, breaking ties randomly.

[4] Not all sentences in the dataset are successfully chart-mined. Due to the complexity of the precision grammar we use, the parser is unlikely to complete the parsing chart for extremely long sentences (over 50 words). Moreover, sentences which do not receive any spanning edge over the verb and the particle are not considered as an indicative event. Nevertheless, the coverage of the chart mining is much higher than the full-parse coverage of the grammar.

[5] Noting that the Penn POS tagset captures essentially the compositional vs. non-compositional VPC distinction required in the extraction task, through the use of the RP (prepositional particle, for non-compositional VPCs) and RB (adverb, for compositional VPCs) tags.

4.3 Results

The results of our experiments are summarised in Table 3. For the naïve baseline and the chart mining-based models, the results are averaged over 5-fold cross validation.

We evaluate the methods in the form of the three tasks described in Table 2. Formally, GOLD VPC equates to extracting $\langle v, p, s\rangle$ tuples from the subset of gold-standard $\langle v, p\rangle$ tuples; FULL equates to extracting $\langle v, p, s\rangle$ tuples for all VPC candidates; and VPC equates to extracting $\langle v, p\rangle$ tuples (ignoring valence) over all VPC candidates. In each case, we present the precision (P), recall (R) and F-score ($\beta = 1$: F). For multi-category classifications (i.e. the two tasks where we predict the valence s, indicated as "All" in Table 3), we micro-average the precision and recall over the two VPC categories, and calculate the F-score as their harmonic mean.

From the results, it is obvious that the chart mining-based model performs best overall, and indeed for most of the measures presented. The Charniak parser-based extraction method performs reasonably well, especially in the VPC+valence extraction task over the FULL task, where the recall was higher than the chart mining method. Although not reported here, we observe a marked improvement in the results for the Charniak parser when the VPC types attested in the WSJ are not filtered from the test set. This indicates that the statistical parser relies heavily on lexicalised VPC information, while the chart mining model is much more syntax-oriented. In error analysis of the data, we observed that the Charniak parser was noticeably more accurate at extracting VPCs where the verb was frequent (our method, of course, did not have access to the base frequency of the simplex verb), underlining again the power of lexicalisation. This points to two possibilities: (1) the potential for our method to similarly benefit from lexicalisation if we were to remove the constraint on ignoring any pre-existing lexical entries for the verb; and (2) the possibility for hybridising between lexicalised models for frequent verbs and unlexicalised models for infrequent verbs. Having said this, it is important to reinforce that lexical acquisition is usually performed in the absence of lexicalised probabilities, as if we have prior knowledge of the lexical item, there is no need to extract it. In this sense, the first set of results in Table 3 over Gold VPCs are the most informative, and illustrate the potential of the proposed approach.

From the results of all the models, it would appear that intransitive VPCs are more difficult to extract than transitive VPCs. This is partly because the dataset we use is unbalanced: the number of transitive VPC types is about twice the number of intransitive VPCs. Also, the much lower numbers over the FULL set compared to the GOLD VPC set are due to the fact that only 1/8 of the candidates are true VPCs.

5 Discussion and Future Work

The inventory of features we propose for VPC extraction is just one illustration of how partial parse results can be used in lexical acquisition tasks. The general chart mining technique can easily be adapted to learn other challenging linguistic phenomena, such as the countability of nouns (Baldwin and Bond, 2003), subcategorization properties of verbs or nouns (Korhonen, 2002), and general multiword expression (MWE) extraction (Baldwin and Kim, 2009). With MWE extraction, e.g., even though some MWEs are fixed and have no internal syntactic variability, such as *ad hoc*, there is a very large proportion of idioms that allow various degrees of internal variability, and with a variable number of elements. For example, the idiom *spill the beans* allows internal modification (*spill mountains of beans*), passivisation (*The beans were spilled in the latest edition of the report*), topicalisation (*The beans, the opposition spilled*), and so forth (Sag et al., 2002). In general, however, the exact degree of variability of an idiom is difficult to predict (Riehemann, 2001). The chart mining technique we propose here, which makes use of partial parse results, may facilitate the automatic recognition task of even more flexible idioms, based on the encouraging results for VPCs.

The main advantage, though, of chart mining is that parsing with precision grammars does not any longer have to assume complete coverage, as has traditionally been the case. As an immediate consequence, the possibility of applying our chart mining technique to evolving medium-sized grammars makes it especially interesting for lexical acquisi-

Task	VPC Type	Naïve Baseline			Charniak Parser			Chart-Mining

tion over low-density languages, for instance, where there is a real need for rapid-prototyping of language resources.

The chart mining approach we propose in this paper is couched in the bottom-up chart parsing paradigm, based exclusively on passive edges. As future work, we would also like to look into the top-level active edges (those active edges that are never completed), as an indication of failed assumptions. Moreover, it would be interesting to investigate the applicability of the technique in other parsing strategies, e.g., head-corner or left-corner parsing. Finally, it would also be interesting to investigate whether by using the features we acquire from chart mining enhanced with information on the prevalence of certain patterns, we could achieve performance improvements over broader-coverage treebank parsers such as the Charniak parser.

6 Conclusion

We have proposed a chart mining technique for lexical acquisition based on partial parsing with precision grammars. We applied the proposed method to the task of extracting English verb particle constructions from a prescribed set of corpus instances. Our results showed that simple unlexicalised features mined from the chart can be used to effectively extract VPCs, and that the model outperforms a probabilistic baseline and the Charniak parser at VPC extraction.

Products of Random Latent Variable Grammars

Slav Petrov
Google Research
New York, NY, 10011
slav@google.com

Abstract

We show that the automatically induced latent variable grammars of Petrov et al. (2006) vary widely in their underlying representations, depending on their EM initialization point. We use this to our advantage, combining multiple automatically learned grammars into an unweighted product model, which gives significantly improved performance over state-of-the-art individual grammars. In our model, the probability of a constituent is estimated as a product of posteriors obtained from multiple grammars that differ only in the random seed used for initialization, without any learning or tuning of combination weights. Despite its simplicity, a product of eight automatically learned grammars improves parsing accuracy from 90.2% to 91.8% on English, and from 80.3% to 84.5% on German.

1 Introduction

Learning a context-free grammar for parsing requires the estimation of a more highly articulated model than the one embodied by the observed treebank. This is because the naive treebank grammar (Charniak, 1996) is too permissive, making unrealistic context-freedom assumptions. For example, it postulates that there is only one type of noun phrase (NP), which can appear in all positions (subject, object, etc.), regardless of case, number or gender. As a result, the grammar can generate millions of (incorrect) parse trees for a given sentence, and has a flat posterior distribution. High accuracy grammars therefore add soft constraints on the way categories can be combined, and enrich the label set with additional information. These constraints can be lexicalized (Collins, 1999; Charniak, 2000), unlexicalized (Johnson, 1998; Klein and Manning, 2003b) or automatically learned (Matsuzaki et al., 2005; Petrov et al., 2006). The constraints serve the purpose of weakening the independence assumptions, and reduce the number of possible (but incorrect) parses.

Here, we focus on the latent variable approach of Petrov et al. (2006), where an Expectation Maximization (EM) algorithm is used to induce a hierarchy of increasingly more refined grammars. Each round of refinement introduces new constraints on how constituents can be combined, which in turn leads to a higher parsing accuracy. However, EM is a local method, and there are no guarantees that it will find the same grammars when initialized from different starting points. In fact, it turns out that even though the final performance of these grammars is consistently high, there are significant variations in the learned refinements.

We use these variations to our advantage, and treat grammars learned from different random seeds as independent and equipotent experts. We use a product distribution for joint prediction, which gives more peaked posteriors than a sum, and enforces all constraints of the individual grammars, without the need to tune mixing weights. It should be noted here that our focus is on improving parsing performance using a single underlying grammar class, which is somewhat orthogonal to the issue of parser combination, that has been studied elsewhere in the literature (Sagae and Lavie, 2006; Fossum and Knight, 2009; Zhang et al., 2009). In contrast to that line of work, we also do not restrict ourselves to working with k-best output, but work directly with a packed forest representation of the posteriors, much in the spirit of Huang (2008), except that we work with several forests rather than rescoring a single one.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 19–27,
Los Angeles, California, June 2010.

In our experimental section we give empirical answers to some of the remaining theoretical questions. We address the question of averaging versus multiplying classifier predictions, we investigate different ways of introducing more diversity into the underlying grammars, and also compare combining partial (constituent-level) and complete (tree-level) predictions. Quite serendipitously, the simplest approaches work best in our experiments. A product of eight latent variable grammars, learned on the same data, and only differing in the seed used in the random number generator that initialized EM, improves parsing accuracy from 90.2% to 91.8% on English, and from 80.3% to 84.5% on German. These parsing results are even better than those obtained by discriminative systems which have access to additional non-local features (Charniak and Johnson, 2005; Huang, 2008).

2 Latent Variable Grammars

Before giving the details of our model, we briefly review the basic properties of latent variable grammars. Learning latent variable grammars consists of two tasks: (1) determining the data representation (the set of context-free productions to be used in the grammar), and (2) estimating the parameters of the model (the production probabilities). We focus on the randomness introduced by the EM algorithm and refer the reader to Matsuzaki et al. (2005) and Petrov et al. (2006) for a more general introduction.

2.1 Split & Merge Learning

Latent variable grammars split the coarse (but observed) grammar categories of a treebank into more fine-grained (but hidden) subcategories, which are better suited for modeling the syntax of natural languages (e.g. NP becomes NP_1 through NP_k). Accordingly, each grammar production A→BC over observed categories A,B,C is split into a set of productions $\mathrm{A}_x \rightarrow \mathrm{B}_y \mathrm{C}_z$ over hidden categories A_x,B_y,C_z. Computing the joint likelihood of the observed parse trees T and sentences w requires summing over all derivations t over split subcategories:

$$\prod_i \mathrm{P}(w_i, T_i) = \prod_i \sum_{t:T_i} \mathrm{P}(w_i, t) \qquad (1)$$

Matsuzaki et al. (2005) derive an EM algorithm for maximizing the joint likelihood, and Petrov et al. (2006) extend this algorithm to use a split&merge procedure to adaptively determine the optimal number of subcategories for each observed category. Starting from a completely markovized X-Bar grammar, each category is split in two, generating eight new productions for each original binary production. To break symmetries, the production probabilities are perturbed by 1% of random noise. EM is then initialized with this starting point and used to climb the highly non-convex objective function given in Eq. 1. Each splitting step is followed by a merging step, which uses a likelihood ratio test to reverse the least useful half of the splits. Learning proceeds by iterating between those two steps for six rounds. To prevent overfitting, the production probabilities are linearly smoothed by shrinking them towards their common base category.

2.2 EM induced Randomness

While the split&merge procedure described above is shown in Petrov et al. (2006) to reduce the variance in final performance, we found after closer examination that there are substantial differences in the patterns learned by the grammars. Since the initialization is not systematically biased in any way, one can obtain different grammars by simply changing the seed of the random number generator. We trained 16 different grammars by initializing the random number generator with seed values 1 through 16, but without biasing the initialization in any other way. Figure 1 shows that the number of subcategories allocated to each observed category varies significantly between the different initialization points, especially for the phrasal categories. Figure 2 shows posteriors over the most frequent subcategories given their base category for the first four grammars. Clearly, EM is allocating the latent variables in very different ways in each case.

As a more quantitative measure of difference,[1] we evaluated all 16 grammars on sections 22 and 24 of the Penn Treebank. Figure 3 shows the performance on those two sets, and reveals that there is no single grammar that achieves the best score on both. While the parsing accuracies are consistently high,[2] there

[1] While cherry-picking similarities is fairly straight-forward, it is less obvious how to quantify differences.

[2] Note that despite their variance, the performance is always higher than the one of the lexicalized parser of Charniak (2000).

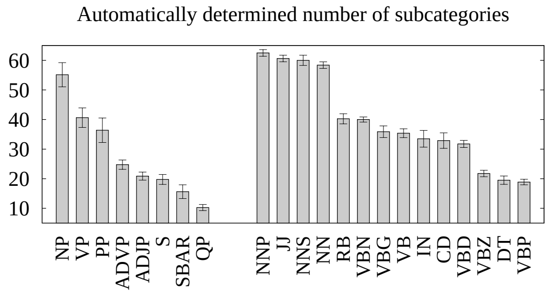

Figure 1: There is large variance in the number of subcategories (error bars correspond to one standard deviation).

is only a weak correlation between the accuracies on the two evaluation sets (Pearson coefficient 0.34). This suggests that no single grammar should be preferred over the others. In previous work (Petrov et al., 2006; Petrov and Klein, 2007) the final grammar was chosen based on its performance on a held-out set (section 22), and corresponds to the second best grammar in Figure 3 (because only 8 different grammars were trained).

A more detailed error analysis is given in Figure 4, where we show a breakdown of F_1 scores for selected phrasal categories in addition to the overall F_1 score and exact match (on the WSJ development set). While grammar G_2 has the highest overall F_1 score, its exact match is not particularly high, and it turns out to be the weakest at predicting quantifier phrases (QP). Similarly, the performance of the other grammars varies between the different error measures, indicating again that no single grammar dominates the others.

3 A Simple Product Model

It should be clear by now that simply varying the random seed used for initialization causes EM to discover very different latent variable grammars. While this behavior is worrisome in general, it turns out that we can use it to our advantage in this particular case. Recall that we are using EM to learn both, the data representation, as well as the parameters of the model. Our analysis showed that changing the initialization point results in learning grammars that vary quite significantly in the errors they make, but have comparable overall accuracies. This suggests that the different local maxima found by EM correspond to different data representations rather than to suboptimal parameter estimates.

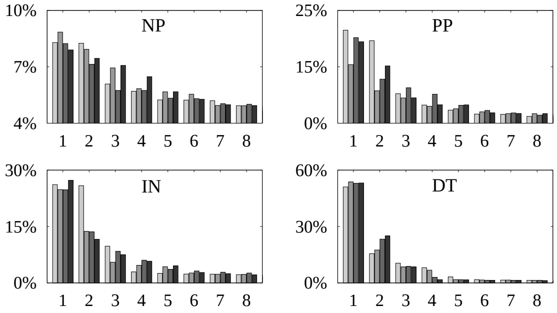

Figure 2: Posterior probabilities of the eight most frequent hidden subcategories given their observed base categories. The four grammars (indicated by shading) are populating the subcategories in very different ways.

To leverage the strengths of the individual grammars, we combine them in a product model. Product models have the nice property that their Kullback-Liebler divergence from the true distribution will always be smaller than the average of the KL divergences of the individual distributions (Hinton, 2001). Therefore, as long as no individual grammar G_i is significantly worse than the others, we can only benefit from combining multiple latent variable grammars and searching for the tree that maximizes

$$\mathrm{P}(T|w) \propto \prod_i \mathrm{P}(T|w, \mathrm{G}_i) \tag{2}$$

Here, we are making the assumption that the individual grammars are conditionally independent, which is of course not true in theory, but holds surprisingly well in practice. To avoid this assumption, we could use a sum model, but we will show in Section 4.1 that the product formulation performs significantly better. Intuitively speaking, products have the advantage that the final prediction has a high posterior under *all* models, giving each model veto power. This is exactly the behavior that we need in the case of parsing, where each grammar has learned different constraints for ruling out improbable parses.

3.1 Learning

Joint training of our product model would couple the parameters of the individual grammars, necessitating the computation of an intractable global partition function (Brown and Hinton, 2001). Instead, we use EM to train each grammar independently,

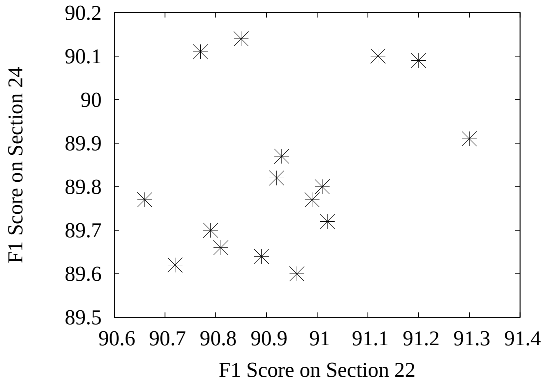

Figure 3: Parsing accuracies for grammars learned from different random seeds. The large variance and weak correlation suggest that no single grammar is to be preferred.

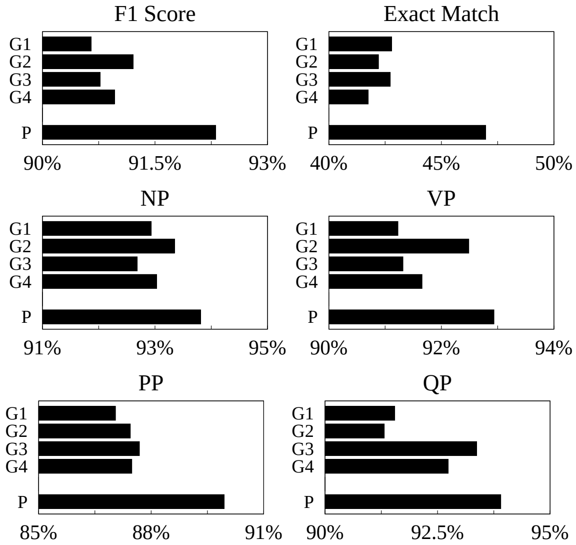

Figure 4: Breakdown of different accuracy measures for four randomly selected grammars (G_1-G_4), as well as a product model (P) that uses those four grammars. Note that no single grammar does well on all measures, while the product model does significantly better on all.

but from a different, randomly chosen starting point. To emphasize, we do not introduce any systematic bias (but see Section 4.3 for some experiments), or attempt to train the models to be maximally different (Hinton, 2002) – we simply train a random collection of grammars by varying the random seed used for initialization. We found in our experiments that the randomness provided by EM is sufficient to achieve diversity among the individual grammars, and gives results that are as good as more involved training procedures. Xu and Jelinek (2004) made a similar observation when learning random forests for language modeling.

Our model is reminiscent of Logarithmic Opinion Pools (Bordley, 1982) and Products of Experts (Hinton, 2001).[3] However, because we believe that none of the underlying grammars should be favored, we deliberately do not use any combination weights.

3.2 Inference

Computing the most likely parse tree is intractable for latent variable grammars (Sima'an, 2002), and therefore also for our product model. This is because there are exponentially many derivations over split subcategories that correspond to a single parse tree over unsplit categories, and there is no dynamic program to efficiently marginalize out the latent variables. Previous work on parse risk minimization has addressed this problem in two different ways: by changing the objective function, or by constraining the search space (Goodman, 1996; Titov and Henderson, 2006; Petrov and Klein, 2007).

The simplest approach is to stick to likelihood as the objective function, but to limit the search space to a set of high quality candidates $\mathcal{T}$:

$$T^* = \operatorname*{argmax}_{T \in \mathcal{T}} \mathrm{P}(T|w) \qquad (3)$$

Because the likelihood of a given parse tree can be computed exactly for our product model (Eq. 2), the quality of this approximation is only limited by the quality of the candidate list. To generate the candidate list, we produce k-best lists of Viterbi derivations with the efficient algorithm of Huang and Chiang (2005), and erase the subcategory information to obtain parse trees over unsplit categories. We refer to this approximation as TREE-LEVEL inference, because it considers a list of complete trees from the underlying grammars, and selects the tree that has the highest likelihood under the product model. While the k-best lists are of very high quality, this is a fairly crude and unsatisfactory way of approximating the posterior distribution of the product model, as it does not allow the synthesis of new trees based on tree fragments from different grammars.

An alternative is to use a tractable objective function that allows the efficient exploration of the entire

[3] As a matter of fact, Hinton (2001) mentions syntactic parsing as one of the motivating examples for Products of Experts.

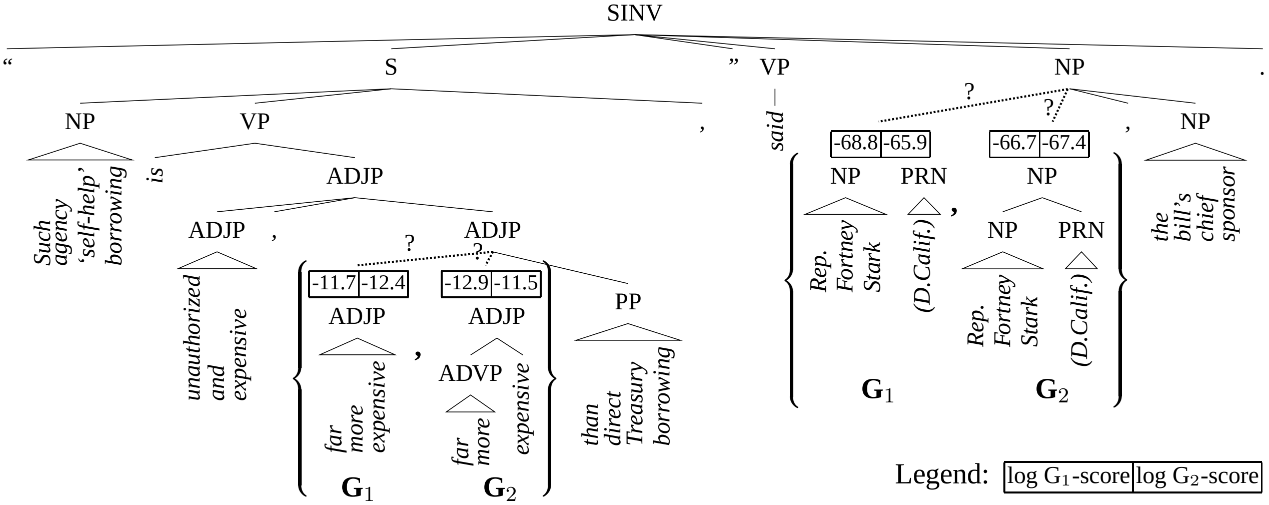

Figure 5: Grammar G_1 has a preference for flat structures, while grammar G_2 prefers deeper hierarchical structures. Both grammars therefore make one mistake each on their own. However, the correct parse tree (which uses a flat ADJP in the first slot and a hierarchical NP in the second) scores highest under the product model.

search space. Petrov and Klein (2007) present such an objective function, which maximizes the product of expected correct productions r:

$$T^* = \underset{T}{\operatorname{argmax}} \prod_{r \in T} \mathbb{E}(r|w) \tag{4}$$

These expectations can be easily computed from the inside/outside scores, similarly as in the maximum bracket recall algorithm of Goodman (1996), or in the variational approximation of Matsuzaki et al. (2005). We extend the algorithm to work over posterior distributions from multiple grammars, by aggregating their expectations into a product. In practice, we use a packed forest representation to approximate the posterior distribution, as in Huang (2008). We refer to this approximation as CONSTITUENT-LEVEL, because it allows us to form new parse trees from individual constituents.

Figure 5 illustrates a real case where the product model was able to construct a completely correct parse tree from two partially correct ones. In the example, one of the underlying grammars (G_1) had an imperfect recall score, because of its preference for flat structures (it missed an NP node in the second part of the sentence). In contrast, the other grammar (G_2) favors deeper structures, and therefore introduced a superfluous ADVP node. The product model gives each underlying grammar veto power, and picks the least controversial tree (which is the correct one in this case). Note that a sum model allows the most confident model to dominate the decision, and would chose the incorrect hierarchical ADJP construction here (as one can verify using the provided model scores).

To make inference efficient, we can use the same coarse-to-fine pruning techniques as Petrov and Klein (2007). We generate a hierarchy of projected grammars for each individual grammar and parse with each one in sequence. Because only the very last pass requires scores from the different underlying grammars, this computation can be trivially parallelized across multiple CPUs. Additionally, the first (X-Bar) pruning pass needs to be computed only once because it is shared among all grammars. Since the X-Bar pass is the bottleneck of the multipass scheme (using nearly 50% of the total processing time), the overhead of using a product model is quite manageable. It would have also been possible to use A*-search for factored models (Klein and Manning, 2003a; Sun and Tsujii, 2009), but we did not attempt this in the present work.

4 Experiments

In our experiments, we follow the standard setups described in Table 1, and use the EVALB tool for computing parsing figures. Unless noted otherwise, we use CONSTITUENT-LEVEL inference. All our experiments are based on the publicly available BerkeleyParser.[4]

4.1 (Weighted) Product vs. (Weighted) Sum

A great deal has been written on the topic of products versus sums of probability distributions for joint prediction (Genest and Zidek, 1986; Tax et al., 2000). However, those theoretical results do not apply directly here, because we are using multiple randomly permuted models from the same class, rather models from different classes. To shed some light on this issue, we addressed the question empirically, and combined two grammars into an unweighted product model, and also an unweighted sum model. The individual grammars had parsing accuracies (F_1) of 91.2 and 90.7 respectively, and their product (91.7) clearly outperformed their sum (91.3). When more grammars are added, the gap widens even further, and the trends persist independently of whether the models use TREE-LEVEL or CONSTITUENT-LEVEL inference. At least for the case of unweighted combinations, the product distribution seems to be superior.

In related work, Zhang et al. (2009) achieve excellent results with a weighted sum model. Using weights learned on a held-out set and rescoring 50-best lists from Charniak (2000) and Petrov et al. (2006), they obtain an F_1 score of 91.0 (which they further improve to 91.4 using a voting scheme). We replicated their experiment, but used an unweighted product of the two model scores. Using TREE-LEVEL inference, we obtained an F_1 score of 91.6, suggesting that weighting is not so important in the product case, as long as the classifiers are of comparable quality.[6] This is in line with previous work on product models, where weighting has been important when combining heterogenous classifiers (Heskes, 1998), and less important when the classifiers are of similar accuracy (Smith et al., 2005).

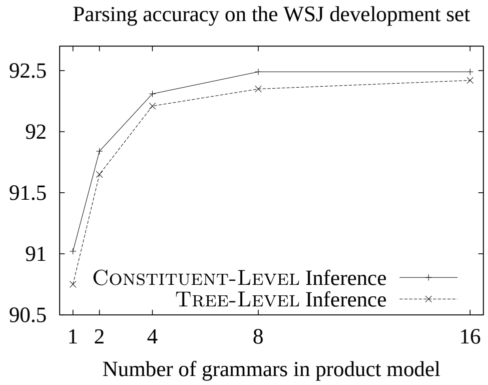

Figure 6: Adding more grammars to the product model improves parsing accuracy, while CONSTITUENT-LEVEL inference gives consistently better results.

4.2 Tree-Level vs. Constituent-Level Inference

Figure 6 shows that accuracy increases when more grammars are added to the product model, but levels off after eight grammars. The plot also compares our two inference approximations, and shows that CONSTITUENT-LEVEL inference results in a small (0.2), but consistent improvement in F_1 score.

A first thought might be that the improvement is due to the limited scope of the k-best lists. However, this is not the case, as the results hold even when the candidate set for CONSTITUENT-LEVEL inference is constrained to trees from the k-best lists. While the packed forrest representation can very efficiently encode an exponential set of parse trees, in our case the k-best lists appear to be already very diverse because they are generated by multiple grammars. Starting at 96.1 for a single latent variable grammar, merging two 50-best lists from different grammars gives an oracle score of 97.4, and adding more k-best lists further improves the oracle score to 98.6 for 16 grammars. This compares favorably to the results of Huang (2008), where the oracle score over a pruned forest is shown to be 97.8 (compared to 96.7 for a 50-best list).

The accuracy improvement can instead be explained by the change in the objective function. Recall from section Section 3.2, that CONSTITUENT-LEVEL inference maximizes the expected number of correct productions, while TREE-LEVEL inference maximizes tree-likelihood. It is therefore not too surprising that the two objective functions select the same tree only 41% of the time, even when limited to the same candidate set. Maximizing the

[5] See Gildea (2001) for the exact setup.

[6] The unweighted sum model, however, underperforms the individual models with an F_1 score of only 90.3.

expected number of correct productions is superior for F_1 score (see the one grammar case in Figure 6). However, as to be expected, likelihood is better for exact match, giving a score of 47.6% vs. 46.8%.

4.3 Systematic Bias

Diversity among the underlying models is what gives combined models their strength. One way of increasing diversity is by modifying the feature sets of the individual models (Baldridge and Osborne, 2008; Smith and Osborne, 2007). This approach has the disadvantage that it reduces the performance of the individual models, and is not directly applicable for latent variable grammars because the features are automatically learned. Alternatively, one can introduce diversity by changing the training distribution. Bagging (Breiman, 1996) and Boosting (Freund and Shapire, 1996) fall into this category, but have had limited success for parsing (Henderson and Brill, 2000). Furthermore boosting is impractical here, because it requires training dozens of grammars in sequence.

Since training a single grammar takes roughly one day, we opted for a different, parallelizable way of changing the training distribution. In a first experiment, we divided the training set into two disjoint sets, and trained separate grammars on each half. These truly disjoint grammars had low F_1 scores of 89.4 and 89.6 respectively (because they were trained on less data). Their combination unfortunately also achieves only an accuracy of 90.9, which is lower than what we get when training a single grammar on the entire training set. In another experiment, we used a cross-validation setup where individual sections of the treebank were held out. The resulting grammars had parsing accuracies of about 90.5, and the product model was again not able to overcome the lower starting point, despite the potentially larger diversity among the underlying grammars. It appears that any systematic bias that lowers the accuracy of the individual grammars also hurts the final performance of the product model.

4.4 Product Distribution as Smoothing

Smith et al. (2005) interpret Logarithmic Opinion Pools (LOPs) as a smoothing technique. They compare regularizing Conditional Random Fields (CRFs) with Gaussian priors (Lafferty et al., 2001), to training a set of unregularized CRFs over different feature sets and combining them in an LOP. In their experiments, both approaches work comparably well, but their combination, an LOP of regularized CRFs works best.

Not too surprisingly, we find this to be the case here as well. The parameters of each latent variable grammar are typically smoothed in a linear fashion to prevent excessive overfitting (Petrov et al., 2006). While all the experiments so far used smoothed grammars, we reran the experiments also with a set of unsmoothed grammars. The individual unsmoothed grammars have on average an 1.2% lower accuracy. Even though our product model is able to increase accuracy by combining multiple grammars, the gap to the smoothed models remains consistent. This suggests that the product model is doing more than just smoothing. In fact, because the product distribution is more peaked, it seems to be doing the opposite of smoothing.

4.5 Final Results

Our final model uses an unweighted product of eight grammars trained by initializing the random number generator with seeds 1 through 8. Table 2 shows our test set results (obtained with CONSTITUENT-LEVEL inference), and compares them to related work. There is a large body of work that has reported parsing accuracies for English, and we have grouped the different methods into categories for better overview.

Our results on the English in-domain test set are higher than those obtained by any single component parser (SINGLE). The other methods quoted in Table 2 operate over the output of one or more single component parsers and are therefore largely orthogonal to our line of work. It is nonetheless exciting to see that our product model is competitive with the discriminative rescoring methods (RE) of Charniak and Johnson (2005) and Huang (2008), achieving higher F_1 scores but lower exact match. These two methods work on top of the Charniak (2000) parser, and it would be possible to exchange that parser with our product model. We did not attempt this experiment, but we expect that those methods would stack well with our model, because they use primarily non-local features that are not available in a context-free grammar.

Techniques like self-training (SELF) and system combinations (COMBO) can further improve parsing accuracies, but are also orthogonal to our work. In particular the COMBO methods seem related to our work, but are very different in their nature. While we use multiple grammars in our work, all grammars are from the same model class for us. In contrast, those methods rely on a diverse set of individual parsers, each of which requires a significant effort to build. Furthermore, those techniques have largely relied on different voting schemes in the past (Henderson and Brill, 1999; Sagae and Lavie, 2006), and only more recently have started using actual posteriors from the underlying models (Fossum and Knight, 2009; Zhang et al., 2009). Even then, those methods operate only over k-best lists, and we are the first to work directly with parse forests from multiple grammars.

It is also interesting to note that the best results in Zhang et al. (2009) are achieved by combining k-best lists from a latent variable grammar of Petrov et al. (2006) with the self-trained reranking parser of McClosky et al. (2006). Clearly, replacing the single latent variable grammar with a product of latent variable grammars ought to improve performance.

The results on the other two corpora are similar. A product of latent variable grammars very significantly outperforms a single latent variable grammar and sets new standards for the state-of-the-art.

We also analyzed the errors of the product models. In addition to the illustrative example in Figure 5, we computed detailed error metrics for different phrasal categories. Figure 4 shows that a product of four random grammars is always better than even the best underlying grammar. The individual grammars seem to learn different sets of constraints, and the product model is able to model them all at once, giving consistent accuracy improvements across all metrics.

5 Conclusions

We presented a simple product model that significantly improves parsing accuracies on different domains and languages. Our model leverages multiple automatically learned latent variable grammars, which differ only in the seed of the random number generator used to initialize the EM learning algorithm. As our analysis showed, the grammars vary widely, making very different errors. This is in part due to the fact that EM is used not only for estimating the parameters of the grammar, but also to determine the set of context-free productions that underlie it. Because the resulting data representations are largely independent, they can be easily combined in an unweighted product model. The product model does not require any additional training and is capable of significantly improving the state-of-the-art in parsing accuracy. It remains to be seen if a similar approach can be used in other cases where EM converges to widely varying local maxima.

Abstract

Current statistical parsers tend to perform well only on their training domain and nearby genres. While strong performance on a few related domains is sufficient for many situations, it is advantageous for parsers to be able to generalize to a wide variety of domains. When parsing document collections involving heterogeneous domains (e.g. the web), the optimal parsing model for each document is typically not obvious. We study this problem as a new task — *multiple source parser adaptation*. Our system trains on corpora from many different domains. It learns not only statistics of those domains but quantitative measures of domain differences and how those differences affect parsing accuracy. Given a specific target text, the resulting system proposes linear combinations of parsing models trained on the source corpora. Tested across six domains, our system outperforms all non-oracle baselines including the best domain-independent parsing model. Thus, we are able to demonstrate the value of customizing parsing models to specific domains.

1 Introduction

In statistical parsing literature, it is common to see parsers trained and tested on the same textual domain (Charniak and Johnson, 2005; McClosky et al., 2006a; Petrov and Klein, 2007; Carreras et al., 2008; Suzuki et al., 2009, among others). Unfortunately, the performance of these systems degrades on sentences drawn from a different domain. This issue can be seen across different parsing models (Sekine, 1997; Gildea, 2001; Bacchiani et al., 2006; McClosky et al., 2006b). Given that some aspects of syntax are domain dependent (typically at the lexical level), single parsing models tend to not perform well across all domains (see Table 1). Thus, statistical parsers inevitably learn some domain-specific properties in addition to the more general properties of a language's syntax. Recently, Daumé III (2007) and Finkel and Manning (2009) showed techniques for training models that attempt to separate domain-specific and general properties. However, even when given models for multiple training domains, it is not straightforward to determine which model performs best on an arbitrary piece of novel text.

This problem comes to the fore when one wants to parse document collections where each document is potentially its own domain. This shows up particularly when parsing the web. Recently, there has been much interest in applying parsers to the web for the purposes of information extraction and other forms of analysis (c.f. the CLSP 2009 summer workshop "Parsing the Web: Large-Scale Syntactic Processing"). The scale of the web demands an automatic solution to the domain detection and adaptation problems. Furthermore, it is not obvious that human annotators can determine the optimal parsing models for each web page.

Our goal is to study this exact problem. We create a new parsing task, *multiple source parser adaptation*, designed to capture cross-domain performance along with evaluation metrics and baselines. Our new task involves training parsing models on labeled and unlabeled corpora from a variety of domains (*source domains*). This is in contrast to standard domain adaptation tasks where there is a single source domain. For evaluation, one is given a text (*target text*) but not the identity of its domain. The challenge is determining how to best use the available

resources from training to maximize accuracy across multiple target texts.

Broadly put, we model how domain differences influence parsing accuracy. This is done by taking several computational measures of domain differences between the target text and each source domain. We use these features in a simple linear regression model which is trained to predict the accuracy of a parsing model (or, more generally, a mixture of parsing models) on a target text. To parse the target text, one simply uses the mixture of parsing models with the highest predicted accuracy. We show that our method is able to predict these accuracies quite well and thus effectively rank parsing models formed from mixtures of labeled and automatically labeled corpora.

In Section 2, we detail recent work on similar tasks. Our regression-based approach is covered in Section 3. We describe an evaluation strategy in Section 4. Section 5 presents new baselines which are intended to give a sense of current approaches and their limitations. The results of our experiments are detailed in Section 6 where we show that our system outperforms all non-oracle baselines. We conclude with a discussion and future work (Section 7).

2 Related work

The closest work to ours is Plank and Sima'an (2008), where unlabeled text is used to group sentences from WSJ into subdomains. The authors create a model for each subdomain which weights trees from its subdomain more highly than others. Given the domain specific models, they consider different parse combination strategies. Unfortunately, these methods do not yield a statistically significant improvement.

Multiple source domain adaptation has been done for other tasks (e.g. classification in (Blitzer et al., 2007; Daumé III, 2007; Dredze and Crammer, 2008)) and is related to multitask learning. Daumé III (2007) shows that an extremely simple method delivers solid performance on a number of domain adaptation classification tasks. This is achieved by making a copy of each feature for each source domain plus the "general" pseudodomain (for capturing domain independent features). This allows the classifier to directly model which features are domain-specific. Finkel and Manning (2009) demonstrate the hierarchical Bayesian extension of this where domain-specific models draw from a general base distribution. This is applied to classification (named entity recognition) as well as dependency parsing. These works describe how to train models in many different domains but sidestep the problem of domain detection. Thus, our work is orthogonal to theirs.

Our domain detection strategy draws on work in parser accuracy prediction (Ravi et al., 2008; Kawahara and Uchimoto, 2008). These works aim to predict the parser performance on a given target sentence. Ravi et al. (2008) frame this as a regression problem. Kawahara and Uchimoto (2008) treat it as a binary classification task and predict whether a specific parse is at a certain level of accuracy or higher. Ravi et al. (2008) show that their system can be used to return a ranking over different parsing models which we extend to the multiple domain setting. They also demonstrate that training their model on WSJ allows them to accurately predict parsing accuracy on the BROWN corpus. In contrast, our models are trained over multiple domains to model which factors influence cross-domain performance.

3 Approach

We start with the assumption that all target domains are mixtures of our source domains.[1] Intuitively, these mixtures should give higher probability mass to more similar source domains. This raises the question of how to measure the similarity between domains. Our method uses multiple complementary similarity measures between the target and each source. We feed these similarity measures into a regression model which learns how domain dissimilarities hurt parse accuracy. Thus, to parse a target domain, we need only find the input that maximizes the regression function — that is, the highest scoring mixture of source domains. Our system is similar to Ravi et al. (2008) in that both use regression to predict f-scores and some of the features are related.

3.1 Features

Our features are designed to help the regression model determine if a particular source domain mixture is well suited for a target domain as well as the quality of a source domain mixture. While we explored a large number of features, we present here only the three that were chosen by our feature selection method (Section 6.2).

Two of our features, COSINETOP50 and UNKWORDS, are designed to approximate how similar the target domain is to a specific source domain. Only the surface form of the target text and automatic analyses are available (e.g. we can tag or parse the target text, but cannot use gold tags or trees).

Relative word frequencies are an important indicator of domain. Cosine similarity uses a spatial representation to summarize the word frequencies in a corpus as a single vector. A common method is to represent each corpus as a vector of frequencies of the k most frequent words (Schütze, 1995). This method assigns high similarity to domains with a large amount of overlap in the high-frequency vocabulary items. We experimented with several orders of magnitude for k (our feature selection method later chose $k = 50$ — see Section 6.2).

Our second feature for comparing domains, UNKWORDS, returns the percentage of words in one domain which never appear in the other domain. This can be done on the word type or token level. We opt for tokens since unknown words pose problems for parsing each time they occur. UNKWORDS provides the percentage of words in the source domain that are never seen in the target domain. Whereas COSINETOP50 examines how similar the high frequency words are from one domain, UNKWORDS tends to focus on the overlap of low frequency words.

As described, COSINETOP50 and UNKWORDS are functions only of two source domains and do not take the mixing weights of source domains into account. We experimented with several methods of incorporating mixing weights into the feature value. In practice, the one which worked best for us is to divide the mixture weight of the source domain by the raw feature value. This has the nice property that when a source is not used, the adjusted feature value is zero regardless of the raw feature value.

From pilot studies, we learned that a uniform mixture of available source domains gave strong results (further details on this in Section 5). Our last feature, ENTROPY, is intended to let the regression system leverage this and measures the entropy of the distribution over source domains. This provides a sense of uniformity.

3.2 Predicting cross-domain accuracy

For a given source domain mixture, we can create a parsing model by linearly interpolating the parsing model statistics from each source domain. The key component of our approach is a domain-aware linear regression model which predicts how well a specific parsing model will do on a given target text. The linear regressor is given values from the three features from the previous section (COSINETOP50, UNKWORDS, and ENTROPY) and returns an estimate of the f-score the parsing model would achieve the target text.

Training data for the regressor consists of examples of source domain mixtures and their actual f-scores on target texts. To produce this, we randomly sampled source domain mixtures, created parsing models for those mixtures, and then evaluated the parsing models on all of our target texts.

We used a simple technique for randomly sam-

[1] This may seem like a major limitation, but as we will show later, our method works quite well at incorporating self-trained (automatically parsed) corpora which can typically be obtained for any domain.

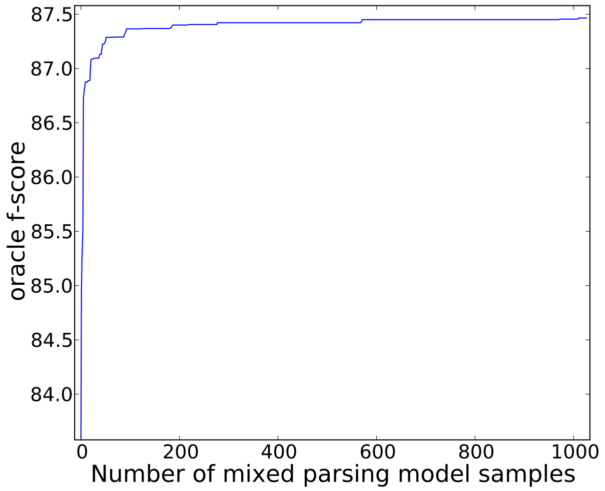

Figure 1: Cumulative oracle f-score (averaged over all target domains) as more models are randomly sampled. Most of the improvement comes the first 200 samples indicating that our samples seem to be sufficient to cover the space of good source domain mixtures.

pling source domain mixtures. First, we sample the number of source domains to use. We draw values from an exponential distribution and take their integer value until we obtain a number between two and the number of source domains. This is parametrized so that we typically only use a few corpora but still have some chance of using all of them. Once we know the number of source domains, we sample their identities uniformly at random without replacement from the list of all source domains. Finally, we sample the weights for the source domains uniformly from a simplex. The dimension of the simplex is the same as the number of source domains so we end up with a probability distribution over the sampled source domains.

In total, we sampled 1,040 source domain mixtures. We evaluated each of these source domain mixtures on the six target domains giving us 6,240 data points in total. One may be concerned that this is insufficient to cover the large space of source domain mixtures. However, we show in Figure 1 that only about 200 samples are sufficient to achieve good oracle performance[2] in practice.

Table 2: List of domains allowed in single round of evaluation. In each round, the evaluation corpus is t. $\mathbf{C}$ is the set of all target domains.

4 Evaluation

Multiple-source domain adaptation is a new task for parsing and thus some thought must be given to evaluation methodology. We describe two evaluation scenarios which differ in how foreign the target text is from our source domains. Schemas for these evaluation scenarios are shown in Table 2. Note that training and testing here refer to training and testing of our regression model, **not** the parsing models.

In the first scenario, *out-of-domain evaluation*, one target domain is completely removed from consideration and only used to evaluate proposed models at test time. The regressor is trained on training points that use any of the remaining corpora, $\mathbf{C} \setminus \{t\}$, as sources or targets. For example, if $t = \text{WSJ}$, we can train the regressor on all data points which don't use WSJ (or any self-trained corpora derived from WSJ) as a source or target domain. At test time, we are given the text of WSJ's test set. From this, our system creates a parsing model using the remaining available corpora for parsing the raw WSJ text.

This evaluation scenario is intended to evaluate how well our system can adapt to an entirely new domain with only raw text from the new domain (for example, parsing biomedical text when none is available in our list of source domains). Ideally, we would have a large number of web pages or other documents from other domains which we could use solely for evaluation. Unfortunately, at this time, only a handful of domains have been annotated with constituency structures under the same

[2] We calculate this by picking the best available model for each target domain and taking the average of their f-scores. This can pick different models for each target domain.

annotation guidelines. Instead, we hold out each hand-annotated domain, t, (including any automatically parsed corpora derived from that source domain) as a test set in a round-robin fashion.[3] For each round of the round robin we obtain an f-score and we report the mean and variance of the f-scores for each model.

The second scenario, *in-domain evaluation*, allows the target domain, t, to be used as a source domain in training but not as a target domain. This is intended to evaluate the situation where the target domain is not actually that different from our source domains. The in-domain evaluation can approximate how our system would perform when, for example, we have WSJ as a source domain and the target text is news from a source other than WSJ. Thus, our model still has to learn that WSJ and the North American News Text corpus (NANC) are good for parsing news text like WSJ without seeing any direct evaluations of the sort (WSJ and NANC can be used in models which are evaluated on all *other* corpora, though).

5 Baselines

Given that this is a new task for parsing, we needed to create baselines which demonstrate the current approaches to multiple-source domain adaptation. One approach is to take all available corpora and mix them together uniformly.[4] The UNIFORM baseline does exactly this using the available hand-built training corpora. SELF-TRAINED UNIFORM uses self-trained corpora as well. In the out-of-domain scenario, these exclude the held out domain, but in the in-domain setting, the held out domain is included. These baselines are similar to the ALL and WEIGHTED baselines in Daumé III (2007).

Another simple baseline is to use the same parsing model regardless of target domain. This is how large heterogeneous document collections are typically parsed currently. We use the WSJ corpus since it is the best single corpus for parsing all six target domains (see Table 1). We refer to this baseline as FIXED SET: WSJ. In the out-of-domain scenario, we fall back to SELF-TRAINED UNIFORM when the target domain is WSJ while the in-domain scenario uses the WSJ model throughout.

There are several interesting oracle baselines as well which serve to measure the limits of our approach. These baselines examine the resulting f-scores of models and pick the best model according to some criteria. The first oracle baseline is BEST SINGLE CORPUS which parses each corpus with the source domain that maximizes performance on the target domain. In almost all cases, this baseline selects each corpus to parse itself.

Our second oracle baseline, BEST SEEN, chooses the best parsing model from all those explored for each test set. Recall that while training the regression model in Section 3.2, we needed to explore many possible source domain mixtures to approximate the complete space of mixed parsing models. To the extent that we can fully explore the space of mixed parsing models, this baseline represents an upper bound for model mixing approaches. Since fully exploring the space of possible weightings is intractable, it is not a true upper bound. While it is theoretically possible to beat this pseudo-upper bound, (indeed, this is the mark of a good domain detection system) it is far from easy. We provide BEST SINGLE CORPUS and BEST SEEN for both in-domain and out-of-domain scenarios. The out-of-domain scenario restricts the set of possible models to those not including the target domain.

Finally, we searched for the BEST OVERALL MODEL. This is the model with the highest average f-score across all six target domains. This baseline can be thought of as an oracle version of FIXED SET: WSJ and demonstrates the limit of using a single parsing model regardless of target domain. Naturally, the very nature of this baseline places it only in the in-domain evaluation scenario. Since it was able to select the model according to f-scores on our six target domains, its performance on domains outside that set is not guaranteed.

To provide a better sense of the space of mixed parsing models, we also provide the WORST SEEN baseline which picks the worst model available for a specific target corpus.[5]

[3] Thus, the schemas in Table 2 are schemas for each round.

[4] Accounting for size so that the larger corpora don't overwhelm the smaller ones.

[5] This turns out to be GENIA for all corpora other than GENIA and SWBD when the target domain is GENIA.

6 Experiments

Our experiments use the Charniak (2000) generative parser. We describe the corpora used in our nine source and six target domains in Section 6.1. In Section 6.2, we provide a greedy strategy for picking features to include in our regression model. The results of our experiments are in Section 6.3.

6.1 Corpora

We aimed to include as many different domains as possible annotated under compatible schemes. We also tried to include human-annotated corpora and automatically labeled corpora (self-trained corpora as in McClosky et al. (2006a) which have been shown to work well across domains). Our final set includes text from news (WSJ, NANC), broadcast news (ETT), literature (BROWN, GUTENBERG), biomedical (GENIA, MEDLINE), spontaneous speech (SWBD), and the British National Corpus (BNC). In our experiments, self-trained corpora cannot be used as target domains since we lack gold annotations and BNC is not used as a source domain due to its size. An overview of our corpora is shown in Table 3.

We use news articles portion of the Wall Street Journal corpus (WSJ) from the Penn Treebank (Marcus et al., 1993) in conjunction with the self-trained North American News Text Corpus (NANC, Graff (1995)). The English Translation Treebank, ETT (Bies, 2007), is the translation[6] of broadcast news in Arabic. For literature, we use the BROWN corpus (Francis and Kučera, 1979) and the same division as (Gildea, 2001; Bacchiani et al., 2006; McClosky et al., 2006b). We also use raw sentences which we downloaded from Project Gutenberg[7] as a self-trained corpus. The Switchboard corpus (SWBD) consists of transcribed telephone conversations. While the original trees include disfluency information, we assume our speech corpora have had speech repairs excised (e.g. using a system such as Johnson et al. (2004)). Our biomedical data comes from the GENIA treebank[8] (Tateisi et al., 2005), a corpus of abstracts from the Medline database.[9] We downloaded additional sentences from Medline for our self-trained MEDLINE corpus. Unlike the other two self-trained corpora, we include two versions of MEDLINE. These differ on whether they were parsed using GENIA or WSJ as a base model to study the effect on cross-domain performance. Finally, we use a small number of sentences from the British National Corpus (BNC) (Foster and van Genabith, 2008).[10] The sentences were chosen randomly, so each one is potentially from a different domain. On the other hand, BNC can be thought of as its own domain in that it contains significant lexical differences from the American English used in our other corpora.

We preprocessed the corpora to standardize many of the annotation differences. Thus, our results on them may be slightly different than other works on these corpora. Nevertheless, these changes should not significantly impact overall the performance.

6.2 Feature selection

While our final model uses only three features, we considered many other possible features (not described due to space constraints). In order to explore these without hill climbing on our test data, we created a round-robin tuning scenario. Since the out-of-domain evaluation scenario holds out one target domain, this gives us six test evaluation rounds. For each of these six rounds, we hold out one of the remaining five target domains for tuning. This gives us 30 tuning evaluation rounds and we pick our features to optimize our aggregate performance over all of them. A model that performs well in this situation has proven that it has useful features which transfer to unknown target domains.

The next step is to determine the loss function to minimize. Our primary guide is *oracle f-score loss* which we determine as follows. We take all test data points (i.e. mixed parsing models evaluated on the target domain) and predict their f-scores with our model. In particular for this measure, we are interested in the point with the highest predicted f-score. We take its actual f-score which we call the *candidate f-score*. When tuning, we know the true f-scores of all test points. The difference between the highest f-score (the oracle f-score for

[6] The transcription and translation were done by humans.

this dataset) and the candidate f-score is the oracle f-score loss. Ties need to be handled correctly to avoid degenerate models.[11] If there is a tie for highest predicted f-score, the candidate f-score is the one with the *lowest* actual f-score. This approach is conservative but ensures that regression models which give everything the same predicted f-score do not receive zero oracle f-score loss.

Armed with a tuning regime and a loss function, we created a procedure to pick the combination of features to use. We used a parallelized best-first search procedure. At each round, it expanded the current best set of features by adding or removing each feature where 'best' was determined by the loss function. We explored over 6,000 settings, though the best setting of (UNKWORDS, COSINETOP50, ENTROPY) was found within the first 200 settings explored. The best setting obtains an oracle f-score loss of 0.37 and a root mean squared error of 0.48 — these numbers are quite low and show the high accuracy of our regression model (similar to those in Ravi et al. (2008)). Additionally, the features are complementary in that UNKWORDS focuses on low frequency words whereas COSINETOP50 looks only at high frequency words and ENTROPY functions as a regularizer.

6.3 Results

We present an overview of our final results for out-of-domain and in-domain evaluation in Table 4. The results include the f-score macro-averaged over the six target domains and their standard deviation.

In both situations, the FIXED SET: WSJ baseline performs fairly poorly. Not surprisingly, assuming all of our target domains are close enough to WSJ works badly for our set of target domains and it does particularly poorly on SWBD and GENIA. On average, the UNIFORM baseline does slightly better for out-of-domain and over 3% better for in-domain. UNIFORM actually does fairly well on out-of-domain except on GENIA. In general, using more source domains is better which partially explains the success of UNIFORM. This seems to be the case since even if a source domain is terribly mismatched with the target domain, it may still be able to fill in some holes left by the other source domains. Of course, if it overpowers more relevant domains, performance may suffer. The SELF-TRAINED UNIFORM baseline uses even more source domains as well as the largest ones. In both scenarios, this dramatically improves performance and is the second best non-oracle system. This baseline provides more evidence as to the power of self-training for improving parser adaptation. If we excluded all self-trained corpora, our performance on this task would be substantially worse. We believe the self-trained corpora are beneficial in this task since they help reduce data sparsity of smaller corpora. The BEST SINGLE CORPUS baseline is poor in the out-of-domain scenario primarily because the actual best single corpus is excluded by the task specification in most cases. When we move to in-domain, this baseline improves

[11] For example, regression models which assign every parsing model the same f-score.

Oracle	Baseline or model	Average f-score
●	Worst seen	62.0 ± 6.1
●	Best single corpus	81.0 ± 2.9
	Fixed set: WSJ	81.0 ± 3.5
	Uniform	81.4 ± 3.6

	Our model	84.0 ± 2.5
●	Best seen	84.3 ± 2.6

(a) Out-of-domain evaluation

Oracle	Baseline or model	Average f-score
	Fixed set: WSJ	82.0 ± 4.8
	Uniform	85.4 ± 2.4
●	Best single corpus	85.6 ± 2.9
	Self-trained uniform	86.1 ± 2.0
●	Best overall model	86.2 ± 1.9
	Our model	86.9 ± 2.4
●	Best seen	87.5 ± 2.1

(b) In-domain evaluation

Table 4: Baselines and final results for the two multiple-source domain adaptation evaluation scenarios. Results include f-scores, macro-averaged over all six target domains and their standard deviations.

but is still worse than SELF-TRAINED UNIFORM on average. It beats SELF-TRAINED UNIFORM primarily on WSJ, SWBD, and GENIA indicating that these three domains are best when not diluted by others. By definition, the WORST SEEN baseline does terribly, almost 20% worse then BEST SINGLE CORPUS.

Our model is the best non-oracle system for both evaluation scenarios. For out-of-domain evaluation, our system is only 0.3% worse than the BEST SEEN models for each target domain. For the in-domain scenario, we are within 0.6% of the BEST SEEN models. For a sense of scale, our out-of-domain and in-domain f-scores on WSJ are 83.1% and 89.8% respectively. Both numbers are quite close to the BEST SEEN baseline. Additionally, our model is 0.7% better than the BEST OVERALL MODEL. Recall that the BEST OVERALL MODEL is the single model with the best performance across all six target domains.[12] By beating this baseline, we show that there is value in customizing parsing models to the target domain. It is also interesting that the BEST OVERALL MODEL is only marginally better than SELF-TRAINED UNIFORM. Without any further information about the target corpus, an uninformed prior appears best.

7 Discussion

We have shown that for both out-of-domain and in-domain evaluations, our system is well adapted to predicting the effects of domain divergence on parsing accuracy. Using the parsing model with the highest predicted f-score leads to great performance in practice. There is a substantial benefit to doing this over existing approaches (using the same model for all domains or mixing all training data together uniformly). Creating a number of domain-specific models and mixing them together as needed is a viable approach.

One can think of our system as trying to estimate document-level context. Our representation of this context is simply a distribution over our source domains, but one can imagine more complex options such as a high-dimensional vector space. Additionally, our model separates domain and syntax estimation, but a future direction is to learn these jointly. This would combine our work with (Daumé III, 2007; Finkel and Manning, 2009).

We have focused on the Charniak (2000) parser, the first stage in the two stage Charniak and Johnson (2005) reranking parser. Applying our methods to other generative parsers (such as (Collins, 1999; Petrov and Klein, 2007)) is trivial, but it is less clear how our methods can be applied to the discriminative reranker component of the two stage parser. One avenue of approach is to incorporate the domain representation into the feature space, as in Daumé III (2007) but with more complex domain information.

Acknowledgments

This work was performed while the first author was at Brown and supported by DARPA GALE contract HR0011-06-2-0001. We would like to thank the BLLIP team and our anonymous reviewers for their comments.

[12] Somewhat surprisingly, the best overall model uses almost entirely self-trained corpora consisting of 9.5% GUTENBERG, 60.3% NANC, 26.0% MEDLINE (by GENIA), and 4.2% SWBD.

Abstract

This paper investigates using prosodic information in the form of ToBI break indexes for parsing spontaneous speech. We revisit two previously studied approaches, one that hurt parsing performance and one that achieved minor improvements, and propose a new method that aims to better integrate prosodic breaks into parsing. Although these approaches can improve the performance of basic probabilistic context free grammar (PCFG) parsers, they all fail to produce fine-grained PCFG models with latent annotations (PCFG-LA) (Matsuzaki et al., 2005; Petrov and Klein, 2007) that perform significantly better than the baseline PCFG-LA model that does not use break indexes, partially due to mis-alignments between automatic prosodic breaks and true phrase boundaries. We propose two alternative ways to restrict the search space of the prosodically enriched parser models to the n-best parses from the baseline PCFG-LA parser to avoid egregious parses caused by incorrect breaks. Our experiments show that all of the prosodically enriched parser models can then achieve significant improvement over the baseline PCFG-LA parser.

1 Introduction

Speech conveys more than a sequence of words to a listener. An important additional type of information that phoneticians investigate is called prosody, which includes phenomena such as pauses, pitch, energy, duration, grouping, and emphasis. For a review of the role of prosody in processing spoken language, see (Cutler et al., 1997). Prosody can help with the disambiguation of lexical meaning (via accents and tones) and sentence type (e.g., yes-no question versus statement), provide discourse-level information like focus, prominence, and discourse segment, and help a listener to discern a speaker's emotion or hesitancy, etc. Prosody often draws a listener's attention to important information through contrastive pitch or duration patterns associated words or phrases. In addition, prosodic cues can help one to segment speech into chunks that are hypothesized to have a hierarchical structure, although not necessarily identical to that of syntax. This suggests that prosodic cues may help in the parsing of speech inputs, the topic of this paper.

Prosodic information such as pause length, duration of words and phones, pitch contours, energy contours, and their normalized values have been used in speech processing tasks like sentence boundary detection (Liu et al., 2005). In contrast, other researchers use linguistic encoding schemes like ToBI (Silverman et al., 1992), which encodes tones, the degree of juncture between words, and prominence symbolically. For example, a simplified ToBI encoding scheme uses the symbol 4 for major intonational breaks, p for hesitation, and 1 for all other breaks (Dreyer and Shafran, 2007). In the literature, there have been several attempts to integrate prosodic information to improve parse accuracy of speech transcripts. These studies have used either quantized acoustic measurements of prosody or automatically detected break indexes.

Gregory et al. (2004) attempted to integrate quantized prosodic features as additional tokens in the same manner that punctuation marks are added into text. Although punctuation marks can significantly improve parse accuracy of newswire text, the quantized prosodic tokens were found harm-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 37–45,
Los Angeles, California, June 2010.

ful to parse accuracy when inserted into human-generated speech transcripts of the Switchboard corpus. The authors hypothesized that the inserted pseudo-punctuation break n-gram dependencies in the parser model, leading to lower accuracies. However, another possible cause is that the prosody has not been effectively utilized due to the fact that it is overloaded; it not only provides information about phrases, but also about the state of the speaker and his/her sentence planning process. Hence, the prosodic information may at times be more harmful than helpful to parsing performance.

In a follow-on experiment, Kahn et al. (2005), instead of using raw quantized prosodic features, used three classes of automatically detected ToBI break indexes (1, 4, or p) and their posteriors. Rather than directly incorporating the breaks into the parse trees, they used the breaks to generate additional features for re-ranking the n-best parse trees from a generative parsing model trained without prosody. They were able to obtain a significant 0.6% improvement on Switchboard over the generative parser, and a more modest 0.1% to 0.2% improvement over the reranking model that also utilizes syntactic features.

Dreyer and Shafran (2007) added prosodic breaks into a generative parsing model with latent variables. They utilized three classes of ToBI break indexes (1, 4, and p), automatically predicted by the approach described in (Dreyer and Shafran, 2007; Harper et al., 2005). Breaks were modeled as a sequence of observations parallel to the sentence and each break was generated by the preterminal of the preceding word, assuming that the observation of a break, b, was conditionally independent of its preceding word, w, given preterminal X:

$$P(w, b|X) = P(w|X)P(b|X) \quad (1)$$

Their approach has advantages over (Gregory et al., 2004) in that it does not break n-gram dependencies in parse modeling. It also has disadvantages in that the breaks are modeled by preterminals rather than higher level nonterminals, and thus cannot directly affect phrasing in a basic PCFG grammar. However, they addressed this independence drawback by splitting each nonterminal into latent tags so that the impact of prosodic breaks could be percolated into the phrasing process through the interaction of latent tags. They achieved a minor 0.2% improvement over their baseline model without prosodic cues and also found that prosodic breaks can be used to build more compact grammars.

In this paper, we re-investigate the models of (Gregory et al., 2004) and (Dreyer and Shafran, 2007), and propose a new way of modeling that can potentially address the shortcomings of the two previous approaches. We also attribute part of the failure or ineffectiveness of the previously investigated approaches to errors in the quantized prosodic tokens or automatic break indexes, which are predicted based only on acoustic cues and could misalign with phrase boundaries. We illustrate that these prosodically enriched models are in fact highly effective if we systematically eliminate bad phrase and hesitation breaks given their projection onto the reference parse trees. Inspired by this, we propose two alternative rescoring methods to restrict the search space of the prosodically enriched parser models to the n-best parses from the baseline PCFG-LA parser to avoid egregious parse trees. The effectiveness of our rescoring method suggests that the reranking approach of (Kahn et al., 2005) was successful not only because of their prosodic feature design, but also because they restrict the search space for reranking to n-best lists generated by a syntactic model alone.

2 Experimental Setup

Due to our goal of investigating the effect of prosodic information on the accuracy of state of the art parsing of conversational speech, we utilize both Penn Switchboard (Godfrey et al., 1992) and Fisher treebanks (Harper et al., 2005; Bies et al., 2006), for which we also had automatically generated break indexes from (Dreyer and Shafran, 2007; Harper et al., 2005)[1]. The Fisher treebank is a higher quality parsing resource than Switchboard due to its greater use of audio and refined specifications for sentence segmentation and disfluency markups, and so we utilize its eval set for our parser evaluation; the first 1,020 trees (7,184 words) were used for development and the remaining 3,917 trees (29,173 words) for evaluation. We utilized the Fisher dev1 and dev2 sets containing 16,519 trees (112,717 words) as the main training data source and used the Penn Switchboard

[1] A small fraction of words in the Switchboard treebank could not be aligned with the break indexes that were produced based on a later refinement of the transcription. We chose not to alter the Switchboard treebank, so in cases of missing break values, we heuristically added break *1* to words in the middle of a sentence and *4* to words that end a sentence.

treebank containing 110,504 trees (837,863 words) as an additional training source to evaluate the effect of training data size on parsing performance. The treebank trees are normalized by downcasing all terminal strings and deleting punctuation, empty nodes, and nonterminal-yield unary rules that are not related to edits.

We will compare[2] three prosodically enriched PCFG models described in the next section, with a baseline PCFG parser. We will also utilize a state of the art PCFG-LA parser (Petrov and Klein, 2007; Huang and Harper, 2009) to examine the effect of prosodic enrichment[3]. Unlike (Kahn et al., 2005), we do not remove EDITED regions prior to parsing because parsing of EDITED regions is likely to benefit from prosodic information. Also, parses from all models are compared with the gold standard parses in the Fisher evaluation set using SParseval bracket scoring (Harper et al., 2005; Roark et al., 2006) without flattening the EDITED constituents.

3 Methods of Integrating Breaks

Rather than using quantized raw acoustic features as in (Gregory et al., 2004), we use automatically generated ToBI break indexes as in (Dreyer and Shafran, 2007; Kahn et al., 2005) as the prosodic cues, and investigate three alternative methods of modeling prosodic breaks. Figure 1 shows parse trees for the four models for processing the spontaneous speech transcription *she's she would do*, where the speaker hesitated after saying *she's* and then resumed with another utterance *she would do*. Each word input into the parser has an associated break index represented by the symbol 1, 4, or p enclosed in asterisks indicating the break after the word. The automatically detected break *4* after the contraction is a strong indicator of an intonational phrase boundary that might provide helpful information for parsing if modeled appropriately. Figure 1 (a) shows the reference parse tree (thus the name REGULAR) where the break indexes are not utilized.

The first method to incorporate break indexes, BRKINSERT, shown in Figure 1 (b), treats the *p* and *4* breaks as tokens, placing them under the highest nonterminal nodes so that the order of words and breaks remain unchanged in the terminals. This is similar to (Gregory et al., 2004), except that automatically generated ToBI breaks are used rather than quantized raw prosodic tokens.

(a) REGULAR (b) BRKINSERT

(c) BRKPOS (d) BRKPHRASE

Figure 1: Modeling Methods

The second method, BRKPOS, shown in Figure 1 (c), treats breaks as a sequence of observations parallel to the words in the sentence as in (Dreyer and Shafran, 2007). The dotted edges in Figure 1 (c) represent the relation between preterminals and prosodic breaks, and we call them *prosodic rewrites*, with analogy to grammar rewrites and lexical rewrites. The generation of words and prosodic breaks is assumed to be conditionally independent given the preterminal, as in Equation 1.

The third new method, BRKPHRASE, shown in Figure 1 (d), also treats breaks as a sequence of observations parallel to the sentence; however, rather than associating the prosodic breaks with the preterminals, each is generated by the highest nonterminal (including preterminal) in the parse tree that covers the preceding word as the right-most terminal. The observation of break, b, is assumed to be conditionally independent of grammar or lexical rewrite, r, given the nonterminal X:

$$P(r, b|X) = P(r|X)P(b|X) \qquad (2)$$

The relation is indicated by the dotted edges in Figure 1 (d), and it is also called a *prosodic rewrite*. The potential advantage of BRKPHRASE is that it does not break or fragment n-gram dependencies of the grammar rewrites, as in the BRKINSERT method, and it directly models the dependency between breaks and phrases, which the BRKPOS method explicitly lacks.

4 Model Training

Since automatically generated prosodic breaks are incorporated into the parse trees deterministi-

[2] We use Bikel's randomized parsing evaluation comparator to determine the significance ($p < 0.005$) of the difference between two parsers' outputs.

[3] Due to the randomness of parameter initialization in the learning of PCFG-LA models with increasing numbers of latent tags, we train each latent variable grammar with 10 different seeds and report the average F score on the evaluation set.

cally for all of the three enrichment methods (BRKINSERT, BRKPOS, and BRKPHRASE), training a basic PCFG is straightforward; we simply pull the counts of grammar rules, lexical rewrites, or prosodic rewrites from the treebank and normalize them to obtain their probabilities.

As is well known in the parsing community, the basic PCFG does not provide state-of-the-art performance due to its strong independence assumptions. We can relax these assumptions by explicitly incorporating more information into the conditional history, as in Charniak's parser (Charniak, 2000); however, this would require sophisticated engineering efforts to decide what to include in the history and how to smooth probabilities appropriately due to data sparsity. In this paper, we utilize PCFG-LA models (Matsuzaki et al., 2005; Petrov and Klein, 2007) that split each nonterminal into a set of latent tags and learn complex dependencies among the latent tags automatically during training. The resulting model is still a PCFG, but it is probabilistically context free on the latent tags, and the interaction among the latent tags is able to implicitly capture higher order dependencies among the original nonterminals and observations. We follow the approach in (Huang and Harper, 2009) to train the PCFG-LA models.

5 Parsing

In a basic PCFG without latent variables, the goal of maximum probability parsing is to find the most likely parse tree given a sentence based on the grammar. Suppose our grammar is binarized (so it contains only unary and binary grammar rules). Given an input sentence $w_1^n = w_1, w_2, \cdots, w_n$, the inside probability, $P(i, j, X)$, of the most likely sub-tree that is rooted at nonterminal X and generates subsequence w_i^j can be computed recursively by:

$$P(i,j,X) = \max(\max_{Y} P(i,j,Y)P(X \to Y),$$
$$\max_{i<k<j,Y,Z} P(i,k,Y)P(k+1,j,Z)P(X \to Y\,Z)) \quad (3)$$

Backtracing the search process then returns the most likely parse tree for the REGULAR grammar.

The same parsing algorithm can be directly applied to the BRKINSERT grammar given that the break indexes are inserted appropriately into the input sentence as additional tokens. Minor modification is needed to extend the same parsing algorithm to the BRKPOS grammar. The only difference is that the inside probability of a preterminal is set according to Equation 1. The rest of the algorithm proceeds as in Equation 3.

However, parsing with the BRKPHRASE grammar is more complicated because whether a nonterminal generates a break or not is determined by whether it is the highest nonterminal that covers the preceding word as its right-most terminal. In this case, the input observation also contains a sequence of break indexes $b_1^n = b_1, b_2, \cdots, b_n$ that is parallel to the input sentence $w_1^n = w_1, w_2, \cdots, w_n$. Let $P(i, j, X, 0)$ be the probability of the most likely sub-tree rooted at nonterminal X over span (i, j) that generates word sequence w_i^j, as well as break index sequence b_i^{j-1}, excluding b_j. According to the independence assumption in Equation 2, with the addition of prosodic edge $X \to b_j$, the same sub-tree also has the highest probability, denoted by $P(i, j, X, 1)$, of generating word sequence w_i^j together with the break index sequence b_i^j. Thus we have:

$$P(i,j,X,1) = P(i,j,X,0)P(b_j|X) \quad (4)$$

The structural constraint that a break index is only generated by the highest nonterminal that covers the preceding word as the right-most terminal enables a dynamic programming algorithm to compute $P(i, j, X, 0)$ and thus $P(i, j, X, 1)$ efficiently. If the sub-tree (without the prosodic edge that generates b_j) over span (i, j) is constructed from a unary rule rewrite $X \to Y$, then the root nonterminal Y of some best sub-tree over the same span (i, j) can not generate break b_j because it has a higher nonterminal X that also covers word w_j as its right-most terminal. If the sub-tree is constructed from a binary rule rewrite $X \to Y Z$, then the root nonterminal Y of some best sub-tree over some span (i, k) will generate break b_k because Y is the highest nonterminal that covers word w_k as the right-most terminal[4]. In contrast, the root nonterminal Z of some best sub-tree over some span $(k+1, j)$ can not generate break b_j because Z has a higher nonterminal X that also covers word w_j as its right-most terminal. Hence,

[4] Use of left-branching is required for the BRKPHRASE method to ensure that the prosodic breaks are associated with the original nonterminals, not intermediate nonterminals introduced by binarization. Binarization is needed for efficient parametrization of PCFG-LA models and left- versus right-branching binarization does not significantly affect model performance; hence, we use left-branching for all models.

$P(i,j,X,1)$ and $P(i,j,X,0)$ can be computed recursively by Equation 4 above and Equation 5 below:

$$P(i,j,X,0) = \max(\max_{Y} P(i,j,Y,0)P(X \to Y), \max_{i<k<j,Y,Z} P(i,k,Y,1)P(k+1,j,Z,0)P(X \to Y\,Z)) \quad (5)$$

Although dynamic programming algorithms exist for maximum probability decoding of basic PCFGs without latent annotations for all four methods, it is an NP hard problem to find the most likely parse tree using PCFG-LA models. Several alternative decoding algorithms have been proposed in the literature for parsing with latent variable grammars. We use the best performing max-rule-product decoding algorithm, which searches for the best parse tree that maximizes the product of the posterior rule (either grammar, lexical, or prosodic) probabilities, as described in (Petrov and Klein, 2007) for our models with latent annotations and extend the dynamic parsing algorithm described in Equation 5 for the BRKPHRASE grammar with latent annotations.

6 Results on the Fisher Corpus

6.1 Prosodically Enriched Models

Table 1 reports the parsing accuracy of the four basic PCFGs without latent annotations when trained on the Fisher training data. All of the grammars have a low F score of around 65% due to the overly strong and incorrect independence assumptions. We observe that the BRKPHRASE grammar benefits most from breaks, significantly improving the baseline accuracy from 64.9% to 67.2%, followed by the BRKINSERT grammar, which at 66.2% achieves a smaller improvement. The BRKPOS grammar benefits the least among the three because breaks are attached to the preterminals and thus have less impact on phrasing due to the independence assumptions in the basic PCFG. In contrast, both the BRKPHRASE and BRKINSERT methods directly model the relationship between breaks and phrase boundaries through governing nonterminals; however, the BRKPHRASE method does not directly change any of the grammar rules in contrast to the BRKINSERT method that more or less breaks n-gram dependencies and fragments rule probabilities.

The bars labeled DIRECT in Figure 2 report the parsing performance of the four PCFG-LA models trained on Fisher. The introduction of latent annotations significantly boosts parsing accuracies, providing relative improvements ranging from 16.8% up to 19.0% when trained on Fisher training data due to the fact that the PCFG-LA models are able to automatically learn more complex dependencies not captured by basic PCFGs.

REGULAR	BRKINSERT	BRKPOS	BRKPHRASE
64.9	66.2	65.2	**67.2**

Table 1: Fisher evaluation parsing results for the basic PCFGs without latent annotations trained on the Fisher training set.

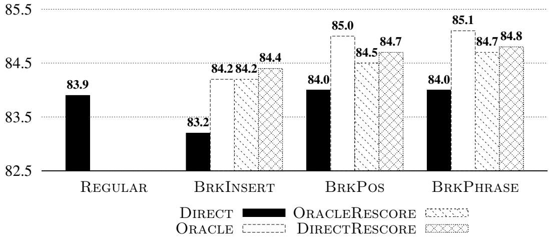

Figure 2: Parsing results on the Fisher evaluation set of the PCFG-LA models trained on the Fisher training data. The DIRECT bars represent direct parsing results for models trained and evaluated on the original data, ORACLE bars for models trained and evaluated on the modified oracle data (see Subsection 6.2), and the ORACLE-RESCORE and DIRECTRESCORE bars for results of the two rescoring approaches (described in Subsection 6.3) on the original evaluation data.

However, the prosodically enriched methods do not significantly improve upon the REGULAR baseline after the introduction of latent annotations. The BRKPHRASE method only achieves a minor insignificant 0.1% improvement over the REGULAR baseline; whereas, the BRKINSERT method is a significant 0.7% worse than the baseline. Similar results for BRKINSERT were reported in (Gregory et al., 2004), where they attributed the degradation to the fact that the insertion of the prosodic "punctuation" breaks the n-gram dependencies. Another possible cause is that the insertion of "bad" breaks that do not align with true phrase boundaries hurts performance more than the benefits gained from "good" breaks due to the tightly integrated relationship between phrases and breaks. For the BRKPOS method, the impact of break indexes is implicitly percolated to the nonterminals through the interaction among latent tags, as discussed in (Dreyer and Shafran, 2007), and its performance may thus be less affected by the "bad" breaks. With latent annotations (in contrast to the basic PCFG), the model is now significantly better than BRKINSERT and is on par with BRKPHRASE.

6.2 Models with Oracle Breaks

In order to determine whether "bad" breaks limit the improvements in parsing performance from prosodic enrichment, we conducted a simple oracle experiment where all *p* and *4* breaks that did not align with phrase boundaries in the treebank were systematically converted to *1* breaks[5]. When trained and evaluated on this modified oracle data, all three prosodically enriched latent variable models improve by about 1% and were then able to achieve significant improvements over the REGULAR PCFG-LA baseline, as shown by the bars labeled ORACLE in Figure 2. It should be noted, however, that the BRKINSERT method is much less effective than the other two methods in the oracle experiment, suggesting that broken n-gram dependencies affect the model in addition to the erroneous breaks.

6.3 N-Best Re-Scoring

As mentioned previously, prosody does not only provide information about phrases, but also about the state of the speaker and his/her sentence planning process. Given that our break detector utilizes only acoustic knowledge to predict breaks, the recognized *p* and *4* breaks may not correctly reflect hesitations and phrase boundaries. Incorrectly recognized breaks could hurt parsing more than the benefit brought from the correctly recognized breaks, as demonstrated by superior performance of the prosodically enhanced models in the oracle experiment. We next describe two alternative methods to make better use of automatic breaks.

In the first approach, which is called ORACLERESCORE, we train the prosodically enhanced grammars on cleaned-up break-annotated training data, where misclassified *p* and *4* breaks are converted to *1* breaks (as in the oracle experiment). If these grammars were used to directly parse the test sentences with automatically detected (unmodified) breaks, the results would be quite poor due to mismatch between the training and testing conditions. However, we can automatically bias against potentially misclassified *p* and *4* breaks if we utilize information provided by n-best parses from the baseline REGULAR PCFG-LA grammar. For each hypothesized parse tree in the n-best list, the *p* and *4* breaks that do not align with the phrase boundaries of the hypothesized parse tree are converted to *1* breaks, and then a new score is computed using the product of posterior rule probabilities[6], as in the max-rule-product criterion, for the hypothesized parse tree using the grammars trained on the cleaned-up training data. In this approach, we convert the posterior probability, $P(T|W,B)$, of parse tree T given words W and breaks B to $P(B'|W,B)P(T|W,B')$, where B' is the new break sequence constrained by T, and simplify it to $P(T|W,B')$, assuming that conversions to a new sequence of breaks as constrained by a hypothesized parse tree are equally probable given the original sequence of breaks. We consider this to be a reasonable assumption for a small n-best ($n = 50$) list with reasonably good quality.

In the second approach, called DIRECTRESCORE, we train the prosodically enhanced PCFG-LA models using unmodified, automatic breaks, and then use them to rescore the n-best lists produced by the REGULAR PCFG-LA model to avoid the poorer parse trees caused by fully trusting automatic break indexes. The size of the n-best list should not be too small or too large, or the results would be like directly parsing with REGULAR when $n = 1$ or with the prosodically enriched model when $n \to \infty$.

The ORACLERESCORE and DIRECTRESCORE bars in Figure 2 report the performance of the prosodically enriched models with the corresponding rescoring method. Both methods use the same 50-best lists produced by the baseline REGULAR PCFG-LA model using the max-rule-product criterion. Both rescoring methods produce significant improvements in the performance of all three prosodically enriched PCFG-LA models. The previously ineffective (0.7% worse than REGULAR) BRKINSERT PCFG-LA model is now 0.3% and 0.5% better than the REGULAR baseline using the ORACLERESCORE and DIRECTRESCORE approaches, respectively. The best performing BRKPOS and BRKPHRASE rescoring models are 0.6-0.9% better than the REGULAR baseline. It is interesting to note that rescoring with models trained on cleaned up prosodic breaks is somewhat poorer

[5] Other sources of errors include misclassification of *p* breaks as *1* or *4* and misclassification of *4* breaks as *1* or *p*. Although these errors are not repaired in the oracle experiment, fixing them could potentially provide greater gains.

[6] The product of posterior rule probabilities of a parse tree is more suitable for rescoring than the joint probability of the parse tree and the observables (words and breaks) because the breaks are possibly different for different trees.

than models trained using all automatic breaks.

7 Models with Augmented Training Data

Figure 3 reports the evaluation results for models that are trained on the combination of Fisher and Switchboard training data. With the additional Switchboard training data, the nonterminals can be split into more fine-grained latent tags, enabling the learning of deeper dependencies without over-fitting the limited sized Fisher training data. This improved all models by at least 2.6% absolute. Note also that the patterns observed for models trained using the larger training set are quite similar to those from using the smaller training set in Figure 2. The prosodically enriched models all benefit significantly from the oracle breaks and from the rescoring methods. The BrkPos and BrkPhrase methods, with the additional training data, also achieve significant improvements over the Regular baseline without rescoring.

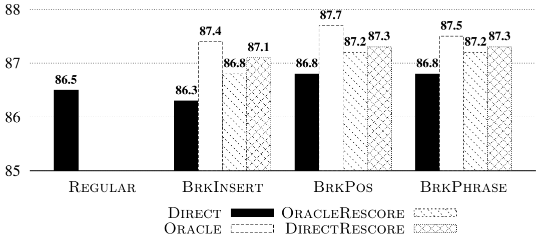

Figure 3: Parsing results on the Fisher evaluation set of the PCFG-LA models trained on the Fisher+Switchboard training data.

8 Error Analysis

In this section, we compare the errors of the BrkPhrase PCFG-LA model and the DirectRescore approach for that model to each other and to the baseline PCFG-LA model without prosodic breaks. All models are trained and tested on Fisher as in Section 6. The results using other prosodically enhanced PCFG-LA models and their rescoring alternatives show similar patterns.

Figure 4 depicts the difference in F scores between BrkPhrase and Regular and between BrkPhrase+DirectRescore and Regular on a tree-by-tree basis in a 2D plot. Each quadrant also contains +/– signs roughly describing how much BrkPhrase+DirectRescore is better (+) or worse (–) than BrkPhrase and a pair of numbers (a, b), in which a represents the percentage of sentences in that quadrant containing *p* or *4* breaks that do not align with true phrase boundaries, and b represents the percentage of such *p* and *4* breaks among the total number of *p* and *4* breaks in that quadrant.

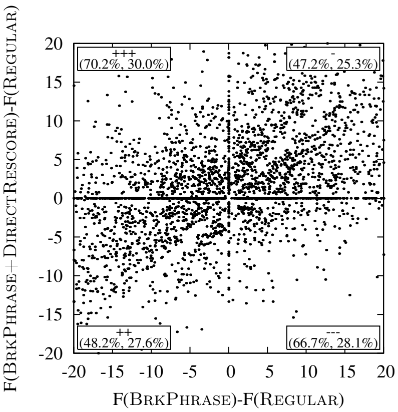

Figure 4: 2D plot of the difference in F scores between BrkPhrase and Regular and between BrkPhrase+DirectRescore and Regular, on a tree-by-tree basis, where each dot represents a test sentence. Each quadrant also contains +/– signs roughly describing how much BrkPhrase+DirectRescore is better (+) or worse (–) than BrkPhrase and a pair of numbers (a, b), in which a represents the percentage of sentences in that quadrant containing *p* or *4* breaks that do not align with true phrase boundaries, and b represents the percentage of such *p* and *4* breaks among the total number of *p* and *4* breaks in that quadrant.

Each dot in the top-right quadrant represents a test sentence for which both BrkPhrase and BrkPhrase+DirectRescore produce better trees than the baseline Regular PCFG-LA model. The BrkPhrase+DirectRescore approach is on average slightly worse than the BrkPhrase method (hence the single minus sign), although it also often produces better parses than BrkPhrase alone. In contrast, the BrkPhrase+DirectRescore approach on average makes many fewer errors than BrkPhrase (hence + +) as can be observed in the bottom-left quadrant, where both approaches produce worse parse trees than the Regular baseline. The most interesting quadrant is on the top-left where the BrkPhrase approach always produces worse parses than the Regular baseline while the BrkPhrase+DirectRescore approach is able to avoid these errors while producing better parses than the baseline (hence + + +). Although the BrkPhrase+DirectRescore approach can also produce worse parses than Regular, as in the bottom-right quadrant (hence – – –), altogether the quadrants suggest that, by restricting the search space to the n-best lists produced by the baseline REGULAR parser, the BRKPHRASE+DIRECTRESCORE approach is able to avoid many bad parses trees at the expense of somewhat poorer parses in cases when BRKPHRASE is able to benefit from the full search space.

The reader should note that the top-left quadrant of Figure 4 has the highest percentage (70.2%) of sentences with "bad" *p* and *4* breaks and the highest percentage (30.0%) of such "bad" breaks among all breaks. This evidence supports our argument that "bad" breaks are harmful to parsing performance and some parse errors caused by misleading breaks can be resolved by limiting the search space of the prosodically enriched models to the n-best lists produced by the baseline REGULAR parser. However, the significant presence of "bad" breaks in the top-right quadrant also suggests that the prosodically enriched models are able to produce better parses than the baseline despite the presence of "bad" breaks, probably because the models are trained on the mixture of both "good" and "bad" breaks and are able to somehow learn to use "good" breaks while avoiding being misled by "bad" breaks.

	REGULAR	BRKPHRASE	BRKPHRASE +DIRECTRESCORE
NP	90.4	90.4	**90.9**
VP	84.7	84.7	**85.6**
S	84.4	84.3	**85.2**
INTJ	93.0	**93.4**	**93.4**
PP	76.5	76.7	**77.9**
EDITED	60.4	62.2	**63.3**
SBAR	67.2	67.0	**68.8**

Table 2: F scores of the seven most frequent non-terminals of the REGULAR, BRKPHRASE, and BRKPHRASE+DIRECTRESCORE models.

Table 2 reports the F scores of the seven most frequent phrases for the REGULAR, BRKPHRASE, and BRKPHRASE+DIRECTRESCORE methods trained on Fisher. When comparing the BRKPHRASE method to REGULAR, the break indexes help to improve the score for edits most, followed by interjections and prepositional phrases; however, they do not improve the accuracy of any of the other phrases. The BRKPHRASE+DIRECTRESCORE approach obtains improvements on all of the major phrases.

Figure 5 (a) shows a reference parse tree of a test sentence. The REGULAR approach correctly parses the first half (omitted) of the sentence but it fails to correctly interpret the second half (as shown). The BRKPHRASE approach, in contrast, is misguided by the incorrectly classified interruption point *p* after word "has", and so produces an incorrect parse early in the sentence. The BRKPHRASE+DIRECTRESCORE approach is able to provide the correct tree given the n-best list produced by the REGULAR approach, despite the break index errors.

9 Conclusions

We have investigated using prosodic information in the form of automatically detected ToBI break indexes for parsing spontaneous speech by comparing three prosodic enrichment methods. Although prosodic enrichment improves the basic PCFGs, that performance gain disappears when latent variables are used, partly due to the impact of misclassified ("bad") breaks that are assigned to words that do not occur at phrase boundaries. However, we find that by simply restricting the search space of the three prosodically enriched latent variable parser models to the n-best parses from the baseline PCFG-LA parser, all of them attain significant improvements. Our analysis more fully explains the positive results achieved by (Kahn et al., 2005) from reranking with prosodic features and suggests that the hypothesis that inserted prosodic punctuation breaks n-gram dependencies only partially explains the negative results of (Gregory et al., 2004). Our findings from the oracle experiment suggest that integrating ToBI classification with syntactic parsing should increase the accuracy of both tasks.

Acknowledgments

We would like to thank Izhak Shafran for providing break indexes for Fisher and Switchboard and for comments on an earlier draft of this paper. This research was supported in part by NSF IIS-0703859. Using Confusion Networks for Speech Summarization

Abstract

For extractive meeting summarization, previous studies have shown performance degradation when using speech recognition transcripts because of the relatively high speech recognition errors on meeting recordings. In this paper we investigated using confusion networks to improve the summarization performance on the ASR condition under an unsupervised framework by considering more word candidates and their confidence scores. Our experimental results showed improved summarization performance using our proposed approach, with more contribution from leveraging the confidence scores. We also observed that using these rich speech recognition results can extract similar or even better summary segments than using human transcripts.

1 Introduction

Speech summarization has received increasing interest recently. It is a very useful technique that can help users to browse a large amount of speech recordings. The problem we study in this paper is extractive meeting summarization, which selects the most representative segments from the meeting transcripts to form a summary. Compared to text summarization, speech summarization is more challenging because of not only its more spontaneous style, but also word errors in automatic speech recognition (ASR) output. Intuitively the incorrect words have a negative impact on downstream summarization performance. Previous research has evaluated summarization using either the human transcripts or ASR output with word errors. Most of the prior work showed that performance using ASR output is consistently lower (to different extent) comparing to that using human transcripts no matter whether supervised or unsupervised approaches were used.

To address the problem caused by imperfect recognition transcripts, in this paper we investigate using rich speech recognition results for summarization. N-best hypotheses, word lattices, and confusion networks have been widely used as an interface between ASR and subsequent spoken language processing tasks, such as machine translation, spoken document retrieval (Chelba et al., 2007; Chia et al., 2008), and shown outperforming using 1-best hypotheses. However, studies using these rich speech recognition results for speech summarization are very limited. In this paper, we demonstrate the feasibility of using confusion networks under an unsupervised MMR (maximum marginal relevance) framework to improve summarization performance. Our experimental results show better performance over using 1-best hypotheses with more improvement observed from using confidence measure of the words. Moreover, we find that the selected summary segments are similar to or even better than those generated using human transcripts.

2 Related Work

Many techniques have been proposed for the meeting summarization task, including both unsupervised and supervised approaches. Since we use unsupervised methods in this study, we will not describe previous work using supervised approaches because of the space limit. Unsupervised meth-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 46–54,
Los Angeles, California, June 2010.

ods are simple and robust to different corpora, and do not need any human labeled data for training. MMR was introduced in (Carbonell and Goldstein, 1998) for text summarization, and was used widely in meeting summarization (Murray et al., 2005a; Xie and Liu, 2008). Latent semantic analysis (LSA) approaches have also been used (Murray et al., 2005a), which can better measure document similarity at the semantic level rather than relying on literal word matching. In (Gillick et al., 2009), the authors introduced a concept-based global optimization framework using integer linear programming (ILP), where concepts were used as the minimum units, and the important sentences were extracted to cover as many concepts as possible. They showed better performance than MMR. In a follow-up study, (Xie et al., 2009) incorporated sentence information in this ILP framework. Graph-based methods, such as LexRank (Erkan and Radev, 2004), have been originally used for extractive text summarization, where the document is modeled as a graph and sentences as nodes, and sentences are ranked according to its similarity with other nodes. (Garg et al., 2009) proposed ClusterRank, a modified graph-based method in order to take into account the conversational speech style in meetings. Recently (Lin et al., 2009) suggested to formulate the summarization task as optimizing submodular functions defined on the document's semantic graph, and showed better performance comparing to other graph-based approaches.

Rich speech recognition results, such as N-best hypotheses and confusion networks, were first used in multi-pass ASR systems to improve speech recognition performance (Stolcke et al., 1997; Mangu et al., 2000). They have been widely used in many subsequent spoken language processing tasks, such as machine translation, spoken document understanding and retrieval. Confusion network decoding was applied to combine the outputs of multiple machine translation systems (Sim et al., 2007; Matusov et al., 2006). In the task of spoken document retrieval, (Chia et al., 2008) proposed to compute the expected word counts from document and query lattices, and estimate the statistical models from these counts, and reported better retrieval accuracy than using only 1-best transcripts. (Hakkani-Tur et al., 2006) investigated using confusion networks for name entity detection and extraction and user intent classification. They also obtained better performance than using ASR 1-best output.

There is very limited previous work using more than 1-best ASR output for speech summarization. Several studies used acoustic confidence scores in the 1-best ASR hypothesis in the summarization systems (Valenza et al., 1999; Zechner and Waibel, 2000; Hori and Furui, 2003). (Liu et al., 2010) evaluated using n-best hypotheses for meeting summarization, and showed improved performance with the gain coming mainly from the first few candidates. In (Lin and Chen, 2009), confusion networks and position specific posterior lattices were considered in a generative summarization framework for Chinese broadcast news summarization, and they showed promising results by using more ASR hypotheses. We investigate using confusion networks for meeting summarization in this study. This work differs from (Lin and Chen, 2009) in terms of the language and genre used in the summarization task, as well as the summarization approaches. We also perform more analysis on the impact of confidence scores, different pruning methods, and different ways to present system summaries.

3 Summarization Approach

In this section, we first describe the baseline summarization framework, and then how we apply it to confusion networks.

3.1 Maximum Marginal Relevance (MMR)

MMR is a widely used unsupervised approach in text and speech summarization, and has been shown perform well. We chose this method as the basic framework for summarization because of its simplicity and efficiency. We expect this is a good starting point for the study of feasibility of using confusion networks for summarization. For each sentence segment S_i in one document D, its score ($MMR(i)$) is calculated using Equation 1 according to its similarity to the entire document ($Sim_1(S_i, D)$) and the similarity to the already extracted summary ($Sim_2(S_i, Summ)$).

$$MMR(i) = \lambda \times Sim_1(S_i, D) - (1 - \lambda) \times Sim_2(S_i, Summ) \tag{1}$$

where parameter λ is used to balance the two factors to ensure the selected summary sentences are relevant to the entire document (thus important), and compact enough (by removing redundancy with the currently selected summary sentences). Cosine similarity can be used to compute the similarity of two text segments. If each segment is represented as a vector, cosine similarity between two vectors (V_1, V_2) is measured using the following equation:

$$sim(V_1, V_2) = \frac{\sum_i t_{1i} t_{2i}}{\sqrt{\sum_i t_{1i}^2} \times \sqrt{\sum_i t_{2i}^2}} \qquad (2)$$

where t_i is the term weight for a word w_i, for which we can use the TFIDF (term frequency, inverse document frequency) value, as widely used in the field of information retrieval.

3.2 Using Confusion Networks for Summarization

Confusion networks (CNs) have been used in many natural language processing tasks. Figure 1 shows a CN example for a sentence segment. It is a directed word graph from the starting node to the end node. Each edge represents a word with its associated posterior probability. There are several word candidates for each position. "-" in the CN represents a NULL hypothesis. Each path in the graph is a sentence hypothesis. For the example in Figure 1, *"I HAVE IT VERY FINE"* is the best hypothesis consisting of words with the highest probabilities for each position. Compared to N-best lists, confusion networks are a more compact and powerful representation for word candidates. We expect the rich information contained in the confusion networks (i.e., more word candidates and associated posterior probabilities) can help to determine words' importance for summarization.

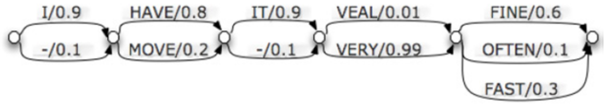

Figure 1: An example of confusion networks.

The core problems when using confusion networks under the MMR summarization framework are the definitions for S_i, D, and $Summ$, as shown in Equation 1. The extractive summary unit (for each S_i) we use is the segment provided by the recognizer. This is often different from syntactic or semantic meaningful unit (e.g., a sentence), but is a more realistic setup. Most of the previous studies for speech summarization used human labeled sentences as extraction units (for human transcripts, or map them to ASR output), which is not the real scenario when performing speech summarization on the ASR condition. In the future, we will use automatic sentence segmentation results, which we expect are better units than pause-based segmentation used in ASR. We still use a vector space model to represent each summarization unit S_i. The entire document (D) and the current selected summary ($Summ$) are formed by simply concatenating the corresponding segments S_i together. In the following, we describe different ways to represent the segments and how to present the final summary.

A. Segmentation representation

First, we construct the vector for each segment simply using all the word candidates in the CNs, without considering any confidence measure or posterior probability information. The same TFIDF computation is used as before, i.e., counting the number of times a word appears (TF) and how many documents it appears (used to calculate IDF).

Second, we leverage the confidence scores to build the vector. For the term frequency of word w_i, we calculate it by summing up its posterior probabilities $p(w_{ik})$ at each position k, that is,

$$TF(w_i) = \sum_k p(w_{ik}) \qquad (3)$$

Similarly, the IDF values can also be computed using the confidence scores. The traditional method for calculating a word's IDF uses the ratio of the total number of documents (N) and the number of documents containing this word. Using the confidence scores, we calculate the IDF values as follows,

$$IDF(w_i) = log(\frac{N}{\sum_D (\max_k p(w_{ik}))}) \qquad (4)$$

If a word w_i appears in the document, we find its maximum posterior probability among all the positions it occurs in the CNs, which is used to signal w_i's soft appearance in this document. We add these soft counts for all the documents as the denominator in Equation 4. Different from the traditional IDF calculation method, where the number of documents containing a word is an integer number, here the denominator can be any real number.

B. Confusion network pruning

The above vectors are constructed using the entire confusion networks. We may also use the pruned ones, in which the words with low posterior probabilities are removed beforehand. This can avoid the impact of noisy words, and increase the system speed as well. We investigate three different pruning methods, listed below.

- absolute pruning: In this method, we delete words if their posterior probabilities are lower than a predefined threshold, i.e., $p(w_i) < \theta$.
- max_diff pruning: First for each position k, we find the maximum probability among all the word candidates: $Pmax_k = \max_j p(w_{jk})$. Then we remove a word w_i in this position if the absolute difference of its probability with the maximum score is larger than a predefined threshold, i.e., $Pmax_k - p(w_{ik}) > \theta$.
- max_ratio pruning: This is similar to the above one, but instead of absolute difference, we use the ratio of their probabilities, i.e., $\frac{p(w_{ik})}{Pmax_k} < \theta$.

Again, for the last two pruning methods, the comparison is done for each position in the CNs.

C. Summary rendering

With a proper way of representing the text segments, we then extract the summary segments using the MMR method described in Section 3.1. Once the summary segments are selected using the confusion network input, another problem we need to address is how to present the final summary. When using the human transcripts or the 1-best ASR hypothesis for summarization, we can simply concatenate the corresponding transcripts of the selected sentence segments as the final summary for the users. However, when using the confusion networks as the representation of each sentence segment, we only know which segments are selected by the summarization system. To provide the final summary to the users, there are two choices. We can either use the best hypothesis from CNs of those selected segments as a text summary; or return the speech segments to the users to allow them to play it back. We will evaluate both methods in this paper. For the latter, in order to use similar word based performance measures, we will use the corresponding reference transcripts in order to focus on evaluation of the correctness of the selected summary segments.

4 Experiments

4.1 Corpus and Evaluation Measurement

We use the ICSI meeting corpus, which contains 75 recordings from natural meetings (most are research discussions) (Janin et al., 2003). Each meeting is about an hour long and has multiple speakers. These meetings have been transcribed, and annotated with extractive summaries (Murray et al., 2005b). The ASR output is obtained from a state-of-the-art SRI speech recognition system, including the confusion network for each sentence segment (Stolcke et al., 2006). The word error rate (WER) is about 38.2% on the entire corpus.

The same 6 meetings as in (Murray et al., 2005a; Xie and Liu, 2008; Gillick et al., 2009; Lin et al., 2009) are used as the test set in this study. Furthermore, 6 other meetings were randomly selected from the remaining 69 meetings in the corpus to form a development set. Each meeting in the development set has only one human-annotated summary; whereas for the test meetings, we use three summaries from different annotators as references for performance evaluation. The lengths of the reference summaries are not fixed and vary across annotators and meetings. The average word compression ratio for the test set is 14.3%, and the mean deviation is 2.9%. We generated summaries with the word compression ratio ranging from 13% to 18%, and only provide the best results in this paper.

To evaluate summarization performance, we use ROUGE (Lin, 2004), which has been widely used in previous studies of speech summarization (Zhang et al., 2007; Murray et al., 2005a; Zhu and Penn, 2006). ROUGE compares the system generated summary with reference summaries (there can be more than one reference summary), and measures different matches, such as N-gram, longest common sequence, and skip bigrams. In this paper, we present our results using both ROUGE-1 and

ROUGE-2 F-scores.

4.2 Characteristics of CNs

First we perform some analysis of the confusion networks using the development set data. We define two measurements:

- Word coverage. This is to verify that CNs contain more correct words than the 1-best hypotheses. It is defined as the percentage of the words in human transcripts (measured using word types) that appear in the CNs. We use word types in this measurement since we are using a vector space model and the multiple occurrence of a word only affects its term weights, not the dimension of the vector. Note that for this analysis, we do not perform alignment that is needed in word error rate measure — we do not care whether a word appears in the exact location; as long as a word appears in the segment, its effect on the vector space model is the same (since it is a bag-of-words model).

- Average node density. This is the average number of candidate words for each position in the confusion networks.

Figure 2 shows the analysis results for these two metrics, which are the average values on the development set. In this analysis we used absolute pruning method, and the results are presented for different pruning thresholds. For a comparison, we also include the results using the 1-best hypotheses (shown as the dotted line in the figure), which has an average node density of 1, and the word coverage of 71.55%. When the pruning threshold is 0, the results correspond to the original CNs without pruning.

We can see that the confusion networks include much more correct words than 1-best hypotheses (word coverage is 89.3% vs. 71.55%). When increasing the pruning thresholds, the word coverage decreases following roughly a linear pattern. When the pruning threshold is 0.45, the word coverage of the pruned CNs is 71.15%, lower than 1-best hypotheses. For node density, the non-pruned CNs have an average density of 11.04. With a very small pruning threshold of 0.01, the density decreases rapidly to 2.11. The density falls less than 2 when the threshold is 0.02, which means that for some nodes there is only one word candidate preserved after pruning (i.e., only one word has a posterior probability higher than 0.02). When the threshold increases to 0.4, the density is less than 1 (0.99), showing that on average there is less than one candidate left for each position. This is consistent with the word coverage results — when the pruning threshold is larger than 0.45, the confusion networks have less word coverage than 1-best hypotheses because even the top word hypotheses are deleted. Therefore, for our following experiments we only use the thresholds $\theta \leq 0.45$ for absolute pruning.

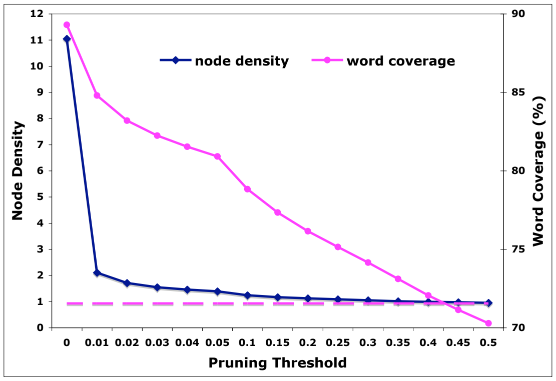

Figure 2: Average node density and word coverage of the confusion networks on the development set.

Note that the results in the figure are based on absolute pruning. We also performed analysis using the other two pruning methods described in Section 3.2. For those methods, because the decision is made by comparing each word's posterior probability with the maximum score for that position, we can guarantee that at least the best word candidate is included in the pruned CNs. We varied the pruning threshold from 0 to 0.95 for these pruning methods, and observed similar patterns as in absolute pruning for the word coverage and node density analysis. As expected, the fewer word candidates are pruned, the better word coverage and higher node density the pruned CNs have.

4.3 Summarization Results

4.3.1 Results on dev set using 1-best hypothesis and human transcripts

We generate the baseline summarization result using the best hypotheses from the confusion networks. The summary sentences are extracted using the MMR method introduced in Section 3.1. The term weighting is the traditional TFIDF value. The ROUGE-1 and ROUGE-2 scores for the baseline are listed in Table 1.

Because in this paper our task is to evaluate the summarization performance using ASR output, we generate an oracle result, where the summary extraction and IDF calculation are based on the human transcripts for each ASR segment. These results are also presented in Table 1. Comparing the results for the two testing conditions, ASR output and human transcripts, we can see the performance degradation due to recognition errors. The difference between them seems to be large enough to warrant investigation of using rich ASR output for improved summarization performance.

	ROUGE-1	ROUGE-2
Baseline: best hyp	65.60	26.83
Human transcript	69.98	33.21

Table 1: ROUGE results (%) using 1-best hypotheses and human transcripts on the development set.

4.3.2 Results on the dev set using CNs

A. Effect of segmentation representation

We evaluate the effect on summarization using different vector representations based on confusion networks. Table 2 shows the results on the development set using various input under the MMR framework. We also include the results using 1-best and human transcripts in the table as a comparison. The third row in the table uses the 1-best hypothesis, but the term weight for each word is calculated by considering its posterior probability in the CNs (denoted by "wp"). We calculate the TF and IDF values using Equation 3 and 4 introduced in Section 3.2. The other representations in the table are for the non-pruned and pruned CNs based on different pruning methods, and with or without using the posteriors to calculate term weights.

segment representation		ROUGE-1	ROUGE-2
Best hyp		65.60	26.83
Best hyp (wp)		66.83	29.84
Non-pruned CNs		66.58	28.22
Non-pruned CNs (wp)		66.47	29.27
Pruned CNs	Absolute	**67.44**	29.02
	Absolute (wp)	66.98	**29.99**
	Max_diff	67.29	28.97
	Max_diff (wp)	67.10	29.76
	Max_ratio	**67.43**	28.97
	Max_ratio (wp)	67.06	29.90
Human transcript		69.98	33.21

Table 2: ROUGE results (%) on the development set using different vector representations based on confusion networks: non-pruned and pruned, using posterior probabilities ("wp") and without using them.

In general, we find that using confusion networks improves the summarization performance comparing with the baseline. Since CNs contain more candidate words and posterior probabilities, a natural question to ask is, which factor contributes more to the improved performance? We can compare the results in Table 2 across different conditions that use the same candidate words, one with standard TFIDF, and the other with posteriors for TFIDF, or that use different candidate words and the same setup for TFIDF calculation. Our results show that there is more improvement using our proposed method for TFIDF calculation based on posterior probabilities, especially ROUGE-2 scores. Even when just using 1-best hypotheses, if we consider posteriors, we can obtain very competitive results. There is also a difference in the effect of using posterior probabilities. When using the top hypotheses representation, posteriors help both ROUGE-1 and ROUGE-2 scores; when using confusion networks, non-pruned or pruned, using posterior probabilities improves ROUGE-2 results, but not ROUGE-1.

Our results show that adding more candidates in the vector representation does not necessarily help summarization. Using the pruned CNs yields better performance than the non-pruned ones. There is not much difference among different pruning methods. Overall, the best results are achieved by using pruned CNs: best ROUGE-1 result without using posterior probabilities, and best ROUGE-2 scores when using posteriors.

B. Presenting summaries using human transcripts

segment representation		ROUGE-1	ROUGE-2
Best hyp		68.26	32.25
Best hyp (wp)		69.16	33.99
Non-pruned CNs		69.28	33.49
Non-pruned CNs (wp)		67.84	32.95
Pruned CNs	Absolute	69.66	34.06
	Absolute (wp)	69.37	34.25
	Max_diff	**69.88**	34.17
	Max_diff (wp)	69.38	33.94
	Max_ratio	69.76	34.06
	Max_ratio (wp)	69.44	**34.39**
Human transcript		69.98	33.21

Table 3: ROUGE results (%) on the development set using different segment representations, with the summaries constructed using the corresponding human transcripts for the selected segments.

In the above experiments, we construct the final summary using the best hypotheses from the confusion networks once the summary sentence segments are determined. Although we notice obvious improvement comparing with the baseline results, the ROUGE scores are still much lower than using the human transcripts. One reason for this is the speech recognition errors. Even if we select the correct utterance segment as in the reference summary segments, the system performance is still penalized when calculating the ROUGE scores. In order to avoid the impact of word errors and focus on evaluating whether we have selected the correct segments, next we use the corresponding human transcripts of the selected segments to obtain performance measures. The results from this experiment are shown in Table 3 for different segment representations.

We can see that the summaries formed using human transcripts are much better comparing with the results presented in Table 2. These two setups use the same utterance segments. The only difference lies in the construction of the final summary for performance measurement, using the top hypotheses or the corresponding human transcripts for the selected segments. We also notice that the difference between using 1-best hypothesis and human transcripts is greatly reduced using this new summary formulation. This suggests that the incorrect word hypotheses do not have a very negative impact in terms of selecting summary segments; however, word errors still account for a significant part of the performance degradation on ASR condition when using word-based metrics for evaluation. Using the best hypotheses with their posterior probabilities we can obtain similar ROUGE-1 score and a little higher ROUGE-2 score comparing to the results using human transcripts. The performance can be further improved using the pruned CNs.

Note that when using the non-pruned CNs and posterior probabilities for term weighting, the ROUGE scores are worse than most of other conditions. We performed some analysis and found that one reason for this is the selection of some poor segments. Most of the word candidates in the non-pruned CNs have very low confidence scores, resulting in high IDF values using our proposed methods. Since some top hypotheses are NULL words in the poorly selected summary segments, it did not affect the results when using the best hypothesis for evaluation, but when using human transcripts, it leads to lower precision and worse overall F-scores. This is not a problem for the pruned CNs since words with low probabilities have been pruned beforehand, and thus do not impact segment selection. We will investigate better methods for term weighting to address this issue in our future work.

These experimental results prove that using the confusion networks and confidence scores can help select the correct sentence segments. Even though the 1-best WER is quite high, if we can consider more word candidates and/or their confidence scores, this will not impact the process of selecting summary segments. We can achieve similar performance as using human transcripts, and sometimes even slightly better performance. This suggests using more word candidates and their confidence scores results in better term weighting and representation in the vector space model. Some previous work showed that using word confidence scores can help minimize the WER of the extracted summaries, which then lead to better summarization performance. However, we think the main reason for the improvement in our study is from selecting better utterances, as shown in Table 3. In our experiments, because different setups select different segments as the summary, we can not directly compare the WER of extracted summaries, and analyze whether lower WER is also helpful for better sum-

	output summary			
	best hypotheses		human transcripts	
	R-1	R-2	R-1	R-2
Best hyp	65.73	26.79	68.60	32.03
Best hyp (wp)	65.92	27.27	68.91	32.69
Pruned CNs	66.47	27.73	69.53	34.05
Human transcript	N/A	N/A	69.08	33.33

Table 4: ROUGE results (%) on the test set.

marization performance. In our future work, we will perform more analysis along this direction.

4.3.3 Experimental results on test set

The summarization results on the test set are presented in Table 4. We show four different evaluation conditions: baseline using the top hypotheses, best hypotheses with posterior probabilities, pruned CNs, and using human transcripts. For each condition, the final summary is evaluated using the best hypotheses or the corresponding human transcripts of the selected segments. The summarization system setups (the pruning method and threshold, λ value in MMR function, and word compression ratio) used for the test set are decided based on the results on the development set.

For the results on the test set, we observe similar trends as on the development set. Using the confidence scores and confusion networks can improve the summarization performance comparing with the baseline. The performance improvements from "Best hyp" to "Best hyp (wp)" and from "Best hyp (wp)" to "Pruned CNs" using both ROUGE-1 and ROUGE-2 measures are statistically significant according to the paired t-test ($p < 0.05$). When the final summary is presented using the human transcripts of the selected segments, we observe slightly better results using pruned CNs than using human transcripts as input for summarization, although the difference is not statistically significant. This shows that using confusion networks can compensate for the impact from recognition errors and still allow us to select correct summary segments.

5 Conclusion and Future Work

Previous research has shown performance degradation when using ASR output for meeting summarization because of word errors. To address this problem, in this paper we proposed to use confusion networks for speech summarization. Under the MMR framework, we introduced a vector representation for the segments by using more word candidates in CNs and their associated posterior probabilities. We evaluated the effectiveness of using different confusion networks, the non-pruned ones, and the ones pruned using three different methods, i.e., absolute, max_diff and max_ratio pruning. Our experimental results on the ICSI meeting corpus showed that even when we only use the top hypotheses from the CNs, considering the word posterior probabilities can improve the summarization performance on both ROUGE-1 and ROUGE-2 scores. By using the pruned CNs we can obtain further improvement. We found that more gain in ROUGE-2 results was yielded by our proposed soft term weighting method based on posterior probabilities. Our experiments also demonstrated that it is possible to use confusion networks to achieve similar or even better performance than using human transcripts if the goal is to select the right segments. This is important since one possible rendering of summarization results is to return the audio segments to the users, which does not suffer from recognition errors.

In our experiments, we observed less improvement from considering more word candidates than using the confidence scores. One possible reason is that the confusion networks we used are too confident. For example, on average 90.45% of the candidate words have a posterior probability lower than 0.01. Therefore, even though the correct words were included in the confusion networks, their contribution may not be significant enough because of low term weights. In addition, low probabilities also cause problems to our proposed soft IDF computation. In our future work, we will investigate probability normalization methods and other techniques for term weighting to cope with these problems.

Abstract

Mobile devices are becoming the dominant mode of information access despite being cumbersome to input text using small keyboards and browsing web pages on small screens. We present `Qme!`, a speech-based question-answering system that allows for spoken queries and retrieves *answers* to the questions instead of web pages. We present bootstrap methods to distinguish dynamic questions from static questions and we show the benefits of tight coupling of speech recognition and retrieval components of the system.

1 Introduction

Access to information has moved from desktop and laptop computers in office and home environments to be an any place, any time activity due to mobile devices. Although mobile devices have small keyboards that make typing text input cumbersome compared to conventional desktop and laptops, the ability to access unlimited amount of information, almost everywhere, through the Internet, using these devices have made them pervasive.

Even so, information access using text input on mobile devices with small screens and soft/small keyboards is tedious and unnatural. In addition, by the *mobile* nature of these devices, users often like to use them in hands-busy environments, ruling out the possibility of typing text. We address this issue by allowing the user to query an information repository using speech. We expect that spoken language queries to be a more natural and less cumbersome way of information access using mobile devices.

A second issue we address is related to directly and precisely answering the user's query beyond serving web pages. This is in contrast to the current approach where a user types in a query using keywords to a search engine, browses the returned results on the small screen to select a potentially relevant document, suitably magnifies the screen to view the document and searches for the answer to her question in the document. By providing a method for the user to pose her query in natural language and presenting the relevant answer(s) to her question, we expect the user's information need to be fulfilled in a shorter period of time.

We present a speech-driven question answering system, `Qme!`, as a solution toward addressing these two issues. The system provides a natural input modality – spoken language input – for the users to pose their information need and presents a collection of *answers* that potentially address the information need directly. For a subclass of questions that we term *static* questions, the system retrieves the answers from an archive of human generated answers to questions. This ensures higher accuracy for the answers retrieved (if found in the archive) and also allows us to retrieve related questions on the user's topic of interest. For a second subclass of questions that we term *dynamic* questions, the system retrieves the answer from information databases accessible over the Internet using web forms.

The layout of the paper is as follows. In Section 2, we review the related literature. In Section 3, we illustrate the system for speech-driven question answering. We present the retrieval methods we used to implement the system in Section 4. In Section 5, we discuss and evaluate our approach to tight coupling of speech recognition and search components. In Section 6, we present bootstrap techniques to distinguish dynamic questions from static questions, and evaluate the efficacy of these techniques on a test corpus. We conclude in Section 7.

2 Related Work

Early question-answering (QA) systems, such as Baseball (Green et al., 1961) and Lunar (Woods, 1973) were carefully hand-crafted to answer questions in a limited domain, similar to the QA components of ELIZA (Weizenbaum, 1966) and SHRDLU (Winograd, 1972). However, there has been a resurgence of QA systems following the TREC conferences with an emphasis on answering factoid questions. This work on text-based question-answering which is comprehensively summarized

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 55–63,
Los Angeles, California, June 2010.

in (Maybury, 2004), range widely in terms of linguistic sophistication. At one end of the spectrum, There are linguistically motivated systems (Katz, 1997; Waldinger et al., 2004) that analyze the user's question and attempt to synthesize a coherent answer by aggregating the relevant facts. At the other end of the spectrum, there are data intensive systems (Dumais et al., 2002) that attempt to use the redundancy of the web to arrive at an answer for factoid style questions. There are also variants of such QA techniques that involve an interaction and use context to resolve ambiguity (Yang et al., 2006). In contrast to these approaches, our method matches the user's query against the *questions* in a large corpus of question-answer pairs and retrieves the associated answer.

In the information retrieval community, QA systems attempt to retrieve precise segments of a document instead of the entire document. In (Tomuro and Lytinen, 2004), the authors match the user's query against a frequently-asked-questions (FAQ) database and select the answer whose question matches most closely to the user's question. An extension of this idea is explored in (Xue et al., 2008; Jeon et al., 2005), where the authors match the user's query to a community collected QA archive such as (Yahoo!, 2009; MSN-QnA, 2009). Our approach is similar to both these lines of work in spirit, although the user's query for our system originates as a spoken query, in contrast to the text queries in previous work. We also address the issue of noisy speech recognition and assess the value of tight integration of speech recognition and search in terms of improving the overall performance of the system. A novelty in this paper is our method to address dynamic questions as a seamless extension to answering static questions.

Also related is the literature on voice-search applications (Microsoft, 2009; Google, 2009; YellowPages, 2009; vlingo.com, 2009) that provide a spoken language interface to business directories and return phone numbers, addresses and web sites of businesses. User input is typically not a free flowing natural language query and is limited to expressions with a business name and a location. In our system, users can avail of the full range of natural language expressions to express their information need.

And finally, our method of retrieving answers to dynamic questions has relevance to the database and meta search community. There is growing interest in this community to mine the "hidden" web – information repositories that are behind web forms – and provide a unified meta-interface to such information sources, for example, web sites related travel, or car dealerships. Dynamic questions can be seen as providing a natural language interface (NLI) to such web forms, similar to early work on NLI to databases (Androutsopoulos, 1995).

3 Speech-driven Question Retrieval System

We describe the speech-driven query retrieval application in this section. The user of this application provides a spoken language query to a mobile device intending to find an answer to the question. Some example users' inputs are[1] *what is the fastest animal in water*, *how do I fix a leaky dishwasher*, *why is the sky blue*. The result of the speech recognizer is used to search a large corpus of question-answer pairs to retrieve the answers pertinent to the user's static questions. For the dynamic questions, the answers are retrieved by querying a web form from the appropriate web site (e.g www.fandango.com for movie information). The result from the speech recognizer can be a single-best string or a weighted word lattice.[2] The retrieved results are ranked using different metrics discussed in the next section. In Figure 2, we illustrate the answers that `Qme!` returns for static and dynamic quesitons.

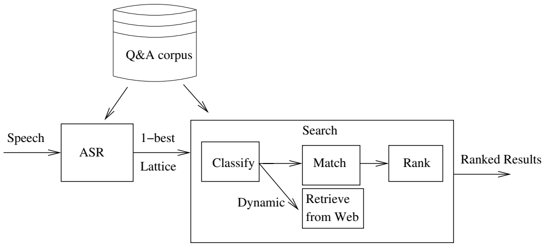

Figure 1: The architecture of the speech-driven question-answering system

4 Methods of Retrieval

We formulate the problem of answering static questions as follows. Given a question-answer archive $\mathbf{QA} = \{(q_1, a_1), (q_2, a_2), \ldots, (q_N, a_N)\}$

[1] The query is not constrained to be of any specific question type (for example, *what, where, when, how*).

[2] For this paper, the ASR used to recognize these utterances incorporates an acoustic model adapted to speech collected from mobile devices and a four-gram language model that is built from the corpus of questions.

Figure 2: Retrieval results for static and dynamic questions using `Qme`!

of N question-answer pairs, and a user's question q_u, the task is to retrieve a subset $\mathbf{QA^r} = \{(q_1^r, a_1^r), (q_2^r, a_2^r), \ldots, (q_M^r, a_M^r)\}$ $M << N$ using a selection function $Select$ and rank the members of $\mathbf{QA^r}$ using a scoring function $Score$ such that $Score(q_u, (q_i^r, a_i^r)) > Score(q_u, (q_{i+1}^r, a_{i+1}^r))$. Here, we assume
$Score(q_u, (q_i^r, a_i^r)) = Score(q_u, q_i^r)$.

The $Select$ function is intended to select the matching questions that have high "semantic" similarity to the user's question. However, given there is no objective function that measures semantic similarity, we approximate it using different metrics discussed below.

Ranking of the members of the retrieved set can be based on the scores computed during the selection step or can be independently computed based on other criteria such as popularity of the question, credibility of the source, temporal recency of the answer, geographical proximity to the answer origin.

4.1 Question Retrieval Metrics

We retrieve QA pairs from the data repository based on the similarity of match between the user's query and each of the set of questions (d) in the repository. To measure the similarity, we have experimented with the following metrics.

1. **TF-IDF metric**: The user input query and the document (in our case, questions in the repository) are represented as bag-of-n-grams (aka terms). The term weights are computed using a combination of term frequency (tf) and inverse document frequency (idf) (Robertson, 2004). If $Q = q_1, q_2, \ldots, q_n$ is a user query, then the aggregated score for a document d using a unigram model of the query and the document is given as in Equation 1. For a given query, the documents with the highest total term weight are presented as retrieved results. Terms can also be defined as n-gram sequences of a query and a document. In our experiments, we have used up to 4-grams as terms to retrieve and rank documents.

$$Score(d) = \sum_{w \in Q} tf_{w,d} \times idf_w \qquad (1)$$

2. **String Comparison Metrics:** Since the length of the user query and the query to be retrieved are similar in length, we use string comparison methods such as Levenshtein edit distance (Levenshtein, 1966) and n-gram overlap (BLEU-score) (Papineni et al., 2002) as similarity metrics.

We compare the search effectiveness of these similarity metrics in Section 5.3.

5 Tightly coupling ASR and Search

Most of the speech-driven search systems use the 1-best output from the ASR as the query for the search component. Given that ASR 1-best output is likely to be erroneous, this serialization of the ASR and search components might result in suboptimal search accuracy. A lattice representation of the ASR output, in particular, a word-confusion network (WCN) transformation of the lattice, compactly encodes the n-best hypothesis with the flexibility of pruning alternatives at each word position. An example of a WCN is shown in Figure 3. The weights on the arcs are to be interpreted as costs and the best path in the WCN is the lowest cost path from the start state (0) to the final state (4). Note that the 1-best path is *how old is mama*, while the input speech was *how old is obama* which also is in the WCN, but at a higher cost.

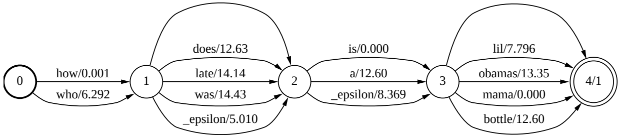

Figure 3: A sample word confusion network with arc costs as negative logarithm of the posterior probabilities.

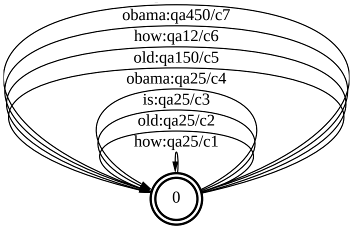

Figure 4: Example of an FST representing the search index.

5.1 Representing Search Index as an FST

Lucene (Hatcher and Gospodnetic., 2004) is an off-the-shelf search engine that implements the TF-IDF metric. But, we have implemented our own search engine using finite-state transducers (FST) for this reason. The oracle word/phrase accuracy using n-best hypotheses of an ASR is usually far greater than the 1-best output. However, using each of the n-best ($n > 1$) hypothesis as a separate query to the search component is computationally sub-optimal since the strings in the n-best hypotheses usually share large subsequences with each other. The FST representation of the search index allows us to efficiently consider lattices/WCNs as input queries.

The FST search index is built as follows. We index each question-answer (QA) pair from our repository ((q_i, a_i), qa_i for short) using the words (w_{q_i}) in question q_i. This index is represented as a weighted finite-state transducer (*SearchFST*) as shown in Figure 4. Here a word w_{q_i} (e.g *old*) is the input symbol for a set of arcs whose output symbol is the index of the QA pairs where *old* appears in the question. The weight of the arc $c_{(w_{q_i},q_i)}$ is one of the similarity based weights discussed in Section 4.1. As can be seen from Figure 4, the words *how*, *old*, *is* and *obama* contribute a score to the question-answer pair *qa25*; while other pairs, *qa150, qa12, qa450* are scored by only one of these words.

5.2 Search Process using FSTs

A user's speech query, after speech recognition, is represented as an FSA (either 1-best or WCN), a *QueryFSA*. The *QueryFSA* (denoted as q) is then transformed into another FSA (*NgramFSA(q)*) that represents the set of n-grams of the *QueryFSA*. Due to the arc costs from WCNs, the *NgramFSA* for a WCN is a weighted FSA. The *NgramFSA* is composed with the *SearchFST* and we obtain all the arcs $(w_q, qa_{w_q}, c_{(w_q,qa_{w_q})})$ where w_q is a query term, qa_{w_q} is a QA index with the query term and, $c_{(w_q,qa_{w_q})}$ is the weight associated with that pair. Using this information, we aggregate the weight for a QA pair (qa_q) across all query words and rank the retrieved QAs in the descending order of this aggregated weight. We select the top N QA pairs from this ranked list. The query composition, QA weight aggregation and selection of top N QA pairs are computed with finite-state transducer operations as shown in Equations 2 to 5.[3]

$$D1 = \pi_2(NgramFSA(q) \circ SearchFST) \quad (2)$$

$$R1 = fsmbestpath(D1, 1) \quad (3)$$

$$D2 = \pi_2(NgramFSA(R1) \circ SearchFST) \quad (4)$$

$$TopN = fsmbestpath(fsmdeterminize(D2), N) \quad (5)$$

The process of retrieving documents using the Levenshtein-based string similarity metric can also be encoded as a composition of FSTs.

5.3 Experiments and Results

We have a fairly large data set consisting of over a million question-answer pairs collected by harvesting the web. In order to evaluate the retrieval methods discussed earlier, we use two test sets of QA pairs: a *Seen* set of 450 QA pairs and an *Unseen* set of 645 QA pairs. The queries in the *Seen* set have an exact match with some question in the database, while the queries in the *Unseen* set may not match any question in the database exactly. [4] The questions in the *Unseen* set, however, like those in the *Seen* set, also have a human generated answer that is used in our evaluations.

For each query, we retrieve the twenty most relevant QA pairs, ranked in descending order of the value of the particular metric under consideration. However, depending on whether the user query is a seen or an unseen query, the evaluation of the relevance of the retrieved question-answer pairs is different as discussed below.[5]

[3] We have dropped the need to convert the weights into the *real* semiring for aggregation, to simplify the discussion.

[4] There may however be semantically matching questions.

[5] The reason it is not a recall and precision curve is that, for the "seen" query set, the retrieval for the questions is a zero/one boolean accuracy. For the "unseen" query set there is no perfect match with the input question in the query database, and so we determine the closeness of the questions based on the closeness of the answers. Coherence attempts to capture the homogenity of the questions retrieved, with the assumption that the user might want to see similar questions as the returned results.

5.3.1 Evaluation Metrics

For the set of *Seen* queries, we evaluate the relevance of the retrieved top-20 question-answer pairs in two ways:

1. Retrieval Accuracy of Top-N results: We evaluate whether the question that matches the user query exactly is located in the top-1, top-5, top-10, top-20 or not in top-20 of the retrieved questions.

2. Coherence metric: We compute the coherence of the retrieved set as the mean of the BLEU-score between the input query and the set of top-5 retrieved questions. The intuition is that we do not want the top-5 retrieved QA pairs to distract the user by not being relevant to the user's query.

For the set of *Unseen* queries, since there are no questions in the database that exactly match the input query, we evaluate the relevance of the top-20 retrieved question-answer pairs in the following way. For each of the 645 *Unseen* queries, we know the human-generated answer. We manually annotated each unseen query with the *Best-Matched* QA pair whose answer was the closest semantic match to the human-generated answer for that unseen query. We evaluate the position of the Best-Matched QA in the list of top twenty retrieved QA pairs for each retrieval method.

5.3.2 Results

On the *Seen* set of queries, as expected the retrieval accuracy scores for the various retrieval techniques performed exceedingly well. The unigram based *tf.idf* method retrieved 93% of the user's query in the first position, 97% in one of top-5 positions and 100% in one of top-10 positions. All the other retrieval methods retrieved the user's query in the first position for all the *Seen* queries (100% accuracy).

In Table 1, we tabulate the results of the Coherence scores for the top-5 questions retrieved using the different retrieval techniques for the *Seen* set of queries. Here, the higher the n-gram the more coherent is the set of the results to the user's query. It is interesting to note that the BLEU-score and Levenshtein similarity driven retrieval methods do not differ significantly in their scores from the n-gram *tf.idf* based metrics.

Method		Coherence Metric for top-5 results
TF-IDF	unigram	61.58
	bigram	66.23
	trigram	66.23
	4-gram	69.74
BLEU-score		66.29
Levenshtein		67.36

Table 1: Coherence metric results for top-5 queries retrieved using different retrieval techniques for the *seen* set.

In Table 2, we present the retrieval results using different methods on the *Unseen* queries. For 240 of the 645 unseen queries, the human expert found that that there was no answer in the data repository that could be considered semantically equivalent to the human-generated response to that query. So, these 240 queries cannot be answered using the current database. For the remaining 405 unseen queries, over 60% have their Best-Matched question-answer pair retrieved in the top-1 position. We expect the coverage to improve considerably by increasing the size of the QA archive.

Method		Top-1	Top-20
TFIDF	Unigram	69.13	75.81
	Bigram	62.46	67.41
	Trigram	61.97	65.93
	4-gram	56.54	58.77
	WCN	70.12	78.52
Levenshtein		67.9	77.29
BLEU-score		72.0	75.31

Table 2: Retrieval results for the Unseen queries

5.3.3 Speech-driven query retrieval

In Equation 6, we show the tight integration of WCNs and *SearchFST* using the FST composition operation (∘). λ is used to scale the weights[6] from the acoustic/language models on the WCNs against the weights on the *SearchFST*. As before, we use Equation 3 to retrieve the top N QA pairs. The tight integration is expected to improve both the ASR and Search accuracies by co-constraining both components.

$$D = \pi_2(Unigrams(WCN)^{\lambda} \circ SearchFST) \quad (6)$$

For this experiment, we use the speech utterances corresponding to the *Unseen* set as the test set. We use a different set of 250 *speech* queries as the

[6] fixed using the development set

development set. In Table 3, we show the Word and Sentence Accuracy measures for the best path in the WCN before and after the composition of *SearchFST* with the WCN on the development and test sets. We note that by integrating the constraints from the search index, the ASR accuracies can be improved by about 1% absolute.

Set	# of utterances	Word Accuracy	Sentence Accuracy
Dev Set	250	77.1(78.2)	54(54)
Test Set	645	70.8(72.1)	36.7(37.1)

Table 3: ASR accuracies of the best path before and after (in parenthesis) the composition of SearchFST

Since we have the speech utterances of the *Unseen* set, we were also able to compute the search results obtained by integrating the ASR WCNs with the *SearchFST*, as shown in line 5 of Table 2. These results show that the the integration of the ASR WCNs with the *SearchFST* produces higher search accuracy compared to ASR 1-best.

6 Dynamic and Static Questions

Storing previously answered questions and their answers allows Qme! to retrieve the answers to a subclass of questions quickly and accurately. We term this subclass as *static* questions since the answers to these questions remain the same irrespective of when and where the questions are asked. Examples of such questions are *What is the speed of light?*, *When is George Washington's birthday?*. In contrast, there is a subclass of questions, which we term *dynamic* questions, for which the answers depend on when and where they are asked. For such questions the above method results in less than satisfactory and sometimes inaccurate answers. Examples of such questions are *What is the stock price of General Motors?*, *Who won the game last night?*, *What is playing at the theaters near me?*.

We define *dynamic* questions as questions whose answers change more frequently than once a year. In dynamic questions, there may be no explicit reference to time, unlike the questions in the TERQAS corpus (Radev and Sundheim., 2002) which explicitly refer to the temporal properties of the entities being questioned or the relative ordering of past and future events. The time-dependency of a dynamic question lies in the temporal nature of its answer. For example, consider the dynamic question, "What is the address of the theater 'White Christmas' is playing at in New York?". White Christmas is a seasonal play that plays in New York every year for a few weeks in December and January, but it does not necessarily at the same theater every year. So, depending when this question is asked, the answer will be different.

Interest in temporal analysis for question-answering has been growing since the late 1990's. Early work on temporal expressions identification using a tagger led to the development of TimeML (Pustejovsky et al., 2001), a markup language for annotating temporal expressions and events in text. Other examples include QA-by-Dossier with Constraints (Prager et al., 2004), a method of improving QA accuracy by asking auxiliary questions related to the original question in order to temporally verify and restrict the original answer. (Moldovan et al., 2005) detect and represent temporally related events in natural language using logical form representation. (Saquete et al., 2009) use the temporal relations in a question to decompose it into simpler questions, the answers of which are recomposed to produce the answers to the original question.

6.1 Dynamic/Static Classification

We automatically classify questions as dynamic and static questions. Answers to static questions can be retrieved from the QA archive. To answer dynamic questions, we query the database(s) associated with the topic of the question through web forms on the Internet. We use a topic classifier to detect the topic of a question followed by a dynamic/static classifier trained on questions related to a topic, as shown in figure 5. Given the question *what movies are playing around me?*, we detect it is a movie related dynamic question and query a movie information web site (e.g. www.fandango.com) to retrieve the results based on the user's GPS information.

Stocks Q.
Movies Q.
Sports Q.
Dynamic /Static Classification
Dynamic /Static Classification
Dynamic /Static Classification

Figure 5: Chaining two classifiers

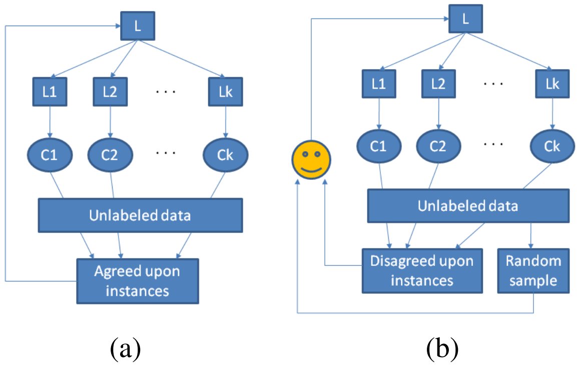
We used supervised learning to train the topic classifier, since our entire dataset is annotated by human experts with topic labels. In contrast, to train a dynamic/static classifier, we experimented with the following three different techniques.

Baseline: We treat questions as dynamic if they contain temporal indexicals, e.g. *today*, *now*, *this week*, *two summers ago*, *currently*, *recently*, which were based on the TimeML corpus. We also included spatial indexicals such as *here*, and other substrings such as *cost of* and *how much is*. A question is considered static if it does not contain any such words/phrases.

Self-training with bagging: The general self-training with bagging algorithm (Banko and Brill, 2001) is presented in Table 6 and illustrated in Figure 7(a). The benefit of self-training is that we can build a better classifier than that built from the small seed corpus by simply adding in the large unlabeled corpus without requiring hand-labeling.

1. Create k bags of data, each of size $|L|$, by sampling with replacement from labeled set L.
2. Train k classifiers; one classifier on each of k bags.
3. Each classifier predicts labels of the unlabeled set.
4. The N labeled instances that j of k classifiers agree on with the highest average confidence is added to the labeled set L, to produce a new labeled set L'.
5. Repeat all 5 steps until stopping criteria is reached.

Figure 6: Self-training with bagging



(a) (b)

Figure 7: (a) Self-training with bagging (b) Committee-based active-learning

In order to prevent a bias towards the majority class, in step 4, we ensure that the distribution of the static and dynamic questions remains the same as in the annotated seed corpus. The benefit of bagging (Breiman, 1996) is to present different views of the same training set, and thus have a way to assess the certainty with which a potential training instance can be labeled.

Active-learning: This is another popular method for training classifiers when not much annotated data is available. The key idea in active learning is to annotate only those instances of the dataset that are most difficult for the classifier to learn to classify. It is expected that training classifiers using this method shows better performance than if samples were chosen randomly for the same human annotation effort. Figure 7(b) illustrates the algorithm and Figure 8 describes the algorithm, also known as committee-based active-learning (Banko and Brill, 2001).

1. Create k bags of data, each of size $|L|$, by sampling with replacement from the labeled set L.
2. Train k classifiers, one on each bag of the k bags.
3. Each classifier predicts the labels of the unlabeled set.
4. Choose N instances from the unlabeled set for human labeling. $N/2$ of the instances are those whose labels the committee of classifiers have highest vote entropy (uncertainity). The other $N/2$ of the instances are selected randomly from the unlabeled set.
5. Repeat all 5 steps until stopping criteria is reached.

Figure 8: Active Learning algorithm

We used the maximum entropy classifier in Llama (Haffner, 2006) for all of the above classification tasks.

6.2 Experiments and Results

6.2.1 Topic Classification

The topic classifier was trained using a training set consisted of over one million questions downloaded from the web which were manually labeled by human experts as part of answering the questions. The test set consisted of 15,000 randomly selected questions. Word trigrams of the question are used as features for a MaxEnt classifier which outputs a score distribution on all of the 104 possible topic labels. The error rate results for models selecting the top topic and the top two topics according to the score distribution are shown in Table 4. As can be seen these error rates are far lower than the baseline model of selecting the most frequent topic.

Model	Error Rate
Baseline	98.79%
Top topic	23.9%
Top-two topics	12.23%

Table 4: Results of topic classification

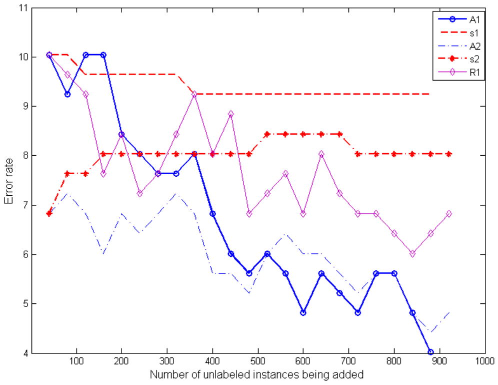


Figure 9: Change in classification results

6.2.2 Dynamic/static Classification

As mentioned before, we experimented with three different approaches to bootstrapping a dynamic/static question classifier. We evaluate these methods on a 250 question test set drawn from the broad topic of *Movies*. For the baseline model, we used the words/phrases discussed earlier based on temporal and spatial indexicals. For the "supervised" model, we use the baseline model to tag 500K examples and use the machine-annotated corpus to train a MaxEnt binary classifier with word trigrams as features. The error rate in Table 5 shows that it performs better than the baseline model mostly due to better lexical coverage contributed by the 500K examples.

Training approach	Lowest Error rate
Baseline	27.70%
"Supervised" learning	22.09%
Self-training	8.84%
Active-learning	4.02%

Table 5: Best Results of dynamic/static classification

In the *self-training* approach, we start with a small seed corpus of 250 hand-labeled examples from the *Movies* topic annotated with dynamic or static tags. We used the same set of 500K unlabeled examples as before and word trigrams from the question were used as the features for a MaxEnt classifier. We used 11 bags in the *bagging* phase of this approach and required that all 11 classifiers agree unanimously about the label of a new instance. Of all such instances, we randomly selected N instances to be added to the training set of the next iteration, while maintaining the distribution of the static and dynamic questions to be the same as that in the seed corpus. We experimented with various values of N, the number of newly labeled instances added at each iteration. The error rate at initialization is 10.4% compared to 22.1% of the "supervised" approach which can be directly attributed to the 250 hand-labeled questions. The lowest error rate of the self-training approach, obtained at N=100, is 8.84%, as shown in Table 5. In Figure 9, we show the change in error rate for N=40 (line S1 in the graph) and N=100 (line S2 in the graph).

For the *active learning* approach, we used the same set of 250 questions as the seed corpus, the same set of 500K unlabeled examples, the same test set, and the same set of word trigrams features as in the self-training approach. We used 11 bags for the bagging phase and selected top 20 new unlabeled instances on which the 11 classifiers had the greatest vote entropy to be presented to the human labeler for annotation. We also randomly selected 20 instances from the rest of the unlabeled set to be presented for annotation. The best error rate of this classifier on the test set is 4.02%, as shown in Table 5. The error rate over successive iterations is shown by line A1 in Figure 9.

In order to illustrate the benefits of selecting the examples *actively*, we repeated the experiment described above but with all 40 unlabeled instances selected randomly for annotation. The error rate over successive iterations is shown by line R1 in Figure 9. Comparing A1 to R1, we see that the error decreases faster when we select some of the unlabeled instances for annotation actively at each iteration.

7 Conclusion

In this paper, we have presented a system `Qme!`, a speech-driven question-answering system for mobile devices. We have proposed a query retrieval model for question-answering and demonstrated the mutual benefits of tightly coupling the ASR and Search components of the system. We have presented a novel concept of distinguishing questions that need dynamic information to be answered from those questions whose answers can be retrieved from an archive. We have shown results on bootstrapping such a classifier using semi-supervised learning techniques.

Dialogue-Oriented Review Summary Generation for Spoken Dialogue Recommendation Systems

Jingjing Liu, Stephanie Seneff, Victor Zue
MIT Computer Science & Artificial Intelligence Laboratory
32 Vassar Street, Cambridge, MA 02139
{jingl, seneff, zue}@csail.mit.edu

Abstract

In this paper we present an opinion summarization technique in spoken dialogue systems. Opinion mining has been well studied for years, but very few have considered its application in spoken dialogue systems. Review summarization, when applied to real dialogue systems, is much more complicated than pure text-based summarization. We conduct a systematic study on dialogue-system-oriented review analysis and propose a three-level framework for a recommendation dialogue system. In previous work we have explored a linguistic parsing approach to phrase extraction from reviews. In this paper we will describe an approach using statistical models such as decision trees and SVMs to select the most representative phrases from the extracted phrase set. We will also explain how to generate informative yet concise review summaries for dialogue purposes. Experimental results in the restaurant domain show that the proposed approach using decision tree algorithms achieves an outperformance of 13% compared to SVM models and an improvement of 36% over a heuristic rule baseline. Experiments also show that the decision-tree-based phrase selection model can achieve rather reliable predictions on the phrase label, comparable to human judgment. The proposed statistical approach is based on domain-independent learning features and can be extended to other domains effectively.

1 Introduction

Spoken dialogue systems are presently available for many purposes, such as weather inquiry (Zue et al., 2000), bus schedules and route guidance (Raux et al., 2003), customer service (Gorin et al., 1997), and train timetable inquiry (Eckert et al., 1993). These systems have been well developed for laboratory research, and some have become commercially viable.

The next generation of *intelligent* dialogue systems is expected to go beyond factoid question answering and straightforward task fulfillment, by providing active assistance and subjective recommendations, thus behaving more like human agents. For example, an intelligent dialogue system may suggest which airline is a better choice, considering cost, flight duration, take-off time, available seats, etc.; or suggest which digital camera is the most popular among teenagers or highest rated by professional photographers; or which restaurant is a perfect spot for a semi-formal business meeting or a romantic date.

Luckily, there are enormous amounts of reviews published by general users on the web every day. These are perfect resources for providing subjective recommendations and collective opinions. If there exists a systematic framework that harvests these reviews from general users, extracts the essence from the reviews and presents it appropriately in human-computer conversations, then we can enable dialogue systems to behave like a human shopping assistant, a travel agent, or a local friend who tells you where to find the best restaurant.

Summarization from online reviews, therefore, plays an important role for such dialogue systems. There have been previous studies on review analysis for text-based summarization systems (Mei et al., 2007; Titov and McDonald, 2008a; Branavan et al., 2008). Mixture models and topic models are used to predict the underlying topics of each document and generate a phrase-level summary. An aspect rating on each facet is also automatically

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 64–72,
Los Angeles, California, June 2010.

learned with statistical models (Snyder and Barzilay, 2007; Titov and McDonald, 2008b; Baccianella et al., 2009). These approaches are all very effective, and the review databases generated are well presented.

So the first thought for developing a recommendation dialogue system is to use such a categorized summary in a table-lookup fashion. For example, a dialogue system for restaurant recommendations can look up a summary table as exemplified in Table 1, and generate a response utterance from each row: "Restaurant A has good service and bad food; restaurant B has good service and good food; restaurant C has great service and nice atmosphere; restaurant D has poor service and reasonable price."

Restaurant	**Summary**
A	Good service, bad food,
B	Good service, good food
C	Great service, nice atmosphere
D	Poor service, reasonable price

Table 1. A partial table of categorization-based review summaries.

Such a dialogue system is, however, not very informative. First of all, there is too much redundancy. Long utterances repeated in the same pattern on the same topic are quite boring, and the information density is very low. Second, such a summary is too coarse-grained to be helpful. A user querying a restaurant recommendation system expects more *fine-grained* information such as house specials, wine selections and choices on desserts rather than just general 'good food.'

In contrast to a 'text' summarization system, the textual space in a dialogue turn is often very limited. Speech is inherently serial, and it cannot be skipped and scanned easily. A dialogue system which speaks long diatribes in each single conversation turn would likely not be well received. We believe that the best unit of review summary for dialogue purposes is short succinct phrases (e.g., 'amazing sauce' and 'romantic ambiance') which are catalogued into categories to answer *high-level questions* such as "How is the *food* at this restaurant?" or "What about the *atmosphere*?" Also, domain-specific phrases are greatly needed to generate correct answers to *specific queries*, such as "Which restaurants have *fresh sushi*?" and "Show me restaurants that serve *fantastic cocktails*."

Thus, the generally used correlated topic models, although very effective in text-based systems, are not quite suitable for interactive dialogue systems. The missing piece is an *HCI-oriented* (*human computer interaction)*, *fine-grained*, *informative* yet *concise* review summarization. A good recommendation system should be able to provide sufficient yet specific information to help users choose a restaurant, a movie or a consumer product. Figure 1 shows an example of a conversation with a good recommendation system, which 1) provides a *generalized yet high-density* review summary in *human-friendly dialogue*; 2) provides both a *coarse-grained* summary (e.g., 'authentic food') and *fine-grained* information such as house specialties.

U: Are there any French restaurants in Cambridge?
S: There are *five French restaurants* in Cambridge. *Most of them are on Backbay Street. And most of them have attentive service.*
U: Show me the ones that have nice ambiance.
S: *Two of them have nice ambiance*, Pierrot Bistrot Francais and Coriander.
U: How about the food?
S: *Pierrot Bistrot Francais has authentic food, fresh salad, and absolutely delicious spaghetti carbonara. The food at Coriander is below average. It has very greasy chicken tikka masala and dry bread.*

Figure 1. Example of a conversation with a good recommendation dialogue system ('U' denotes the user and 'S' denotes the dialogue system. The responses to the user queries are produced by our system and the actual dialogue was an illustration of system capacities).

Therefore, the task of developing recommendation dialogue systems is decomposed into three problems: 1) how to extract *context-related* phrases, both *coarse-grained* and *fine-grained*, from online reviews; 2) how to select a *representative set* from the extracted phrases to create an *informative yet concise dialogue-oriented* summary database; 3) how to generate *human-friendly dialogue responses* from the review summary database.

To tackle these problems, we propose a *three-level framework*. In previous work (Liu and Seneff, 2009), we explored the first level by proposing a linguistic parse-and-paraphrase paradigm for review phrase extraction. In this paper, we address the second problem: dialogue-oriented review summary generation. We propose an automatic approach to classifying high/low informative phrases using statistical models. Experiments conducted on a restaurant-domain dataset indicate that the proposed approach can predict phrase labels consistently with human judgment and can generate high-quality review summaries for dialogue purposes.

The rest of the paper is organized as follows: Section 2 gives an overview of the three-level framework for recommendation dialogue systems. In Section 3, we explain the proposed approach to dialogue-oriented review summary generation. Section 4 provides a systematic evaluation of the proposed approach, and Section 5 gives a further discussion on the experimental results. Section 6 summarizes the paper as well as pointing to future work.

2 System Overview

The three-level framework of a review-summary-based recommendation dialogue system is shown in Figure 2. The bottom level is linguistic phrase extraction. In previous work (Liu and Seneff, 2009), we employed a probabilistic lexicalized grammar to parse review sentences into a hierarchical representation, which we call a *linguistic frame*. From the linguistic frames, phrases are extracted by capturing a set of adjective-noun relationships. Adverbs and negations conjoined with the adjectives are also captured. We also calculated a numerical score for sentiment strength for each adjective and adverb, and further applied a cumulative offset model to assign a sentiment score to each phrase.

The approach relies on linguistic features that are independent of frequency statistics; therefore it can retrieve very rare phrases such as ‘very greasy chicken tikka masala’ and ‘absolutely delicious spaghetti carbonara’, which are very hard to derive from correlated topic models. Experimental results showed that the linguistic paradigm outperforms existing methods of phrase extraction which employ shallow parsing features (e.g., part-of-speech). The main contribution came from the linguistic frame, which preserves linguistic structure of a sentence by encoding different layers of semantic dependencies. This allows us to employ more sophisticated high-level linguistic features (e.g., long distance semantic dependencies) for phrase extraction.

However, the linguistic approach fails to distinguish highly informative and relevant phrases from uninformative ones (e.g., ‘drunken husband’, ‘whole staff’). To apply these extracted phrases within a recommendation dialogue system, we have to filter out low quality or irrelevant phrases and maintain a concise summary database. This is the second level: dialogue-oriented review summary generation.

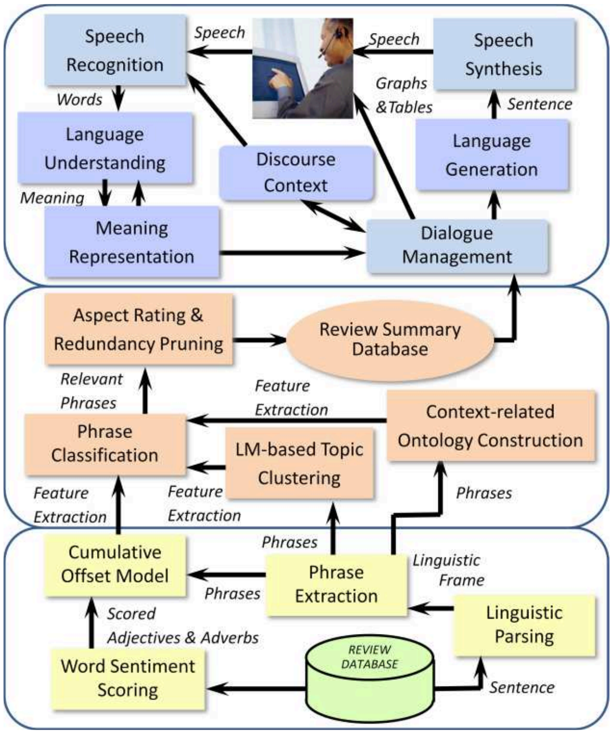

Figure 2. Three-level framework of review-based recommendation dialogue systems.

The standard of *highly informative and relevant* phrases is a very subjective problem. To gain insights on human judgment on this, the first two authors separately labeled a set of review-related phrases in a restaurant domain as ‘good’ and ‘bad’ summary phrases. We surveyed several subjects, all of whom indicated that, when querying a dialogue system for information about a restaurant, they care much more about special dishes served in this restaurant than generic descriptions such as ‘good food.’ This knowledge informed the annotation task: to judge whether a phrase delivered by a dialogue recommendation system would be helpful for users to make a decision. Surprisingly, although this is a difficult and subjective problem, the judgment from the two annotators is substantially consistent. By examining the annotations we observed that phrases such as 'great value' and 'good quality' are often treated as 'uninformative' as they are too common to be representative for a particular product, a restaurant or a movie. Phrases with neutral sentiment (e.g., 'green beans' and 'whole staff') are often considered as uninformative too. Phrases on specific topics such as house specialties (e.g., 'absolutely delicious spaghetti carbonara') are what the annotators care about most and are often considered as highly relevant, even though they may have only been seen once in a large database.

Driven by these criteria, from each phrase we extract a set of *statistical* features such as unigram/bigram probabilities and *sentiment* features such as sentiment orientation degree of the phrase, as well as underlying *semantic* features (e.g., whether the topic of the phrase fits in a domain-specific ontology). Classification models such as SVMs and decision tree algorithms are then trained on these features to automatically classify high/low informative phrases. Phrases identified as 'good' candidates are further pruned and catalogued to create concise summaries for dialogue purposes.

After generating the review summary database, the third level is to modify the response generation component in dialogue systems to create generalized and interactive conversations, as exemplified in Figure 1. The utterance from users is piped through speech recognition and language understanding. The meaning representation is then sent to the dialogue management component for *review-summary database lookup*. A response is then generated by the language generation component, and a speech utterance is generated by the synthesizer and sent back to the user. The dialogue system implementation is beyond the scope of this paper and will be discussed later in a separate paper.

3 Dialogue-oriented Review Summary Generation

Given an inquiry from users, the answer from a recommendation system should be helpful and relevant. So the first task is to identify a phrase as 'helpful' or not. The task of identifying a phrase as informative and relevant, therefore, is defined as a classification problem:

$$y = \bar{\theta} \cdot \bar{x} = \sum_{i=1}^{n} \theta_i x_i \qquad (1)$$

where y is the label of a phrase, assigned as '1' if the phrase is highly informative and relevant, and '-1' if the phrase is uninformative. $\bar{x}$ is the feature vector extracted from the phrase, and $\bar{\theta}$ is the coefficient vector.

We employ statistical models such as SVMs (Joachims, 1998) and decision trees (Quinlan, 1986) to train the classification model. For model learning, we employ a feature set including *statistical features*, *sentiment features* and *semantic features.*

Generally speaking, phrases with neutral sentiment are less informative than those with strong sentiment, either positive or negative. For example, 'fried seafood appetizer', 'baked halibut', 'electronic bill' and 'red drink' do not indicate whether a restaurant is worth trying, as they did not express whether the fried seafood appetizer or the baked halibut are good or bad. Therefore, we take the sentiment score of each phrase generated from a cumulative offset model (Liu and Seneff, 2009) as a *sentiment feature*. Sentiment scores of phrases are exemplified in Table 2 (on a scale of 1 to 5).

Phrase	Sc.	Phrase	Sc.
really welcoming atmosphere	4.8	truly amazing flavor	4.6
perfect portions	4.4	very tasty meat	4.3
busy place	3.1	typical Italian restaurant	3.1
a little bit high price	2.2	pretty bad soup	1.8
sloppy service	1.8	absolute worst service	1.4

Table 2. Examples of sentiment scores of phrases.

We also employ a set of *statistical features* for model training, such as the unigram probability of the adjective in a phrase, the unigram probability of the noun in a phrase, the unigram probability of the phrase and the bigram probability of the adjective-noun pair in a phrase.

Statistical features, however, fail to reveal the underlying semantic meaning of phrases. For example, phrases 'greasy chicken tikka masala' and 'drunken husband' have the same *n*-gram probabilities in our corpus (a single observation), but they should certainly not be treated as the same. To capture the semantic meanings of phrases, we first cluster the topics of phrases into generic semantic categories. The language-model based algorithm is given by:

$$P(t_c|\, t_i) = \sum_{a \in A} P(t_c|a) \cdot P(a|t_i)$$

$$= \sum_{a \in A} \frac{P(a,t_c)}{P(a)} \cdot \frac{P(a,t_i)}{P(t_i)}$$

$$= \frac{1}{P(t_i)} \sum_{a \in A} \frac{1}{P(a)} \cdot P(a,t_c) \cdot P(a,t_i) \qquad (2)$$

where A represents the set of all the adjectives in the corpus. We select a small set of initial topics with the highest frequency counts (e.g., 'food', 'service' and 'atmosphere'). For each of the other topics t_c (e.g., 'chicken', 'waitress' and 'décor'), we calculate its similarity with each initial topic t_i based on the bigram probability statistics. For those topics with conditional probability higher than a threshold for an initial topic t_i, we assign them to the cluster of t_i. We use this as a *semantic feature*, e.g., whether the topic of a phrase belongs to a generic semantic category. Table 3 gives some clustering examples.

Category	Relevant Topics
food	appetizer, beer, bread, fish, fries, ice cream, margaritas, menu, pizza, pasta, rib, roll, sauce, seafood, sandwich, steak, sushi, dessert, cocktail, brunch
service	waiter, staff, management, server, hostess, chef, bartender, waitstaff
atmosphere	décor, ambiance, music, vibe, setting, environment, crowd
price	bill, pricing, prices

Table 3. Topic to semantic category clustering.

This language-model-based method relies on bigram probability statistics and can well cluster highly frequent topics. Categories such as 'service' and 'atmosphere' contain very limited related topics, most of which have high frequencies (e.g., 'waiter', 'staff', 'ambiance' and 'vibe'). The category 'food', however, is very domain-specific and contains a very large vocabulary, from generic sub-categories such as 'sushi', 'dessert' and 'sandwich' as shown in the examples, to specific courses such as 'bosc pear bread pudding' and 'herb roasted vermont pheasant wine cap mushrooms'. These domain-specific topics have very low frequencies, yet they are very relevant and valuable. But many of them are discarded by the clustering. It would be a similar case in other domains. For example, consumer products, movies and books all have domain-independent semantic categories (e.g., 'price' and 'released date') and domain-specific categories (e.g., technical features of consumer products, casts of movies and authors of books).

To recover these context-relevant topics, we employ domain context relations such as a *context-related ontology*. A context-related ontology can be constructed from structured web resources such as online menus of restaurants, names of actors and actresses from movie databases, and specifications of products from online shops. An example of a partial online menu of a restaurant is shown in Figure 3. From these structured web resources, we can build up a hierarchical ontology, based on which a set of *semantic features* can be extracted (e.g., whether a phrase contains a course name, or an actress's name, or a dimension of technical features of a consumer product).

Entree
Roasted Pork Loin Wrapped In Bacon with watermelon and red onion salad spicy honey-mustard bbq sauce
Spicy Halibut And Clam Roast with bacon braised greens, white beans and black trumpet mushrooms
Parmesan and Caramelized Shallot Wrapper Style Ravioli turnip greens and white truffle oil
Herb Roasted Vermont Pheasant Wine Cap Mushrooms, Pearl Onions and Fava Beans
Dessert
Chocolate Tasting Plate of white chocolate bombe milk chocolate creme brulée and dark chocolate flourless cake
White Fruit Tasting Plate of warm apple strudel butterscotch, Bosc Pear bread pudding and toasted coconut panna cotta

↓

Entrée	Pork loin, bacon, watermelon, red onion salad, honey, mustard, bbq sauce
Dessert	Chocolate, milk, crème brulee, cake

Figure 3. Example of a partial online menu and an exemplary ontology derived.

After the classification, phrases identified as 'highly informative and relevant' are clustered into different aspects according to the semantic category clustering and the hierarchical ontology. An average sentiment score for each aspect is then calculated:

$$ave(s_t) = \frac{\sum_{j \in N_s} r_j}{|N_s|} \qquad (3)$$

where s_t represents the aspect s of entry t (e.g., a restaurant, a movie, or a consumer product), N_s represents the set of phrases in the cluster of aspect s, and r_j represents the sentiment score of phrase j in the cluster.

The set of phrases selected for one entry may come from several reviews on this single entry, and many of them may include the same noun (e.g., 'good fish', 'not bad fish' and 'above-average fish' for one restaurant). Thus, the next step is multi-phrase redundancy resolution. We select the phrase with a sentiment score closest to the average score of its cluster as the most representative phrase on each topic:

$$m = argmin_{j \in N_i}(|r_j - ave(s_t)|) \quad (4)$$

where $ave(s_t)$ represents the average sentiment score of aspect s, N_i represents the set of phrases on the same topic i in the cluster s, and r_j represents the sentiment score of phrase j.

This sequence of topic categorization, ontology construction, phrase pruning and redundancy elimination leads to a summary database, which can be utilized for dialogue generation in spoken recommendation systems. A review summary database entry generated by the proposed approaches is exemplified in Figure 4.

```
{ restaurant "dali restaurant and tapas bar"
    :atmosphere ( "wonderful evening", "cozy atmos-
                phere", "fun decor", "romantic date" )
    :atmosphere_rating "4.1"
    :food ( "very fresh ingredients",  "tasty fish",
          "creative dishes",  "good sangria" )
    :food_rating "3.9"
    :service ( "fast service" )
    :service_rating "3.9"
    :general ("romantic restaurant","small space" )
    :general_rating "3.6"              }
```

Figure 4. Example of a review summary database entry generated by the proposed approaches.

4 Experiments

In this project, we substantiate the proposed approach in a restaurant domain for our spoken dialogue system (Gruenstein and Seneff, 2007), which is a web-based multimodal dialogue system allowing users to inquire about information about restaurants, museums, subways, etc. We harvested a data collection of 137,569 reviews on 24,043 restaurants in 9 cities in the U.S. from an online restaurant evaluation website[1]. From the dataset, 857,466 sentences were subjected to parse analysis; and a total of 434,372 phrases (114,369 unique ones) were extracted from the parsable subset (78.6%) of the sentences.

Most pros/cons consist of well-formatted phrases; thus, we select 3,000 phrases extracted from pros/cons as training data. To generate a human judgment-consistent training set, we manually label the training samples with 'good' and 'bad' labels. We then randomly select a subset of 3,000 phrases extracted from review texts as the test set and label the phrases. The kappa agreement between two sets of annotations is 0.73, indicating substantial consistency. We use the two annotation sets as the ground truth.

To extract context-related semantic features, we collect a large pool of well-formatted menus from an online resource[2], which contains 16,141 restaurant menus. Based on the hierarchical structure of these collected menus, we build up a context-related ontology and extract a set of semantic features from the ontology, such as whether the topic of a phrase is on *category-level* (e.g., 'entrée', 'dessert', 'appetizers', 'salad'), whether the topic is on *course-level* (e.g., 'Roasted Pork Loin', 'Spicy Halibut and Clam Roast'), and whether the topic is on *ingredient-level* (e.g., 'beans', 'chicken', 'mushrooms', 'scallop').

We employ the three types of features as aforementioned to train the SVMs and the decision tree models. To select the most valuable features for model training, we conducted a set of leave-one-feature-out experiments for both the SVMs and the decision tree models. We found that all the features except the *adjective unigram probability* contribute positively to model learning. From further data analysis we observed that many phrases with popular adjectives have context-unrelated nouns, which makes the adjective unigram probability fail to become a dominant factor for phrase relevance. Using the adjective unigram probability as a learning feature will mislead the system into trusting an adjective that is common but has a poor bigram affinity to the noun in the phrase. Thus, we eliminate this feature for both the SVMs and the decision tree learning.

[1] http://www.citysearch.com

[2] http://www.menupages.com

To evaluate the performance of the classification models, we take a set of intuitively motivated heuristic rules as the baseline. Figure 5 gives the pseudo-code of the heuristic rule algorithm, which uses variations of all the features except the unigram probability of adjectives.

```
If(sentiment score of the phrase exists)
  if(sentiment score is within neutral range) label=-1;
  else
     if(phrase appeared in the training data)
        if((3<frequency of phrase < 100))   label = 1;
        else
           if(frequency of phrase >= 100)   label = -1;
           else    if(topic belongs to ontology)  label = 1;
                   else   label = -1;
     else
          if(topic belongs to ontology)   label = 1;
          else   label = -1;
else
   if(phrase appeared in the training data)
        if((3<frequency of phrase < 100))
             if(topic belongs to ontology)  label = 1;
              else   label = -1;
        else
           if(frequency of phrase >= 100)   label = -1;
           else
              if(topic belongs to ontology)  label = 1;
              else   if(frequency of noun > 100) label = 1;
                     else   label = -1;
   else
       if(topic belongs to ontology)  label = 1;
       else     if(frequency of noun > 100)   label = 1;
                else   label = -1;
```

Figure 5. Pseudo-code of the heuristic rule algorithm.

The performance of classification by different models is shown in Table 4. Although the heuristic rule algorithm is complicated and involves human knowledge, the statistical models trained by SVMs and the decision tree algorithms both outperform the baseline significantly. The SVM model outperforms the baseline by 10.5% and 11.9% on the two annotation sets respectively. The decision tree model outperforms the baseline by 16.4% and 23.2% (average relative improvement of 36%), and it also outperforms the SVM model by 5.9% and 11.3% (average relative improvement of 13%).

The classification model using the decision tree algorithm can achieve a precision of 77.9% and 74.5% compared with the ground truth, which is quite comparable to human judgment (the precision of one annotation set based on the other is 74%). This shows that the decision tree model can predict phrase labels as reliably as human judgment.

	Baseline	**SVM**	**Decision tree**
Annotation 1	61.5%	72.0%	**77.9%**
Annotation 2	51.3%	63.2%	**74.5%**

Table 4. Precision of phrase classification using the heuristic rule baseline, the SVM model, and the decision tree algorithm.

To gain further insight on the contributions of each feature set to the decision tree learning, Table 5 gives the experimental results on leaving each feature out of model training. As shown, without semantic features, the precision is 70.6% and 65.4% on the two annotation sets, lower by 7.3% and 9.1% than the case of training the model with all the features (77.9% and 74.5%). This shows that the semantic features significantly contribute to the decision tree learning.

Feature set	**A1**	**A2**
all features	**77.9%**	**74.5%**
without bigram probability of adjective-noun pair	56.6% (-21.3%)	63.9% (-10.6%)
without unigram probability of the phrase	57.6% (-20.3%)	64.3% (-10.2%)
without unigram probability of the noun	59.8% (-18.1%)	67.8% (-6.7%)
without sentiment score of the phrase	63.4% (-14.5%)	66.6% (-7.9%)
without underlying semantic features	70.6% (-7.3%)	65.4% (-9.1%)

Table 5. Performance of the decision tree model by leaving each feature out of model training ('A1' and 'A2' represent the annotation set 1 and 2 respectively).

The experimental results also show that the feature of bigram probability of the adjective-noun pair contributes the most to the model learning. Without this feature, the precision drops by 21.3% and 10.6%, reaching the lowest precision among all the leave-one-out experiments. This confirms our observation that although a single adjective is not dominant, the pair of the adjective and the noun that co-occurs with it plays an important role in the classification.

The sentiment of phrases also plays an important role. Without sentiment features, the precision drops to 63.4% and 66.6% respectively on the two annotations, decreasing by 14.5% and 7.9%. This shows that the sentiment features contribute significantly to the classification.

5 Discussions

Experimental results show that the decision tree algorithm outperforms the SVMs on this particular classification problem, and it outperforms the heuristic rule baseline significantly. Thus, although the identification of informativeness and relevance of phrases is a rather subjective problem, which is difficult to predict using only human knowledge, it can be well defined by decision trees. Part of the reason is that the decision tree algorithm can make better use of a combination of Boolean value features (e.g., whether a topic belongs to a context-related ontology) and continuous value features. Also, as the phrase classification task is very subjective, it is very similar to a 'hierarchical *if-else* decision problem' in human cognition, where decision tree algorithms can fit well. Figure 6 shows a partial simplified decision tree learned from our model, which can give an intuitive idea of the decision tree models.

6 Related Work

Sentiment classification and opinion mining have been well studied for years. Most studies have focused on text-based systems, such as document-level sentiment classification and sentence-level opinion aggregation (Turney, 2002; Pang et al., 2002; Dave et al., 2003; Hu and Liu, 2004; Popescu and Etzioni, 2005; Wilson et al., 2005; Zhuang et al., 2006; Kim and Hovy, 2006).

There was a study conducted by Carenini et al. in 2006, which proposed a combination of a sentence extraction-based approach and a language generation-based approach for summarizing evaluative arguments. In our work, we utilize a lower-level phrase-based extraction approach, which utilizes high level linguistic features and syntactic structure to capture phrase patterns.

There was also a study on using reviews to generate a dictionary of mappings between semantic representations and realizations of concepts for dialogue systems (Higashinaka et al., 2006; Higashinaka, 2007). They also used the association between user ratings and reviews to capture semantic-syntactic structure mappings. A set of filtering rules was manually created to eliminate low-quality mappings. In our approach, we use an automatic approach to classifying high/low informative phrases. The learning features are domain-independent with no hand-crafted rules, and can be extended to other domains effortlessly.

7 Conclusions

In this paper we proposed a three-level framework for review-based recommendation dialogue systems, including linguistic phrase extraction, dialogue-oriented review summary generation, and human-friendly dialogue generation. The contributions of this paper are three-fold: 1) it identified and defined the research goal of utilizing opinion summarization for real human-computer conversation; 2) it formulated an evaluation methodology for high-density review summary for dialogue purposes; 3) it proposed an approach to automatic classification of high/low informative phrases using a decision tree model. Experimental results showed that the decision tree model significantly outperforms a heuristic rule baseline and the SVM model, and can resolve the phrase classification problem comparably to humans consistently.

Future work will focus on: 1) applying the sentiment scoring model to noun/verb sentiment assessment; 2) application of the review summary generation approach in other domains and other languages; 3) data collection on user engagement with our dialogue systems involving review-summary evaluation.

Abstract

Extraction of entities from ad creatives is an important problem that can benefit many computational advertising tasks. Supervised and semi-supervised solutions rely on labeled data which is expensive, time consuming, and difficult to procure for ad creatives. A small set of manually derived constraints on feature expectations over unlabeled data can be used to *partially* and *probabilistically* label large amounts of data. Utilizing recent work in constraint-based semi-supervised learning, this paper injects light weight supervision specified as these "constraints" into a semi-Markov conditional random field model of entity extraction in ad creatives. Relying solely on the constraints, the model is trained on a set of unlabeled ads using an online learning algorithm. We demonstrate significant accuracy improvements on a manually labeled test set as compared to a baseline dictionary approach. We also achieve accuracy that approaches a fully supervised classifier.

1 Introduction

Growth and competition in web search in recent years has created an increasing need for improvements in organic and sponsored search. While foundational approaches still focus on matching the exact words of a search to potential results, there is emerging need to better understand the underlying *intent* in queries and documents. The implicit intent is particularly important when little text is available, such as for user queries and advertiser creatives.

This work specifically explores the extraction of named-entities, i.e. discovering and labeling phrases in ad creatives. For example, for an ad "Move to San Francisco!", we would like to extract the entity *san francisco* and label it a CITY. Similarly, for an ad "Find DVD players at Amazon", we would extract *dvd players* as a PRODUCT and *amazon* as a ORGNAME. The named-entities provide important features to downstream tasks about what words and phrases are important, as well as information on the intent. Much recent research has focused on extracting useful information from text advertisement creatives that can be used for better retrieval and ranking of ads. Semantic annotation of queries and ad creatives allows for more powerful retrieval models. Structured representations of semantics, like the one studied in our task, can be directly framed as information extraction tasks, such as segmentation and named-entity recognition.

Information extraction methods commonly rely on labeled data for training the models. The human labeling of ad creatives would have to provide the complete segmentation and entity labels for the ads, which the information extraction algorithm would then rely on as the truth. For entity extraction from advertisements this involves familiarity with a large number of different domains, such as electronics, transportation, apparel, lodging, sports, dining, services, *etc*. This leads to an arduous and time consuming labeling process that can result in noisy and error-prone data. The problem is further compounded by the inherent ambiguity of the task, leading to the human editors often presenting conflicting and incorrect labeling.

Similar problems, to a certain degree, are also faced by a number of other machine learning tasks where completely relying on the labeled data leads to unsatisfactory results. To counter the noisy and sparse labels, *semi-supervised learning* meth-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 73–81,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

ods utilize unlabeled data to improve the model (see (Chapelle et al., 2006) for an overview). Furthermore, recent work on *constraint-based semi-supervised learning* allows domain experts to easily provide additional light supervision, enabling the learning algorithm to learn using the prior domain knowledge, labeled and unlabeled data (Chang et al., 2007; Mann and McCallum, 2008; Bellare et al., 2009; Singh et al., 2010).

Prior domain knowledge, if it can be easily expressed and incorporated into the learning algorithm, can often be a high-quality and cheap substitute for labeled data. For example, previous work has often used dictionaries or *lexicons* (lists of phrases of a particular label) to bootstrap the model (Agichtein and Ganti, 2004; Canisius and Sporleder, 2007), leading to a *partial* labeling of the data. Domain knowledge can also be more *probabilistic* in nature, representing the probability of certain token taking on a certain label. For most tasks, labeled data is a convenient representation of the domain knowledge, but for complex domains such as structured information extraction from ads, these alternative easily expressible representations may be as effective as labeled data.

Our approach to solving the the named entity extraction problem for ads relies completely on domain knowledge not expressed as labeled data, an approach that is termed *minimally supervised*. Each ad creative is represented as a semi-Markov conditional random field that probabilistically represents the segmentation and labeling of the creative. External domain knowledge is expressed as a set of targets for the expectations of a small subset of the features of the model. We use *alternating projections* (Bellare et al., 2009) to train our model using this knowledge, relying on the rest of the features of the model to "dissipate" the knowledge. Topic model and co-occurrence based features help this propagation by generalizing the supervision to a large number of similar ads.

This method is applied to a large dataset of text advertisements sampled from a variety of different domains. The minimally supervised model performs significantly better than a model that incorporates the domain knowledge as hard constraints. Our model also performs competitively when compared to a supervised model trained on labeled data from a similar domain (web search queries).

Background material on semi-CRFs and constraint based semi-supervised learning is summarized in Section 2. In Section 3, we describe the problem of named entity recognition in ad creatives as a semi-CRF, and describe the features in Section 4. The constraints that we use to inject supervision into our model are listed in Section 5. We demonstrate the success of our approach in Section 6. This work is compared with related literature in Section 7.

2 Background

This section covers introductory material on the probabilistic representation of our model (semi-Markov conditional random fields) and the constraint-driven semi-supervised method that we use to inject supervision into the model.

2.1 Semi-Markov Conditional Random Fields

Conditional Random Fields (CRFs) (Lafferty et al., 2001) use a Markov random field to model the conditional probability $P(\mathbf{y}|\mathbf{x})$. CRFs are commonly used to learn sequential models, where the Markov field is a linear-chain, and $\mathbf{y}$ is a linear sequence of labels and each label $y_i \in \mathcal{Y}$. Let $\mathbf{f}$ be a vector of *local feature functions* $\mathbf{f} = \langle f^1, \ldots, f^K \rangle$, each of which maps a pair $(\mathbf{x}, \mathbf{y})$ and an index i to a measurement $f^k(i, \mathbf{x}, \mathbf{y}) \in \Re$. Let $\mathbf{f}(i, \mathbf{x}, \mathbf{y})$ be the vector of these measurements, and let $\mathbf{F}(\mathbf{x}, \mathbf{y}) = \sum_i^{|\mathbf{x}|} \mathbf{f}(i, \mathbf{x}, \mathbf{y})$. CRFs use these feature functions in conjunction with the parameters θ to represent the conditional probability as follows:

$$P(\mathbf{y}|\mathbf{x}, \theta) = \frac{1}{Z(\mathbf{x})} e^{\theta \cdot \mathbf{F}(\mathbf{x}, \mathbf{y})}$$

where $Z(x) = \sum_{\mathbf{y}'} e^{\theta \cdot \mathbf{F}(\mathbf{x}, \mathbf{y}')}$.

For sequential models where the same labels appear within a sequence as contiguous blocks (*e.g.*, named entity recognition) it is more convenient to represent these blocks directly as *segments*. This representation was formulated as *semi-Markov conditional random fields (Semi-CRFs)* in (Sarawagi and Cohen, 2004). The *segmentation* of a sequence is represented by $\mathbf{s} = \langle s_1, \ldots, s_p \rangle$ where each *segment* $s_j = \langle t_j, u_j, y_j \rangle$ consists of a *start position* t_j, an *end position* u_j, and a *label* $y_j \in \mathcal{Y}$. Similar to the CRF, let $\mathbf{g}$ be the vector of *segment feature* *functions* $\mathbf{g} = \langle g^1, \ldots, g^K \rangle$, each of which maps the pair $(\mathbf{x}, \mathbf{s})$ and an index j to a measurement $g^k(j, \mathbf{x}, \mathbf{s}) \in \Re$, and $\mathbf{G}(\mathbf{x}, \mathbf{s}) = \sum_j^{|\mathbf{s}|} \mathbf{g}(j, \mathbf{x}, \mathbf{s})$. The conditional probability is represented as:

$$P(\mathbf{s}|\mathbf{x}, \theta) = \frac{1}{Z(\mathbf{x})} e^{\theta \cdot \mathbf{G}(\mathbf{x}, \mathbf{s})}$$

where $Z(x) = \sum_{\mathbf{s}'} e^{\theta \cdot \mathbf{G}(\mathbf{x}, \mathbf{s}')}$. To assert the Markovian assumption, each $g^k(j, \mathbf{x}, \mathbf{s})$ only computes features based on $\mathbf{x}$, s_j, and y_{j-1}[1].

An exact inference algorithm was described in (Sarawagi and Cohen, 2004), and was later improved to be more efficient (Sarawagi, 2006).

2.2 Constraint Driven Learning Using Alternating Projections

Recent work in semi-supervised learning uses constraints as external supervision (Chang et al., 2007; Mann and McCallum, 2008; Bellare et al., 2009; Singh et al., 2010). These external constraints are specified as constraints on the expectations of a set of auxiliary features $\mathbf{g}' = \{g'_1, \ldots, g'_k\}$ over the unlabeled data. In particular, given the targets $\mathbf{u} = \{u_1, \ldots, u_k\}$ corresponding to the auxiliary features $\mathbf{g}'$, the constraints can take different forms, for example $\mathbb{L}_2$ penalty ($\frac{1}{2\beta}\|u_i - \sum_j E_p[g'_i(x_j, s)]\|_2^2 = 0$), $\mathbb{L}_1$ box constraints ($|u_i - \sum_j E_p[g'_i(x_j, s)]| \leq \beta$) and Affine constraints[2] ($E_p[g'_i(x, s)] \leq u_i$). In this work, we only use the affine form of the constraints.

For an example, using domain knowledge, we may know that token "arizona" should get the label STATE in at least half of the occurrences in our data. To capture this, we introduce an auxiliary feature g' : [[Label=STATE *given* Token="arizona"]]. The affine constraint is written as $E_p[g'(x, y)] \geq 0.5$.

These constraints have been incorporated into learning using Alternating Projections (Bellare et al., 2009). Instead of directly optimizing an objective function that includes the constraints, this method considers two distributions, p_λ and $q_{\lambda,\mu}$, where $p_\lambda(\mathbf{s}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} e^{\lambda \cdot \mathbf{G}(\mathbf{x}, \mathbf{s})}$ is the usual semi-Markov model, and $q_{\lambda,\mu} = \frac{1}{Z(\mathbf{x})} e^{(\lambda \cdot \mathbf{G}(\mathbf{x}, \mathbf{s}) + \mu \cdot \mathbf{G}'(\mathbf{x}, \mathbf{s}))}$ is an auxiliary distribution that satisfies the constraints and has low divergence with the model p_λ.

In the batch setting, parameters λ and μ are learned using an EM-like algorithm, where μ is fixed while optimizing λ and vice versa. Each of the updates in these steps decomposes according to the instances, leading to a stochastic gradient based online algorithm, as follows:

1. For $t = 1, \ldots, T$, let $\eta = \frac{1}{t + t_0}$ where $t_0 = 1/\eta_0$, η_0 the initial learning rate. Let labeled and unlabeled data set sizes be m and $n - m$ respectively. Let the initial parameters be λ^0 and μ^0, and α be the weight of $\mathbb{L}_2$ regularization on λ.

2. For a new *labeled* instance x_t with segmentation s_t, set $\mu^t = \mu^{t-1}$ and $\lambda^t = \lambda^{t-1} + \eta\left[\mathbf{g}(x_t, s_t) - E_{p_{\lambda^{t-1}}}[\mathbf{g}(x_t, s)] - \frac{\alpha \lambda^{t-1}}{n}\right]$.

3. For a new *unlabeled* instance x_t, $\mu^t = \mu^{t-1} + \eta\left[\frac{u}{(n-m)} - E_{q_{\lambda^{t-1},\mu^{t-1}}}[\mathbf{g}'(x_t, s)]\right]$ and $\lambda^t = \lambda^{t-1} + \eta\left[E_{q_{\lambda^{t-1},\mu^{t-1}}}[\mathbf{g}(x_t, s)] - E_{p_{\lambda^{t-1}}}[\mathbf{g}(x_t, s)] - \frac{\alpha \lambda^{t-1}}{n}\right]$.

Online training enables scaling the approach to large data sets, as is the case with ads. In our approach we rely only on unlabeled data ($m = 0$, and step 2 of the above algorithm does not apply).

3 Model

Most text ads consist of a brief *title* and an accompanying *abstract* that provides additional information. The objective of our paper is to extract the named-entity phrases within these titles and abstracts, then label them with a *type* from a predetermined taxonomy. An example of such an extraction is shown in Fig 1.

We represent the ad creatives as a sequence of individual tokens, with a special token inserted between the title and the abstract of the ad. The distribution over possible phrases and labels of the ad is expressed as a semi-Markov conditional random field, as described earlier in Section 2.1.

3.1 Label Taxonomy

In most applications of CRFs and semi-CRFs, the domain of labels is a fixed set $\mathcal{Y}$, where each label indexes into one value. Instead, in our approach, we represent our set of labels as a taxonomy (tree). The labels higher in the taxonomy are more generic (for

[1] i.e. $g^k(j, \mathbf{x}, \mathbf{s})$ can be written as $g^k(y_{j-1}, \mathbf{x}, s_j)$

[2] where $E_p[g]$ represents the expectation of g over the unlabeled data using the model p.

Ad Title: Bradley International Airport Hotel

Ad Abstract: Marriott Hartford, CT Airport hotel - free shuttle service & parking.

Output: Bradley International Airport Hotel
Marriott Hartford, CT Airport hotel free shuttle service & parking.

Label	Segment
Place: Airport	Bradley International
Business: Travel	Hotel
OrgName: Lodging	Marriott
Place: City	Hartford
Place: State	CT
Business: Travel	hotel
Product: Travel	shuttle service & parking.

Figure 1: **Example Prediction:** An example of an ad creative (title and abstract), along with a set of probable extracted entities. Note that even in this relatively simple example, there is some ambiguity about what is the correct segmentation and labeling.

instance, Place) and the labels lower in the taxonomy are more specific (for instance, State may be a child of Place). The taxonomy of labels that we use for tagging phrases is shown in Figure 2.

When the model predicts a label for a segment, it can be from any of the levels in the tree. The benefits of this is multi-fold. First, this allows the model to be flexible in predicting labels at a lower (or higher) level based on its confidence. For example, the model may have enough evidence to label "san francisco" a City, however, for "georgia" it may not have enough context to discriminate between State or Country, but could confidently label it a Place. Secondly, this also allows us to design the features over multiple levels of label granularity, which leads to a more expressive model. Expectation constraints can be specified over this expanded set of features, at any level of the taxonomy.

In order to incorporate the nested labels into our model, we observe that every feature that fires for a non-leaf label should also fire for all descendants of that label, *e.g.* every feature that is active for label Place should also be active for a label City, Country, *etc* [3]. Following the observation, for every feature $g^k(\mathbf{x}, \langle t_j, u_j, y_j \rangle)$ that is active, we also fire $\forall y' \in \mathrm{desc}(y_j), g^k(\mathbf{x}, \langle t_j, u_j, y' \rangle)$[4]. The same procedure is applied to the constraints.

4 Features

Our learning algorithm relies on constraints $\mathbf{g}'$ as supervision to extract entities, but even though constraints are designed to be generic they do not cover the whole dataset. The learning algorithm needs to propagate the supervision to instances where the constraints are not applicable, guided by the set of feature functions $\mathbf{g}$. More expressive and relevant features will provide better propagation. Even though these feature functions represent the "unsupervised" part of the model (in that they are only dependent on the unlabeled sequences), they play an important role in propagating the supervision throughout the dataset.

4.1 Sequence and Segment Features

Our first set of features are the commonly used features employed in linear-chain sequence models such as CRFs and HMMs. These consist of factors between each token and its corresponding label, and neighboring labels. They also include transition factors between the labels. These are *local feature functions* that are defined only over pairs of token-wise

[3] Note that this argument works similarly for the taxonomy represented as a DAG, where the descendants are of a node are all nodes reachable from it. We do not explore this structure of the taxonomy in this paper.

[4] This example describes when $g^k(y_{j-1}, \mathbf{x}, s_j)$ ignores y_{j-1}. For the usual case $g^k(y_{j-1}, \mathbf{x}, s_j)$, features between all pairs of descendants of y_{j-1} and y_j are enabled.

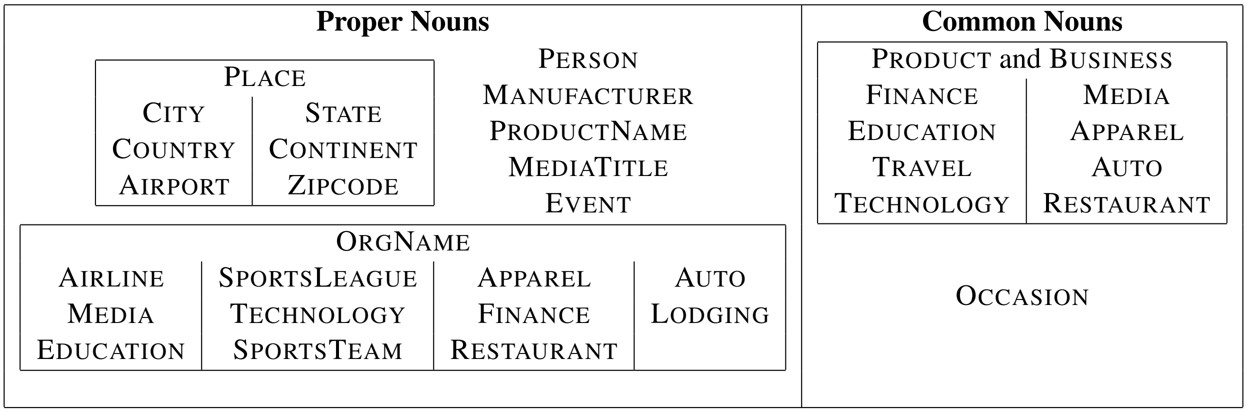

Figure 2: **Label Taxonomy:** The set of labels that are used are shown grouped by the parent label. PRODUCT and BUSINESS labels have been merged for brevity, i.e. there are two labels of each child label shown (e.g. PRODUCT: AUTO and BUSINESS: AUTO). An additional label OTHER is used for the tokens that do not belong to any entities.

labels y_j and y_{j-1}. To utilize the semi-Markov representation that allows features over the predicted segmentation, we add the segment length and prefix/suffix tokens of the segment as features.

4.2 Segment Clusters

Although the sequence and segment features capture a lot of useful information, they are not sufficient for propagation. For example, if we have a constraint about the token "london" being a CITY, but not about "boston", the model can only rely on similar contexts between 'london" and 'boston" to propagate the information. To allow more complicated propagation to occur, we use features based on a clustering of segments.

The segment cluster features are based on similarity between segments from English sentences. A large corpus of English documents were taken from web, from which 5.1 billion unique sentences were extracted. Using the co-occurrence of segments in the sentences as a distance measure, K-Means is used to identify clusters of segments as described in (Pantel et al., 2009). The cluster identity of each segment is added as a feature to the model, capturing the intuition that segments that appear in the same cluster should get the same label.

4.3 Topic Model

Most of the ads lie in separate domains with very little overlap, for example travel and electronics. Additional information about the domain can be very useful for identifying entities in the ad. For example, consider the token "amazon". It may be difficult to discern whether the token refers to the geographical region or the website from just the features in the model, however given that the domain of the ad is travel (or conversely, electronics), the choice becomes easier.

The problem of domain identification is often posed as a document classification task, which requires labeled data to train and thus is not applicable for our task. Additionally, we are not concerned with accurately specifying the exact domain of each ad, instead any information about similarity between ads according to their domains is helpful. This kind of representation can be obtained in an unsupervised fashion by using topic cluster models (Steyvers and Griffiths, 2007; Blei et al., 2003). Given a large set of unlabeled documents, topic models define a distribution of topics over each document, such that documents that are similar to each other have similar topic distributions.

The LDA (Blei et al., 2003) implementation of topic models in the Mallet toolkit (McCallum, 2002) was used to construct a model with 1000 topics for a dataset containing 3 million ads. For each ad, the discrete distribution over the topics, in conjunction with each possible label, was added as a feature. This captures a potential for each label given an approximation of the ad's domain captured as topics.

5 Constraints

Constraints are used to inject light supervision into the learning algorithm and are defined as targets u for expectations of features G' over the data. Any feature that can be included in the model can be used as a constraint. This allows us to capture a variety of different forms of domain knowledge, some of which we shall explore in this section.

Labeled data x_l, s_l can be incorporated as a special case when constraints have a target expectation of 1.0 for the features that are defined only for the sequence x_l and with segmentation s_l. This allows us to easily use labeled data in form of constraints, but in this work we do not include any labeled data. A more interesting case is that of partial labeling, where the domain expert may have prior knowledge about the probability that certain tokens and/or contexts result in a specific label. These constraints can cover more instances than labeled data, however they only provide partial and stochastic labels. All of the constraints described in this section are also included as simple features.

Many different methods have been suggested in recent work for finding the correct target values for the feature expectations. First, if ample labeled data is available, features expectations can be calculated, and assumptions can be made that the same expectations hold for the unlabeled data. This method cannot be applied to our work due to lack of labeled data. Second, for certain constraints, the prior knowledge can be used directly to specify these values. Third, if the constraints are an output of a previous machine learning model, we can use that model's confidence in the prediction as the target expectation of the constraint. Finally, a search for the ideal values of the target expectations can be performed by evaluating on small evaluation data. Our target values for feature expectations were set based on domain knowledge, then adjusted manually based on minimal manual examination of examples on a small held-out data set.

5.1 Dictionary-Based

Dictionary constraints are the form of constraints that apply to the feature between an individual token and its label. For a set of tokens in the dictionary, the constraints specify which label they are likely to be. Dictionaries can be easily constructed using various sources, for example product databases, lexicons, manual collections, or predictions from other models. These dictionary constraints are often used to bootstrap models (Agichtein and Ganti, 2004; Canisius and Sporleder, 2007) and have also been used in the ads domain (Li et al., 2009). For our application, we rely on dictionary constraints from two sources.

First, the predictions of a previous model are used to construct a dictionary. A model for entity extraction is trained on a large amount of labeled search query data. The domain and style of web queries differs from advertisements, but the set of labels is essentially the same. The supervised query entity extraction model is used to infer segments and labels for the ads domain, and each of the predicted segments are added to the dictionary of the corresponding predicted label. Even though the predictions of the model are not perfect (see Section 6.1) the predictions of some of the labels are of high precision, and thus can be used for supervision in form of noisy dictionary constraints.

The second source of prior information for dictionary constraints are external databases. Lists of various types of places can be obtained easily, for example CITY, COUNTRY, STATE, AIRPORT, etc. Additionally, product databases available internally to our research group are used for MANUFACTURERS, BRANDS, PRODUCTS, MEDIATITLE, etc. Some of these databases are noisy, and the constraints based on them are given lower target expectations.

5.2 Pattern-Based

Prior knowledge can often be easily expressed as patterns that appear for a specific domain. Pattern based matching has been used to express supervision for information extraction tasks (Califf and Mooney, 1999; Muslea, 1999). The usual use case involves a domain expert specifying a number of "prototypical" patterns, while additional patterns are discovered based on these initial patterns.

We incorporate noisy forms of patterns as constraints. Simple regular expression based patterns were used to identify and label segments for a few domains (*e.g.* "flights to {PLACE}" and "looking for {PRODUCT}?"). We do not employ a pattern-discovery algorithm for finding other contexts; the model propagates these labels, as before, using the features of the rest of the model. However if the output of a pattern-discovery algorithm is available, it can be directly incorporated into the model as additional constraints.

5.3 Domain-Based

A number of label-independent constraints are also added to avoid unrealistic segmentation predictions. For example, an expectation over segment lengths was included, which denotes that the segment length is usually 1 or 2, and almost never more than 6. A constraint is also added to avoid segments that overlap the separator token between title and abstract by ensuring that the segment that includes the separator token is always of length 1 and of label OTHER. Finally, an additional constraint ensures that the label OTHER is the most common label.

6 Results

The feature expectations of the model are calculated with modifications to an open source semi-CRF package[5]. We collect two datasets of ad creatives randomly sampled from Yahoo!'s ads database: a smaller dataset contains 14k ads and a larger dataset of 42k ads. The ads were not restricted to any particular domain (such as travel, electronics, etc.). The average length of the complete ad text was ∼14 tokens. Preprocessing of the text involved lower-casing, basic cleaning, and stemming.

The training time for each iteration through the data was ∼90 minutes for the smaller dataset and ∼360 minutes for the larger dataset. Inference over the dataset, using Viterbi decoding for semi-CRFs, took a total of ∼8 and ∼32 minutes. The initial learning rate η is set to 10.0.

6.1 Discussion

We compare our approach to a baseline "Dictionary" system that deterministically selects a label based on the dictionaries described in Section 5.1. A segment is given a label corresponding to the dictionary it appears in, or OTHER if it does not appear in any dictionary. In addition, we compare to an external supervised system that has been trained on tens-of-thousands of manually-annotated search queries that use the same taxonomy (the same system as used in Section 5.1 to derive dictionaries). This CRF-based model contains mostly the same features as our unsupervised system, and approximates what a fully supervised system might achieve, although it is trained on search queries. Results for our approach and these two systems are presented in Table 1. Our evaluation data consists of 2,157 randomly sampled ads that were manually labeled by professional editors. This labeled data size was too small to sufficiently train a supervised semi-CRF model that out-performed the dictionary baseline for our task (which consists of 45 potential labels).

We measure the token-wise accuracy and macro F-score over the manually labeled dataset. Typically, these metrics measure only exact matches between the true and the predicted label, but this leads to cases where the model may predict PLACE for a true CITY. To allow a "partial credit" for these cases, we introduce "weighted" version of these measures, where a predicted label is given 0.5 credit if the true label is its direct child or parent, and 0.25 credit if the true label is a sibling. Our F-score measures the recall of all true labels except OTHER and similarly the precision of all predicted labels except OTHER. We focus on these labels because the OTHER label is mostly uninformative for downstream tasks. The token-wise accuracy over all labels (including OTHER) is included as "Overall Accuracy".

Our method significantly outperforms the baseline dictionary method while approaching the results obtained with the sophisticated supervised model. Overall accuracy is 50% greater than the dictionary baseline, and comes within 10% of the supervised model[6]. Increasing unlabeled data from 14k to 42k ads provides an increase in overall accuracy and non-OTHER precision, but somewhat reduces recall for the remaining labels. We also include the F2-score which gives more weight to recall, because we are interested in extracting informative labels for downstream models (which may be able to compensate for a lower precision in label prediction). Our model trained on 14k samples out-performs the query-based supervised model in terms of F2, which is promising for future work that will incorporate predicted labels in ad retrieval and ranking systems.

[6] Comparisons and trends for normal and weighted measures are consistent throughout the results.

Table 1: **Evaluation:** Token-wise accuracy and F-score for the methods evaluated on labeled data (Normal / *Weighted*)

Metric	Dictionary	Our Method (14k)	Our Method (42k)	Query-based Sup. Model
Overall Accuracy	0.454 / *0.466*	0.596 / *0.627*	0.629 / *0.649*	0.665 / *0.685*
non-OTHER Recall	0.170 / *0.205*	0.329 / *0.412*	0.271 / *0.325*	0.286 / *0.342*
non-OTHER Precision	0.136 / *0.163*	0.265 / *0.333*	0.297 / *0.357*	0.392 / *0.469*
F1-score	0.151 / *0.182*	0.293 / *0.368*	0.283 / *0.340*	0.331 / *0.395*
F2-score	0.162 / *0.195*	0.313 / *0.393*	0.276 / *0.331*	0.303 / *0.361*

7 Related Work

Extraction of structured information from text is of interest to a large number of communities. However, in the ads domain, the task has usually been simplified to that of classification or ranking. Previous work has focused on retrieval (Raghavan and Iyer, 2008), user click prediction (Shaparenko et al., 2009; Richardson et al., 2007; Ciaramita et al., 2008), ad relevance (Hillard et al., 2010) and bounce rate prediction (Sculley et al., 2009). As far we know, our method is the only one that aims to solve a much more complex task of segmentation and entity extraction from ad creatives. Supervised methods are a poor choice to solve this task as they require large amounts of labeled ads, which is expensive, time-consuming and noisy. Most semi-supervised methods also rely on *some* labeled data, and scale badly with the size of unlabeled data, which is intractable for most ad databases.

Considerable research has been undertaken to exploit forms of domain knowledge other than labeled data to efficiently train a model while utilizing the unlabeled data. These include methods that express domain knowledge as constraints on features, which have shown to provide high accuracy on natural language datasets (Chang et al., 2007; Chang et al., 2008; Mann and McCallum, 2008; Bellare et al., 2009; Singh et al., 2010). We use the method of alternating projections for constraint-driven learning (Bellare et al., 2009) since it specifies constraints on feature expectations instead of less intuitive constraints on feature parameters (as in (Chang et al., 2008)). Additionally, the alternating projection method is computationally more efficient than Generalized Expectation (Mann and McCallum, 2008) and can be applied in an online fashion using stochastic gradient.

Our approach is most similar to (Li et al., 2009), which uses semi-supervised learning for CRFs to extract structured information from user queries. They also use a constraint-driven method that utilizes an external data source. Their method, however, relies on labeled data for part of the supervision while our method uses only unlabeled data. Also, evaluation was only shown for a small domain of user queries, while our work does not restrict itself to any specific domain of ads for evaluation.

8 Conclusions

Although important for a number of tasks in sponsored search, extraction of structured information from text advertisements is not a well-studied problem. The difficulty of the problem lies in the expensive, time-consuming and error-prone labeling process. In this work, the aim was to explore machine learning methods that do not use labeled data, relying instead on light supervision specified as constraints on feature expectations. The results clearly show this *minimally-supervised* method performs significantly better than a dictionary based baseline. Our method also approaches the performance of a supervised model trained to extract entities from web search queries. These findings strongly suggest that domain knowledge expressed in forms other than directly labeled data may be preferable in domains for which labeling data is unsuitable.

The most important limitation lies in the fact that specifying the target expectations of constraints is an ad-hoc process, and robustness of the semi-supervised learning method to noise in these target values needs to be investigated. Further research will also explore using the extracted entities from advertisements to improve downstream sponsored search tasks.

Abstract

Taxonomies are an important resource for a variety of Natural Language Processing (NLP) applications. Despite this, the current state-of-the-art methods in taxonomy learning have disregarded word polysemy, in effect, developing taxonomies that conflate word senses. In this paper, we present an unsupervised method that builds a taxonomy of senses learned automatically from an unlabelled corpus. Our evaluation on two WordNet-derived taxonomies shows that the learned taxonomies capture a higher number of correct taxonomic relations compared to those produced by traditional distributional similarity approaches that merge senses by grouping the features of each word into a single vector.

1 Introduction

A concept or a sense, s, can be defined as the meaning of a word or a multiword expression. A concept s can be linguistically realised by more than one word while at the same time a word w can be the linguistic realisation of more than one concept. Given a set of concepts S, taxonomy learning is the task of hierarchically classifying the elements in S in an *automatic* manner. For example, consider a set of concepts linguistically realised by the words/multiword expressions *LAN, computer network, internet, meshwork, gauze, snood*. Taxonomy learning methods produce taxonomies, such as the ones shown in Figures 1 (a) and 1 (b).

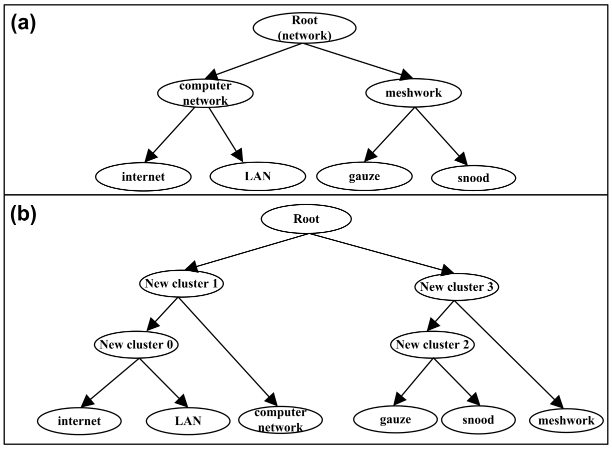

Figure 1: A labelled and an unlabelled concept taxonomy

By observing Figure 1 (a), we can express **IS-A** statements, such as *Internet* **IS-A** *Computer Network* etc. However, the same does not apply to the taxonomy in Figure 1 (b), since this taxonomy is not fully labelled. Despite this, its hierarchical organisation clearly shows that the concepts are divided into groups, which are further subdivided into subgroups and so forth, until we reach a level where each concept belongs to its own group. Unlabelled taxonomies are typically produced by agglomerative hierarchical clustering algorithms (King, 1967; Sneath and Sokal, 1973).

The knowledge encoded in taxonomies can be utilised in a range of NLP applications. For instance, taxonomies can be used in information retrieval to expand a user query with semantically related words or to enhance document representation by abstracting from plain words and adding conceptual information (Cimiano, 2006). WordNet's (Fellbaum, 1998) taxonomic relations have also been used in Word Sense Disambiguation (WSD) (Navigli and Velardi, 2004b). In named entity recognition, methods relying on gazetteers could make

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 82–90,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

use of automatically acquired taxonomies (Cimiano, 2006), while question answering systems have also benefited (Moldovan and Novischi, 2002).

Despite the wide uses of taxonomies, the majority of methods disregard or do not deal effectively with word polysemy, in effect, developing taxonomies that conflate the senses of words (see Section 2). In this work, we show that Word Sense Induction (WSI) can be effectively employed to address this limitation of existing methods.

We present a novel method that employs WSI to generate the different senses of a set of target words from an unlabelled corpus and then produces a taxonomy of senses using Hierarchical Agglomerative Clustering (HAC) (King, 1967; Sneath and Sokal, 1973). We evaluate our method on two WordNet-derived sub-taxonomies and show that our method leads to the development of concept hierarchies that capture a higher number of correct taxonomic relations in comparison to those generated by current distributional similarity approaches.

2 Related work

Initial research on taxonomy learning focused on identifying in a given text lexico-syntactic patterns that suggest hyponymy relations (Hearst, 1992). For instance, the pattern NP_0 *such as* $NP_1, \ldots, NP_n$ suggests that NP_0 is a hypernym of NP_i. For example, given the phrase *Fruits, such as oranges, apples,...*, the above pattern would suggest that *fruit* is a hypernym of *orange* and *apple*. These pattern-based approaches operate at the word level by learning lexical relations between words rather than between senses of words.

In the same spirit, other work attempted to exploit the regularities of dictionary entries to identify hyponymy relations (Amsler, 1981). For example in WordNet, *WAN* is defined as *a computer network that spans* .... Hence, one can easily induce that *WAN* is a hyponym of *computer network* by assuming that the first noun phrase in the definition is a hypernym of the target word. These approaches learn lexical relations at the sense level since dictionaries separate the senses of a word. However this would be true if and only if the glosses of the dictionaries were sense-annotated, which is not the case for the majority of electronic dictionaries (Cimiano, 2006). Another limitation is that taxonomies are built according to the sense distinctions present in dictionaries and not according to the actual use of words in the corpus.

The majority of taxonomy learning approaches are based on the *distributional hypothesis* (Harris, 1968). Typically, distributional similarity methods (Cimiano et al., 2004; Cimiano et al., 2005; Faure and Nédellec, 1998; Reinberger and Spyns, 2004; Caraballo, 1999) utilise syntactic dependencies such as subject/verb, object/verb relations, conjunctive and appositive constructions and others. These dependencies are used to extract the features that serve as the dimensions of the vector space. Each target noun is then represented as a vector of extracted features where the frequency of co-occurrence of the target noun with each feature is used to calculate the weight of that feature. The constructed vectors are the input to hierarchical clustering or *formal concept analysis* (Ganter and Wille, 1999) to produce a taxonomy. These approaches assume that a target noun is monosemous creating one vector of features for each target noun. This limitation can lead to a number of problems.

Firstly, the constructed taxonomies might be biased towards the inclusion of taxonomic relationships between the most frequent senses of target nouns, ignoring interesting taxonomic relations where less frequent senses are present. For example, consider the word *house*. Current distributional similarity methods would possibly capture the hyponyms of its Most Frequent Sense (MFS[1]), however ignoring the hyponyms of less frequent senses of *house*, e.g. *casino*, *theater*, etc. Given that word senses typically follow a Zipf distribution, these methods construct vectors dominated by the MFS of words. This bias significantly degrades the usefulness of learned taxonomies.

Secondly, given that distributional similarity approaches rely on the computation of pairwise similarities between target words, merging their senses to a single vector might lead to unreliable similarity estimates. For example, merging the features of the different senses of *house* could provide a lower similarity with its monosemous hyponym *beach house*, since only the first sense of *house* is related to *beach*

[1] WordNet: A dwelling that serves as living quarters ...

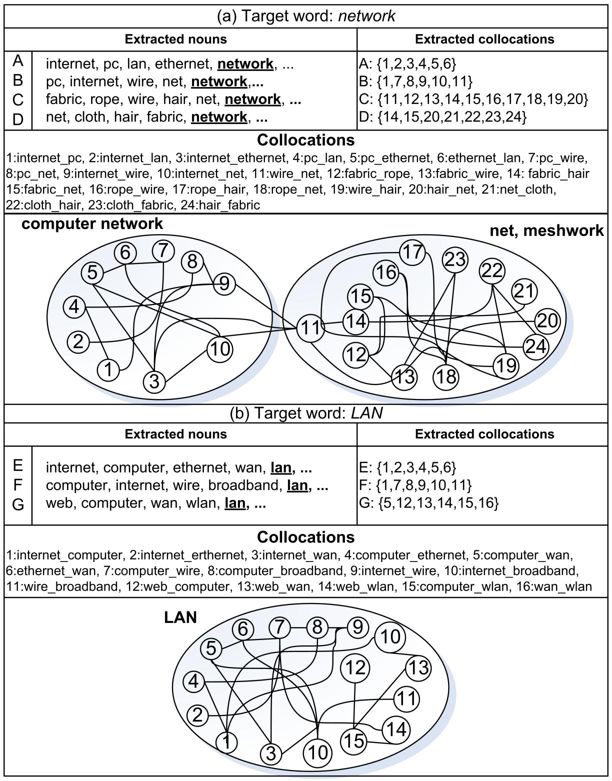
house. This problem might lead both to inclusion of incorrect or loss of correct taxonomic relations. In our work, we aim to overcome these drawbacks by identifying the different senses with which target words appear in text and then building a hierarchy of the identified senses.

Soft clustering approaches (Reinberger and Spyns, 2004; Reinberger et al., 2003) have also been applied to taxonomy learning to deal with polysemy. These methods associate each verb with a vector of features, where each feature is a noun appearing as a subject or object of that verb. That way a noun can appear in different vectors, hence in different clusters during hierarchical clustering as a result of its polysemy. However, the underlying assumption is that a verb is monosemous with respect to its associated vector of nouns. This assumption is not always valid and can cause the problems mentioned above.

Other work in taxonomy learning exploits the head/modifier relationships to create taxonomic relations (Buitelaar et al., 2004; Hwang, 1999; Sánchez and Moreno, 2005). These relations are used to create: (1) a class (concept) for each head, and (2) subclasses by adding nominal or adjectival modifiers. For example, *credit card* **IS-A** *card*. The corresponding hyponymy relations are learned at the lexical level disregarding word polysemy. Some of these approaches identified the problem of polysemy and applied sense disambiguation with respect to WordNet in order to capture the different senses of a target term (Navigli and Velardi, 2004b; Navigli and Velardi, 2004a). Specifically, the taxonomy built by exploiting head/modifiers relations was modified according to WordNet's hyponymy relations between senses of disambiguated terms. One important deficiency of using sense disambiguation is that dictionaries miss many domain-specific senses. Additionally, the fixed-list of senses paradigm prohibits learning word senses according to their use in context. The use of sense induction we propose in this paper aims to overcome these limitations.

3 Method

Given a set of words W, a WSI method is applied to each $w_i \in W$ (Section 3.1). The outcome of the first stage is a set of senses, S, where each $s_i^w \in S$ denotes the i-th sense of word $w \in W$. This set of senses is the input to hierarchical clustering that produces a hierarchy of senses (Section 3.2).



(a) Target word: *network*

	Extracted nouns	Extracted collocations
A	internet, pc, lan, ethernet, **network**, ...	A: {1,2,3,4,5,6}
B	pc, internet, wire, net, **network**,...	B: {1,7,8,9,10,11}
C	fabric, rope, wire, hair, net, **network**, ...	C: {11,12,13,14,15,16,17,18,19,20}
D	net, cloth, hair, fabric, **network**, ...	D: {14,15,20,21,22,23,24}

Collocations

1:internet_pc, 2:internet_lan, 3:internet_ethernet, 4:pc_lan, 5:pc_ethernet, 6:ethernet_lan, 7:pc_wire, 8:pc_net, 9:internet_wire, 10:internet_net, 11:wire_net, 12:fabric_rope, 13:fabric_wire, 14: fabric_hair 15:fabric_net, 16:rope_wire, 17:rope_hair, 18:rope_net, 19:wire_hair, 20:hair_net, 21:net_cloth, 22:cloth_hair, 23:cloth_fabric, 24:hair_fabric

(b) Target word: *LAN*

	Extracted nouns	Extracted collocations
E	internet, computer, ethernet, wan, **lan, ...**	E: {1,2,3,4,5,6}
F	computer, internet, wire, broadband, **lan, ...**	F: {1,7,8,9,10,11}
G	web, computer, wan, wlan, **lan, ...**	G: {5,12,13,14,15,16}

Collocations

1:internet_computer, 2:internet_erthernet, 3:internet_wan, 4:computer_ethernet, 5:computer_wan, 6:ethernet_wan, 7:computer_wire, 8:computer_broadband, 9:internet_wire, 10:internet_broadband, 11:wire_broadband, 12:web_computer, 13:web_wan, 14:web_wlan, 15:computer_wlan, 16:wan_wlan

Figure 2: WSI for *network* & *LAN*

3.1 Word sense induction

WSI is the task of identifying the senses of a target word in a given text. Recent WSI methods were evaluated under the framework of SemEval-2007 WSI task (SWSI) (Agirre and Soroa, 2007). The evaluation framework defines two types of assessment, i.e. evaluation in: (1) a clustering and (2) a WSD setting. Based on this evaluation, we selected the method of Klapaftis & Manandhar (2008) (henceforth referred to as KM) that achieves high F-score in both evaluation schemes as compared to the systems participating in SWSI. We briefly describe KM mentioning its parameters used in our evaluation (Section 4). Figures 2 (a) and 2 (b) describe the different steps for inducing the senses of the target words *network* and *LAN*.

Corpus preprocessing: The input to KM is a base corpus *bc*, in which the target word w appears in each paragraph. In Figure 2 (a), the base corpus consists of the paragraphs *A*, *B*, *C* and *D*. The aim of this stage is to capture nouns contextually related to w. Initially, the target word is removed from bc, part-of-speech tagging is applied to each paragraph, only nouns are kept and lemmatised. In the next step, the distribution of each noun is compared to the distribution of the same noun in a reference corpus[2] using the log-likelihood ratio (G^2) (Dunning, 1993). Nouns with a G^2 below a pre-specified threshold (parameter p_1) are removed from each paragraph. Figure 2 (a) shows the remaining nouns for each paragraph of bc.

Graph creation & clustering: In the setting of KM, a collocation is a juxtaposition of two nouns within the same paragraph. Thus, each noun is combined with any other noun yielding a total of $\binom{N}{2}$ collocations for a paragraph with N nouns. Each collocation, c_{ij}, is assigned a weight that measures the relative frequency of two nouns co-occurring. This weight is the average of the conditional probabilities $p(n_i|n_j)$ and $p(n_j|n_i)$, where $p(n_i|n_j) = \frac{f(c_{ij})}{f(n_j)}$, $f(c_{ij})$ is the number of paragraphs nouns n_i, n_j co-occur and $f(n_j)$ is the number of paragraphs in which n_j appears. Collocations are filtered with respect to their frequency (parameter p_2) and weight (parameter p_3). Each retained collocation is represented as a vertex. Edges between vertices are present, if two collocations co-occur in one or more paragraphs. Figure 2 (a) shows that this process has generated 24 collocations for the target word *network*. On the top right of the figure we also observe the collocations associated with each paragraph.

In the next step, a smoothing technique is applied to discover new edges between vertices. The weight applied to each edge connecting vertices v_i and v_j (collocations c_{ab}, c_{de}) is the maximum of their conditional probabilities ($\max(p(c_{ab}|c_{de}), p(c_{de}|c_{ab}))$). Finally, the graph is clustered using Chinese whispers (Biemann, 2006). The final output is a set of senses, each one represented by a set of contextually related collocations. In Figure 2, we generated two senses for *network* and one sense for *LAN*.

3.2 Hierarchical clustering of senses

Given the set of senses S, our task at this point is to hierarchically classify the senses using HAC. Consider for example the words *network* and *LAN*, and let us assume that the WSI process has generated the senses in Figures 2 (a) and 2 (b). HAC operates by treating each sense as a singleton cluster and then successively merging the most similar clusters according to a pre-defined similarity function. This process iterates until all clusters have been merged into a single cluster taken to be the *root*.

Senses	computer network	meshwork	LAN
computer network	1	0.0	0.66
meshwork	0.0	1	0.14
LAN	0.66	0.14	1

Table 1: Similarity matrix for HAC.

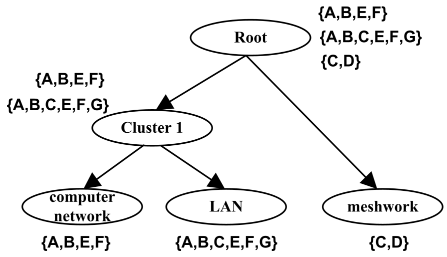


Figure 3: WSI & HAC example

To calculate the pairwise similarities between senses we exploit the attributes that represent each sense, i.e. their collocations. Let BC be the corpus resulting from the union of the base corpora of all words in W. In our example, BC would consist of the paragraphs, in which the words *network* and *LAN* appear, i.e. *A*, *B*, ..., *G*. An induced sense tags a paragraph, if one or more of its collocations appear in that paragraph. Thus, each induced sense is associated with a set of paragraph labels that denote the paragraphs tagged by that sense. Figure 3 shows the paragraph labels tagged by each sense of our example. Finally, given two senses s_i^a, s_i^b and their corresponding sets of tagged paragraphs f_i^a and f_i^b, we use the Jaccard coefficient to calculate their similarity, i.e. $\text{JC}(s_i^a, s_i^b) = \frac{|\text{f}_i^a \cap \text{f}_i^b|}{|\text{f}_i^a \cup \text{f}_i^b|}$, where s_j^k denotes the j-th sense of word k. The resulting similarity matrix of our example is shown in Table 1. Given that matrix, HAC would first group *computer network* and *LAN* as they have the highest similarity (Figure 3). In the final iteration, the remaining two clusters (*Cluster 1* & *meshwork*) would be grouped to the *root*.

An important parameter of HAC is the choice of the technique for calculating cluster similarities. Note that as we move towards the higher levels of

[2] The British National Corpus, 2001, Distributed by Oxford University Computing Services.

the taxonomy clusters contain more than one sets of tagged paragraphs (Figure 3 - *Cluster 1*), hence the choice of the similarity function is crucial. We experiment with three techniques, i.e. *single-linkage*, *complete-linkage* and *average-linkage*. The first one defines the similarity between two clusters as the maximum similarity among all the pairs of their corresponding feature sets. The second considers the minimum similarity among all the pairs, while the third calculates the average similarity of all the pairs.

4 Evaluation

We evaluate our method with respect to two WordNet-derived sub-taxonomies (Section 4.3). For that reason, it is necessary to map the induced senses to WordNet before applying HAC. Note that the mapping process might map more than one induced senses to the same WordNet sense. In that case, these induced senses are merged to a single one along with their corresponding collocations.

4.1 Mapping WSI clusters to WordNet senses

The process of mapping the induced senses to WordNet is straightforward. Let $w \in W$ be a word with n senses in WordNet. A WordNet sense i of w is denoted by ws_i^w, $i = [1, n]$. Let us also assume that the WSI method has produced m senses for w, where each sense j is denoted as s_j^w, $j = [1, m]$. Each induced sense s_j^w is associated with a set of features f_j^w as in the previous section. These features are the paragraphs (paragraph labels) of BC tagged by s_j^w. In the next step, each WordNet sense ws_i^w is associated with its WordNet signature g_i^w that contains the following semantic features: hypernyms/hyponyms, meronyms/holonyms and synonyms of ws_i^w. For example, the signature of the fifth WordNet sense of *network* would contain *internet*, *cyberspace* and other semantically related words. Table 2 shows partial signatures for each sense of *network*.

The signature g_i^w is used to formalise the WordNet sense ws_i^w as a set of features q_i^w. These features are the paragraphs (paragraph labels) of BC that contain one or more of the aforementioned semantically related to ws_i^w words that exist in g_i^w. Given an induced sense s_j^w, a similarity score is calculated between s_j^w and each WordNet sense of w. The maximum score determines the WordNet sense label that will be assigned to s_j^w, i.e. $label(s_j^w) = \text{argmax}_i \, JC(f_j^w, q_i^w)$, where JC is the Jaccard similarity coefficient. In the example of Figure 2 (a), the *computer network* sense would be mapped to the fifth WordNet sense of *network*, since there is a significant overlap between the paragraphs tagged by the induced and that WordNet sense.

WordNet sense	Semantically related words/phrases
1	reticulum, RF, RAS
2	communication system/equipment
3	gauze, snood, tulle
4	reseau, reticle, reticulation
5	net, internet, cyberspace

Table 2: Semantically related words/phrases to *network*

4.2 Evaluation measures

For the purposes of this section we present one gold standard taxonomy (Figure 1 (a)) and a second derived from our method (Figure 1 (b)). The comparison of these taxonomies is based on the *semantic cotopy* of a node, which has also been used in (Maedche and Staab, 2002; Cimiano et al., 2005). In particular, the semantic cotopy of a node is defined as the set of all its super- and subnodes excluding the *root* and including that node. For example, the semantic cotopy of *computer network* in Figure 1 (a) is $\{$*computer network, internet, LAN*$\}$. There are two issues, which make the evaluation difficult.

The first one is that HAC produces a taxonomy in which all internal nodes are unlabelled, as opposed to the gold standard taxonomy. In Figure 1 (b), we have manually labelled internal nodes with their IDs for clarity. For example, the semantic cotopy of the node *New Cluster 1* in Figure 1 (b) is $\{$*computer network, internet, LAN, New Cluster 1, New Cluster 0*$\}$. By comparing the cotopies of nodes *computer network* in Figure 1 (a) and *New Cluster 1* in Figure 1 (b), we observe that the automatic method has successfully grouped all of the hypernyms and hyponyms of *computer network* under *New Cluster 1*. However, the corresponding cotopies are not identical, because the cotopy of *New Cluster 1* also includes the labels produced by HAC.

To deal with this problem, we use a version of semantic cotopy for nodes in the automatically learned taxonomy which excludes nodes that do not exist in WordNet. That way the semantic cotopies of *New Cluster 1* in Figure 1 (b) and *computer network* in

Figure 1 (a) will yield maximum similarity.

The second issue is that the nodes that exist in the gold standard taxonomy are leaf nodes in the automatically learned taxonomy. As a result, the semantic cotopy of *LAN* in Figure 1 (b) is {*LAN*} since all of its supernodes do not exist in WordNet. In contrast, the semantic cotopy of *LAN* in Figure 1 (a) is {*LAN, computer network*}. We observe that there is an overlap between the two cotopies derived by the existence of the same concept in both taxonomies, i.e. *LAN*. In fact, all of the leaf nodes of a learned taxonomy will have a small overlap with the corresponding concept in the gold standard. For this problem, we observe that in our automatically learned taxonomies it does not make sense to calculate the semantic cotopy of leaf nodes. On the contrary, we need to evaluate the internal nodes that group the leaf nodes. Let us assume the following notation:

T_A = *automatically learned taxonomy*
η_i = *node in a taxonomy*
$C(T_A)$ = *internal nodes + leaf nodes of* T_A
$I(T_A)$ = *internal nodes of* T_A
T_G = *gold standard taxonomy*
$C(T_G)$ = *internal nodes + leaf nodes of* T_G
$I(T_G)$ = *internal nodes of* T_G
$hyper(\eta_i)$ = *supernodes of* η_i *excluding the root*
$hypo(\eta_i)$ = *subnodes of* η_i *including* η_i
For $\eta_i \in I(T_A)$, the semantic cotopy is defined as:
$SC'(\eta_i) = (hyper(\eta_i) \cup hypo(\eta_i)) \cap C(T_G)$
For $\eta_i \in C(T_G)$, the semantic cotopy is defined as:
$SC''(\eta_i) = (hyper(\eta_i) \cup hypo(\eta_i))$

$$P(\eta_i, \eta_j) = \frac{|SC'(\eta_i) \cap SC''(\eta_j)|}{|SC'(\eta_i)|} \quad (1)$$

$$R(\eta_i, \eta_j) = \frac{|SC'(\eta_i) \cap SC''(\eta_j)|}{|SC''(\eta_j)|} \quad (2)$$

$$F(\eta_i, \eta_j) = \frac{2P(\eta_i, \eta_j)R(\eta_i, \eta_j)}{P(\eta_i, \eta_j) + R(\eta_i, \eta_j)} \quad (3)$$

Precision, recall and harmonic mean of node $\eta_i \in I(T_A)$ with respect to node $\eta_j \in C(T_G)$ are defined in Equations 1, 2 and 3. The F-score, FS, of node $\eta_i \in I(T_A)$ is the maximum F attained at any $\eta_j \in C(T_G)$ ($FS(\eta_i) = \mathrm{argmax}_j\, F(\eta_i, \eta_j)$). Finally, the similarity TS of the entire taxonomy to the gold standard taxonomy is the average of the F-scores of each $\eta_i \in I(T_A)$ (Equation 4). The $TS(T_A, T_G)$ in Figure 1 is 0.9. All nodes of T_A have a perfect match, apart from *New Cluster 0* and *New Cluster 2*, which are matched against *computer network* and *meshwork* respectively, having a perfect precision but a lower recall since the cotopies of *computer network* and *meshwork* consist of three concepts. The automatically learned taxonomy has two redundant clusters that decrease its similarity.

$$TS(T_A, T_G) = \frac{1}{|I(T_A)|} \sum_{\eta_i \in I(T_A)} FS(\eta_i) \quad (4)$$

The similarity measure $TS(T_A, T_G)$ provides the similarity of the automatically learned taxonomy to the gold standard one, but it is not symmetric. Calculating the taxonomic similarity one way might not provide accurate results, in cases where T_A misses senses of the gold standard. This is due to the fact that we would only evaluate the internal nodes of T_A, partially ignoring the fact that T_A might have missed some parts of the gold standard taxonomy. For that reason, we also calculate $TS(T_G, T_A)$ which provides the similarity of the gold standard taxonomy to the automatically learned one. Finally, taxonomic similarities are combined to produce their harmonic mean (Equation 5).

$$TxSm(T_A, T_G) = \frac{2TS(T_G, T_A)TS(T_A, T_G)}{TS(T_G, T_A) + TS(T_A, T_G)} \quad (5)$$

4.3 Evaluation datasets & setting

The first gold standard taxonomy is derived by extracting from WordNet all the hyponyms of the senses of the word *network*. The extracted taxonomy contains 29 senses linguistically realized by 24 word sets (one sense might be expressed with more than one words), since *network* has 5 senses and *reseau* has 2 senses in the gold standard taxonomy. Note that we have disregarded senses only expressed by multiword expressions. The average polysemy of words is around 1.7. The second taxonomy is derived by extracting the concepts under the senses of the word *speaker*. The *speaker* taxonomy contains 52 senses linguistically realized by 50 word sets, since *speaker* has 3 senses included in the taxonomy. The average polysemy of words is around 1.58.

To create our datasets[3] we use the *Yahoo!* search api[4]. For each word w in each of the datasets, we is-

[3] Available in http://www.cs.york.ac.uk/aig/projects/indect/taxlearn

[4] http://developer.yahoo.com/search/ [Accessed:10/06/2009]

Parameter	Range
G^2 threshold (p_1)	5,10
Collocation frequency (p_2)	4,6,8
Collocation weight (p_3)	0.1,0.2,0.3,0.4

Table 3: Chosen parameters for the KM WSI method.

sue a query to *Yahoo!* that contains w and we download a maximum of 1000 pages. In cases where a particular sense is expressed by more than one word, the query was formulated by including all the words and putting the keyword *OR* between them. For each page we extracted fragments of text (paragraphs) that occur in <p> </p> html tags. We extracted 58956 and 78691 paragraphs for the *network* and *speaker* dataset respectively. The reason we extracted on average less content for the second dataset was that *Yahoo!* provided a small number of results for rare words such as *alliterator*, *anecdotist*, etc.

Table 3 shows the parameter ranges for the WSI method. Our method is evaluated according to these parameters. Our first baseline is *RAND*, which performs a random hierarchical clustering of senses to produce a binary tree. In each iteration two clusters are randomly chosen and form a new cluster, until we end up with one cluster taken to be the root. The performance of *RAND* is calculated by executing the random algorithm 10 times and then averaging the results. The second baseline is the taxonomy most frequent sense baseline (*TL MFS*), in which we do not perform WSI. Instead, given a parameter setting and a word w, all the collocations of w are grouped into one vector, which will possibly be dominated by collocations related to the MFS of w. WordNet mapping takes place and finally HAC with average-linkage is applied to create the taxonomy.

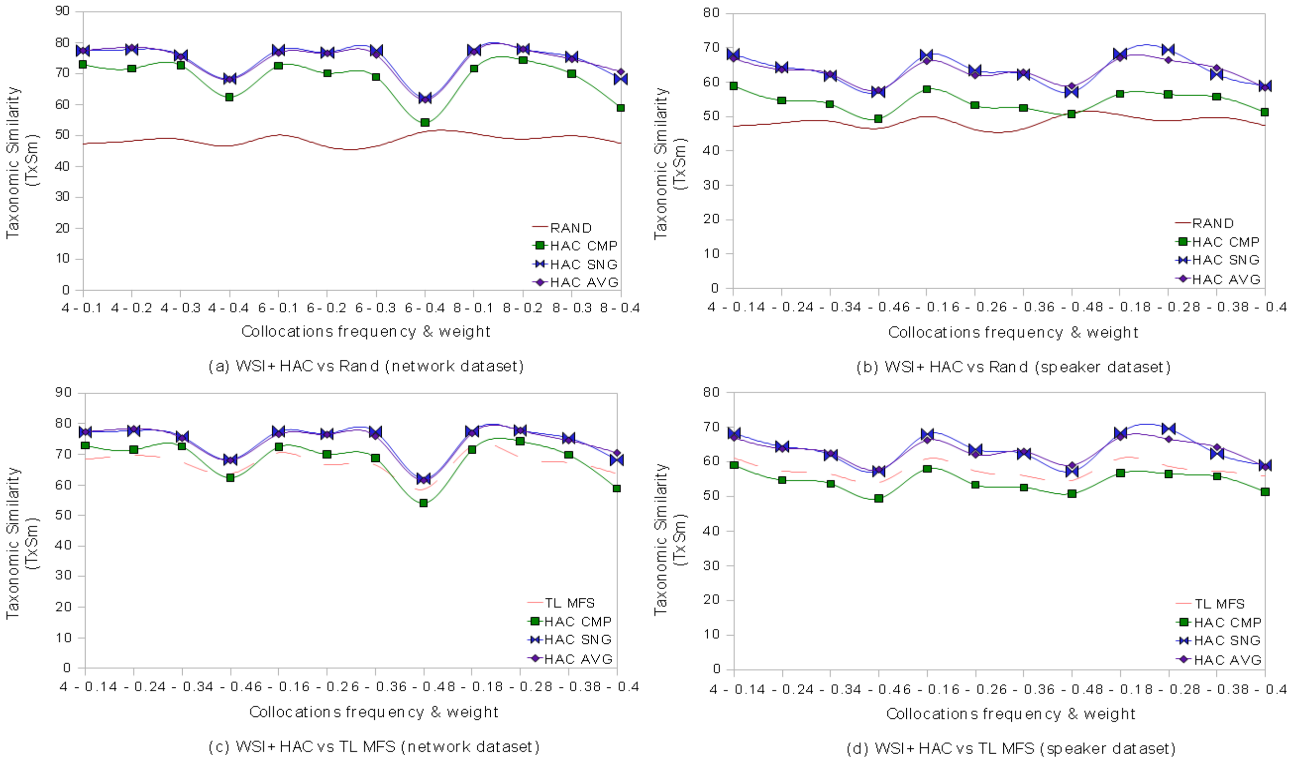
4.4 Results & discussion

Figures 4 (a) and 4 (b) show the performance of *HAC* with single-linkage (*HAC SNG*), average-linkage (*HAC AVG*) and complete-linkage (*HAC CMP*) against *RAND* for $p_1 = 5$ and different combinations of p_2 and p_3. It is clear that *HAC SNG* and *HAC AVG* outperform *RAND* by very large margins under all parameter combinations. In the *network* dataset, both of them achieve their highest distance from *RAND* (27.84%) at $p_2 = 8$ and $p_3 = 0.2$. In the *speaker* dataset, their highest distance from *RAND* (20.97% and 19.63% respectively) is achieved at $p_2 = 4$ and $p_3 = 0.1$. *HAC CMP* performs worse than the other HAC versions, yet it clearly outperforms *RAND* in all but one parameter combinations ($p_1 = 5$, $p_2 = 6$, $p_3 = 0.4$) in the *speaker dataset*.

Generally, for collocation weight equal to 0.4 the performance of all HAC versions drops. At this high collocation weight the WSI method produces a larger number of small clusters than in lower thresholds. This issue negatively affects both the mapping process and HAC. For example in the *speaker* dataset, for $p_1 = 5$, $p_2 = 8$ and $p_3 = 0.1$ our taxonomies contained 86.54% of the gold standard taxonomy senses. Increasing the collocation weight to 0.2 did not have any effect, but increasing the weight to 0.3 and then 0.4 led to 71.15% and 65.38% sense coverage. Overall, our conclusion is that all HAC versions exploit the WSI method and learn useful information better than chance. The picture is the same for $p_1 = 10$.

Figures 4 (c) and 4 (d) show the performance of HAC versions against the *TL MFS* baseline in the same parameter setting as above. We observe that both *HAC SNG* and *HAC AVG* perform significantly better than *TL MFS* apart from $p_3 = 0.4$, in which case all *HAC* versions perform worse. In the *network* dataset, the largest performance difference for *HAC SNG* is 10.12% and for *HAC AVG* 9.9% at $p_2 = 6$ and $p_3 = 0.2$. In the *speaker* dataset, the largest performance difference for *HAC SNG* is 10.83% and for *HAC AVG* 7.83% at $p_2 = 8$ and $p_3 = 0.2$. *HAC CMP* performs worse than *TL MFS* under most parameter settings in both datasets. The picture is the same for $p_1 = 10$.

Overall, the analysis of the WSI-based taxonomy learning approach against *TL MFS* shows that *HAC SNG* and *HAC AVG* perform better than *TL MFS* under all parameter combinations for both datasets. The main reason for their superior performance is that their learned taxonomies contain a higher number of senses than *TL MFS* as a result of the sense induction process. This greater sense coverage leads to the discovery of a higher number of correct taxonomic relations between senses than *TL MFS*, hence in a better performance. To conclude, our results verify our hypothesis and suggest that the unsupervised learning of word senses contributes to producing taxonomies with a higher similarity to the gold standard ones than traditional distributional similarity methods.



(a) WSI+HAC vs Rand (network dataset)

(b) WSI+HAC vs Rand (speaker dataset)

(d) WSI+HAC vs TL MFS (speaker dataset)

Figure 4: Performance analysis of the proposed method for $p_1 = 5$ and different combinations of p_2 and p_3.

Despite that, our evaluation also shows that in most cases *HAC CMP* is unable to exploit the induced senses and performs worse than *TL MFS*, *HAC SNG* and *HAC AVG*. This result was not expected, since *HAC SNG* employs a local criterion to merge two clusters and does not consider the global structure of the clusters, in effect, being biased towards elongated clusters. The observation of the gold standard taxonomies shows that they consist both of cohyponym concepts which are expected to be contextually related, but also of cohyponyms which are not expected to appear in similar contexts. For example, someone would expect a high similarity between *WAN*, *LAN*, or between *snood* and *tulle*. However, the same does not apply for *snood* and *cheesecloth* or *tulle* and *grillwork*, because *cheesecloth* and *grillwork* appear in significantly different contexts than *snood* and *tulle*. Despite that, all of them are cohyponyms. This issue is more prevalent in the *speaker* dataset, where concepts such as *loudspeaker*, *tannoy*, *woofer* are expected to be contextually related, while cohyponyms such as *whisperer*, *lecturer* and *interviewer* are not. This means that the gold standard taxonomies include elongated clusters and explains the superior performance of *HAC SNG*. This issue is not affecting *HAC AVG*, but it has a significant effect on *HAC CMP*. Generally, *HAC CMP* employs a non-local criterion by considering the diameter of a candidate cluster. This results in compact clusters with small diameters, as opposed to elongated ones.

5 Conclusion

We presented an unsupervised method for taxonomy learning that employs WSI to identify the senses of target words and then builds a taxonomy of these senses using HAC. We have shown that dealing with polysemy by means of sense induction helps to develop taxonomies that capture a higher number of correct taxonomic relations than traditional distributional similarity methods, which associate each target word with one vector of features, in effect, merging its senses.

Abstract

The question of how meaning might be acquired by young children and represented by adult speakers of a language is one of the most debated topics in cognitive science. Existing semantic representation models are primarily *amodal* based on information provided by the linguistic input despite ample evidence indicating that the cognitive system is also sensitive to perceptual information. In this work we exploit the vast resource of images and associated documents available on the web and develop a model of multimodal meaning representation which is based on the linguistic and visual context. Experimental results show that a closer correspondence to human data can be obtained by taking the visual modality into account.

1 Introduction

The representation and modeling of word meaning has been a central problem in cognitive science and natural language processing. Both disciplines are concerned with how semantic knowledge is acquired, organized, and ultimately used in language processing and understanding. A popular tradition of studying semantic representation has been driven by the assumption that word meaning can be learned from the linguistic environment. Words that are similar in meaning tend to behave similarly in terms of their distributions across different contexts. *Semantic space* models, among which Latent Semantic Analysis (LSA, Landauer and Dumais 1997) is perhaps known best, operationalize this idea by capturing word meaning *quantitatively* in terms of simple co-occurrence statistics. Each word w is represented by a k element vector reflecting the local distributional context of w relative to k context words. More recently, *topic models* have been gaining ground as a more structured representation of word meaning. In contrast to more standard semantic space models where word senses are conflated into a single representation, topic models assume that words observed in a corpus manifest some latent structure — word meaning is a probability distribution over a set of topics (corresponding to coarse-grained senses). Each topic is a probability distribution over words, and the content of the topic is reflected in the words to which it assigns high probability.

Semantic space (and topic) models are extracted from real language corpora, and thus provide a direct means of investigating the influence of the statistics of language on semantic representation. They have been successful in explaining a wide range of behavioral data — examples include lexical priming, deep dyslexia, text comprehension, synonym selection, and human similarity judgments (see Landauer and Dumais 1997 and the references therein). They also underlie a large number of natural language processing (NLP) tasks including lexicon acquisition, word sense discrimination, text segmentation and notably information retrieval. Despite their popularity, these models offer a somewhat impoverished representation of word meaning based solely on information provided by the linguistic input.

Many experimental studies in language acquisition suggest that word meaning arises not only from exposure to the linguistic environment but also from our interaction with the physical world. For example, infants are from an early age able to form perceptually-based category representations (Quinn et al., 1993). Perhaps unsurprisingly, words that refer to concrete entities and actions are among the first words being learned as these are directly observable in the environment (Bornstein et al., 2004). Experimental evidence also shows that children respond to categories on the basis of visual features, e.g., they generalize object names to new objects often on the basis of similarity in shape (Landau et al., 1998) and texture (Jones et al., 1991).

In this paper we aim to develop a unified mod-

eling framework of word meaning that captures the mutual dependence between the linguistic and visual context. This is a challenging task for at least two reasons. First, in order to emulate the environment within which word meanings are acquired, we must have recourse to a corpus of verbal descriptions and their associated images. Such corpora are in short supply compared to the large volumes of solely textual data. Secondly, our model should integrate linguistic and visual information in a single representation. It is unlikely that we have separate representations for different aspects of word meaning (Rogers et al., 2004).

We meet the first challenge by exploiting multimodal corpora, namely collections of documents that contain pictures. Although large scale corpora with a one-to-one correspondence between words and images are difficult to come by, datasets that contain images and text are ubiquitous. For example, online news documents are often accompanied by pictures. Using this data, we develop a model that combines textual and visual information to learn semantic representations. We assume that images and their surrounding text have been generated by a shared set of latent variables or topics. Our model follows the general rationale of topic models — it is based upon the idea that documents are mixtures of topics. Importantly, our topics are inferred from the *joint* distribution of textual and visual words. Our experimental results show that a closer correspondence to human word similarity and association can be obtained by taking the visual modality into account.

2 Related Work

The bulk of previous work has focused on models of semantic representation that are based solely on textual data. Many of these models represent words as vectors in a high-dimensional space (e.g., Landauer and Dumais 1997), whereas probabilistic alternatives view documents as mixtures of topics, where words are represented according to their likelihood in each topic (e.g., Steyvers and Griffiths 2007). Both approaches allow for the estimation of similarity between words. Spatial models compare words using distance metrics (e.g., cosine), while probabilistic models measure similarity between terms according to the degree to which they share the same topic distributions.

Within cognitive science, the problem of how words are grounded in perceptual representations has attracted some attention. Previous modeling efforts have been relatively small-scale, using either artificial images, or data gathered from a few subjects in the lab. Furthermore, the proposed models work well for the tasks at hand (e.g., either word learning or object categorization) but are not designed as a general-purpose meaning representation. For example, Yu (2005) integrates visual information in a computational model of lexical acquisition and object categorization. The model learns a mapping between words and visual features from data provided by (four) subjects reading a children's story. In a similar vein, Roy (2002) considers the problem of learning which words or word sequences refer to objects in a synthetic image consisting of ten rectangles. Andrews et al. (2009) present a probabilistic model that incorporates perceptual information (indirectly) by combining distributional information gathered from corpus data with speaker generated feature norms[1] (which are also word-based).

Much work in computer vision attempts to learn the underlying connections between visual features and words from examples of images annotated with description keywords. The aim here is to enhance image-based applications (e.g., search or retrieval) by developing models that can label images with keywords *automatically*. Most methods discover the correlations between visual features and words by introducing latent variables. Standard latent semantic analysis (LSA) and its probabilistic variant (PLSA) have been applied to this task (Pan et al., 2004; Hofmann, 2001; Monay and Gatica-Perez, 2007). More sophisticated approaches estimate the joint distribution of words and regional image features, whilst treating annotation as a problem of statistical inference in a graphical model (Blei and Jordan, 2003; Barnard et al., 2002).

Our own work aims to develop a model of semantic representation that takes visual context into account. We do not model explicitly the correspondence of words and visual features, or learn a mapping between words and visual features. Rather, we develop a multimodal representation of meaning which is based on visual information and distributional statistics. We hypothesize that visual features are crucial in acquiring and representing meaning

[1] Participants are given a series of object names and for each object they are asked to name all the properties they can think of that are characteristic of the object.

Michelle Obama fever hits the UK

In the UK on her first visit as first lady, Michelle Obama seems to be making just as big an impact. She has attracted as much interest and column inches as her husband on this London trip; creating a buzz with her dazzling outfits, her own schedule of events and her own fanbase. Outside Buckingham Palace, as crowds gathered in anticipation of the Obamas' arrival, Mrs Obama's star appeal was apparent.

Table 1: Each article in the document collection contains a document (the title is shown in boldface), and image with related content.

and conversely, that linguistic information can be useful in isolating salient visual features. Our model extracts a semantic representation from large document collections and their associated images without any human involvement. Contrary to Andrews et al. (2009) we use visual features directly without relying on speaker generated norms. Furthermore, unlike most work in image annotation, we do not employ any goldstandard data where images have been manually labeled with their description keywords.

3 Semantic Representation Model

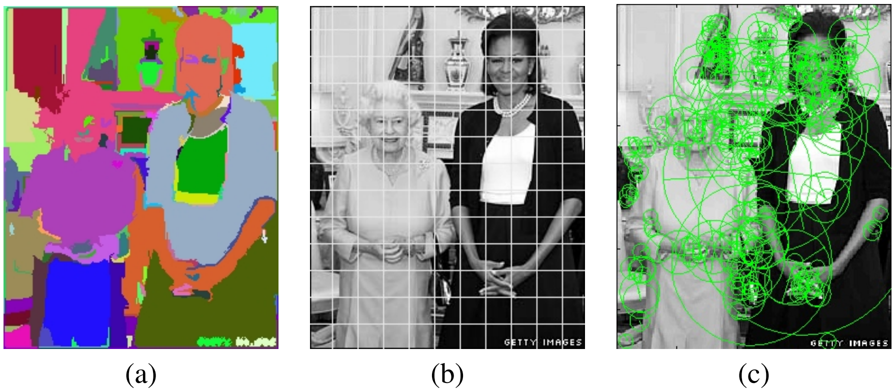
Much like LSA and the related topic models our model creates semantic representations from large document collections. Importantly, we assume that the documents are paired with images which in turn describe some of the document's content. Our experiments make use of news articles which are often accompanied with images illustrating events, objects or people mentioned in the text. Other datasets with similar properties include Wikipedia entries and their accompanying pictures, illustrated stories, and consumer photo collections. An example news article and its associated image is shown in Table 1 (we provide more detail on the database we used in our experiments in Section 4).

Our model exploits the redundancy inherent in this multimodal collection. Specifically, we assume that the images and their surrounding text have been generated by a shared set of topics. A potential stumbling block here is the fact that images and documents represent distinct modalities: images are commonly described by a continuous feature space (e.g., color, shape, texture; Barnard et al. 2002; Blei and Jordan 2003), whereas words are discrete. Fortunately, we can convert the visual features from a continuous onto a discrete space, thereby rendering image features more like word units. In the following we describe how we do this and then move on to present an extension of Latent Dirichlet Allocation (LDA, Blei and Jordan 2003), a topic model that can be used to represent meaning as a probability distribution over a set of multimodal topics. Finally, we discuss how word similarity can be measured under this model.

3.1 Image Processing

A large number of image processing techniques have been developed in computer vision for extracting meaningful features which are subsequently used in a modeling task. For example, a common first step to all automatic image annotation methods is partitioning the image into regions, using either an image segmentation algorithm (such as normalized cuts; Shi and Malik 2000) or a fixed-grid layout (Feng et al., 2004). In the first case the image is represented by irregular regions (see Figure 1(a)), whereas in the second case the image is partitioned into smaller scale regions which are uniformly extracted from a fixed grid (see Figure 1(b)). The obtained regions are further represented by a standard set of features including color, shape, and texture. These can be treated as continuous vectors (Blei and Jordan, 2003) or in quantized form (Barnard et al., 2002).

Despite much progress in image segmentation, there is currently no automatic algorithm that can reliably divide an image into meaningful parts. Extracting features from small local regions is thus preferable, especially for image collections that are diverse and have low resolution (this is often the case for news images). In our work we identify local regions using a difference-of-Gaussians point detector (see Figure 1(c)). This representation is based on descriptors computed over automatically detected image regions. It provides a much richer (and hopefully more informative) feature space compared to the alternative image representations discussed above. For example, an image segmentation algorithm, would extract at most 20 regions from the image in Figure 1; uniform grid segmentation yields 143



(a) (b) (c)

Figure 1: Image partitioned into regions of varying granularity using (a) the normalized cut image segmentation algorithm, (b) uniform grid segmentation, and (c) the SIFT point detector.

(11 × 13) regions, whereas an average of 240 points (depending on the image content) are detected. A non-sparse feature representation is critical in our case, since we usually do not have more than one image per document.

We compute local image descriptors using the the Scale Invariant Feature Transform (SIFT) algorithm (Lowe, 1999). Importantly, SIFT descriptors are designed to be invariant to small shifts in position, changes in illumination, noise, and viewpoint and can be used to perform reliable matching between different views of an object or scene (Mikolajczyk and Schmid, 2003; Lowe, 1999). We further quantize the SIFT descriptors using the K-means clustering algorithm to obtain a discrete set of visual terms (visiterms) which form our visual vocabulary Voc_V. Each entry in this vocabulary stands for a group of image regions which are similar in content or appearance and assumed to originate from similar objects. More formally, each image I is expressed in a bag-of-words format vector, $[v_1, v_2, ..., v_L]$, where $v_i = n$ only if I has n regions labeled with v_i. Since both images and documents in our corpus are now represented as bags-of-words, and since we assume that the visual and textual modalities express the same content, we can go a step further and represent the document and its associated image as a mixture of verbal and visual words d_{Mix}. We will then learn a topic model on this concatenated representation of visual and textual information.

3.2 Topic Model

Latent Dirichlet Allocation (Blei et al., 2003; Griffiths et al., 2007) is a probabilistic model of text generation. LDA models each document using a mixture over K topics, which are in turn characterized as distributions over words. The words in the document are generated by repeatedly sampling a topic according to the topic distribution, and selecting a word given the chosen topic. Under this framework, the problem of meaning representation is expressed as one of statistical inference: given some data — textual and visual words — infer the latent structure from which it was generated. Word meaning is thus modeled as a probability distribution over a set of latent multimodal topics.

LDA can be represented as a three level hierarchical Bayesian model. Given a corpus consisting of M documents, the generative process for a document d is as follows. We first draw the mixing proportion over topics θ_d from a Dirichlet prior with parameters α. Next, for each of the N_d words w_{dn} in document d, a topic z_{dn} is first drawn from a multinomial distribution with parameters θ_{dn}. The probability of a word token w taking on value i given that topic $z = j$ is parametrized using a matrix β with $b_{ij} = p(w = i|z = j)$. Integrating out θ_d's and z_{dn}'s, gives $P(D|\alpha, \beta)$, the probability of a corpus (or document collection):

$$\prod_{d=1}^{M}\int P(\theta_d|\alpha)\left(\prod_{n=1}^{N_d}\sum_{z_{dn}} P(z_{dn}|\theta_d)P(w_{dn}|z_{dn},\beta)\right)d\theta_d$$

The central computational problem in topic modeling is to compute the posterior distribution $P(\theta, \mathbf{z}|\mathbf{w}, \alpha, \beta)$ of the hidden variables given a document $\mathbf{w} = (w_1, w_2, \ldots, w_N)$. Although this distribution is intractable in general, a variety of approximate inference algorithms have been proposed in the literature including variational inference which our model adopts. Blei et al. (2003) introduce a set of variational parameters, γ and ϕ, and show that a tight lower bound on the log likelihood of the probability can be found using the following optimization procedure:

$$(\gamma^*,\phi^*) = \underset{\gamma,\phi}{\operatorname{argmin}} D(q(\theta,\mathbf{z}|\gamma,\phi)||p(\theta,\mathbf{z}|\mathbf{w},\alpha,\beta))$$

Here, D denotes the Kullback-Leibler (KL) divergence between the true posterior and the variational distribution $q(\theta,\mathbf{z}|\gamma,\phi)$ defined as: $q(\theta,\mathbf{z}|\gamma,\phi) = q(\theta|\gamma)\prod_{n=1}^{N} q(z_n|\phi_n)$, where the Dirichlet parameter γ and the multinomial parameters $(\phi_1,\dots,\phi_N)$ are the free variational parameters. Notice that the optimization of parameters $(\gamma^*(\mathbf{w}),\phi^*(\mathbf{w}))$ is document-specific (whereas α is corpus specific).

Previous applications of LDA (e.g., to document classification or information retrieval) typically make use of the posterior Dirichlet parameters $\gamma^*(\mathbf{w})$ associated with a given document. We are not so much interested in γ as we wish to obtain a semantic representation for a given word across documents. We therefore train the LDA model sketched above on a corpus of multimodal documents $\{d_{Mix}\}$ consisting of both textual and visual words. We select the number of topics, K, and apply the LDA algorithm to obtain the β parameters, where β represents the probability of a word w_i given a topic z_j, $p(w_i|z_j) = \beta_{ij}$. The meaning of w_i is thus extracted from β and is a K-element vector, whose components correspond to the probability of w_i given each latent topic assumed to have generated the document collection.

3.3 Similarity Measures

The ability to accurately measure the similarity or association between two words is often used as a diagnostic for the psychological validity of semantic representation models. In the topic model described above, the similarity between two words w_1 and w_2 can be intuitively measured by the extent to which they share the same topics (Griffiths et al., 2007). For example, we may use the KL divergence to measure the difference between the distributions p and q:

$$D(p,q) = \sum_{j=1}^{K} p_j \log_2 \frac{p_j}{q_j}$$

where p and q are shorthand for $P(w_1|z_j)$ and $P(w_2|z_j)$, respectively.

The KL divergence is asymmetric and in many applications, it is preferable to apply a symmetric measure such as the Jensen Shannon (JS) divergence. The latter measures the "distance" between p and q through $\frac{(p+q)}{2}$, the average of p and q:

$$JS(p,q) = \frac{1}{2}\left[D(p,\frac{(p+q)}{2}) + D(q,\frac{(p+q)}{2})\right]$$

An alternative approach to expressing the similarity between two words is proposed in Griffiths et al. (2007). The underlying idea is that word association can be expressed as a conditional distribution. If we have seen word w_1, then we can determine the probability that w_2 will be also generated by computing $P(w_2|w_1)$. Although the LDA generative model allows documents to contain multiple topics, here it is assumed that both w_1 and w_2 came from a single topic:

$$P(w_2|w_1) = \sum_{z=1}^{K} P(w_2|z)P(z|w_1)$$

$$P(z|w_1) \propto P(w_1|z)P(z)$$

where $p(z)$ is uniform, a single topic is sampled from the distribution $P(z|w_1)$, and an overall estimate is obtained by averaging over all topics K.

Griffiths et al. (2007) report results on modeling human association norms using exclusively $P(w_2|w_1)$. We are not aware of any previous work that empirically assesses which measure is best at capturing semantic similarity. We undertake such an empirical comparison as it is not a priory obvious how similarity is best modeled under a multimodal representation.

4 Experimental Setup

In this section we discuss our experimental design for assessing the performance of the model presented above. We give details on our training procedure and parameter estimation and present the baseline method used for comparison with our model.

Data We trained the multimodal topic model on the corpus created in Feng and Lapata (2008). It contains 3,361 documents that have been downloaded from the BBC News website.[2] Each document comes with an image that depicts some of its content. The images are usually 203 pixels wide

[2] http://news.bbc.co.uk/

and 152 pixels high. The average document length is 133.85 words. The corpus has 542,414 words in total. Our experiments used a vocabulary of 6,253 textual words. These were words that occurred at least five times in the whole corpus, excluding stopwords. The accompanying images were preprocessed as follows. We first extracted SIFT features from each image (150 on average) which we subsequently quantized into a discrete set of visual terms using *K*-means. As we explain below, we determined an optimal value for *K* experimentally.

Evaluation Our evaluation experiments compared the multimodal topic model against a standard text-based topic model trained on the same corpus whilst ignoring the images. Both models were assessed on two related tasks, that have been previously used to evaluate semantic representation models, namely word association and word similarity.

In order to simulate word association, we used the human norms collected by Nelson et al. (1999).[3] These were established by presenting a large number of participants with a cue word (e.g., *rice*) and asking them to name an associate word in response (e.g., *Chinese, wedding, food, white*). For each word, the norms provide a set of associates and the frequencies with which they were named. We can thus compute the probability distribution over associates for each cue. Analogously, we can estimate the degree of similarity between a cue and its associates using our model (and any of the measures in Section 3.3). And consequently examine (using correlation analysis) the degree of linear relationship between the human cue-associate probabilities and the automatically derived similarity values. We also report how many times the word with the highest probability under the model was the first associate in the norms. The norms contain 10,127 unique words in total. Of these, we created semantic representations for the 3,895 words that appeared in our corpus.

Our word similarity experiment used the WordSim353 test collection (Finkelstein et al., 2002) which consists of relatedness judgments for word pairs. For each pair, a similarity judgment (on a scale of 0 to 10) was elicited from human subjects (e.g., *tiger-cat* are very similar, whereas *delay–racism* are not). The average rating for each pair represents an estimate of the perceived similarity of the two words. The task varies slightly from word association. Here, participants are asked to rate perceived similarity rather than generate the first word that came into their head in response to a cue word. The collection contains similarity ratings for 353 word pairs. Of these, we constructed semantic representations for the 254 that appeared in our corpus. We also evaluated how well model produced similarities correlate with human ratings. Throughout this paper we report correlation coefficients using Pearson's *r*.

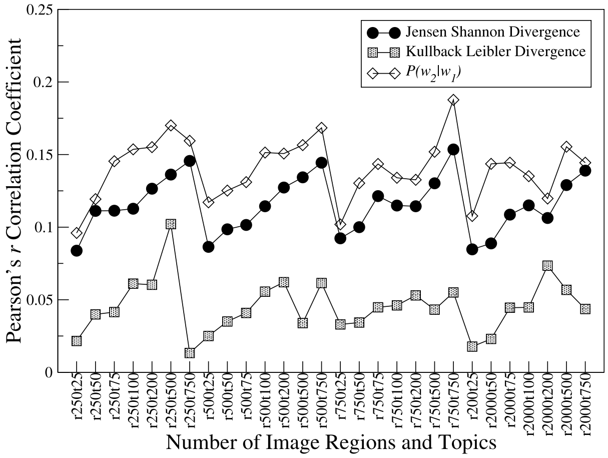


Figure 2: Performance of multimodal topic model on predicting word association under varying topics and visual terms (development set).

5 Experimental Results

Model Selection The multimodal topic model has several parameters that must be instantiated. These include the quantization of the image features, the number of topics, the choice of similarity function, and the values for α and β. We explored the parameter space on held-out data. Specifically, we fit the parameters for the word association and similarity models separately using a third of the association norms and WordSim353 similarity judgments, respectively. As mentioned in Section 3.1 we used *K*-means to quantize the image features into a discrete set of visual terms. We varied *K* from 250 to 2000. We also varied the number of topics from 25 to 750 for both the multimodal and text-based topic models. The parameter α was set to 0.1 and β was initialized randomly. The model was trained using variational Bayes until convergence of its bound on the likelihood objective. This took 1,000 iterations.

Figure 2 shows how word association performance varies on the development set with different numbers of topics (t) and visual terms (r) according

[3] `http://www.usf.edu/Freeassociation`.

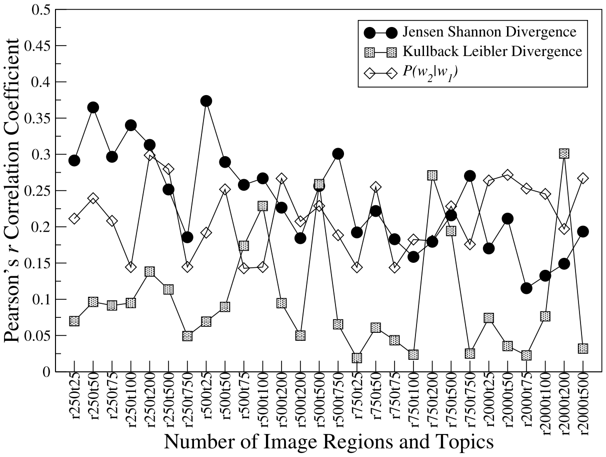

Figure 3: Performance of multimodal topic model on predicting word similarity under varying topics and visual terms (development set).

to three similarity measures: KL divergence, JS divergence, and $P(w_2|w_1)$, the probability of word w_2 given w_1 (see Section 3.3). Figure 3 shows results on the development set for the word similarity task. As far as word association is concerned, we obtain best results with $P(w_2|w_1)$, 750 visual terms and 750 topics ($r = 0.188$). On word similarity, JS performs best with 500 visual terms and 25 topics ($r = 0.374$). It is not surprising that $P(w_2|w_1)$ works best for word association. The measure expresses the associative relations between words as a conditional distribution over potential response words w_2 for cue word w_1. A symmetric function is more appropriate for word similarity as the task involves measuring the degree to which to words share some meaning (expressed as topics in our model) rather than whether a word is likely to be generated as a response to another word. These differences also lead to different parametrizations of the semantic space. A rich visual term vocabulary (750 terms) is needed for modeling association as broader aspects of word meaning are taken into account, whereas a sparser more focused representation (with 500 visual terms and 25 overall topics) is better at isolating the common semantic content between two words. We explored the parameter space for the text-based topic model in a similar fashion. On the word association task the best correlation coefficient was achieved with 750 topics and $P(w_2|w_1)$ ($r = 0.139$). On word similarity, the best results were obtained with 75 topics and the JS divergence ($r = 0.309$).

Model	Word Association	Word Similarity
UpperBnd	0.400	0.545
MixLDA	0.123	0.318
TxtLDA	0.077	0.247

Table 2: Model performance on word association and similarity (test set).

Model Comparison Table 2 summarizes our results on the test set using the optimal set of parameters as established on the development set. The first row shows how well humans agree with each other on the two tasks (UpperBnd). We estimated the intersubject correlation using leave-one-out resampling[4] (Weiss and Kulikowski, 1991). As can be seen, in all cases the topic model based on textual and visual modalities (MixLDA) outperforms the model relying solely on textual information (TxtLDA). The differences in performance are statistically significant ($p < 0.05$) using a t-test (Cohen and Cohen, 1983).

Steyvers and Griffiths (2007) also predict word association using Nelson's norms and a state-of-the-art LDA model. Although they do not report correlations, they compute how many times the word with the highest probability $P(w_2|w_1)$ under the model was the first associate in the human norms. Using a considerably larger corpus (37,651 documents), they reach an accuracy of 16.15%. Our corpus contains 3,361 documents, the MixLDA model performs at 14.15% and the LDA model at 13.16%. Using a vector-based model trained on the BNC corpus (100M words), Washtell and Markert (2009) report a correlation of 0.167 on the same association data set, whereas our model achieves a correlation of 0.123. With respect to word similarity, Marton et al. (2009) report correlations within the range of 0.31–0.54 using different instantiations of a vector-based model trained on the BNC with a vocabulary of 33,000 words. Our MixLDA model obtains a correlation of 0.318 with a vocabulary five times smaller (6,253 words). Although these results are not strictly comparable due to the different nature and size of the training data, they give some indication of the quality of our model in the context of other approaches that exploit only the textual modality. Besides, our intent is not to report the best performance possible,

[4] We correlated the data obtained from each participant with the ratings obtained from all other participants and report the average.

but to show that a model of meaning representation is more accurate when taking visual information into account.

Table 3 shows some examples of the topics found by our model, which largely form coherent blocks of semantically related words. In general, we observe that the model using image features tends to prefer words that visualize easily (e.g., CONSOLE, XBOX). Furthermore, the visual modality helps obtain crisper meaning distinctions. Here, SCHUMACHER is a very probable world for the "game" cluster. This is because the Formula One driver appears as a character in several video games discussed and depicted in our corpus. For comparison the "game" cluster for the text-based LDA model contains the words: GAME, USE, INTERNET, SITE, USE, SET, ONLINE, WEB, NETWORK, MURRAY, PLAY, MATCH, GOOD, WAY, BREAK, TECHNOLOGY, WORK, NEW, TIME, SECOND.

We believe the model presented here works better than a vanilla text-based topic model for at least three reasons: (1) the visual information helps create better clusters (i.e., conceptual representations) which in turn are used to measure similarity or association; these clusters themselves are amodal but express commonalities across the visual and textual modalities; (2) the model is also able to capture perceptual correlations between words. For example, RED is the most frequent associate for APPLE in Nelson's norms. This association is captured in our visual features (pictures with apples cluster with pictures showing red objects) even though RED does not co-occur with APPLE in our data; (3) finally, even in cases where two words are visually very different in terms of shape or color (e.g., BANANA and APPLE), they tend to appear in images with similar structure (e.g., on tables, in bowls, as being held or eaten by someone) and thus often share some common element of meaning.

6 Conclusion

In this paper we developed a computational model that unifies visual and linguistic representations of word meaning. The model learns from natural language corpora paired with images under the assumption that visual terms and words are generated by mixtures of latent topics. We have shown that a closer correspondence to human data can be obtained by explicitly taking the visual modality into account in comparison to a model that estimates the topic structure solely from the textual modality. Beyond word similarity and association, the approach is promising for modeling word learning and categorization as well as a wide range of priming studies. Outwith cognitive science, we hope that some of the work described here might be of relevance to more applied tasks such as thesaurus acquisition, word sense disambiguation, multimodal search, image retrieval, and summarization.

Future improvements include developing a nonparametric version that jointly *learns* how many visual terms and topics are optimal. Currently, the size of the visual vocabulary and the number of topics are parameters in the model, that must be tuned separately for different tasks and corpora. Another extension concerns the creation of visual terms. Our model assumes that an image is a bag of words. The assumption is convenient for modeling purposes, but clearly false in the context of visual processing. Image descriptors found closely to each other are likely to represent the same object and should form one term rather than several distinct ones (Wang and Grimson, 2007). Taking the spatial structure among visual words into account would yield better topics and overall better semantic representations. Analogously, we could represent documents by their syntactic structure (Boyd-Graber and Blei, 2009).

Abstract

This paper introduces the novel task of topic coherence evaluation, whereby a set of words, as generated by a topic model, is rated for coherence or interpretability. We apply a range of topic scoring models to the evaluation task, drawing on WordNet, Wikipedia and the Google search engine, and existing research on lexical similarity/relatedness. In comparison with human scores for a set of learned topics over two distinct datasets, we show a simple co-occurrence measure based on pointwise mutual information over Wikipedia data is able to achieve results for the task at or nearing the level of inter-annotator correlation, and that other Wikipedia-based lexical relatedness methods also achieve strong results. Google produces strong, if less consistent, results, while our results over WordNet are patchy at best.

1 Introduction

There has traditionally been strong interest within computational linguistics in techniques for learning sets of words (aka topics) which capture the latent semantics of a document or document collection, in the form of methods such as latent semantic analysis (Deerwester et al., 1990), probabilistic latent semantic analysis (Hofmann, 2001), random projection (Widdows and Ferraro, 2008), and more recently, latent Dirichlet allocation (Blei et al., 2003; Griffiths and Steyvers, 2004). Such methods have been successfully applied to a myriad of tasks including word sense discrimination (Brody and Lapata, 2009), document summarisation (Haghighi and Vanderwende, 2009), areal linguistic analysis (Daume III, 2009) and text segmentation (Sun et al., 2008). In each case, *extrinsic* evaluation has been used to demonstrate the effectiveness of the learned topics in the application domain, but standardly, no attempt has been made to perform *intrinsic* evaluation of the topics themselves, either qualitatively or quantitatively. In machine learning, on the other hand, researchers have modified and extended topic models in a variety of ways, and evaluated *intrinsically* in terms of model perplexity (Wallach et al., 2009), but there has been less effort on *qualitative* understanding of the semantic nature of the learned topics.

This research seeks to fill the gap between topic evaluation in computational linguistics and machine learning, in developing techniques to perform intrinsic qualitative evaluation of learned topics. That is, we develop methods for evaluating the quality of a given topic, in terms of its coherence to a human. After learning topics from a collection of news articles and a collection of books, we ask humans to decide whether individual learned topics are coherent, in terms of their interpretability and association with a single over-arching semantic concept. We then propose models to predict topic coherence, based on resources such as WordNet, Wikipedia and the Google search engine, and methods ranging from ontological similarity to link overlap and term co-occurrence. Over topics learned from two distinct datasets, we demonstrate that there is remarkable inter-annotator agreement on what is a coherent topic, and additionally that our methods based on Wikipedia are able to achieve nearly perfect agreement with humans over the evaluation of topic coherence.

This research forms part of a larger research agenda on the utility of topic modelling in gisting and visualising document collections, and ultimately enhancing search/discovery interfaces over

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 100–108,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

document collections (Newman et al., to appeara). Evaluating topic coherence is a component of the larger question of what are good topics, what characteristics of a document collection make it more amenable to topic modelling, and how can the potential of topic modelling be harnessed for human consumption (Newman et al., to appearb).

2 Related Work

Most earlier work on intrinsically evaluating learned topics has been on the basis of perplexity results, where a model is learned on a collection of training documents, then the log probability of the unseen test documents is computed using that learned model. Usually perplexity is reported, which is the inverse of the geometric mean per-word likelihood. Perplexity is useful for model selection and adjusting parameters (e.g. number of topics T), and is the standard way of demonstrating the advantage of one model over another. Wallach et al. (2009) presented efficient and unbiased methods for computing perplexity and evaluating almost any type of topic model.

While statistical evaluation of topic models is reasonably well understood, there has been much less work on evaluating the intrinsic *semantic* quality of topics learned by topic models, which could have a far greater impact on the overall value of topic modeling for end-user applications. Some researchers have started to address this problem, including Mei et al. (2007) who presented approaches for automatic labeling of topics (which is core to the question of coherence and semantic interpretability), and Griffiths and Steyvers (2006) who applied topic models to word sense discrimination tasks. Misra et al. (2008) used topic modelling to identify semantically incoherent documents within a document collection (vs. coherent *topics*, as targeted in this research). Chang et al. (2009) presented the first human-evaluation of topic models by creating a task where humans were asked to identify which word in a list of five topic words had been randomly switched with a word from another topic. This work showed some possibly counter-intuitive results, where in some cases humans preferred models with higher perplexity. This type of result shows the need for further exploring measures other than perplexity for evaluating topic models. In earlier work, we carried out preliminary experimentation using pointwise mutual information and Google results to evaluate topic coherence over the same set of topics as used in this research (Newman et al., 2009).

Part of this research takes inspiration from the work on automatic evaluation in machine translation (Papineni et al., 2002) and automatic summarisation (Lin, 2004). Here, the development of automated methods with high correlation with human subjects has opened the door to large-scale automated evaluation of system outputs, revolutionising the respective fields. While our aspirations are more modest, the basic aim is the same: to develop a fully-automated method for evaluating a well-grounded task, which achieves near-human correlation.

3 Topic Modelling

In order to evaluate topic modelling, we require a topic model and set of topics for a given document collection. While the evaluation methodology we describe generalises to any method which generates sets of words, all of our experiments are based on *Latent Dirichlet Allocation* (LDA, aka *Discrete Principal Component Analysis*), on the grounds that it is a state-of-the-art method for generating topics.

LDA is a Bayesian graphical model for text document collections represented by bags-of-words (see Blei et al. (2003), Griffiths and Steyvers (2004), Buntine and Jakulin (2004)). In a topic model, each document in the collection of D documents is modelled as a multinomial distribution over T topics, where each topic is a multinomial distribution over W words. Typically, only a small number of words are important (have high likelihood) in each topic, and only a small number of topics are present in each document.

The collapsed Gibbs sampled topic model simultaneously learns the topics and the mixture of topics in documents by iteratively sampling the topic assignment z to every word in every document, using the Gibbs sampling update:

$$p(z_{id} = t | x_{id} = w, \mathbf{z}^{\neg id}) \propto \frac{N_{wt}^{\neg id} + \beta}{\sum_w N_{wt}^{\neg id} + W\beta} \; \frac{N_{td}^{\neg id} + \alpha}{\sum_t N_{td}^{\neg id} + T\alpha}$$

where $z_{id} = t$ is the assignment of the i^{th} word in document d to topic t, $x_{id} = w$ indicates that the current observed word is w, and $\mathbf{z}^{\neg id}$ is the vector of all topic assignments not including the current word. N_{wt} represents integer count arrays (with the subscripts denoting what is counted), and α and β are Dirichlet priors.

The maximum a posterior (MAP) estimates of the topics $p(w|t), t = 1 \ldots T$ are given by:

$$p(w|t) = \frac{N_{wt} + \beta}{\sum_w N_{wt} + W\beta}$$

We will follow the convention of representing a topic via its top-n words, ordered by $p(w|t)$. Here, we use the top-ten words, as they usually provide sufficient detail to convey the subject of a topic, and distinguish one topic from another. For the remainder of this paper, we will refer to individual topics by its list of top-ten words, denoted by $\mathbf{w} = (w_1, \ldots, w_{10})$.

4 Topic Evaluation Methods

We experiment with scoring methods based on WordNet (Section 4.1), Wikipedia (Section 4.2) and the Google search engine (Section 4.3). In the case of Google, we query for the entire topic, but with WordNet and Wikipedia, this takes the form of scoring each word-pair in a given topic $\mathbf{w}$ based on the component words $(w_1, \ldots, w_{10})$. Given some (symmetric) word-similarity measure $D(w_i, w_j)$, two straightforward ways of producing a combined score from the 45 (i.e. $\binom{10}{2}$) word-pair scores are: (1) the arithmetic mean, and (2) the median, as follows:

$$\text{Mean-D-Score}(\mathbf{w}) = \text{mean}\{\text{D}(w_i, w_j), ij \in 1 \ldots 10, i < j\}$$

$$\text{Median-D-Score}(\mathbf{w}) = \text{median}\{\text{D}(w_i, w_j), ij \in 1 \ldots 10, i < j\}$$

Intuitively, the median seems the more natural representation, as it is less affected by outlier scores, but we experiment with both, and fall back to empirical verification of which is the better combination method.

4.1 WordNet similarity

WordNet (Fellbaum, 1998) is a lexical ontology that represents word sense via "synsets", which are structured in a hypernym/hyponym hierarchy (nouns) or hypernym/troponym hierarchy (verbs). WordNet additionally links both synsets and words via lexical relations including antonymy, morphological derivation and holonymy/meronym.

In parallel with the development of WordNet, a number of computational methods for calculating the semantic relatedness/similarity between synset pairs (i.e. sense-specified word pairs) have been developed, as we outline below. These methods apply to *synset* rather than word pairs, so to generate a single score for a given word pair, we look up each word in WordNet and exhaustively generate scores for each sense pairing defined by them, and calculate their arithmetic mean.[1]

The majority of the methods (all methods other than HSO, VECTOR and LESK) are restricted to operating strictly over hierarchical links within a single hierarchy. As the verb and noun hierarchies are not connected (other than via derivational links), this means that it is generally not possible to calculate the similarity between noun and verb senses, for example. In such cases, we simply drop the synset pairing in question from our calculation of the mean.

The least common subsumer (LCS) is a common feature to a number of the measures, and is defined as the deepest node in the hierarchy that subsumes both of the synsets under question.

For all our experiments over WordNet, we use the `WordNet::Similarity` package.

Path distance (PATH)

The simplest of the WordNet-based measures is to count the number of nodes visited while going from one word to another via the hypernym hierarchy. The path distance between two nodes is defined as the number of nodes that lie on the shortest path between two words in the hierarchy. This

[1] We also experimented with the median, and trialled filtering the set of senses in a variety of ways, e.g. using only the first sense (the sense with the highest prior) for a given word, or using only the word senses associated with the POS with the highest prior. In all cases, the overall trend was for the correlation with the human scores to drop relative to the mean, so we only present the numbers for the mean in this paper.

count of nodes includes the beginning and ending word nodes.

Leacock-Chodorow (LCH)

The measure of semantic similarity devised by Leacock et al. (1998) finds the shortest path between two WordNet synsets ($sp(c_1, c_2)$) using hypernym and synonym relationships. This path length is then scaled by the maximum depth of WordNet (D), and the log likelihood taken:

$$sim_{lch}(c_1, c_2) = -\log \frac{sp(c_1, c_2)}{2 \cdot D}$$

Wu-Palmer (WUP)

Wu and Palmer (1994) proposed to scale the depth of the two synset nodes ($depth_{c_1}$ and $depth_{c_2}$) by the depth of their LCS ($depth(lcs_{c_1,c_2})$):

$$sim_{wup}(c_1, c_2) = \frac{2 \cdot depth(lcs_{c_1,c_2})}{depth_{c_1} + depth_{c_2} + 2 \cdot depth(lcs_{c_1,c_2})}$$

The scaling means that specific terms (deeper in the hierarchy) that are close together are more semantically similar than more general terms, which have a short path distance between them. Only hypernym relationships are used in this measure, as the LCS is defined by the common member in the concepts' hypernym path.

Hirst-St Onge (HSO)

Hirst and St-Onge (1998) define a measure of semantic similarity based on length and tortuosity of the path between nodes. Hirst and St-Onge attribute directions (up, down and horizontal) to the larger set of WordNet relationships, and identify the path from one word to another utilising all of these relationships. The relatedness score is then computed by the weighted sum of the path length between the two words ($len(c_1, c_2)$) and the number of turns the path makes ($turns(c_1, c_2)$) to take this route:

$$rel_{hso}(c_1, c_2) = C - len(c_1, c_2) - k \times turns(c_1, c_2)$$

where C and k are constants. Additionally, a set of restrictions is placed on the path so that it may not be more than a certain length, may not contain more than a set number of turns, and may only take turns in certain directions.

Resnik Information Content (RES)

Resnik (1995) presents a method for weighting edges in WordNet (avoiding the assumption that all edges between nodes have equal importance), by weighting edges between nodes by their frequency of use in textual corpora.

Resnik found that the most effective measure of comparison using this methodology was to measure the Information Content ($IC(c) = -\log p(c)$) of the subsumer with the greatest Information Content from the set of all concepts that subsumed the two initial concepts ($S(c_1, c_2)$) being compared:

$$sim_{res}(c_1, c_2) = \max_{c \in S(c_1,c_2)} [-\log p(c)]$$

Lin (LIN)

Lin (1998) expanded on the Information Theoretic approach presented by Resnik by scaling the Information Content of each node by the information content of their LCS:

$$sim_{lin}(c_1, c_2) = \frac{2 \times \log p(lcs_{c_1,c_2})}{\log p(c_1) + \log p(c_2)}$$

This measure contrasts the joint content of the two concepts with the difference between them.

Jiang-Conrath (JCN)

Jiang and Conrath (1997) define a measure that utilises the components of the information content of the LCS in a different manner:

$$sim_{jcn}(c_1, c_2) = \frac{1}{IC(a) + IC(b) - 2 \times IC(lcs_{a,b})}$$

Instead of defining commonality and difference as with Lin's measure, the key determinant is the specificity of the two nodes compared with their LCS.

Lesk (LESK)

Lesk (1986) proposed a significantly different approach to lexical similarity to that proposed in the methods presented above, using the lexical overlap in dictionary definitions (or *glosses*) to disambiguate word sense. The sense definitions that contain the most words in common indicate the most likely sense of the word given its co-occurrence with similar word senses. Banerjee and Pedersen (2002) adapted this method to utilise WordNet sense glosses rather than dictionary definitions, and expand the dictionary definitions via ontological links, and it is this method we experiment with in this paper.

Vector (VECTOR)

Schütze (1998) uses the words surrounding a term in a piece of text to form a context vector that describes the context in which the word sense appears. For a set of words associated with a target sense, a context vector is computed as the centroid vector of these words. The centroid context vectors each represent a word sense. To compare word senses, the cosine similarity of the context vectors is used.

4.2 Wikipedia

In the last few years, there has been a surge of interest in using Wikipedia to calculate semantic similarity, using the Wikipedia article content, in-article links and document categories (Strübe and Ponzetto, 2006; Gabrilovich and Markovitch, 2007; Milne and Witten, 2008). We present a selection of such methods below. There are a number of Wikipedia-based scoring methods which we do not present results for here (notably Strübe and Ponzetto (2006) and Gabrilovich and Markovitch (2007)), due to their computational complexity and uncertainty about the full implementation details of the methods.

As with WordNet, a given word will often have multiple entries in Wikipedia, grouped in a disambiguation page. For MIW, RACO and DOCSIM, we apply the same strategy as we did with WordNet, in exhaustively calculating the pairwise scores between the sets of documents associated with each term, and averaging across them.

Milne-Witten (MIW)

Milne and Witten (2008) adapted the Resnik (1995) methodology to utilise the count of links pointing to an article. As Wikipedia is self-referential (articles link to related articles), no external data is needed to find the "referred-to-edness" of a concept. Milne and Witten use an adapted Information Content measure that weights the number of links from one article to another ($c_1 \rightarrow c_2$) by the total number of links to the second article:

$$w(c_1 \rightarrow c_2) = |c_1 \rightarrow c_2| \times \log \sum_{x \in W} \frac{|W|}{|c_1, x)|}$$

where x is an article in W, Wikipedia. This measure provides the similarity of one article to another, however this is asymmetrical. The above metric is used to find the weights of all outlinks from the two articles being compared:

$$\vec{c_1} = (w(c_1 \rightarrow l_1), w(c_1 \rightarrow l_2), \cdots, w(c_1 \rightarrow l_n))$$
$$\vec{c_2} = (w(c_2 \rightarrow l_1), w(c_2 \rightarrow l_2), \cdots, w(c_2 \rightarrow l_n))$$

for the set of links l that is the union of the sets of outlinks from both articles. The overall similarity of the two articles is then calculated by taking the cosine similarity of the two vectors.

Related Article Concept Overlap (RACO)

We also determine the category overlap of two articles by examining the outlinks of both articles, in the form of the Related Article Concept Overlap (RACO) measure. The concept overlap of the sets of respective outlinks is given by the union of the two sets of categories from the outlinks from each article:

$$overlap(c_1, c_1) = \\ |(\bigcup_{l \in ol(c_1)} cat(l)) \bigcap (\bigcup_{l \in ol(c_2)} cat(l))|$$

where $ol(c_1)$ is the set of outlinks from article c_1, and $cat(l)$ is the set of categories of which the article at outlink l is a member. To account for article size (and differing number of outlinks), the Jaccard coefficient is used:

$$rel_{raco}(c_1, c_2) = \\ \frac{|(\bigcup_{l \in ol(c_1)} cat(l)) \bigcap (\bigcup_{l \in ol(c_2)} cat(l))|}{|\bigcup_{l \in ol(c_1)} cat(l)| + |\bigcup_{l \in ol(c_2)} cat(l)|}$$

Document Similarity (DOCSIM)

In addition to these two measures of semantic relatedness, we experiment with simple cosine similarity of the text of Wikipedia articles as a measure of semantic relatedness.

Term Co-occurrence (PMI)

Another variant is to treat Wikipedia as a single meta-document and score word pairs using term co-occurrence. Here, we calculate the pointwise mutual information (PMI) of each word pair, estimated

Selected high-scoring topics (unanimous score=3):
[NEWS] *space earth moon science scientist light nasa mission planet mars ...*
[NEWS] *health disease aids virus vaccine infection hiv cases infected asthma ...*
[BOOKS] *steam engine valve cylinder pressure piston boiler air pump pipe ...*
[BOOKS] *furniture chair table cabinet wood leg mahogany piece oak louis ...*

Selected low-scoring topics (unanimous score=1):
[NEWS] *king bond berry bill ray rate james treas byrd key ...*
[NEWS] *dog moment hand face love self eye turn young character ...*
[BOOKS] *soon short longer carried rest turned raised filled turn allowed ...*
[BOOKS] *act sense adv person ppr plant sax genus applied dis ...*

Table 1: A selection of high-scoring and low-scoring topics

from the entire corpus of over two million English Wikipedia articles (∼1 billion words). PMI has been studied variously in the context of collocation extraction (Pecina, 2008), and is one measure of the statistical independence of observing two words in close proximity. Using a sliding window of 10-words to identify co-occurrence, we computed the PMI of all a given word pair (w_i, w_j) as, following Newman et al. (2009):

$$\text{PMI}(w_i, w_j) = \log \frac{p(w_i, w_j)}{p(w_i)p(w_j)}$$

4.3 Search engine-based similarity

Finally, we present two search engine-based scoring methods, based on Newman et al. (2009). In this case the external data source is the entire World Wide Web, via the Google search engine. Unlike the methods presented above, here we query for the topic in its entirety,[2] meaning that we return a topic-level score rather than scores for individual word or word sense pairs. In each case, we mark each search term with the advanced search option + to search for the terms exactly as is and prevent Google from using synonyms or lexical variants of the term. An example query is: *+space +earth +moon +science +scientist +light +nasa +mission +planet +mars*.

Google title matches (TITLES)

Firstly, we score topics by the relative occurrence of their component words in the titles of documents returned by Google:

$$\text{Google-titles-match}(\mathbf{w}) = \mathbf{1}\,[w_i = v_j]$$

where $i = 1, \ldots, 10$ and $j = 1, \ldots, |V|$, v_j are all the unique terms mentioned in the titles from the top-100 search results, and **1** is the indicator function to count matches. For example, in the top-100 results for our query above, there are 194 matches with the ten topic words, so Google-titles-match$(\mathbf{w}) = 194$.

Google log hits matches (LOGHITS)

Second, we issue queries as above, but return the log number of hits for our query:

$$\text{Google-log-hits}(\mathbf{w}) = \log_{10}(\text{\# results from search for } \mathbf{w})$$

where $\mathbf{w}$ is the search string $+w_1$ $+w_2$ $+w_3$ $\ldots$ $+w_{10}$. For example, our query above returns 171,000 results, so Google-log-hits$(\mathbf{w}) = 5.2$. and the URL titles from the top-100 results include a total of 194 matches with the ten topic words, so for this topic Google-titles-match($\mathbf{w}$)=194.

5 Experimental Setup

We learned topics for two document collections: a collection of news articles, and a collection of books. These collections were chosen to produce sets of topics that have more variable quality than one typically observes when topic modeling highly uniform content. The collection of $D = 55,000$ news articles was selected from English Gigaword, and the collection of $D = 12,000$ books was downloaded from the Internet Archive. We refer to these collections as NEWS and BOOKS, respectively.

Standard procedures were used to tokenize each collection and create the bags-of-words. We learned

topic models of NEWS and BOOKS using $T = 200$ and $T = 400$ topics respectively. We randomly selected a total of 237 topics from the two collections for user scoring. We asked $N = 9$ users to score each of the 237 topics on a 3-point scale where 3="useful" (coherent) and 1="useless" (less coherent).

We provided annotators with a rubric and guidelines on how to judge whether a topic was useful or useless. In addition to showing several examples of useful and useless topics, we instructed users to decide whether the topic was to some extent coherent, meaningful, interpretable, subject-heading-like, and something-you-could-easily-label. For our purposes, the usefulness of a topic can be thought of as whether one could imagine using the topic in a search interface to retrieve documents about a particular subject. One indicator of usefulness is the ease by which one could think of a short label to describe a topic.

Table 1 shows a selection of high- and low-scoring topics, as scored by the $N = 9$ users. The first topic illustrates the notion of labelling coherence, as *space exploration*, e.g., would be an obvious label for the topic. The low-scoring topics display little coherence, and one would not expect them to be useful as categories or facets in a search interface. Note that the useless topics from both collections are not chance artifacts produced by the models, but are in fact stable and robust statistical features in the data sets.

6 Results

The results for the different topic scoring methods over the NEWS and BOOKS collections are presented in Tables 2 and 3, respectively. In each table, we separate out the scoring methods into those based on WordNet (from Section 4.1), those based on Wikipedia (from Section 4.2), and those based on Google (from Section 4.3).

As stated in Section 4, we experiment with two methods for combining the word-pair scores (for all methods other than the two Google methods, which operate natively over a word set), namely the arithmetic mean and median. We present the numbers for these two methods in each table. In each case, we evaluate via Spearman rank correlation, reversing the sign of the calculated ρ value for PATH (as it is the only instance of a distance metric, where the gold-standard is made up of similarity values).

We include the inter-annotator agreement (IAA) in the final row of each table, which we consider to be the upper bound for the task. This is calculated as the average Spearman rank correlation between each annotator and the mean/median of the remaining annotators for that topic. Encouragingly, there is relatively little difference in the IAA between the two datasets; the median-based calculation produces slightly higher ρ values and is empirically the method of choice.[3]

Of all the topic scoring methods tested, PMI (term co-occurrence via simple pointwise mutual information) is the most consistent performer, achieving the best or near-best results over both datasets, and approaching or surpassing the inter-annotator agreement. This indicates both that the task of topic evaluation as defined in this paper is computationally tractable, and that word-pair based co-occurrence is highly successful at modelling topic coherence.

Comparing the different resources, Wikipedia is far and away the most consistent performing, with PMI producing the best results, followed by MiW and RACO, and finally DocSim. There is relatively little difference in results between News and Books for the Wikipedia methods. Google achieves the best results over News, for Titles (actually slightly above the IAA), but the results fall away sharply over Books. The reason for this can be seen in the sample topics in Table 1: the topics for Books tend to be more varied in word class than for News, and contain less proper names; also, the genre of Books is less well represented on the web. We hypothesise that Wikipedia's encyclopedic nature means that it has good coverage over both domains, and thus more robust.

Turning to WordNet, the overall results are markedly better over Books, again largely because of the relative sparsity of proper names in the resource. The results for individual methods are somewhat surprising. Whereas JCn and LCh have been shown to be two of the best-performing methods over lexical similarity tasks (Budanitsky and Hirst, 2005; Agirre et al., 2009), they perform abysmally at the topic scoring task. Indeed, the spread of results across the WordNet similarity methods (notably HSO, JCn, LCh, Lin, Res and WuP) is much greater than we had expected. The single most consistent method is Lesk, which is based on lexical overlap in definition sentences and makes relatively modest use of the WordNet hierarchy. Supplementary evaluation where we filtered out all proper nouns from the topics (based on simple POS priors for each word learned from an automatically-tagged version of the British National Corpus) led to a slight increase in results for the WordNet methods; the full results are omitted for reasons of space. In future work, we intend to carry out error analysis to determine why some of the methods performed so badly, or inconsistently across the two datasets.

There is no clear answer to the question of whether the mean or median is the best method for combining the pair-wise scores.

7 Conclusions

We have proposed the novel task of topic coherence evaluation as a form of intrinsic topic evaluation with relevance in document search/discovery and visualisation applications. We constructed a gold-standard dataset of topic coherence scores over the output of a topic model for two distinct datasets, and evaluated a wide range of topic scoring methods over this dataset, drawing on WordNet, Wikipedia and the Google search engine. The single best-performing method was term co-occurrence within Wikipedia based on pointwise mutual information, which achieve results very close to the inter-annotator agreement for the task. Google was also found to perform well over one of the two datasets, while the results for the WordNet-based methods were overall surprisingly low.

Abstract

Current vector-space models of lexical semantics create a single "prototype" vector to represent the meaning of a word. However, due to lexical ambiguity, encoding word meaning with a single vector is problematic. This paper presents a method that uses clustering to produce multiple "sense-specific" vectors for each word. This approach provides a context-dependent vector representation of word meaning that naturally accommodates homonymy and polysemy. Experimental comparisons to human judgements of semantic similarity for both isolated words as well as words in sentential contexts demonstrate the superiority of this approach over both prototype and exemplar based vector-space models.

1 Introduction

Automatically judging the degree of semantic similarity between words is an important task useful in text classification (Baker and McCallum, 1998), information retrieval (Sanderson, 1994), textual entailment, and other language processing tasks. The standard empirical approach to this task exploits the *distributional hypothesis*, i.e. that similar words appear in similar contexts (Curran and Moens, 2002; Lin and Pantel, 2002; Pereira et al., 1993). Traditionally, word types are represented by a single vector of contextual features derived from co-occurrence information, and semantic similarity is computed using some measure of vector distance (Lee, 1999; Lowe, 2001).

However, due to homonymy and polysemy, capturing the semantics of a word with a single vector is problematic. For example, the word *club* is similar to both *bat* and *association,* which are not at all similar to each other. Word meaning violates the triangle inequality when viewed at the level of word types, posing a problem for vector-space models (Tversky and Gati, 1982). A single "prototype" vector is simply incapable of capturing phenomena such as homonymy and polysemy. Also, most vector-space models are context independent, while the meaning of a word clearly depends on context. The word *club* in "The caveman picked up the *club*" is similar to *bat* in "John hit the robber with a *bat*," but not in "The *bat* flew out of the cave."

We present a new resource-lean vector-space model that represents a word's meaning by a *set* of distinct "sense specific" vectors. The similarity of two isolated words *A* and *B* is defined as the *minimum* distance between one of *A*'s vectors and one of *B*'s vectors. In addition, a context-dependent meaning for a word is determined by choosing one of the vectors in its set based on minimizing the distance to the vector representing the current context. Consequently, the model supports judging the similarity of both words in isolation and words in context.

The set of vectors for a word is determined by unsupervised *word sense discovery* (WSD) (Schütze, 1998), which clusters the contexts in which a word appears. In previous work, vector-space lexical similarity and word sense discovery have been treated as two separate tasks. This paper shows how they can be combined to create an improved vector-space model of lexical semantics. First, a word's contexts are clustered to produce groups of similar context vectors. An average "prototype" vector is then computed separately for each cluster, producing a set of vectors for each word. Finally, as described above, these cluster vectors can be used to determine the se-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 109–117,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

mantic similarity of both isolated words and words in context. The approach is completely modular, and can integrate any clustering method with any traditional vector-space model.

We present experimental comparisons to human judgements of semantic similarity for both isolated words and words in sentential context. The results demonstrate the superiority of a clustered approach over both traditional prototype and exemplar-based vector-space models. For example, given the isolated target word *singer* our method produces the most similar word *vocalist*, while using a single prototype gives *musician*. Given the word *cell* in the context: "The book was published while Piasecki was still in prison, and a copy was delivered to his *cell*." the standard approach produces *protein* while our method yields *incarcerated*.

The remainder of the paper is organized as follows: Section 2 gives relevant background on prototype and exemplar methods for lexical semantics, Section 3 presents our multi-prototype method, Section 4 presents our experimental evaluations, Section 5 discusses future work, and Section 6 concludes.

2 Background

Psychological concept models can be roughly divided into two classes:

1. *Prototype* models represented concepts by an abstract prototypical instance, similar to a cluster centroid in parametric density estimation.

2. *Exemplar* models represent concepts by a concrete set of observed instances, similar to nonparametric approaches to density estimation in statistics (Ashby and Alfonso-Reese, 1995).

Tversky and Gati (1982) famously showed that conceptual similarity violates the triangle inequality, lending evidence for exemplar-based models in psychology. Exemplar models have been previously used for lexical semantics problems such as selectional preference (Erk, 2007) and thematic fit (Vandekerckhove et al., 2009). Individual exemplars can be quite noisy and the model can incur high computational overhead at prediction time since naively computing the similarity between two words using each occurrence in a textual corpus as an exemplar requires $O(n^2)$ comparisons. Instead, the standard approach is to compute a single prototype vector for each word from its occurrences.

Figure 1: Overview of the multi-prototype approach to near-synonym discovery for a single target word independent of context. Occurrences are clustered and cluster centroids are used as prototype vectors. Note the "hurricane" sense of *position* (cluster 3) is not typically considered appropriate in WSD.

This paper presents a *multi-prototype* vector space model for lexical semantics with a single parameter K (the number of clusters) that generalizes both prototype ($K = 1$) and exemplar ($K = N$, the total number of instances) methods. Such models have been widely studied in the Psychology literature (Griffiths et al., 2007; Love et al., 2004; Rosseel, 2002). By employing multiple prototypes per word, vector space models can account for homonymy, polysemy and thematic variation in word usage. Furthermore, such approaches require only $O(K^2)$ comparisons for computing similarity, yielding potential computational savings over the exemplar approach when $K \ll N$, while reaping many of the same benefits.

Previous work on lexical semantic relatedness has focused on two approaches: (1) mining monolingual or bilingual dictionaries or other pre-existing resources to construct networks of related words (Agirre and Edmond, 2006; Ramage et al., 2009), and (2) using the distributional hypothesis to automatically infer a vector-space prototype of word meaning from large corpora (Agirre et al., 2009; Curran, 2004; Harris, 1954). The former approach tends to have greater precision, but depends on hand-crafted dictionaries and cannot, in general, model sense frequency (Budanitsky and Hirst, 2006). The latter approach is fundamentally more scalable as it does not rely on specific resources and can model corpus-specific sense distributions. However, the distributional approach can suffer from poor precision, as thematically similar words (e.g., *singer* and *actor*) and antonyms often occur in similar contexts (Lin et al., 2003).

Unsupervised word-sense discovery has been studied by number of researchers (Agirre and Edmond, 2006; Schütze, 1998). Most work has also focused on corpus-based distributional approaches, varying the vector-space representation, e.g. by incorporating syntactic and co-occurrence information from the words surrounding the target term (Pereira et al., 1993; Pantel and Lin, 2002).

3 Multi-Prototype Vector-Space Models

Our approach is similar to standard vector-space models of word meaning, with the addition of a per-word-type clustering step: Occurrences for a specific word type are collected from the corpus and clustered using any appropriate method (§3.1). Similarity between two word types is then computed as a function of their cluster centroids (§3.2), instead of the centroid of all the word's occurrences. Figure 1 gives an overview of this process.

3.1 Clustering Occurrences

Multiple prototypes for each word w are generated by clustering feature vectors $v(c)$ derived from each occurrence $c \in \mathcal{C}(w)$ in a large textual corpus and collecting the resulting cluster centroids $\pi_k(w), k \in [1, K]$. This approach is commonly employed in unsupervised word sense discovery; however, we do not assume that clusters correspond to traditional word senses. Rather, we only rely on clusters to capture meaningful variation in word usage.

Our experiments employ a *mixture of von Mises-Fisher distributions* (movMF) clustering method with first-order unigram contexts (Banerjee et al., 2005). Feature vectors $v(c)$ are composed of individual features $I(c, f)$, taken as all unigrams occurring $f \in \mathcal{F}$ in a 10-word window around w.

Like spherical k-means (Dhillon and Modha, 2001), movMF models semantic relatedness using cosine similarity, a standard measure of textual similarity. However, movMF introduces an additional per-cluster *concentration* parameter controlling its semantic breadth, allowing it to more accurately model non-uniformities in the distribution of cluster sizes. Based on preliminary experiments comparing various clustering methods, we found movMF gave the best results.

3.2 Measuring Semantic Similarity

The similarity between two words in a multi-prototype model can be computed straightforwardly, requiring only simple modifications to standard distributional similarity methods such as those presented by Curran (2004). Given words w and w', we define two *noncontextual clustered similarity metrics* to measure similarity of isolated words:

$$\text{AvgSim}(w, w') \overset{\text{def}}{=} \frac{1}{K^2}\sum_{j=1}^{K}\sum_{k=1}^{K} d(\pi_k(w), \pi_j(w'))$$

$$\text{MaxSim}(w, w') \overset{\text{def}}{=} \max_{1\le j\le K, 1\le k\le K} d(\pi_k(w), \pi_j(w'))$$

where $d(\cdot, \cdot)$ is a standard distributional similarity measure. In AvgSim, word similarity is computed as the average similarity of all pairs of prototype vectors; In MaxSim the similarity is the maximum over all pairwise prototype similarities. All results reported in this paper use *cosine* similarity, [1]

$$\text{Cos}(w, w') = \frac{\sum_{f\in\mathcal{F}} I(w, f) \cdot I(w', f)}{\sqrt{\sum_{f\in\mathcal{F}} I(w, f)^2}\sqrt{\sum_{f\in\mathcal{F}} I(w', f)^2}}$$

We compare across two different feature functions *tf-idf* weighting and χ^2 weighting, chosen due to their ubiquity in the literature (Agirre et al., 2009; Curran, 2004).

In AvgSim, all prototype pairs contribute equally to the similarity computation, thus two words are judged as similar if many of their senses are similar. MaxSim, on the other hand, only requires a single pair of prototypes to be close for the words to be judged similar. Thus, MaxSim models the similarity of words that share only a single sense (e.g. *bat* and *club*) at the cost of lower robustness to noisy clusters that might be introduced when K is large.

When contextual information is available, AvgSim and MaxSim can be modified to produce

[1] The main results also hold for *weighted Jaccard* similarity.

more precise similarity computations:

$$\text{AvgSimC}(w, w') \overset{\text{def}}{=} \frac{1}{K^2}\sum_{j=1}^{K}\sum_{k=1}^{K} d_{c,w,k}d_{c',w',j}d(\pi_k(w), \pi_j(w'))$$

$$\text{MaxSimC}(w, w') \overset{\text{def}}{=} d(\hat{\pi}(w), \hat{\pi}(w'))$$

where $d_{c,w,k} \overset{\text{def}}{=} d(v(c), \pi_k(w))$ is the likelihood of context c belonging to cluster $\pi_k(w)$, and $\hat{\pi}(w) \overset{\text{def}}{=} \pi_{\arg\max_{1\leq k\leq K} d_{c,w,k}}(w)$, the maximum likelihood cluster for w in context c. Thus, AvgSimC corresponds to *soft cluster assignment*, weighting each similarity term in AvgSim by the likelihood of the word contexts appearing in their respective clusters. MaxSimC corresponds to *hard assignment*, using only the most probable cluster assignment. Note that AvgSim and MaxSim can be thought of as special cases of AvgSimC and MaxSimC with uniform weight to each cluster; hence AvgSimC and MaxSimC can be used to compare words in context to isolated words as well.

4 Experimental Evaluation

4.1 Corpora

We employed two corpora to train our models:

1. A snapshot of English Wikipedia taken on Sept. 29th, 2009. Wikitext markup is removed, as are articles with fewer than 100 words, leaving 2.8M articles with a total of 2.05B words.

2. The third edition English Gigaword corpus, with articles containing fewer than 100 words removed, leaving 6.6M articles and 3.9B words (Graff, 2003).

Wikipedia covers a wider range of sense distributions, whereas Gigaword contains only newswire text and tends to employ fewer senses of most ambiguous words. Our method outperforms baseline methods even on Gigaword, indicating its advantages even when the corpus covers few senses.

4.2 Judging Semantic Similarity

To evaluate the quality of various models, we first compared their lexical similarity measurements to human similarity judgements from the WordSim-353 data set (Finkelstein et al., 2001). This test corpus contains multiple human judgements on 353 word pairs, covering both monosemous and polysemous words, each rated on a 1–10 integer scale. Spearman's rank correlation (ρ) with average human judgements (Agirre et al., 2009) was used to measure the quality of various models.

Figure 2 plots Spearman's ρ on WordSim-353 against the number of clusters (K) for Wikipedia and Gigaword corpora, using pruned *tf-idf* and χ^2 features.[2] In general pruned *tf-idf* features yield higher correlation than χ^2 features. Using AvgSim, the multi-prototype approach ($K > 1$) yields higher correlation than the single-prototype approach ($K = 1$) across all corpora and feature types, achieving state-of-the-art results with pruned *tf-idf* features. This result is statistically significant in all cases for *tf-idf* and for $K \in [2, 10]$ on Wikipedia and $K > 4$ on Gigaword for χ^2 features.[3] MaxSim yields similar performance when $K < 10$ but performance degrades as K increases.

It is possible to circumvent the model-selection problem (choosing the best value of K) by simply combining the prototypes from clusterings of different sizes. This approach represents words using both semantically broad and semantically tight prototypes, similar to hierarchical clustering. Table 1 and Figure 2 (squares) show the result of such a *combined* approach, where the prototypes for clusterings of size 2-5, 10, 20, 50, and 100 are unioned to form a single large prototype set. In general, this approach works about as well as picking the optimal value of K, even outperforming the single best cluster size for Wikipedia.

Finally, we also compared our method to a pure exemplar approach, averaging similarity across all occurrence pairs.[4] Table 1 summarizes the results. The exemplar approach yields significantly higher correlation than the single prototype approach in all cases except Gigaword with *tf-idf* features ($p < 0.05$). Furthermore, it performs significantly *worse*

[2] (**Feature pruning**) We find that results using *tf-idf* features are extremely sensitive to feature pruning while χ^2 features are more robust. In all experiments we prune *tf-idf* features by their overall weight, taking the top 5000. This setting was found to optimize the performance of the single-prototype approach.

[3] Significance is calculated using the large-sample approximation of the Spearman rank *test*; ($p < 0.05$).

[4] Averaging across all pairs was found to yield higher correlation than averaging over the most similar pairs.

Spearman's ρ	prototype	exemplar	multi-prototype (AvgSim)			combined
			$K = 5$	$K = 20$	$K = 50$	
Wikipedia *tf-idf*	0.53±0.02	0.60±0.06	0.69±0.02	0.76±0.01	0.76±0.01	0.77±0.01
Wikipedia χ^2	0.54±0.03	0.65±0.07	0.58±0.02	0.56±0.02	0.52±0.03	0.59±0.04
Gigaword *tf-idf*	0.49±0.02	0.48±0.10	0.64±0.02	0.61±0.02	0.61±0.02	0.62±0.02
Gigaword χ^2	0.25±0.03	0.41±0.14	0.32±0.03	0.35±0.03	0.33±0.03	0.34±0.03

Table 1: Spearman correlation on the WordSim-353 dataset broken down by corpus and feature type.

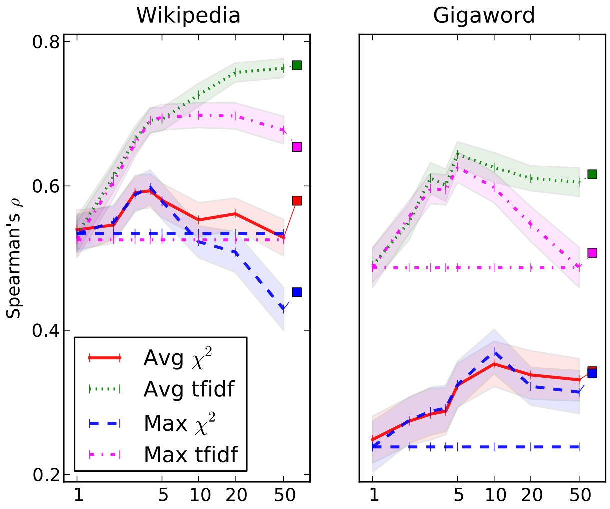

Figure 2: WordSim-353 rank correlation vs. number of clusters (log scale) for both the Wikipedia (left) and Gigaword (right) corpora. Horizontal bars show the performance of single-prototype. Squares indicate performance when combining across clusterings. Error bars depict 95% confidence intervals using the Spearman test. Squares indicate performance when combining across clusterings.

than combined multi-prototype for *tf-idf* features, and does not differ significantly for χ^2 features. Overall this result indicates that multi-prototype performs at least as well as exemplar in the worst case, and significantly outperforms when using the best feature representation / corpus pair.

4.3 Predicting Near-Synonyms

We next evaluated the multi-prototype approach on its ability to determine the most closely related words for a given target word (using the Wikipedia corpus with *tf-idf* features). The top k most similar words were computed for each prototype of each target word. Using a forced-choice setup, human subjects were asked to evaluate the quality of these *near synonyms* relative to those produced by a single prototype. Participants on Amazon's Mechanical Turk[5] (Snow et al., 2008) were asked to choose between two possible alternatives (one from a prototype model and one from a multi-prototype model) as being most similar to a given target word. The target words were presented either in isolation or in a sentential context randomly selected from the corpus. Table 2 lists the ambiguous words used for this task. They are grouped into homonyms (words with very distinct senses) and polysemes (words with related senses). All words were chosen such that their usages occur within the same part of speech.

In the non-contextual task, 79 unique raters completed 7,620 comparisons of which 72 were discarded due to poor performance on a known test set.[6] In the contextual task, 127 raters completed 9,930 comparisons of which 87 were discarded.

For the non-contextual case, Figure 3 left plots the fraction of raters preferring the multi-prototype prediction (using AvgSim) over that of a single prototype as the number of clusters is varied. When asked to choose between the single best word for

[5] http://mturk.com

[6] (**Rater reliability**) The reliability of Mechanical Turk raters is quite variable, so we computed an accuracy score for each rater by including a control question with a known correct answer in each HIT. Control questions were generated by selecting a random word from WordNet 3.0 and including as possible choices a word in the same synset (correct answer) and a word in a synset with a high path distance (incorrect answer). Raters who got less than 50% of these control questions correct, or spent too little time on the HIT were discarded.

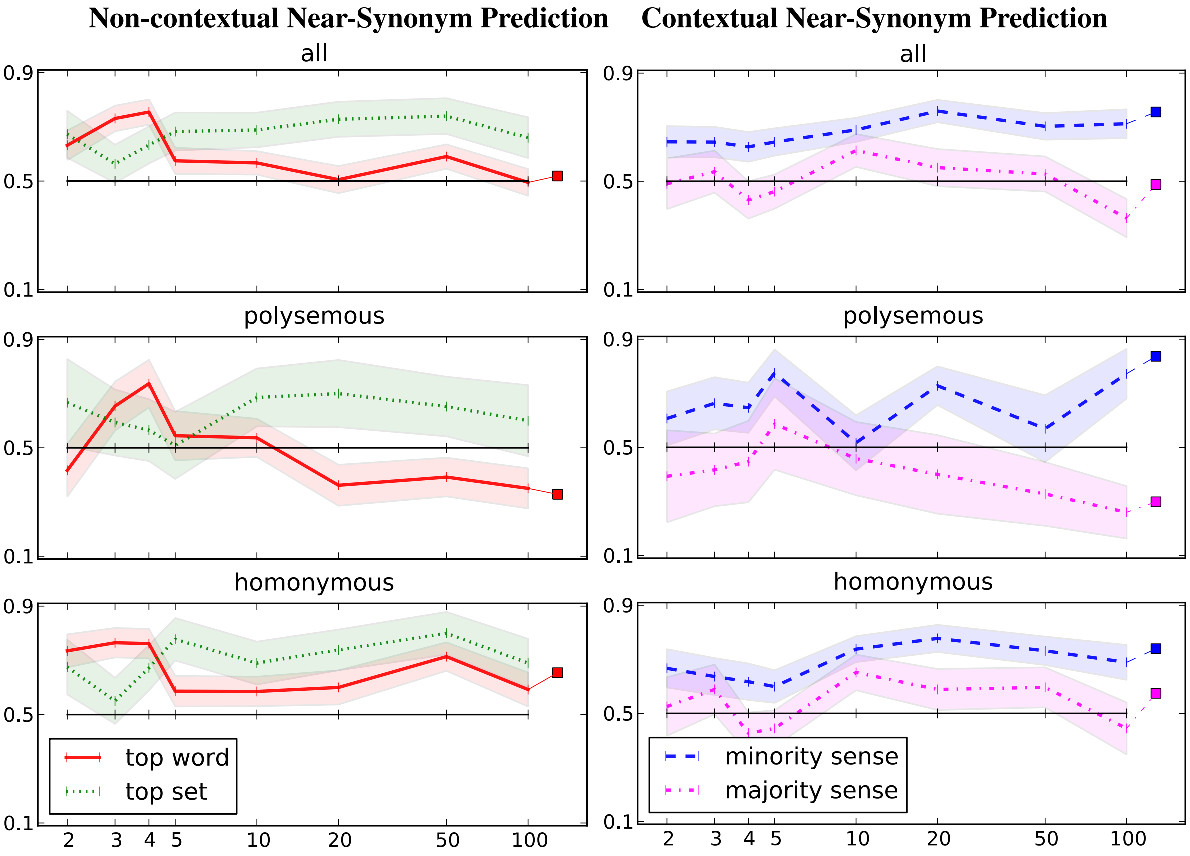

Figure 3: (**left**) Near-synonym evaluation for isolated words showing fraction of raters preferring multi-prototype results vs. number of clusters. Colored squares indicate performance when combining across clusterings. 95% confidence intervals computed using the Wald test. (**right**) Near-synonym evaluation for words in a sentential context chosen either from the minority sense or the majority sense.

each method (**top word**), the multi-prototype prediction is chosen significantly more frequently (i.e. the result is above 0.5) when the number of clusters is small, but the two methods perform similarly for larger numbers of clusters (Wald test, $\alpha = 0.05$.) Clustering more accurately identifies homonyms' clearly distinct senses and produces prototypes that better capture the different uses of these words. As a result, compared to using a single prototype, our approach produces better near-synonyms for homonyms compared to polysemes. However, given the right number of clusters, it also produces better results for polysemous words.

The near-synonym prediction task highlights one of the weaknesses of the multi-prototype approach: as the number of clusters increases, the number of occurrences assigned to each cluster decreases, increasing noise and resulting in some poor prototypes that mainly cover outliers. The word similarity task is somewhat robust to this phenomenon, but synonym prediction is more affected since only the top predicted choice is used. When raters are forced to chose between the top *three* predictions for each method (presented as **top set** in Figure 3 left), the effect of this noise is reduced and the multi-prototype approach remains dominant even for a large number of clusters. This indicates that although more clusters can capture finer-grained sense distinctions, they also can introduce noise.

When presented with words in context (Figure 3 right),[7] raters found no significant difference in the two methods for words used in their majority sense.[8] However, when a minority sense is pre-

[7] Results for the multi-prototype method are generated using AvgSimC (soft assignment) as this was found to significantly outperform MaxSimC.

[8] Sense frequency determined using Google; senses labeled manually by trained human evaluators.

sented (e.g. the “prison” sense of *cell*), raters prefer the choice predicted by the multi-prototype approach. This result is to be expected since the single prototype mainly reflects the majority sense, preventing it from predicting appropriate synonyms for a minority sense. Also, once again, the performance of the multi-prototype approach is better for homonyms than polysemes.

4.4 Predicting Variation in Human Ratings

Variance in pairwise prototype distances can help explain the variance in human similarity judgements for a given word pair. We evaluate this hypothesis empirically on WordSim-353 by computing the Spearman correlation between the *variance* of the per-cluster similarity computations, $\mathbb{V}[D]$, $D \overset{\text{def}}{=} \{d(\pi_k(w), \pi_j(w')) : 1 \leq k, j \leq K\}$, and the variance of the human annotations for that pair. Correlations for each dataset are shown in Figure 4 left. In general, we find a statistically significant *negative* correlation between these values using χ^2 features, indicating that as the entropy of the pairwise cluster similarities increases (i.e., prototypes become more similar, and similarities become uniform), rater disagreement increases. This result is intuitive: if the occurrences of a particular word cannot be easily separated into coherent clusters (perhaps indicating high polysemy instead of homonymy), then human judgement will be naturally more difficult.

Rater variance depends more directly on the actual word similarity: word pairs at the extreme ranges of similarity have significantly lower variance as raters are more certain. By removing word pairs with similarity judgements in the middle two quartile ranges (4.4 to 7.5) we find significantly higher variance correlation (Figure 4 right). This result indicates that multi-prototype similarity variance accounts for a secondary effect separate from the primary effect that variance is naturally lower for ratings in extreme ranges.

Although the *entropy* of the prototypes correlates with the variance of the human ratings, we find that the individual senses captured by each prototype do not correspond to human intuition for a given word, e.g. the “hurricane” sense of *position* in Figure 1. This notion is evaluated empirically by computing the correlation between the predicted similarity using the contextual multi-prototype method and human similarity judgements for different usages of the *same* word. The Usage Similarity (USim) data set collected in Erk et al. (2009) provides such similarity scores from human raters. However, we find no evidence for correlation between USim scores and their corresponding prototype similarity scores ($\rho = 0.04$), indicating that prototype vectors may not correspond well to human senses.

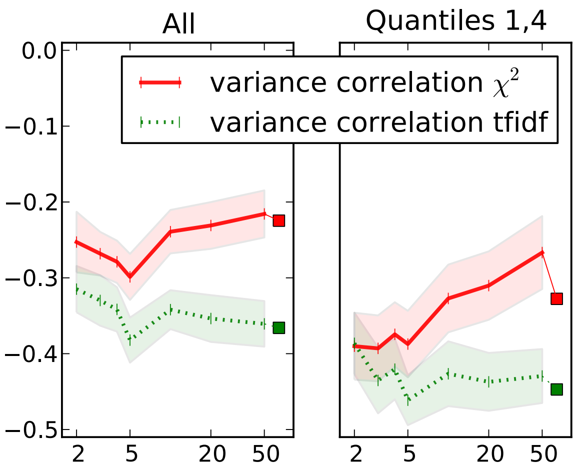

Figure 4: Plots of variance correlation; lower numbers indicate higher negative correlation, i.e. that prototype entropy predicts rater disagreement.

5 Discussion and Future Work

Table 3 compares the inferred synonyms for several target words, generally demonstrating the ability of the multi-prototype model to improve the precision of inferred near-synonyms (e.g. in the case of *singer* or *need*) as well as its ability to include synonyms from less frequent senses (e.g., the *experiment* sense of *research* or the *verify* sense of *prove*). However, there are a number of ways it could be improved:

Feature representations: Multiple prototypes improve Spearman correlation on WordSim-353 compared to previous methods using the same underlying representation (Agirre et al., 2009). However we have not yet evaluated its performance when using more powerful feature representations such those based on Latent or Explicit Semantic Analysis (Deerwester et al., 1990; Gabrilovich and Markovitch, 2007). Due to its modularity, the multi-prototype approach can easily incorporate such advances in order to further improve its effectiveness.

Table 3: Examples of the top 5 inferred near-synonyms using the single- and multi-prototype approaches (with results merged). In general such clustering improves the precision and coverage of the inferred near-synonyms.

Nonparametric clustering: The success of the combined approach indicates that the optimal number of clusters may vary per word. A more principled approach to selecting the number of prototypes per word is to employ a clustering model with infinite capacity, e.g. the Dirichlet Process Mixture Model (Rasmussen, 2000). Such a model would allow naturally more polysemous words to adopt more flexible representations.

Cluster similarity metrics: Besides AvgSim and MaxSim, there are many similarity metrics over mixture models, e.g. KL-divergence, which may correlate better with human similarity judgements.

Comparing to traditional senses: Compared to WordNet, our best-performing clusterings are significantly more fine-grained. Furthermore, they often do not correspond to agreed upon semantic distinctions (e.g., the "hurricane" sense of *position* in Fig. 1). We posit that the finer-grained senses actually capture useful aspects of word meaning, leading to better correlation with WordSim-353. However, it would be good to compare prototypes learned from supervised sense inventories to prototypes produced by automatic clustering.

Joint model: The current method independently clusters the contexts of each word, so the senses discovered for w cannot influence the senses discovered for $w' \neq w$. Sharing statistical strength across similar words could yield better results for rarer words.

6 Conclusions

We presented a resource-light model for vector-space word meaning that represents words as collections of prototype vectors, naturally accounting for lexical ambiguity. The multi-prototype approach uses word sense discovery to partition a word's contexts and construct "sense specific" prototypes for each cluster. Doing so significantly increases the accuracy of lexical-similarity computation as demonstrated by improved correlation with human similarity judgements and generation of better near synonyms according to human evaluators. Furthermore, we show that, although performance is sensitive to the number of prototypes, combining prototypes across a large range of clusterings performs nearly as well as the ex-post best clustering. Finally, variance in the prototype similarities is found to correlate with inter-annotator disagreement, suggesting psychological plausibility.

Abstract

Syntactic machine translation systems currently use word alignments to infer syntactic correspondences between the source and target languages. Instead, we propose an unsupervised ITG alignment model that directly aligns syntactic structures. Our model aligns spans in a source sentence to nodes in a target parse tree. We show that our model produces syntactically consistent analyses where possible, while being robust in the face of syntactic divergence. Alignment quality and end-to-end translation experiments demonstrate that this consistency yields higher quality alignments than our baseline.

1 Introduction

Syntactic machine translation has advanced significantly in recent years, and multiple variants currently achieve state-of-the-art translation quality. Many of these systems exploit linguistically-derived syntactic information either on the target side (Galley et al., 2006), the source side (Huang et al., 2006), or both (Liu et al., 2009). Still others induce their syntax from the data (Chiang, 2005). Despite differences in detail, the vast majority of syntactic methods share a critical dependence on word alignments. In particular, they infer syntactic correspondences between the source and target languages through word alignment patterns, sometimes in combination with constraints from parser outputs.

However, word alignments are not perfect indicators of syntactic alignment, and syntactic systems are very sensitive to word alignment behavior. Even a single spurious word alignment can invalidate a large number of otherwise extractable rules, while unaligned words can result in an exponentially large set of extractable rules to choose from. Researchers have worked to incorporate syntactic information into word alignments, resulting in improvements to both alignment quality (Cherry and Lin, 2006; DeNero and Klein, 2007), and translation quality (May and Knight, 2007; Fossum et al., 2008).

In this paper, we remove the dependence on word alignments and instead directly model the syntactic correspondences in the data, in a manner broadly similar to Yamada and Knight (2001). In particular, we propose an unsupervised model that aligns nodes of a parse tree (or forest) in one language to spans of a sentence in another. Our model is an instance of the inversion transduction grammar (ITG) formalism (Wu, 1997), constrained in such a way that one side of the synchronous derivation respects a syntactic parse. Our model is best suited to systems which use source- or target-side trees only.

The design of our model is such that, for divergent structures, a structurally integrated backoff to flatter word-level (or null) analyses is available. Therefore, our model is empirically robust to the case where syntactic divergence between languages prevents syntactically accurate ITG derivations.

We show that, with appropriate pruning, our model can be efficiently trained on large parallel corpora. When compared to standard word-alignment-backed baselines, our model produces more consistent analyses of parallel sentences, leading to high-count, high-quality transfer rules. End-to-end translation experiments demonstrate that these higher quality rules improve translation quality by 1.0 BLEU over a word-alignment-backed baseline.

2 Syntactic Rule Extraction

Our model is intended for use in syntactic translation models which make use of syntactic parses on either the target (Galley et al., 2006) or source side (Huang et al., 2006; Liu et al., 2006). Our model's

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 118–126,

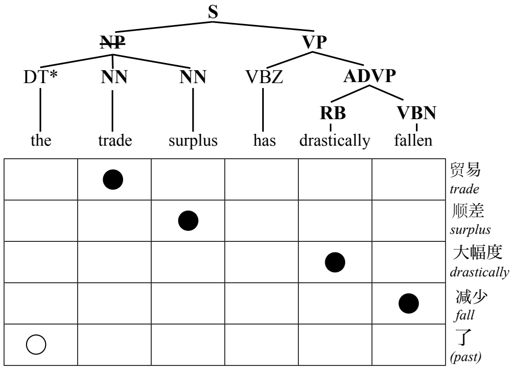

Figure 1: A single incorrect alignment removes an extractable node, and hence several desirable rules. We represent correct extractable nodes in bold, spurious extractable nodes with a *, and incorrectly blocked extractable nodes in bold strikethrough.

chief purpose is to align nodes in the syntactic parse in one language to spans in the other – an alignment we will refer to as a "syntactic" alignment. These alignments are employed by standard syntactic rule extraction algorithms, for example, the GHKM algorithm of Galley et al. (2004). Following that work, we will assume parses are present in the target language, though our model applies in either direction.

Currently, although syntactic systems make use of syntactic alignments, these alignments must be induced indirectly from word-level alignments. Previous work has discussed at length the poor interaction of word-alignments with syntactic rule extraction (DeNero and Klein, 2007; Fossum et al., 2008). For completeness, we provide a brief example of this interaction, but for a more detailed discussion we refer the reader to these presentations.

2.1 Interaction with Word Alignments

Syntactic systems begin rule extraction by first identifying, for each node in the target parse tree, a span of the foreign sentence which (1) contains every source word that aligns to a target word in the yield of the node and (2) contains no source words that align outside that yield. Only nodes for which a non-empty span satisfying (1) and (2) exists may form the root or leaf of a translation rule; for that reason, we will refer to these nodes as *extractable* nodes.

Since extractable nodes are inferred based on word alignments, spurious word alignments can rule out otherwise desirable extraction points. For example, consider the alignment in Figure 1. This alignment, produced by GIZA++ (Och and Ney, 2003), contains 4 correct alignments (the filled circles), but incorrectly aligns *the* to the Chinese past tense marker 了 (the hollow circle). This mistaken alignment produces the incorrect rule (DT → *the* ; 了), and also blocks the extraction of (VBN → *fallen* ; 减少 了).

More high-level syntactic transfer rules are also ruled out, for example, the "*the* insertion rule" (NP → *the* NN$_1$ NN$_2$; NN$_1$ NN$_2$) and the high-level (S → NP$_1$ VP$_2$; NP$_1$ VP$_2$).

3 A Syntactic Alignment Model

The most common approach to avoiding these problems is to inject knowledge about syntactic constraints into a word alignment model (Cherry and Lin, 2006; DeNero and Klein, 2007; Fossum et al., 2008).[1] While syntactically aware, these models remain limited by the word alignment models that underly them.

Here, we describe a model which directly infers alignments of nodes in the target-language parse tree to spans of the source sentence. Formally, our model is an instance of a Synchronous Context-Free Grammar (see Chiang (2004) for a review), or SCFG, which generates an English (target) parse tree T and foreign (source) sentence $\mathbf{f}$ given a target sentence $\mathbf{e}$. The generative process underlying this model produces a derivation d of SCFG rules, from which T and $\mathbf{f}$ can be read off; because we condition on $\mathbf{e}$, the derivations produce $\mathbf{e}$ with probability 1. This model places a distribution over T and $\mathbf{f}$ given by

$$p(T, \mathbf{f} \mid \mathbf{e}) = \sum_{d} p(d \mid \mathbf{e}) = \sum_{d} \prod_{r \in d} p(r \mid \mathbf{e})$$

where the sum is over derivations d which yield T and $\mathbf{f}$. The SCFG rules r come from one of 4 types, pictured in Table 1. In general, because our model can generate English trees, it permits inference over forests. Although we will restrict ourselves to a single parse tree for our experiments, in this section, we discuss the more general case.

[1] One notable exception is May and Knight (2007), who produces syntactic alignments using syntactic rules derived from word-aligned data.

Rule Type	Root	English	Foreign	Example Instantiation								
TERMINAL	E	e	$\mathbf{f}_t$	FOUR	→	*four*		; 四				
UNARY	A	B	$\mathbf{f}_l\ B\ \mathbf{f}_r$	CD	→	FOUR		; ϵ	FOUR	个		
BINARYMONO	A	$B\ C$	$\mathbf{f}_l\ B\ \mathbf{f}_m\ C\ \mathbf{f}_r$	NP	→	NN	NN	; ϵ	NN	的	NN	ϵ
BINARYINV	A	$B\ C$	$\mathbf{f}_l\ C\ \mathbf{f}_m\ B\ \mathbf{f}_r$	PP	→	IN	NP	; 在	NP	ϵ	IN	ϵ

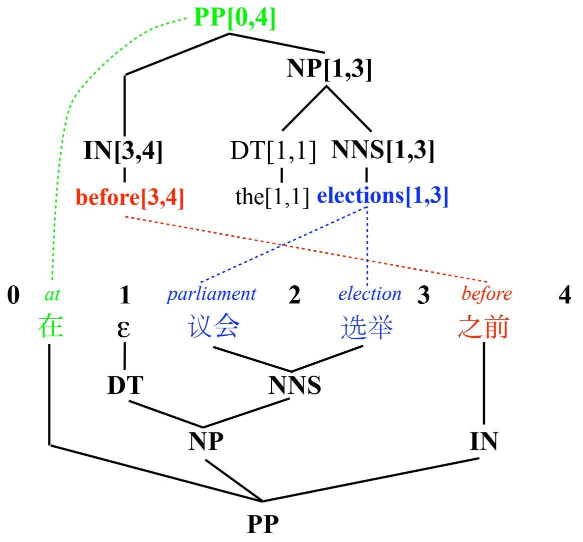
Table 1: Types of rules present in the SCFG describing our model, along with some sample instantiations of each type. Empty word sequences $\mathbf{f}$ have been explicitly marked with an ϵ.

The first rule type is the TERMINAL production, which rewrites a terminal symbol[2] E as its English word e and a (possibly empty) sequence of foreign words $\mathbf{f}_t$. Generally speaking, the majority of foreign words are generated using this rule. It is only when a straightforward word-to-word correspondence cannot be found that our model resorts to generating foreign words elsewhere.

We can also rewrite a non-terminal symbol A using a UNARY production, which on the English side produces a single symbol B, and on the foreign side produces the symbol B, with sequences of words $\mathbf{f}_l$ to its left and $\mathbf{f}_r$ to its right.

Finally, there are two binary productions: BINARYMONO rewrites A with two non-terminals B and C on the English side, and the same non-terminals B and C in monotonic order on the foreign side, with sequences of words $\mathbf{f}_l$, $\mathbf{f}_r$, and $\mathbf{f}_m$ to the left, right, and the middle. BINARYINV inverts the order in which the non-terminals B and C are written on the source side, allowing our model to capture a large subset of possible reorderings (Wu, 1997).

Derivations from this model have two key properties: first, the English side of a derivation is constrained to form a valid constituency parse, as is required in a syntax system with target-side syntax; and second, for each parse node in the English projection, there is exactly one (possibly empty) contiguous span of the foreign side which was generated from that non-terminal or one of its descendants. Identifying extractable nodes from a derivation is thus trivial: any node aligned to a non-empty foreign span is extractable.



PP	→	IN	NP	; 在	NP	IN
NP	→	DT	NNS	; DT	NNS	
IN	→	BEFORE		; BEFORE		
BEFORE	→	before		; 之前		
DT	→	THE		; THE		
THE	→	the		; ϵ		
NNS	→	ELECTIONS		; ELECTIONS		
ELECTIONS	→	elections		; 议会 选举		

Figure 2: *Top:* A synchronous derivation of a small sentence pair fragment under our model. The English projection of the derivation represents a valid constituency parse, while the foreign projection is less constrained. We connect each foreign terminal with a dashed line to the node in the English side of the synchronous derivation at which it is generated. The foreign span assigned to each English node is indicated with indices. All nodes with non-empty spans, shown in boldface, are extractable nodes. *Bottom:* The SCFG rules used in the derivation.

In Figure 2, we show a sample sentence pair fragment as generated by our model. Our model correctly identifies that the English *the* aligns to nothing on the foreign side. Our model also effectively captures the one-to-many alignment[3] of *elections* to 议

[2] For notational convenience, we imagine that for each particular English word e, there is a special preterminal symbol E which produces it. These symbols E act like any other non-terminal in the grammar with respect to the parameterization in Section 3.1. To denote standard non-terminals, we will use A, B, and C.

[3] While our model does not explicitly produce many-to-one alignments, many-to-one rules can be discovered via rule composition (Galley et al., 2006).

会 选举. Finally, our model correctly analyzes the Chinese circumposition 在 . . . 之前 (*before* . . .). In this construction, 之前 carries the meaning of "before", and thus correctly aligns to *before*, while 在 functions as a generic preposition, which our model handles by attaching it to the PP. This analysis permits the extraction of the general rule (PP → IN_1 NP_2 ; 在 NP_2 IN_1), and the more lexicalized (PP → *before* NP ; 在 NP 之前).

3.1 Parameterization

In principle, our model could have one parameter for each instantiation r of a rule type. This model would have an unmanageable number of parameters, producing both computational and modeling issues – it is well known that unsupervised models with large numbers of parameters are prone to degenerate analyses of the data (DeNero et al., 2006). One solution might be to apply an informed prior with a computationally tractable inference procedure (e.g. Cohn and Blunsom (2009) or Liu and Gildea (2009)). We opt here for the simpler, statistically more robust solution of making independence assumptions to keep the number of parameters at a reasonable level.

Concretely, we define the probability of the BINARYMONO rule,[4]

$$p(r = A \rightarrow B\,C; \mathbf{f}_l\ B\ \mathbf{f}_m\ C\ \mathbf{f}_r | A, \mathbf{e}_A)$$

which conditions on the root of the rule A and the English yield $\mathbf{e}_A$, as

$$p_g(A \rightarrow B\,C \mid A, \mathbf{e}_A) \cdot p_{inv}(I \mid B, C) \cdot$$
$$p_{left}(\mathbf{f}_l \mid A, \mathbf{e}_A) \cdot p_{mid}(\mathbf{f}_m \mid A, \mathbf{e}_A) \cdot p_{right}(\mathbf{f}_r \mid A, \mathbf{e}_A)$$

In words, we assume that the rule probability decomposes into a monolingual PCFG grammar probability p_g, an inversion probability p_{inv}, and a probability of left, middle, and right word sequences p_{left}, p_{mid}, and p_{right}.[5] Because we condition on $\mathbf{e}$, the monolingual grammar probability p_g must form a distribution which produces $\mathbf{e}$ with probability 1.[6]

We further assume that the probability of producing a foreign word sequence $\mathbf{f}_l$ decomposes as:

$$p_{left}(\mathbf{f}_l \mid A, \mathbf{e}_A) = p_l(|\mathbf{f}_l| = m \mid A) \prod_{j=1}^{m} p(f_j \mid A, \mathbf{e}_A)$$

where m is the length of the sequence $\mathbf{f}_l$. The parameter p_l is a left length distribution. The probabilities p_{mid}, p_{right}, decompose in the same way, except substituting a separate length distribution p_m and p_r for p_l. For the TERMINAL rule, we emit $\mathbf{f}_t$ with a similarly decomposed distribution p_{term} using length distribution p_w.

We define the probability of generating a foreign word f_j as

$$p(f_j \mid A, \mathbf{e}_A) = \sum_{i \in \mathbf{e}_A} \frac{1}{\mid \mathbf{e}_A \mid} p_t(f_j \mid e_i)$$

with $i \in \mathbf{e}_A$ denoting an index ranging over the indices of the English words contained in $\mathbf{e}_A$. The reader may recognize the above expressions as the probability assigned by IBM Model 1 (Brown et al., 1993) of generating the words $\mathbf{f}_l$ given the words $\mathbf{e}_A$, with one important difference – the length m of the foreign sentence is often not modeled, so the term $p_l(|\mathbf{f}_l| = m \mid A)$ is set to a constant and ignored. Parameterizing this length allows our model to effectively control the number of words produced at different levels of the derivation.

It is worth noting how each parameter affects the model's behavior. The p_t distribution is a standard "translation" table, familiar from the IBM Models. The p_{inv} distribution is a "distortion" parameter, and models the likelihood of inverting non-terminals B and C. This parameter can capture, for example, the high likelihood that prepositions IN and noun phrases NP often invert in Chinese due to its use of postpositions. The non-terminal length distributions p_l, p_m, and p_r model the probability of "backing off" and emitting foreign words at non-terminals when a more refined analysis cannot be found. If these parameters place high mass on 0 length word sequences, this heavily penalizes this backoff behaviour. For the TERMINAL rule, the length distribution p_w parameterizes the number of words produced for a particular English word e, functioning similarly to the "fertilities" employed by IBM Models 3 and 4 (Brown et al., 1993). This allows us

[4] In the text, we only describe the factorization for the BINARYMONO rule. For a parameterization of all rules, we refer the reader to Table 2.

[5] All parameters in our model are multinomial distributions.

[6] A simple case of such a distribution is one which places all of its mass on a single tree. More complex distributions can be obtained by conditioning an arbitrary PCFG on $\mathbf{e}$ (Goodman, 1998).

to model, for example, the tendency of English determiners *the* and *a* translate to nothing in the Chinese, and of English names to align to multiple Chinese words. In general, we expect an English word to usually align to one Chinese word, and so we place a weak Dirichlet prior on on the p_e distribution which puts extra mass on 1-length word sequences. This is helpful for avoiding the "garbage collection" (Moore, 2004) problem for rare words.

3.2 Exploiting Non-Terminal Labels

There are often foreign words that do not correspond well to any English word, which our model must also handle. We elected for a simple augmentation to our model to account for these words. When generating foreign word sequences $\mathbf{f}$ at a non-terminal (i.e. via the UNARY or BINARY productions), we also allow for the production of foreign words from the non-terminal symbol A. We modify $p(f_j \mid \mathbf{e}_A)$ from the previous section to allow production of f_j directly from the non-terminal[7] A:

$$p(f_j \mid \mathbf{e}_A) = p_{nt} \cdot p(f_j \mid A) + (1 - p_{nt}) \cdot \sum_{i \in \mathbf{e}_A} \frac{1}{|\mathbf{e}_A|} p_t(f_j \mid e_i)$$

where p_{nt} is a global binomial parameter which controls how often such alignments are made.

This necessitates the inclusion of parameters like $p_t($ 的 $\mid$ NP$)$ into our translation table. Generally, these parameters do not contain much information, but rather function like a traditional NULL rooted at some position in the tree. However, in some cases, the particular annotation used by the Penn Treebank (Marcus et al., 1993) (and hence most parsers) allows for some interesting parameters to be learned. For example, we found that our aligner often matched the Chinese word 了, which marks the past tense (among other things), to the preterminals VBD and VBN, which denote the English simple past and perfect tense. Additionally, Chinese measure words like 个 and 名 often align to the CD (numeral) preterminal. These generalizations can be quite useful – where a particular number might predict a measure word quite poorly, the generalization that measure words co-occur with the CD tag is very robust.

3.3 Membership in ITG

The generative process which describes our model contains a class of grammars larger than the computationally efficient class of ITG grammars. Fortunately, the parameterization described above not only reduces the number of parameters to a manageable level, but also introduces independence assumptions which permit synchronous binarization (Zhang et al., 2006) of our grammar. Any SCFG that can be synchronously binarized is an ITG, meaning that our parameterization permits efficient inference algorithms which we will make use of in the next section. Although several binarizations are possible, we give one such binarization and its associated probabilities in Table 2.

3.4 Robustness to Syntactic Divergence

Generally speaking, ITG grammars have proven more useful without the monolingual syntactic constraints imposed by a target parse tree. When derivations are restricted to respect a target-side parse tree, many desirable alignments are ruled out when the syntax of the two languages diverges, and alignment quality drops precipitously (Zhang and Gildea, 2004), though attempts have been made to address this issue (Gildea, 2003).

Our model is designed to degrade gracefully in the case of syntactic divergence. Because it can produce foreign words at any level of the derivation, our model can effectively back off to a variant of Model 1 in the case where an ITG derivation that both respects the target parse tree and the desired word-level alignments cannot be found.

For example, consider the sentence pair fragment in Figure 3. It is not possible to produce an ITG derivation of this fragment that both respects the English tree and also aligns all foreign words to their obvious English counterparts. Our model handles this case by attaching the troublesome 明天 at the uppermost VP. This analysis captures 3 of the 4 word-level correspondences, and also permits extraction of abstract rules like (S → NP VP ; NP VP) and (NP → *the* NN ; NN).

Unfortunately, this analysis leaves the English word *tomorrow* with an empty foreign span, permitting extraction of the incorrect translation (VP → *announced tomorrow* ; 公布), among others. Our

[7] For terminal symbols E, this production is not possible.

Rule Type	Root	English side	Foreign side	Probability
TERMINAL	E	e	$\mathbf{w}_t$	$p_{term}(\mathbf{w}_t \mid E)$
UNARY	A	B^u	$\mathbf{w}_l\ B^u$	$p_g(A \rightarrow B \mid A)p_{left}(\mathbf{w}_l \mid A, \mathbf{e}_A)$
	B^u	B	$B\ \mathbf{w}_r$	$p_{right}(\mathbf{w}_r \mid A, \mathbf{e}_A)$
BINARY	A	A^1	$\mathbf{w}_l\ A^1$	$p_{left}(\mathbf{w}_l \mid A, \mathbf{e}_A)$
	A^1	$B\ C^1$	$B\ C^1$	$p_g(A \rightarrow B\ C \mid A)p_{inv}(I\text{=false} \mid B, C)$
	A^1	$B\ C^1$	$C^1\ B$	$p_g(A \rightarrow B\ C \mid A)p_{inv}(I\text{=true} \mid B, C)$
	C^1	C^2	$\mathbf{f}_m\ C^2$	$p_{mid}(\mathbf{f}_m \mid A, \mathbf{e}_A)$
	C^2	C	$C\ \mathbf{f}_r$	$p_{right}(\mathbf{f}_r \mid A, \mathbf{e}_A)$

Table 2: A synchronous binarization of the SCFG describing our model.

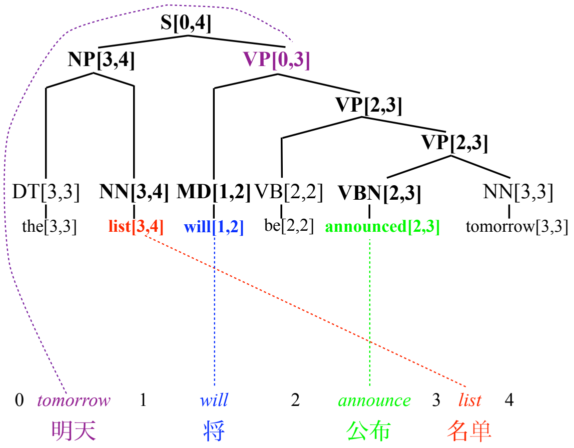


Figure 3: The graceful degradation of our model in the face of syntactic divergence. It is not possible to align all foreign words with their obvious English counterparts with an ITG derivation. Instead, our model analyzes as much as possible, but must resort to emitting 明天 high in the tree.

point here is not that our model's analysis is "correct", but "good enough" without resorting to more computationally complicated models. In general, our model follows an "extract as much as possible" approach. We hypothesize that this approach will capture important syntactic generalizations, but it also risks including low-quality rules. It is an empirical question whether this approach is effective, and we investigate this issue further in Section 5.3.

There are possibilities for improving our model's treatment of syntactic divergence. One option is to allow the model to select trees which are more consistent with the alignment (Burkett et al., 2010), which our model can do since it permits efficient inference over forests. The second is to modify the generative process slightly, perhaps by including the "clone" operator of Gildea (2003).

4 Learning and Inference

4.1 Parameter Estimation

The parameters of our model can be efficiently estimated in an unsupervised fashion using the Expectation-Maximization (EM) algorithm. The E-step requires the computation of expected counts under our model for each multinomial parameter. We omit the details of obtaining expected counts for each distribution, since they can be obtained using simple arithmetic from a single quantity, namely, the expected count of a particular instantiation of a synchronous rule r. This expectation is a standard quantity that can be computed in $O(n^6)$ time using the bitext Inside-Outside dynamic program (Wu, 1997).

4.2 Dynamic Program Pruning

While our model permits $O(n^6)$ inference over a forest of English trees, inference over a full forest would be very slow, and so we fix a single n-ary English tree obtained from a monolingual parser. However, it is worth noting that the English side of the ITG derivation is *not* completely fixed. Where our English trees are more than binary branching, we permit any binarization in our dynamic program.

For efficiency, we also ruled out span alignments that are extremely lopsided, for example, a 1-word English span aligned to a 20-word foreign span. Specifically, we pruned any span alignment in which one side is more than 5 times larger than the other.

Finally, we employ pruning based on high-precision alignments from simpler models (Cherry and Lin, 2007; Haghighi et al., 2009). We compute word-to-word alignments by finding all word pairs which have a posterior of at least 0.7 according to both forward and reverse IBM Model 1 parameters, and prune any span pairs which invalidate more than 3 of these alignments. In total, this pruning re-

Span	P	R	F1
Syntactic Alignment	50.9	**83.0**	**63.1**
GIZA++	**56.1**	67.3	61.2
Rule	P	R	F1
Syntactic Alignment	39.6	**40.3**	**39.9**
GIZA++	**46.2**	34.7	39.6

Table 3: Alignment quality results for our syntactic aligner and our GIZA++ baseline.

duced computation from approximately 1.5 seconds per sentence to about 0.3 seconds per sentence, a speed-up of a factor of 5.

4.3 Decoding

Given a trained model, we extract a tree-to-string alignment as follows: we compute, for each node in the English tree, the posterior probability of a particular foreign span assignment using the same dynamic program needed for EM. We then compute the set of span assignments which maximizes the sum of these posteriors, constrained such that the foreign span assignments nest in the obvious way. This algorithm is a natural synchronous generalization of the monolingual Maximum Constituents Parse algorithm of Goodman (1996).

5 Experiments

5.1 Alignment Quality

We first evaluated our alignments against gold standard annotations. Our training data consisted of the 2261 manually aligned and translated sentences of the Chinese Treebank (Bies et al., 2007) and approximately half a million unlabeled sentences of parallel Chinese-English newswire. The unlabeled data was subsampled (Li et al., 2009) from a larger corpus by selecting sentences which have good tune and test set coverage, and limited to sentences of length at most 40. We parsed the English side of the training data with the Berkeley parser.[8] For our baseline alignments, we used GIZA++, trained in the standard way.[9] We used the *grow-diag-final* alignment heuristic, as we found it outperformed *union* in early experiments.

We trained our unsupervised syntactic aligner on the concatenation of the labelled and unlabelled data. As is standard in unsupervised alignment models, we initialized the translation parameters p_t by first training 5 iterations of IBM Model 1 using the joint training algorithm of Liang et al. (2006), and then trained our model for 5 EM iterations. We extracted syntactic rules using a re-implementation of the Galley et al. (2006) algorithm from both our syntactic alignments and the GIZA++ alignments. We handle null-aligned words by extracting every consistent derivation, and extracted composed rules consisting of at most 3 minimal rules.

We evaluate our alignments against the gold standard in two ways. We calculated Span F-score, which compares the set of extractable nodes paired with a foreign span, and Rule F-score (Fossum et al., 2008) over minimal rules. The results are shown in Table 3. By both measures, our syntactic aligner effectively trades recall for precision when compared to our baseline, slightly increasing overall F-score.

5.2 Translation Quality

For our translation system, we used a re-implementation of the syntactic system of Galley et al. (2006). For the translation rules extracted from our data, we computed standard features based on relative frequency counts, and tuned their weights using MERT (Och, 2003). We also included a language model feature, using a 5-gram language model trained on 220 million words of English text using the SRILM Toolkit (Stolcke, 2002).

For tuning and test data, we used a subset of the NIST MT04 and MT05 with sentences of length at most 40. We used the first 1000 sentences of this set for tuning and the remaining 642 sentences as test data. We used the decoder described in DeNero et al. (2009) during both tuning and testing.

We provide final tune and test set results in Table 4. Our alignments produce a 1.0 BLEU improvement over the baseline. Our reported syntactic results were obtained when rules were thresholded by count; we discuss this in the next section.

5.3 Analysis

As discussed in Section 3.4, our aligner is designed to extract many rules, which risks inadvertently extracting low-quality rules. To quantify this, we first examined the number of rules extracted by our aligner as compared with GIZA++. After relativiz-

[8] `http://code.google.com/p/berkeleyparser/`

[9] 5 iterations of model 1, 5 iterations of HMM, 3 iterations of Model 3, and 3 iterations of Model 4.

	Tune	Test
Syntactic Alignment	**29.78**	**29.83**
GIZA++	28.76	28.84
GIZA++ high count	25.51	25.38

Table 4: Final tune and test set results for our grammars extracted using the baseline GIZA++ alignments and our syntactic aligner. When we filter the GIZA++ grammars with the same count thresholds used for our aligner ("high count"), BLEU score drops substantially.

ing to the tune and test set, we extracted approximately 32 million unique rules using our aligner, but only 3 million with GIZA++. To check that we were not just extracting extra low-count, low-quality rules, we plotted the number of rules with a particular count in Figure 4. We found that while our aligner certainly extracts many more low-count rules, it also extracts many more high-count rules.

Of course, high-count rules are not guaranteed to be high quality. To verify that frequent rules were better for translation, we experimented with various methods of thresholding to remove rules with low count extracted from using aligner. We found in early development found that removing low-count rules improved translation performance substantially. In particular, we settled on the following scheme: we kept all rules with a single foreign terminal on the right-hand side. For entirely lexical (gapless) rules, we kept all rules occurring at least 3 times. For unlexicalized rules, we kept all rules occurring at least 20 times per gap. For rules which mixed gaps and lexical items, we kept all rules occurring at least 10 times per gap. This left us with a grammar about 600 000 rules, the same grammar which gave us our final results reported in Table 4.

In contrast to our syntactic aligner, rules extracted using GIZA++ could not be so aggressively pruned. When pruned using the same count thresholds, accuracy dropped by more than 3.0 BLEU on the tune set, and similarly on the test set (see Table 4). To obtain the accuracy shown in our final results (our best results with GIZA++), we had to adjust the count threshold to include all lexicalized rules, all unlexicalized rules, and mixed rules occurring at least twice per gap. With these count thresholds, the GIZA++ grammar contained about 580 000 rules, roughly the same number as our syntactic grammar.

We also manually searched the grammars for rules that had high count in the syntactically-extracted grammar and low (or 0) count in the GIZA++ grammar. Of course, we can always cherry-pick such examples, but a few rules were illuminating. For example, for the 在 ...之前 construction discussed earlier, our aligner permits extraction of the general rule (PP → IN$_1$ NP$_2$; 在 NP$_2$ IN$_1$) 3087 times, and the lexicalized rule (PP → *before* NP ; 在 NP 之前) 118 times. In constrast, the GIZA++ grammar extracts the latter only 23 times and the former not at all. The more complex rule (NP → NP$_2$, who S$_1$, ; S$_1$ 的 NP$_2$), which captures a common appositive construction, was absent from the GIZA++ grammar but occurred 63 in ours.

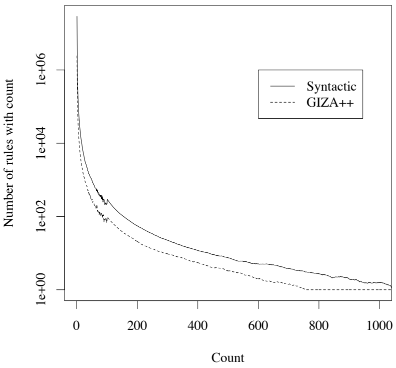

Figure 4: Number of extracted translation rules with a particular count. Grammars extracted from our syntactic aligner produce not only more low-count rules, but also more high-count rules than GIZA++.

6 Conclusion

We have described a syntactic alignment model which explicitly aligns nodes of a syntactic parse in one language to spans in another, making it suitable for use in many syntactic translation systems. Our model is unsupervised and can be efficiently trained with a straightforward application of EM. We have demonstrated that our model can accurately capture many syntactic correspondences, and is robust in the face of syntactic divergence between language pairs. Our aligner permits the extraction of more reliable, high-count rules when compared to a standard word-alignment baseline. These high-count rules also produce improvements in BLEU score.

Joint Parsing and Alignment with Weakly Synchronized Grammars

Abstract

Syntactic machine translation systems extract rules from bilingual, word-aligned, syntactically parsed text, but current systems for parsing and word alignment are at best cascaded and at worst totally independent of one another. This work presents a unified joint model for simultaneous parsing and word alignment. To flexibly model syntactic divergence, we develop a discriminative log-linear model over two parse trees and an ITG derivation which is encouraged but not forced to synchronize with the parses. Our model gives absolute improvements of 3.3 F_1 for English parsing, 2.1 F_1 for Chinese parsing, and 5.5 F_1 for word alignment over each task's independent baseline, giving the best reported results for both Chinese-English word alignment and joint parsing on the parallel portion of the Chinese treebank. We also show an improvement of 1.2 BLEU in downstream MT evaluation over basic HMM alignments.

1 Introduction

Current syntactic machine translation (MT) systems build synchronous context free grammars from aligned syntactic fragments (Galley et al., 2004; Zollmann et al., 2006). Extracting such grammars requires that bilingual word alignments and monolingual syntactic parses be compatible. Because of this, much recent work in both word alignment and parsing has focused on changing aligners to make use of syntactic information (DeNero and Klein, 2007; May and Knight, 2007; Fossum et al., 2008) or changing parsers to make use of word alignments (Smith and Smith, 2004; Burkett and Klein, 2008; Snyder et al., 2009). In the first case, however, parsers do not exploit bilingual information. In the second, word alignment is performed with a model that does not exploit syntactic information. This work presents a single, joint model for parsing and word alignment that allows both pieces to influence one another simultaneously.

While building a joint model seems intuitive, there is no easy way to characterize how word alignments and syntactic parses should relate to each other in general. In the ideal situation, each pair of sentences in a bilingual corpus could be syntactically parsed using a synchronous context-free grammar. Of course, real translations are almost always at least partially syntactically divergent. Therefore, it is unreasonable to expect perfect matches of any kind between the two sides' syntactic trees, much less expect that those matches be well explained at a word level. Indeed, it is sometimes the case that large pieces of a sentence pair are completely asynchronous and can only be explained monolingually.

Our model exploits synchronization where possible to perform more accurately on both word alignment and parsing, but also allows independent models to dictate pieces of parse trees and word alignments when synchronization is impossible. This notion of "weak synchronization" is parameterized and estimated from data to maximize the likelihood of the correct parses and word alignments. Weak synchronization is closely related to the quasi-synchronous models of Smith and Eisner (2006; 2009) and the bilingual parse reranking model of Burkett and Klein (2008), but those models assume that the word alignment of a sentence pair is known and fixed.

To simultaneously model both parses and align-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 127–135,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

ments, our model loosely couples three separate combinatorial structures: monolingual trees in the source and target languages, and a synchronous ITG alignment that links the two languages (but is not constrained to match linguistic syntax). The model has no hard constraints on how these three structures must align, but instead contains a set of "synchronization" features that are used to propagate influence between the three component grammars. The presence of synchronization features couples the parses and alignments, but makes exact inference in the model intractable; we show how to use a variational mean field approximation, both for computing approximate feature expectations during training, and for performing approximate joint inference at test time.

We train our joint model on the parallel, gold word-aligned portion of the Chinese treebank. When evaluated on parsing and word alignment, this model significantly improves over independently-trained baselines: the monolingual parser of Petrov and Klein (2007) and the discriminative word aligner of Haghighi et al. (2009). It also improves over the discriminative, bilingual parsing model of Burkett and Klein (2008), yielding the highest joint parsing F_1 numbers on this data set. Finally, our model improves word alignment in the context of translation, leading to a 1.2 BLEU increase over using HMM word alignments.

2 Joint Parsing and Alignment

Given a source-language sentence, s, and a target-language sentence, s', we wish to predict a source tree t, a target tree t', and some kind of alignment a between them. These structures are illustrated in Figure 1.

To facilitate these predictions, we define a conditional distribution $\mathrm{P}(t, a, t'|s, s')$. We begin with a generic conditional exponential form:

$$\mathrm{P}(t, a, t'|s, s') \propto \exp \theta^{\top} \phi(t, a, t', s, s') \qquad (1)$$

Unfortunately, a generic model of this form is intractable, because we cannot efficiently sum over all triples (t, a, t') without some assumptions about how the features $\phi(t, a, t', s, s')$ decompose.

One natural solution is to restrict our candidate triples to those given by a synchronous context free grammar (SCFG) (Shieber and Schabes, 1990). Figure 1(a) gives a simple example of generation from a log-linearly parameterized synchronous grammar, together with its features. With the SCFG restriction, we can sum over the necessary structures using the $O(n^6)$ bitext inside-outside algorithm, making $\mathrm{P}(t, a, t'|s, s')$ relatively efficient to compute expectations under.

Unfortunately, an SCFG requires that *all* the constituents of each tree, from the root down to the words, are generated perfectly in tandem. The resulting inability to model any level of syntactic divergence prevents accurate modeling of the individual monolingual trees. We will consider the running example from Figure 2 throughout the paper. Here, for instance, the verb phrase *established in such places as Quanzhou, Zhangzhou, etc.* in English does not correspond to any single node in the Chinese tree. A synchronous grammar has no choice but to analyze this sentence incorrectly, either by ignoring this verb phrase in English or postulating an incorrect Chinese constituent that corresponds to it.

Therefore, instead of requiring strict synchronization, our model treats the two monolingual trees and the alignment as separate objects that can vary arbitrarily. However, the model rewards synchronization appropriately when the alignment brings the trees into correspondence.

3 Weakly Synchronized Grammars

We propose a joint model which still gives probabilities on triples (t, a, t'). However, instead of using SCFG rules to synchronously enforce the tree constraints on t and t', we only require that each of t and t' be well-formed under separate monolingual CFGs.

In order to permit efficient enumeration of all possible alignments a, we also restrict a to the set of unlabeled ITG bitrees (Wu, 1997), though again we do not require that a relate to t or t' in any particular way. Although this assumption does limit the space of possible word-level alignments, for the domain we consider (Chinese-English word alignment), the reduced space still contains almost all empirically observed alignments (Haghighi et al., 2009).[1] For

(a) Synchronous Rule

(b) Asynchronous Rule

Figure 1: Source trees, t (right), alignments, a (grid), and target trees, t' (top), and feature decompositions for synchronous (a) and weakly synchronous (b) grammars. Features always condition on bispans and/or anchored syntactic productions, but weakly synchronous grammars permit more general decompositions.

example, in Figure 2, the word alignment is ITG-derivable, and each of the colored rectangles is a bispan in that derivation.

There are no additional constraints beyond the independent, internal structural constraints on t, a, and t'. This decoupling permits derivations like that in Figure 1(b), where the top-level syntactic nodes align, but their children are allowed to diverge. With the three structures separated, our first model is a completely factored decomposition of (1).

Formally, we represent a source tree t as a set of nodes $\{n\}$, each node representing a labeled span. Likewise, a target tree t' is a set of nodes $\{n'\}$.[2] We represent alignments a as sets of *bispans* $\{b\}$, indicated by rectangles in Figure 1.[3] Using this notation, the initial model has the following form:

$$\mathrm{P}(t, a, t'|s, s') \propto \exp\left[\sum_{n \in t} \theta^\top \phi_{\mathcal{F}}(n, s) + \sum_{b \in a} \theta^\top \phi_{\mathcal{A}}(b, s, s') + \sum_{n' \in t'} \theta^\top \phi_{\mathcal{E}}(n', s')\right] \qquad (2)$$

Here $\phi_{\mathcal{F}}(n, s)$ indicates a vector of source node features, $\phi_{\mathcal{E}}(n', s')$ is a vector of target node features, and $\phi_{\mathcal{A}}(b, s, s')$ is a vector of alignment bispan features. Of course, this model is completely asynchronous so far, and fails to couple the trees and alignments at all. To permit soft constraints between the three structures we are modeling, we add a set of *synchronization* features.

For $n \in t$ and $b \in a$, we say that $n \triangleright b$ if n and b both map onto the same span of s. We define $b \triangleleft n'$ analogously for $n' \in t'$. We now consider three different types of synchronization features. Source-alignment synchronization features $\phi_{\triangleright}(n, b)$ are extracted whenever $n \triangleright b$. Similarly, target-alignment features $\phi_{\triangleleft}(b, n')$ are extracted if $b \triangleleft n'$. These features capture phenomena like that of bispan b_7 in Figure 2. Here the Chinese noun 地 synchronizes with the ITG derivation, but the English projection of b_7 is a distituent. Finally, we extract source-target features $\phi_{\bowtie}(n, b, n')$ whenever $n \triangleright b \triangleleft n'$. These features capture complete bispan synchrony (as in bispan b_8) and can be expressed over triples (n, b, n') which happen to align, allowing us to reward synchrony, but not requiring it. All of these licensing conditions are illustrated in Figure 1(b).

With these features added, the final form of the model is:

$$\mathrm{P}(t, a, t'|s, s') \propto \exp\left[\sum_{n \in t} \theta^\top \phi_{\mathcal{F}}(n, s) + \sum_{b \in a} \theta^\top \phi_{\mathcal{A}}(b, s, s') + \sum_{n' \in t'} \theta^\top \phi_{\mathcal{E}}(n', s') + \sum_{n \triangleright b} \theta^\top \phi_{\triangleright}(n, b) + \sum_{b \triangleleft n'} \theta^\top \phi_{\triangleleft}(b, n') + \sum_{n \triangleright b \triangleleft n'} \theta^\top \phi_{\bowtie}(n, b, n')\right] \qquad (3)$$

[2] For expositional clarity, we describe n and n' as labeled spans only. However, in general, features that depend on n or n' are permitted to depend on the entire rule, and do in our final system.

[3] Alignments a link arbitrary spans of s and s' (including non-constituents and individual words). We discuss the relation to word-level alignments in Section 4.

We emphasize that because of the synchronization features, this final form does *not* admit any known efficient dynamic programming for the exact computation of expectations. We will therefore turn to a variational inference method in Section 6.

4 Features

With the model's locality structure defined, we just need to specify the actual feature function, ϕ. We divide the features into three types: parsing features ($\phi_{\mathcal{F}}(n, s)$ and $\phi_{\mathcal{E}}(n', s')$), alignment features ($\phi_{\mathcal{A}}(b, s, s')$) and synchronization features ($\phi_{\triangleright}(n, b)$, $\phi_{\triangleleft}(b, n')$, and $\phi_{\bowtie}(n, b, n')$). We detail each of these in turn here.

4.1 Parsing

The monolingual parsing features we use are simply parsing model scores under the parser of Petrov and Klein (2007). While that parser uses heavily refined PCFGs with rule probabilities defined at the refined symbol level, we interact with its posterior distribution via posterior marginal probabilities over unrefined symbols. In particular, to each unrefined anchored production ${}_i\mathrm{A}_j \rightarrow {}_i\mathrm{B}_k\mathrm{C}_j$, we associate a single feature whose value is the marginal quantity $\log \mathrm{P}({}_i\mathrm{B}_k\mathrm{C}_j | {}_i\mathrm{A}_j, s)$ under the monolingual parser. These scores are the same as the variational rule scores of Matsuzaki et al. (2005).[4]

4.2 Alignment

We begin with the same set of alignment features as Haghighi et al. (2009), which are defined only for terminal bispans. In addition, we include features on nonterminal bispans, including a bias feature, features that measure the difference in size between the source and target spans, features that measure the difference in relative sentence position between the source and target spans, and features that measure the density of word-to-word alignment posteriors under a separate unsupervised word alignment model.

4.3 Synchronization

Our synchronization features are indicators for the syntactic types of the participating nodes. We determine types at both a coarse (more collapsed than Treebank symbols) and fine (Treebank symbol) level. At the coarse level, we distinguish between phrasal nodes (e.g. S, NP), synthetic nodes introduced in the process of binarizing the grammar (e.g. S′, NP′), and part-of-speech nodes (e.g. NN, VBZ). At the fine level, we distinguish all nodes by their exact label. We use coarse and fine types for both partially synchronized (source-alignment or target-alignment) features and completely synchronized (source-alignment-target) features. The inset of Figure 2 shows some sample features. Of course, we could devise even more sophisticated features by using the input text itself. As we shall see, however, our model gives significant improvements with these simple features alone.

5 Learning

We learn the parameters of our model on the parallel portion of the Chinese treebank. Although our model assigns probabilities to entire synchronous derivations of sentences, the parallel Chinese treebank gives alignments only at the word level (1 by 1 bispans in Figure 2). This means that our alignment variable a is not fully observed. Because of this, given a particular word alignment w, we maximize the marginal probability of the set of derivations $\mathcal{A}(w)$ that are consistent with w (Haghighi et al., 2009).[5]

$$\mathcal{L}(\theta) = \log \sum_{a \in \mathcal{A}(w_i)} \mathrm{P}(t_i, a, t'_i | s_i, s'_i)$$

We maximize this objective using standard gradient methods (Nocedal and Wright, 1999). As with fully visible log-linear models, the gradient for the i^{th} sentence pair with respect to θ is a difference of feature expectations:

$$\begin{aligned} \nabla \mathcal{L}(\theta) = & \mathrm{E}_{\mathrm{P}(a|t_i, w_i, t'_i, s_i, s'_i)} \left[\phi(t_i, a, t'_i, s_i, s'_i) \right] \\ & - \mathrm{E}_{\mathrm{P}(t, a, t' | s_i, s'_i)} \left[\phi(t, a, t', s_i, s'_i) \right] \end{aligned} \tag{4}$$

[4] Of course the structure of our model permits any of the additional rule-factored monolingual parsing features that have been described in the parsing literature, but in the present work we focus on the contributions of joint modeling.

[5] We also learn from non-ITG alignments by maximizing the marginal probability of the set of minimum-recall error alignments in the same way as Haghighi et al. (2009)

Figure 2: An example of a Chinese-English sentence pair with parses, word alignments, and a subset of the full optimal ITG derivation, including one totally unsynchronized bispan (b_4), one partially synchronized bispan (b_7), and and fully synchronized bispan (b_8). The inset provides some examples of active synchronization features (see Section 4.3) on these bispans. On this example, the monolingual English parser erroneously attached the lower PP to the VP headed by *established*, and the non-syntactic ITG word aligner misaligned 等 to *such* instead of to *etc.* Our joint model corrected both of these mistakes because it was rewarded for the synchronization of the two NPs joined by b_8.

We cannot efficiently compute the model expectations in this equation exactly. Therefore we turn next to an approximate inference method.

6 Mean Field Inference

Instead of computing the model expectations from (4), we compute the expectations for each sentence pair with respect to a simpler, fully factored distribution $\mathrm{Q}(t,a,t') = q(t)q(a)q(t')$. Rewriting Q in log-linear form, we have:

$$\mathrm{Q}(t,a,t') \propto \exp\left[\sum_{n\in t}\psi_n + \sum_{b\in a}\psi_b + \sum_{n'\in t'}\psi_{n'}\right]$$

Here, the ψ_n, ψ_b and $\psi_{n'}$ are variational parameters which we set to best approximate our weakly synchronized model from (3):

$$\psi^* = \operatorname*{argmin}_{\psi} \mathrm{KL}\left(\mathrm{Q}_\psi || P_\theta(t,a,t'|s,s')\right)$$

Once we have found Q, we compute an approximate gradient by replacing the model expectations with expectations under Q:

$$\mathrm{E}_{\mathrm{Q}(a|w_i)}\left[\phi(t_i,a,t'_i,s_i,s'_i)\right] - \mathrm{E}_{\mathrm{Q}(t,a,t'|s_i,s'_i)}\left[\phi(t,a,t',s_i,s'_i)\right]$$

Now, we will briefly describe how we compute Q. First, note that the parameters ψ of Q factor along individual source nodes, target nodes, and bispans. The combination of the KL objective and our particular factored form of Q make our inference procedure a structured mean field algorithm (Saul and Jordan, 1996). Structured mean field techniques are well-studied in graphical models, and our adaptation in this section to multiple grammars follows standard techniques (see e.g. Wainwright and Jordan, 2008).

Rather than derive the mean field updates for ψ, we describe the algorithm (shown in Figure 3) procedurally. Similar to block Gibbs sampling, we iteratively optimize each component (source parse, target parse, and alignment) of the model in turn, conditioned on the others. Where block Gibbs sampling conditions on fixed trees or ITG derivations, our mean field algorithm maintains uncertainty in

        $\sum_{n, n \rhd b} \sum_{n', b \lhd n'} \mu^{i-1}_n \mu^{i-1}_{n'} \phi_{\bowtie}(n, b, n')\Big)$
  $\mu_b \leftarrow \sum_a q_\psi(a) I(b \in a)$ (bitext inside-outside)

   updates for $\psi^i_{n'}$, $\mu^i_{n'}$ analogous to $\psi^i_n$, $\mu^i_n$

3.  Return variational parameters $\psi$
```

Figure 3: Structured mean field inference for the weakly synchronized model. $I(n \in t)$ is an indicator value for the presence of node n in source tree t.

the form of monolingual parse forests or ITG forests. The key components to this uncertainty are the expected counts of particular source nodes, target nodes, and bispans under the mean field distribution:

$$\mu_n = \sum_t q_\psi(t) I(n \in t)$$

$$\mu_{n'} = \sum_{t'} q_\psi(t') I(n' \in t')$$

$$\mu_b = \sum_a q_\psi(a) I(b \in a)$$

Since dynamic programs exist for summing over each of the individual factors, these expectations can be computed in polynomial time.

6.1 Pruning

Although we can approximate the expectations from (4) in polynomial time using our mean field distribution, in practice we must still prune the ITG forests and monolingual parse forests to allow tractable inference. We prune our ITG forests using the same basic idea as Haghighi et al. (2009), but we employ a technique that allows us to be more aggressive. Where Haghighi et al. (2009) pruned bispans based on how many unsupervised HMM alignments were violated, we first train a maximum-matching word aligner (Taskar et al., 2005) using our supervised data set, which has only half the precision errors of the unsupervised HMM. We then prune every bispan which violates at least three alignments from the maximum-matching aligner. When compared to pruning the bitext forest of our model with Haghighi et al. (2009)'s HMM technique, this new technique allows us to maintain the same level of accuracy while cutting the number of bispans in half.

In addition to pruning the bitext forests, we also prune the syntactic parse forests using the monolingual parsing model scores. For each unrefined anchored production ${}_i\mathrm{A}_j \rightarrow {}_i\mathrm{B}_k\mathrm{C}_j$, we compute the marginal probability $\mathrm{P}({}_i\mathrm{A}_j, {}_i\mathrm{B}_k, {}_k\mathrm{C}_j|s)$ under the monolingual parser (these are equivalent to the maxrule scores from Petrov and Klein 2007). We only include productions where this probability is greater than 10^{-20}. Note that at training time, we are not guaranteed that the gold trees will be included in the pruned forest. Because of this, we replace the gold trees t_i, t'_i with oracle trees from the pruned forest, which can be found efficiently using a variant of the inside algorithm (Huang, 2008).

7 Testing

Once the model has been trained, we still need to determine how to use it to predict parses and word alignments for our test sentence pairs. Ideally, given the sentence pair (s, s'), we would find:

$$\begin{aligned}(t^*, w^*, t'^*) &= \operatorname*{argmax}_{t,w,t'} \mathrm{P}(t, w, t'|s, s') \\ &= \operatorname*{argmax}_{t,w,t'} \sum_{a \in \mathcal{A}(w)} \mathrm{P}(t, a, t'|s, s')\end{aligned}$$

Of course, this is also intractable, so we once again resort to our mean field approximation. This yields the approximate solution:

$$(t^*, w^*, t'^*) = \operatorname*{argmax}_{t,w,t'} \sum_{a \in \mathcal{A}(w)} \mathrm{Q}(t, a, t')$$

However, recall that Q incorporates the model's mutual constraint into the variational parameters, which factor into $q(t)$, $q(a)$, and $q(t')$. This allows us to simplify further, and find the maximum a posteriori assignments under the variational distribution. The trees can be found quickly using the Viterbi inside algorithm on their respective qs. However, the sum for computing w^* under q is still intractable.

As we cannot find the maximum probability word alignment, we provide two alternative approaches for finding w^*. The first is to just find the Viterbi ITG derivation $a^* = \text{argmax}_a\, q(a)$ and then set w^* to contain exactly the 1x1 bispans in a^*. The second method, posterior thresholding, is to compute posterior marginal probabilities under q for each 1x1 cell beginning at position i, j in the word alignment grid:

$$m(i,j) = \sum_a q(a) I((i,i+1,j,j+1) \in a)$$

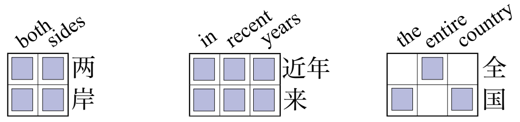
We then include $w(i,j)$ in w^* if $m(w(i,j)) > \tau$, where τ is a threshold chosen to trade off precision and recall. For our experiments, we found that the Viterbi alignment was uniformly worse than posterior thresholding. All the results from the next section use the threshold $\tau = 0.25$.

8 Experiments

We trained and tested our model on the translated portion of the Chinese treebank (Bies et al., 2007), which includes hand annotated Chinese and English parses and word alignments. We separated the data into three sets: *train*, *dev*, and *test*, according to the standard Chinese treebank split. To speed up training, we only used training sentences of length ≤ 50 words, which left us with 1974 of 2261 sentences. We measured the results in two ways. First, we directly measured F_1 for English parsing, Chinese parsing, and word alignment on a held out section of the hand annotated corpus used to train the model. Next, we further evaluated the quality of the word alignments produced by our model by using them as input for a machine translation system.

8.1 Dataset-specific ITG Terminals

The Chinese treebank gold word alignments include significantly more many-to-many word alignments than those used by Haghighi et al. (2009). We are able to produce some of these many-to-many alignments by including new many-to-many terminals in our ITG word aligner, as shown in Figure 4. Our terminal productions sometimes capture non-literal translation like *both sides* or *in recent years*. They also can allow us to capture particular, systematic changes in the annotation standard. For example, the gapped pattern from Figure 4 captures the standard that English word *the* is always aligned to the Chinese head noun in a noun phrase. We featurize these non-terminals with features similar to those of Haghighi et al. (2009), and all of the alignment results we report in Section 8.2 (both joint and ITG) employ these features.



(a) 2x2 (b) 2x3 (c) Gapped 2x3

Figure 4: Examples of phrasal alignments that can be represented by our new ITG terminal bispans.

8.2 Parsing and Word Alignment

To compute features that depend on external models, we needed to train an unsupervised word aligner and monolingual English and Chinese parsers. The unsupervised word aligner was a pair of jointly trained HMMs (Liang et al., 2006), trained on the FBIS corpus. We used the Berkeley Parser (Petrov and Klein, 2007) for both monolingual parsers, with the Chinese parser trained on the full Chinese treebank, and the English parser trained on a concatenation of the Penn WSJ corpus (Marcus et al., 1993) and the English side of *train*.[6]

We compare our parsing results to the monolingual parsing models and to the English-Chinese bilingual reranker of Burkett and Klein (2008), trained on the same dataset. The results are in Table 1. For word alignment, we compare to

[6] To avoid overlap in the data used to train the monolingual parsers and the joint model, at training time, we used a separate version of the Chinese parser, trained only on articles 400-1151 (omitting articles in *train*). For English parsing, we deemed it insufficient to entirely omit the Chinese treebank data from the monolingual parser's training set, as otherwise the monolingual parser would be trained entirely on out-of-domain data. Therefore, at training time we used two separate English parsers: to compute model scores for the *first* half of *train*, we used a parser trained on a concatenation of the WSJ corpus and the *second* half of *train*, and vice versa for the remaining sentences.

	Test Results		
	Ch F_1	Eng F_1	Tot F_1
Monolingual	83.6	81.2	82.5
Reranker	**86.0**	83.8	84.9
Joint	85.7	**84.5**	**85.1**

Table 1: Parsing results. Our joint model has the highest reported F_1 for English-Chinese bilingual parsing.

	Test Results			
	Precision	Recall	AER	F_1
HMM	86.0	58.4	30.0	69.5
ITG	**86.8**	73.4	20.2	79.5
Joint	85.5	**84.6**	**14.9**	**85.0**

Table 2: Word alignment results. Our joint model has the highest reported F_1 for English-Chinese word alignment.

the baseline unsupervised HMM word aligner and to the English-Chinese ITG-based word aligner of Haghighi et al. (2009). The results are in Table 2.

As can be seen, our model makes substantial improvements over the independent models. For parsing, we improve absolute F_1 over the monolingual parsers by 2.1 in Chinese, and by 3.3 in English. For word alignment, we improve absolute F_1 by 5.5 over the non-syntactic ITG word aligner. In addition, our English parsing results are better than those of the Burkett and Klein (2008) bilingual reranker, the current top-performing English-Chinese bilingual parser, despite ours using a much simpler set of synchronization features.

8.3 Machine Translation

We further tested our alignments by using them to train the Joshua machine translation system (Li and Khudanpur, 2008). Table 3 describes the results of our experiments. For all of the systems, we tuned on 1000 sentences of the NIST 2004 and 2005 machine translation evaluations, and tested on 400 sentences of the NIST 2006 MT evaluation. Our training set consisted of 250k sentences of newswire distributed with the GALE project, all of which were sub-sampled to have high Ngram overlap with the tune and test sets. All of our sentences were of length at most 40 words. When building the translation grammars, we used Joshua's default "tight" phrase extraction option. We ran MERT for 4 iterations, optimizing 20 weight vectors per iteration on a 200-best list.

	Rules	Tune	Test
HMM	1.1M	29.0	29.4
ITG	1.5M	**29.9**	30.4†
Joint	1.5M	29.6	**30.6**

Table 3: Tune and test BLEU results for machine translation systems built with different alignment tools. † indicates a statistically significant difference between a system's test performance and the one above it.

Table 3 gives the results. On the test set, we also ran the approximate randomization test suggested by Riezler and Maxwell (2005). We found that our joint parsing and alignment system significantly outperformed the HMM aligner, but the improvement over the ITG aligner was not statistically significant.

9 Conclusion

The quality of statistical machine translation models depends crucially on the quality of word alignments and syntactic parses for the bilingual training corpus. Our work presented the first joint model for parsing and alignment, demonstrating that we can improve results on both of these tasks, as well as on downstream machine translation, by allowing parsers and word aligners to simultaneously inform one another. Crucial to this improved performance is a notion of weak synchronization, which allows our model to learn when pieces of a grammar are synchronized and when they are not. Although exact inference in the weakly synchronized model is intractable, we developed a mean field approximate inference scheme based on monolingual and bitext parsing, allowing for efficient inference.

Abstract

Constrained decoding is of great importance not only for speed but also for translation quality. Previous efforts explore soft syntactic constraints which are based on constituent boundaries deduced from parse trees of the source language. We present a new framework to establish soft constraints based on a more natural alternative: translation boundary rather than constituent boundary. We propose simple classifiers to learn translation boundaries for any source sentences. The classifiers are trained directly on word-aligned corpus without using any additional resources. We report the accuracy of our translation boundary classifiers. We show that using constraints based on translation boundaries predicted by our classifiers achieves significant improvements over the baseline on large-scale Chinese-to-English translation experiments. The new constraints also significantly outperform constituent boundary based syntactic constrains.

1 Introduction

It has been known that phrase-based decoding (phrase segmentation/translation/reordering (Chiang, 2005)) should be constrained to some extent not only for transferring the NP-hard problem (Knight, 1999) into a tractable one in practice but also for improving translation quality. For example, Xiong et al. (2008) find that translation quality can be significantly improved by either prohibiting reorderings around punctuation or restricting reorderings within a 15-word window.

Recently, more linguistically motivated constraints are introduced to improve phrase-based decoding. (Cherry, 2008) and (Marton and Resnik, 2008) introduce syntactic constraints into the standard phrase-based decoding (Koehn et al., 2003) and hierarchical phrase-based decoding (Chiang, 2005) respectively by using a counting feature which accumulates whenever hypotheses violate syntactic boundaries of source-side parse trees. (Xiong et al., 2009) further presents a bracketing model to include thousands of context-sensitive syntactic constraints. All of these approaches achieve their improvements by guiding the phrase-based decoder to prefer translations which respect source-side parse trees.

One major problem with such constituent boundary based constraints is that syntactic structures of the source language do not necessarily reflect translation structures where the source and target language correspond to each other. In this paper, we investigate building classifiers that directly address the problem of *translation boundary*, rather than extracting constituent boundary from source-side parsers built for a different purpose. A translation boundary is a position in the source sequence which begins or ends a *translation zone* [1] spanning multiple source words. In a translation zone, the source phrase is translated as a unit. Reorderings which cross translation zones are not desirable.

Inspired by (Roark and Hollingshead, 2008) which introduces classifiers to decide if a word can begin/end a multi-word constituent, we build two discriminative classifiers to tag each word in the source sequence with a binary class label. The first classifier decides if a word can begin a multi-source-word translation zone; the second classifier decides if a word can end a multi-source-word translation

[1] We will give a formal definition of translation zone in Section 2.

zone. Given a partial translation covering source sequence (i, j) with start word c_i and end word c_j [2], this translation can be penalized if the first classifier decides that the start word c_i can not be a beginning translation boundary or the second classifier decides that the end word c_j can not be an ending translation boundary. In such a way, we can guide the decoder to boost hypotheses that respect translation boundaries and therefore the common translation structure shared by the source and target language, rather than the syntactic structure of the source language.

We report the accuracy of such classifiers by comparing their outputs with "gold" translation boundaries obtained from reference translations on the development set. We integrate translation boundary based constraints into phrase-based decoding and display that they improve translation quality significantly in large-scale experiments. Furthermore, we confirm that they also significantly outperform constituent boundary based syntactic constraints.

2 Beginning and Ending Translation Zones

To better understand the particular task that we address in this paper, we study the distribution of classes of translation boundaries in real-world data. First, we introduce some notations. Given a source sentence $c_1...c_n$, we will say that a word c_i ($1 < i < n$) is in the class B_y if there is a translation zone τ spanning $c_i...c_j$ for some $j > i$; and $c_i \in B_n$ otherwise. Similarly, we will say that a word c_j is in the class E_y if there is a translation zone spanning $c_i...c_j$ for some $j > i$; and $c_j \in E_n$ otherwise.

Here, a translation zone τ is a pair of aligned source phrase and target phrase

$$\tau = (c_i^j, e_p^q)$$

where τ must be consistent with the word alignment M

$$\forall(u, v) \in M, i \leq u \leq j \leftrightarrow p \leq v \leq q$$

By this, we require that no words inside the source phrase c_i^j are aligned to words outside the target phrase e_p^q and that no words outside the source phrase are aligned to words inside the target phrase. This means, in other words, that the source phrase c_i^j is mapped as a unit onto the target phrase e_p^q.

Item	Count (M)	P (%)
Sentences	3.8	–
Words	96.9	–
Words $\in B_y$	22.7	23.4
Words $\in E_y$	41.0	42.3
Words $\notin B_y$ and $\notin E_y$	33.2	34.3

Table 1: Statistics on word classes from our bilingual training data. All numbers are calculated on the source side. P means the percentage.

When defining the B_y and E_y class, we also require that the source phrase c_i^j in the translation zone must contain multiple words ($j > i$). Our interest is the question of whether a sequence of consecutive source words can be translated as a unit (i.e. whether there is a translation zone covering these source words). For a single-word source phrase, if it can be translated separately, it is always translated as a unit in the context of phrase-based decoding. Therefore this question does not exist.

Note that the first word c_1 and the last word c_n are unambiguous in terms of whether they begin or end a translation zone. The first word c_1 must begin a translation zone spanning the whole source sentence. The last word c_n must end a translation zone spanning the whole source sentence. Therefore, our classifiers only need to predict the other $n - 2$ words for a source sentence of length n.

Table 1 shows statistics of word classes from our training data which contain nearly 100M words in approximately 4M sentences. Among these words, only 22.7M words can begin a translation zone which covers multiple source words. 41M words can end a translation zone spanning multiple source words, which accounts for more than 42% in all words. We still have more than 33M words, accounting for 34.3%, which neither begin nor end a multi-source-word translation zone. Apparently, translations that begin/end on words $\in B_y$/$\in E_y$ are preferable to those which begin/end on other words.

Yet another interesting study is to compare translation boundaries with constituent boundaries deduced from source-side parse trees. In doing so, we can know further how well constituent boundary

[2] In this paper, we use c to denote the source language and e the target language.

Classification Task	**Avg. Accuracy (%)**
B_y/B_n	46.9
E_y/E_n	52.2

Table 2: Average classification accuracy on the development set when we treat constituent boundary deducer (according to source-side parse trees) as a translation boundary classifier.

based syntactic constraints can improve translation quality. We pair the source sentences of our development set with each of the reference translations and include the created sentence pairs in our bilingual training corpus. Then we obtain word alignments on the new corpus (see Section 5.1 for the details of learning word alignments). From the word alignments we obtain translation boundaries (see details in the next section). We parse the source sentences of our development set and obtain constituent boundaries from parse trees.

To make a clear comparison with our translation boundary classifiers (see Section 3.3), we treat constituent boundaries deduced from source-side parse trees as output from beginning/ending boundary classifiers: the constituent beginning boundary corresponds to B_y; the constituent ending boundary corresponds to E_y. We have four reference translations for each source sentence. Therefore we have four translation boundary sets, each of which is produced from word alignments between source sentences and one reference translation set. Each of the four translation boundary sets will be used as a gold standard. We calculate classification accuracy for our constituent boundary deducer on each gold standard and average them finally.

Table 2 shows the accuracy results. The average accuracies on the four gold standard sets are very low, especially for the B_y/B_n classification task. In section 3.3, we will show that our translation boundary classifiers achieve higher accuracy than that of constituent boundary deducer. This suggests that pure constituent boundary based constraints are not the best choice to constrain phrase-based decoding.

3 Learning Translation Boundaries

In this section, we investigate building classifiers to predict translation boundaries. First, we elaborate the acquisition of training instances from word alignments. Second, we build two classifiers with simple features on the obtained training instances. Finally, we evaluate our classifiers on the development set using the "gold" translation boundaries obtained from reference translations.

3.1 Obtaining Translation Boundaries from Word Alignments

We can easily obtain constituent boundaries from parse trees. Similarly, if we have a tree covering both source and target sentence, we can easily get translation boundaries from this tree. Fortunately, we can build such a tree directly from word alignments. We use (Zhang et al., 2008)'s shift-reduce algorithm (SRA) to decompose word alignments into hierarchical trees.

Given an arbitrary word-level alignment as an input, SRA is able to output a tree representation of the word alignment (a.k.a **decomposition tree**). Each node of the tree is a translation zone as we defined in the Section 2. Therefore the first word on the source side of each multi-source-word node is a beginning translation boundary ($\in B_y$); the last word on the source side of each multi-source-word node is an ending translation boundary ($\in E_y$).

Figure 1a shows an example of many-to-many alignment, where the source language is Chinese and the target language is English. Each word is indexed with their occurring position from left to right. Figure 1b is the tree representation of the word alignment after hierarchical analysis using SRA. We use $([i, j], [p, q])$ to denote a tree node, where i, j and p, q are the beginning and ending index in the source and target language, respectively. By checking nodes which cover multiple source words, we can easily decide that the source words {过去, 五, 因故} are in the class B_y and any other words are in the class B_n if we want to train a B_y/B_n classifier with class labels $\{B_y, B_n\}$. Similarly, the source words {次, 飞行, 都, 失败} are in the class E_y and any other words are in the class E_n when we train a E_y/E_n classifier with class labels $\{E_y, E_n\}$.

By using SRA on each word-aligned bilingual sentence, as described above, we can tag each source word with two sets of class labels: $\{B_y, B_n\}$ and $\{E_y, E_n\}$. The tagged source sentences will be used to train our two translation boundary classifiers.

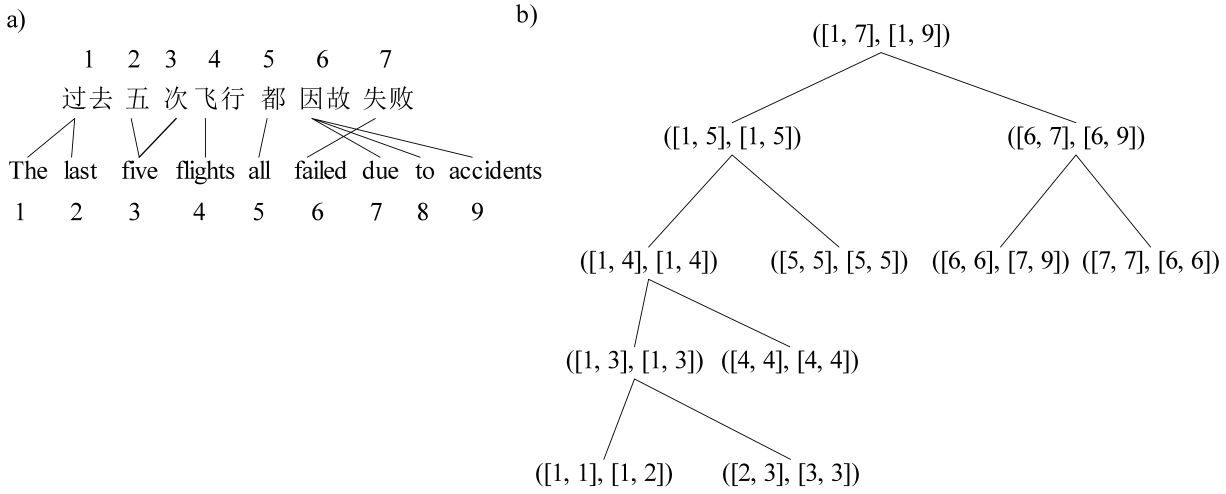

Figure 1: An example of many-to-many word alignment and its tree representation produced by (Zhang et al., 2008)'s shift-reduce algorithm.

3.2 Building Translation Boundary Classifiers

We build two discriminative classifiers based on Maximum Entropy Markov Models (MEMM) (McCallum et al., 2000). One classifier is to predict the word class $\zeta \in \{B_y, B_n\}$ for each source word. The other is to predict the word class $\zeta \in \{E_y, E_n\}$. These two classifiers are separately trained using training instances obtained from our word-aligned training data as demonstrated in the last section.

We use features from surrounding words, including 2 before and 2 after the current word position ($c_{-2}, c_{-1}, c_{+1}, c_{+2}$). We also use class features to train models with Markov order 1 (including class feature $\zeta_{c_{-1}}$), and Markov order 2 (including class features $\zeta_{c_{-1}}, \zeta_{c_{-2}}$).

3.3 Evaluating Translation Boundary Classifiers

How well can we perform these binary classification tasks using the classifiers described above? Can we obtain better translation boundary predictions than extracting constituent boundary from source-side parse trees? To investigate these questions, we evaluate our MEMM based classifiers. We trained them on our 100M-word word-aligned corpus. We ran the two trained classifiers on the development set separately to obtain the B_y/B_n words and E_y/E_n words. Then we built our four gold standards using four reference translation sets as described in Section 2. The average classification accuracy results are shown in Table 3.

	Avg. Accuracy (%)	
Classification Task	MEMM 1	MEMM 2
B_y/B_n	71.7	70.2
E_y/E_n	59.2	58.8

Table 3: Average classification accuracy on the development set for our MEMM based translation boundary classifiers with various Markov orders.

Comparing Table 3 with Table 2, we find that our MEMM based classifiers significantly outperform constituent boundary deducer in predicting translation boundaries, especially in the B_y/B_n classification task, where our MEMM based B_y/B_n classifier (Markov order 1) achieves a relative increase of 52.9% in accuracy over the constituent boundary deducer. In the E_y/E_n classification task, our classifiers also perform much better than constituent boundary deducer.

Then are our MEMM based translation boundary classifiers good enough? The accuracies are still low although they are higher than those of constituent boundary deducer. One reason why we have low accuracies is that our gold standard based evaluation is not established on real gold standards. In other words, we don't have gold standards in terms of translation boundary since different translations

Classification Task	Avg. Accuracy (%)
B_y/B_n	80.6
E_y/E_n	75.7

Table 4: Average classification accuracy on the development set when treating each reference translation set as a boundary classifier.

generate very different translation boundaries. We can measure these differences in reference translations using the same evaluation metric (classification accuracy). We treat each reference translation set as a translation boundary classifier while the other three reference translation sets as gold standards. We calculate the classification accuracy for the current reference translation set and finally average all four accuracies. Table 4 presents the results.

Comparing Table 4 with Table 3, we can see that the accuracy of our translation boundary classification approach is not that low when considering vast divergences of reference translations. The question now becomes, how can classifier output be used to constrain phrase-based decoding, and what is the impact on the system performance of using such constraints.

4 Integrating Translation Boundaries into Decoding

By running the two trained classifiers on the source sentence separately, we obtain two classified word sets: B_y/B_n words, and E_y/E_n words. We can prohibit any translations or reorderings spanning $c_i...c_j$ ($j > i$) where $c_i \notin B_y$ according to the first classifier or $c_j \notin E_y$ according to the second classifier. In such a way, we integrate translation boundaries into phrase-based decoding as hard constraints, which, however, is at the risk of producing no translation covering the whole source sentence.

Alternatively, we introduce soft constraints based on translation boundary that our classifiers predict, similar to constituent boundary based soft constraints in (Cherry, 2008) and (Marton and Resnik, 2008). We add a new feature to the decoder's log-linear model: translation boundary violation counting feature. This counting feature accumulates whenever hypotheses have a partial translation spanning $c_i...c_j$ ($j > i$) where $c_i \notin B_y$ or $c_j \notin E_y$. The weight λ_v of this feature is tuned via minimal error rate training (MERT) (Och, 2003) with other feature weights.

Table 5: Training corpora.

Unlike hard constraints, which simply prevent any hypotheses from violating translation boundaries, soft constraints allow violations of translation boundaries but with a penalty of exp($-\lambda_v C_v$) where C_v is the violation count. By using soft constraints, we can enable the model to prefer hypotheses which are consistent with translation boundaries.

5 Experiment

Our baseline system is a phrase-based system using BTGs (Wu, 1997), which includes a content-dependent reordering model discriminatively trained using reordering examples (Xiong et al., 2006). We carried out various experiments to evaluate the impact of integrating translation boundary based soft constraints into decoding on the system performance on the Chinese-to-English translation task of the NIST MT-05 using large scale training data.

5.1 Experimental Setup

Our training corpora are listed in Table 5. The whole corpora consist of 96.9M Chinese words and 109.5M English words in 3.8M sentence pairs. We ran GIZA++ (Och and Ney, 2000) on the parallel corpora in both directions and then applied the "grow-diag-final" refinement rule (Koehn et al., 2005) to obtain many-to-many word alignments. From the word-aligned corpora, we extracted bilingual phrases and trained our translation model.

We used all corpora in Table 5 except for the United Nations corpus to train our MaxEnt based reordering model (Xiong et al., 2006), which consist of 33.3M Chinese words and 35.8M English words. We built a four-gram language model using the SRILM toolkit (Stolcke, 2002), which was trained on Xinhua section of the English Gigaword corpus (181.1M words).

To train our translation boundary classifiers, we extract training instances from the whole word-aligned corpora, from which we obtain 96.9M training instances for the B_y/B_n and E_y/E_n classifier. We ran the off-the-shelf MaxEnt toolkit (Zhang, 2004) to tune classifier feature weights with Gaussian prior set to 1 to avoid overfitting.

We used the NIST MT-03 evaluation test data as our development set (919 sentences in total, 27.1 words per sentence). The NIST MT-05 test set includes 1082 sentences with an average of 27.4 words per sentence. Both the reference corpus for the NIST MT-03 set and the reference corpus for the NIST MT-05 set contain 4 translations per source sentence. To compare with constituent boundary based constraints, we parsed source sentences of both the development and test sets using a Chinese parser (Xiong et al., 2005) which was trained on the Penn Chinese Treebank with an F_1-score of 79.4%.

Our evaluation metric is case-insensitive BLEU-4 (Papineni et al., 2002) using the shortest reference sentence length for the brevity penalty. Statistical significance in BLEU score differences was tested by paired bootstrap re-sampling (Koehn, 2004).

5.2 Using Translation Boundaries from Reference Translations

The most direct way to investigate the impact on the system performance of using translation boundaries is to integrate "right" translation boundaries into decoding which are directly obtained from reference translations. For both the development set and test set, we have four reference translation sets, which are named ref1, ref2, ref3 and ref4, respectively. For the development set, we used translation boundaries obtained from ref1. Based on these boundaries, we built our translation boundary violation counting feature and tuned its feature weight with other features using MERT. When we obtained the best feature weights λs, we evaluated on the test set using translation boundaries produced from ref1, ref2, ref3 and ref4 of the test set respectively.

System	BLEU-4 (%)
Base	33.05
Ref1	33.99*
Ref2	34.17*
Ref3	33.93*
Ref4	34.21*

Table 6: Results of using translation boundaries obtained from reference translations. *: significantly better than baseline ($p < 0.01$).

Table 6 shows the results. We clearly see that using "right" translation boundaries to build soft constraints significantly improve the performance measured by BLEU score. The best result comes from ref4, which achieves an absolute increase of 1.16 BLEU points over the baseline. We believe that the best result here only indicates the lower bound of potential improvement when using right translation boundaries. If we have consistent translation boundaries on the development and test set (for example, we have the same 4 translators build reference translations for both the development and test set), the performance improvement will be higher.

5.3 Using Automatically Learned Translation Boundaries

The success of using translation boundaries from reference translations inspires us to pursue translation boundaries predicted by our MEMM based classifiers. We ran our MEMM1 (Markov order 1) and MEMM2 (Markov order 2) B_y/B_n and E_y/E_n classifiers on both the development and test set. Based on translation boundaries output by MEMM1 and MEMM2 classifiers, we built our translation boundary violation feature and tuned it on the development set. The evaluation results on the test set are shown in Table 7.

From Table 7 we observe that using soft constraints based on translation boundaries from both our MEMM 1 and MEMM 2 significantly outperform the baseline. Impressively, when using outputs from MEMM 2, we achieve an absolute improvement of almost 1 BLEU point over the baseline. This result is also very close to the best result of using translation boundaries from reference translations.

To compare with constituent boundary based syntactic constraints, we also carried out experiments using two kinds of such constraints. One is the

System	BLEU-4 (%)
Base	33.05
Condeducer	33.18
XP+	33.58*
BestRef	34.21*+
MEMM 1	33.70*
MEMM 2	34.04*+

Table 7: Results of using automatically learned translation boundaries. Condeducer means using pure constituent boundary based soft constraint. XP+ is another constituent boundary based soft constraint but with distinction among special constituent types (Marton and Resnik, 2008). BestRef is the best result using reference translation boundaries in Table 6. MEMM 1 and MEMM 2 are our MEMM based translation boundary classifiers with Markov order 1 and 2. *: significantly better than baseline ($p < 0.01$). +: significantly better than XP+ ($p < 0.01$).

Condeducer which uses pure constituent boundary based syntactic constraint: any partial translations which cross any constituent boundaries will be penalized. The other is the XP+ from (Marton and Resnik, 2008) which only penalizes hypotheses which violate the boundaries of a constituent with a label from {NP, VP, CP, IP, PP, ADVP, QP, LCP, DNP}. The XP+ is the best syntactic constraint among all constraints that Marton and Resnik (2008) use for Chinese-to-English translation.

Still in Table 7, we find that both syntactic constraint Condeducer and XP+ are better than the baseline. But only XP+ is able to obtain significant improvement. Both our MEMM 1 and MEMM 2 outperform Condeducer. MEMM 2 achieves significant improvement over XP+ by approximately 0.5 BLEU points. This comparison suggests that translation boundary is a better option than constituent boundary when we build constraints to restrict phrase-based decoding.

5.4 One Classifier vs. Two Classifiers

Revisiting the classification task in this paper, we can also consider it as a sequence labeling task where the first source word of a translation zone is labeled “B”, the last source word of the translation zone is labeled “E”, and other words are labeled “O”. To complete such a sequence labeling task, we built only one classifier which is still based on MEMM (with Markov order 2) with the same features as described in Section 3.2. We built soft constraints based on the outputs of this classifier and evaluated them on the test set. The case-insensitive BLEU score is 33.62, which is lower than the performance of using two separate classifiers (34.04).

We calculated the accuracy for class “B” by mapping “B” to B_y and “E” and “O” to B_n. The result is 67.9%. Similarly, we obtained the accuracy of class “E”, which is as low as 48.6%. These two accuracies are much lower than those of using two separate classifiers, especially the accuracy of “E”. This suggests that the B_y and E_y are not interrelated tightly. It is better to learn them separately with two classifiers.

Another advantage of using two separate classifiers is that we can explore more constraints. A word c_k can be possibly labeled as B_y by the first classifier and E_y by the second classifier. Therefore we can build soft constraints on span (c_i, c_k) ($c_i \in B_y, c_k \in E_y$) and span (c_k, c_j) ($c_k \in B_y, c_j \in E_y$). This is impossible if we use only one classifier since each word can have only one class label. We can build only one constraint on span (c_i, c_k) or span (c_k, c_j).

6 Related Work

Various approaches incorporate constraints into phrase-based decoding in a soft or hard manner. Our introduction has already briefly mentioned (Cherry, 2008) and (Marton and Resnik, 2008), which utilize source-side parse tree boundary violation counting feature to build soft constraints for phrase-based decoding, and (Xiong et al., 2009), which calculates a score to indicate to what extent a source phrase can be translated as a unit using a bracketing model with richer syntactic features. More previously, (Chiang, 2005) rewards hypotheses whenever they exactly match constituent boundaries of parse trees on the source side.

In addition, hard linguistic constraints are also explored. (Wu and Ng, 1995) employs syntactic bracketing information to constrain search in order to improve speed and accuracy. (Collins et al., 2005) and (Wang et al., 2007) use hard syntactic constraints to perform reorderings according to source-side parse trees. (Xiong et al., 2008) prohibit any swappings which violate punctuation based constraints.

Non-linguistic constraints are also widely used in phrase-based decoding. The IBM and ITG constraints (Zens et al., 2004) are used to restrict reorderings in practical phrase-based systems.

(Berger et al., 1996) introduces the concept of *rift* into a machine translation system, which is similar to our definition of translation boundary. They also use a maximum entropy model to predict whether a source position is a rift based on features only from source sentences. Our work differs from (Berger et al., 1996) in three major respects.

1) We distinguish a segment boundary into two categories: beginning and ending boundary due to their different distributions (see Table 1). However, Berger et al. ignore this difference.

2) We train two classifiers to predict beginning and ending boundary respectively while Berger et al. build only one classifier. Our experiments show that two separate classifiers outperform one classifier.

3) The last difference is how segment boundaries are integrated into a machine translation system. Berger et al. use predicted rifts to divide a long source sentence into a series of smaller segments, which are then translated sequentially in order to increase decoding speed (Brown et al., 1992; Berger et al., 1996). This can be considered as a hard integration, which may undermine translation accuracy given wrongly predicted rifts. We integrate predicted translation boundaries into phrase-based decoding in a soft manner, which improves translation accuracy in terms of BLEU score.

7 Conclusion and Future Work

In this paper, we have presented a simple approach to learn translation boundaries on source sentences. The learned translation boundaries are used to constrain phrase-based decoding in a soft manner. The whole approach has several properties.

- First, it is based on a simple classification task that can achieve considerably high accuracy when taking translation divergences into account using simple models and features.

- Second, the classifier output can be straightforwardly used to constrain phrase-based decoder.

- Finally, we have empirically shown that, to build soft constraints for phrase-based decoding, translation boundary predicted by our classifier is a better choice than constituent boundary deduced from source-side parse tree.

Future work in this direction will involve trying different methods to define more informative translation boundaries, such as a boundary to begin/end a swapping. We would also like to investigate new methods to incorporate automatically learned translation boundaries more efficiently into decoding in an attempt to further improve search in both speed and accuracy.

Abstract

We present a random-walk-based approach to learning paraphrases from bilingual parallel corpora. The corpora are represented as a graph in which a node corresponds to a phrase, and an edge exists between two nodes if their corresponding phrases are aligned in a phrase table. We sample random walks to compute the average number of steps it takes to reach a ranking of paraphrases with better ones being "closer" to a phrase of interest. This approach allows "feature" nodes that represent domain knowledge to be built into the graph, and incorporates truncation techniques to prevent the graph from growing too large for efficiency. Current approaches, by contrast, implicitly presuppose the graph to be bipartite, are limited to finding paraphrases that are of length two away from a phrase, and do not generally permit easy incorporation of domain knowledge. Manual evaluation of generated output shows that our approach outperforms the state-of-the-art system of Callison-Burch (2008).

1 Introduction

Automatically learning paraphrases, or alternative ways of expressing the same meaning, is an active area of NLP research because of its usefulness in a variety of applications, e.g., question answering (Lin and Pantel, 2001; Ravichandran and Hovy, 2002; Reizler et al., 2007), document summarization (Barzilay et al., 1999; McKeown et al., 2002), natural language generation (Iordanskaja et al., 1991; Lenke, 1994; Stede, 1999), machine translation (Kauchak and Barzilay, 2006; Callison-Burch et al., 2006; Madnani et al., 2007).

Early work on paraphrase acquisition has focused on using monolingual parallel corpora (Barzilay and McKeown, 2001; Barzilay and Lee, 2003; Pang et al., 2003; Quirk et al., 2004). While effective, such methods are hampered by the scarcity of monolingual parallel corpora, an obstacle that limits both the quantity and quality of the paraphrases learned. To address this limitation, Bannard and Callison-Burch (2005) focused their attention on the abundance of bilingual parallel corpora. The crux of this system (referred to below as "BCB") is to align phrases in a bilingual parallel corpus and hypothesize English phrases as potential paraphrases if they are aligned to the same phrase in another language (the "pivot"). Callison-Burch (2008) further refines BCB with a system that constrains paraphrases to have the same syntactic structure (Syntactic Bilingual Phrases: SBP).

We take a graphical view of the state-of-the-art BCB and SBP approaches by representing the bilingual parallel corpora as a graph. A node corresponds to a phrase, and an edge exists between two nodes if their corresponding phrases are aligned. This graphical form makes the limitations of the BCB/SBP approaches more evident. The BCB/SBP graph is limited to be bipartite with English nodes on one side and foreign language nodes on the other, and an edge can only exist between nodes on different sides. This neglects information between foreign language nodes that may aid in learning paraphrases. Further, by only considering English nodes that are linked via a foreign language node as potential paraphrases,

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 145–153,
Los Angeles, California, June 2010.

these approaches will fail to find paraphrases separated by distances greater than length two.

In this paper, we present HTP (Hitting Time Paraphraser), a paraphrase learning approach that is based on random walks (Lovász, 1996) and hitting times (Aldous and Fill, 2001). Hitting time measures the average number of steps one needs to take in a random traversal of a graph before reaching a destination node from a source node. Intuitively, the smaller the hitting time from a phrase E to E' (i.e., the closer E' is to E), the more likely it is that E' is a good paraphrase of E. The advantages of HTP are as follows:

- By traversing paths of lengths greater than two, our approach is able to find more paraphrases of a given phrase.
- We do not require the graph to be bipartite. Edges can exist between nodes of different foreign languages if their corresponding phrases are aligned. This allows information from foreign phrase alignments to be used in finding English paraphrases.
- We permit domain knowledge to be easily incorporated as nodes in the graph. This allows domain knowledge to favor good paraphrases over bad ones, thereby improving performance.

In this paper, we focus on learning English paraphrases. However, our system can be applied to learning paraphrases in any language.

We begin by reviewing random walks and hitting times in the next section. Then we describe our paraphrase learning algorithm (Section 3), and report our experiments (Section 4). We discuss related work in Section 5. Finally, we conclude with future work (Section 6).

2 Background

A directed graph consists of a set of nodes V, and a set of edges E. A directed edge is a pair (i, j) where $i, j \in V$. Associated with the graph is a $|V| \times |V|$ adjacency matrix W. Each entry W_{ij} in the matrix is the weight of edge (i, j), or zero if the edge does not exist.

In a *random walk* (Lovász, 1996), we traverse from node to node via the edges. Suppose at time step t, we are at node i. In the next step, we move to its neighbor j with probability proportional to the weight of the edge (i, j), i.e., with probability $W_{ij}/\sum_j W_{ij}$. This probability is known as the *transition probability* from i to j. Note that the transition probabilities from a node to its neighbors sum to 1.

The *hitting time* h_{ij} (Aldous and Fill, 2001) from node i to j is defined as the average number of steps one takes in a random walk starting from i to visit j for the first time. Hitting time has the property of being robust to noise. This is a desirable property for our system which works on bilingual parallel corpora containing numerous spurious alignments between phrases (i.e., edges between nodes). However, as observed by Liben-Nowell and Kleinberg (2003), *hitting time* has the drawback of being sensitive to portions of the graph that are far from the start node because it considers paths of length up to ∞.

To circumvent this problem, Sarkar and Moore (2007) introduced the notion of *truncated* hitting time where random walks are limited to have at most T steps. The truncated hitting time h^T_{ij} from node i to j is defined as the average number of steps one takes to reach j for the first time starting from i in a random walk that is limited to at most T steps. h^T_{ij} is defined to be 0 if $i = j$ or $T = 0$, and to be T if j is not reach in T steps. As $T \rightarrow \infty, h^T_{ij} \rightarrow h_{ij}$.

In a recent work, Sarkar et al. (2008) showed that truncated hitting time can be approximated accurately with high probability by sampling. They run M independent length-T random walks from node i. In m of these runs, node j is visited for the first time at time steps $t^1_j, \ldots, t^m_j$. The *estimated* truncated hitting time is given by

$$\hat{h}^T_{ij} = \frac{\sum_{k=1}^{m} t^k_j}{M} + (1 - \frac{m}{M})T \qquad (1)$$

They also showed that the number of samples of random walks M has to be at least $\frac{1}{2\epsilon^2} \log \frac{2n}{d}$ in order for the estimated truncated hitting time to be a good estimate of the actual truncated hitting time with high probability, i.e., for $P(|\hat{h}^T_{ij} - h^T_{ij}| \leq \epsilon T) \geq 1 - \delta$, where n is the number of nodes in the graph, ϵ and δ are user-specified parameters, and $0 \leq \epsilon, \delta \leq 1$.

3 Hitting Time Paraphraser (HTP)

HTP takes a *query* phrase as input, and outputs a list of paraphrases, with better paraphrases at the top of

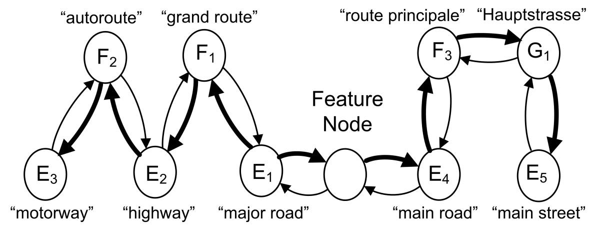

Figure 1: Graph created from English-French (E-F), English-German (E-G), and French-German (F-G) bilingual parallel corpora. Bold edges have large positive weights (high transition probabilities).

the list. HTP also requires as input a set of bilingual parallel corpora that have been processed into phrase tables of the kind used in statistical machine translation.

A bilingual parallel corpus is made up of sentences in two languages. Two sentences that are translations of one another are paired together, and a phrase in one sentence is aligned with a phrase in the other with the same meaning. From such alignments, we can count for a phrase E both the number of times it occurs ($Count_E$), and the number of times it is aligned with a phrase F in the other language ($Count_{E,F}$). With these counts we can estimate the probability of F given E as $P(F|E) = \frac{Count_{E,F}}{Count_E}$.

HTP represents the aligned phrases as a graph. A node corresponds to a phrase, and a directed edge exists from node i to j if their corresponding phrases are aligned. The weight of edge (i, j) is given by $P(j|i)$ which is computed as described in the previous paragraph.

Table 1: The HTP algorithm.

```
function $HTP(E, C, d, n, m, T, \delta, l)$
  input: $E$, query phrase
         $C$, tables of aligned phrases
         $d$, maximum distance of nodes from $E$
         $n$, maximum number of nodes in graph
         $m$, number of samples of random walks
         $T$, maximum number of steps taken by a
           random walk
         $\delta$, probability that estimated truncated hitting
           time deviates from actual value by a large
           margin (see Equation 1)
         $l$, number of top outgoing edges to select at
           each node in a random walk
  output: $(E'_1, \ldots, E'_k)$, paraphrases of $E$ ranked in
          order of increasing hitting times
  calls: $CreateGraph(E, C, d, n)$ creates graph $G$
           from $C$ containing at most $n$ nodes that are
           at most $d$ steps from $E$
         $EstimateHitTimes(E, G, m, T, \delta)$, estimates
           the truncated hitting times of each node in $G$
           by running $m$ random walks
         $PruneNodes((E_1, \ldots, E_k), G)$, removes nodes
           from $G$ if their hitting times is equal to $T$.
         $AddFeatureNodes(G)$, adds nodes
           representing domain knowledge to $G$

$G \leftarrow CreateGraph(E, C, d, n)$
$(E_1, \ldots, E_k) \leftarrow EstimateHitTimes(E, G, m, T, \delta)$
$G' \leftarrow PruneNodes((E_1, \ldots, E_k), G)$
$G'' \leftarrow AddFeatureNodes(G')$
$(E'_1, \ldots, E'_k) \leftarrow EstimateHitTimes(E, G'', m, T, \delta)$
return $(E'_1, \ldots, E'_k)$
```

Figure 1 gives an example of a graph created from English-French, English-German, and French-German parallel corpora. We use this figure to illustrate the strengths of HTP. First, by using moderately long random walks, HTP is able to find paraphrases that are separated by long paths. For example, there is a high probability path of length 4 $(E_1, F_1, E_2, F_2, E_3)$ from E_1 to E_3. Because of the path's high probability, it will appear in many of the random walks starting from E_1 that are sampled on the graph, and thus E_3 will be visited in many of the samples. This causes the truncated hitting time $h^T_{E_1 E_3}$ to be small, allowing HTP to find E_3 as a plausible paraphrase of E_1. Second, by allowing edges between nodes of different foreign languages (i.e., by not requiring the graph to be bipartite), HTP allows strong correlation between foreign language nodes to aid in finding paraphrases. In the figure, even though E_4 and E_5 are not linked via a common foreign language node, there is a high probability path linking them (E_4, F_3, G_1, E_5). This allows HTP to find E_5 as a reasonable paraphrase of E_4. Third, HTP enables domain knowledge to be incorporated as nodes in the graph. For example, we could incorporate the domain knowledge that phrases with lots of unigrams in common are likely to be paraphrases. In Figure 1, the "feature" node represents such knowledge, linking E_4 and E_1 as possible paraphrases even though they have no foreign language nodes in common. Note that such domain knowledge nodes can be linked to arbitrary nodes, not just English ones.

The HTP algorithm is shown in Table 1. It takes as input a query phrase and a set of bilingual phrase tables. The algorithm begins by creating a graph from the phrase tables. Then it estimates the truncated hitting times of each node from the query node by sampling random walks of length T. Next it prunes nodes (and their associated edges) if their truncated hitting times are equal to T. To the resulting graph, it then adds nodes representing domain knowledge and estimates the truncated hitting times of the nodes by sampling random walks as before. Finally, it returns the nodes in the same language as the query phrase in order of increasing hitting times.

3.1 Graph Creation

An obvious approach to creating a graph from bilingual parallel corpora is to create a node for every phrase in the corpora, and two directed edges (i, j) and (j, i) for every aligned phrase pair i and j. Let H refer to the graph that is created in this manner. Such an approach is only tractable for small bilingual parallel corpora that would result in a small H, but not for large corpora containing millions of sentences, such as those described in Section 4.1. Therefore we approximate H with a graph H' that only contains nodes "near" to the node representing the query phrase. Specifically, we perform breadth-first search starting from the query node up to a depth d, or until the number of nodes visited in the search has reached a maximum of n nodes. Some nodes at the periphery of H' have edges to nodes that are not in H' but are in H. For a periphery node j that has edges to nodes $j_1, \ldots, j_k$ outside H', we create a "dummy" node a, and replace edges $(j, j_1), \ldots, (j, j_k)$ with a single edge (j, a) with weight $\sum_{x=1}^{k} W_{j,j_x}$. We also add edges (a, j) and (a, a) (each with a heuristic weight of 0.5). The dummy nodes and their edges approximate the transition probabilities at H''s periphery. Our empirical results show that this approximation works well in practice.

3.2 Graph Pruning

After H' is created, we run M independent length-T random walks on it starting from the query node to estimate the truncated hitting times of all nodes. A node in H' may have many outgoing edges, most of which may be due to spurious phrase alignments. For efficiency, and to reduce the noise due to spurious edges, we select among a node's top l outgoing edges with the highest transition probabilities, when deciding which node to visit next at each step of a random walk

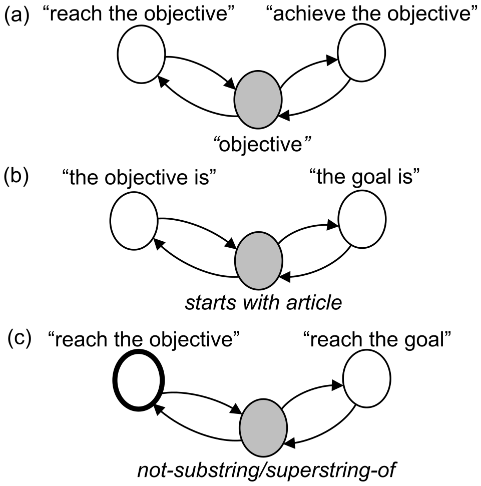

Figure 2: Feature nodes representing domain knowledge. Feature nodes are shaded. The bold node represents a query phrase. (a) n-gram nodes (b) "syntax" nodes (c) "not-substring/superstring-of" nodes.

For each random walk k, we record the first time that a node j is visited t_j^k. Using Equation 1, we estimate the truncated hitting time of each node. Then we remove nodes (and their associated edges) that are far from the query node, i.e., with times equal to T. Such nodes either are not visited in any of the random walks, or are always visited for the first time at step T.

3.3 Adding Domain Knowledge

Next we add nodes representing domain knowledge to the pruned graph. In this version of HTP, we implemented three types of *feature nodes*.

First, we have *n-gram nodes*. These nodes capture the domain knowledge that phrases containing many words in common are likely to be paraphrases. For each 1 to 4-gram that appears in English phrases, we create an n-gram node a. We add directed edges (a, j) and (j, a) if node j represents an English phrase containing n-gram a. For example, in Figure 2(a), "reach the objective" is connected to "objective" because it contains that unigram. Note that such nodes create short paths between nodes with many n-grams in common, thereby reducing the hitting times between them.

Second, we have *"syntax" nodes*, which represent syntactic classes of the start and end words of English phrases. We created classes such as *interrogatives* ("whose", "what", "where", etc.), *articles* ("the", "a", "an"), etc. For each class c, we create syntax nodes a_c and a'_c to respectively represent the conditions that a phrase begins and ends with a word in class c. Directed edges (a_c, j) and (j, a_c) are added if node j starts with a word in class c (similarly we add (a'_c, j) and (j, a'_c) if it ends with a word in class c). For example, in Figure 2(b), "the objective is" is linked to "starts with *article*" because it begins with "the". These syntax nodes allow HTP to capture broad commonalities about structural distribution, without requiring syntactic equivalence as in Callison-Burch 2008 (or the use of a parser).

Third, we have *"not-substring/superstring-of" nodes*. We observed that many English phrases (e.g., "reach the objective" and "reach the") that are superstrings or substrings of each other tend to be aligned to several shared non-English phrases in the bilingual parallel corpora used in our experiments. Most such English phrase pairs are not paraphrases, but they are linked by many short paths via their common aligned foreign phrase, and thus have small hitting times. To counteract this, we create a "not-substring/superstring-of" node a. The query node i is always connected to a via edges (i, a) and (a, i). We add edges (a, j) and (j, a) if English phrase j is not a substring or superstring of the query phrase (see Figure 2(c)).

With the addition of the above, each node representing an English phrase can have four kinds of outgoing edges: edges to foreign phrase nodes, and edges to the three kinds of feature nodes. Let $f_{phrase}, f_{ngram}, f_{syntax}, f_{substring}$ denote the distribution of transition probabilities among the four kinds of outgoing edges. Note that $f_{phrase} + f_{ngram} + f_{syntax} + f_{substring} = 1.0$. These values are user-specified or can be set with tuning data. An outgoing edge from English phrase node i that originally had weight (transition probability) W_{ij} will now have weight $W_{ij} \times f_{phrase}$. All k edges from i to n-gram nodes will have weight $\frac{f_{ngram}}{k}$. Likewise for edges to the other two kinds of feature nodes. Each of the k outgoing edges from a feature node is simply set to have a weight of $\frac{1}{k}$.

After adding the feature nodes, we again run M independent length-T random walks to estimate the truncated hitting times of the nodes, and return the English phrase nodes in order of increasing hitting times.

4 Experiments

We conducted experiments to investigate how HTP compares with the state of the art, and to evaluate the contributions of its components.

4.1 Dataset

We used the Europarl dataset (Koehn, 2005) for our experiments. This dataset contains English transcripts of the proceedings of the European Parliament, and their translations into 10 other European languages. In the dataset, there are about a million sentences per language, and English sentences are aligned with sentences in the other languages. Callison-Burch (2008) aligned English phrases with phrases in each of the other languages using Giza++ (Och and Ney, 2004). We used his English-foreign phrasal alignments which are publicly available on the web at http://ironman.jhu.edu/emnlp08.tar. In addition, we paired sentences of different non-English languages that correspond to the same English sentence, and aligned the phrases using 5 iterations of IBM model 1 in each direction, followed by 5 iterations of HMM alignment with paired training using the algorithm described in Liang et al. (2006). We further used the technique of Chen et al. (2009) to remove a phrase alignment F-G (where F and G are phrases in different foreign languages) if it was always aligned to different phrases in a third "bridge" foreign language. As observed by Chen et al., this helped to remove spurious alignments. We used Finnish as the bridge language; when either F or G is Finnish, we used Spanish as the bridge language; when F and G were Finnish and Spanish, we used English as the bridge language. In our experiments, we used phrases of length 1 to 4 of the following six languages: English, Danish, German, Spanish, Finnish, and Dutch. All the phrasal alignments between each pair of languages (15 in total) were used as input to HTP and its comparison systems. A small subset of the remaining phrase alignments were used for tuning parameters.

4.2 Systems

We compared HTP to the state-of-the-art SBP system (Callison-Burch, 2008). We also investigated the contribution of the feature nodes by running HTP without them. In addition, we ran HTP on a bipartite graph, i.e., one created from English-foreign phrase alignments only without any phrase alignments between foreign languages.

We used Callison-Burch (2008)'s implementation of SBP that is publicly available at http://ironman.jhu.edu/emnlp08.tar. SBP is based on BCB (Bannard and Callison- Burch, 2005) which computes the probability that English phrase E' is a paraphrase of E using the following formula:

$$P(E'|E) \approx \sum_{C \in \mathcal{C}} \sum_{F \in C} P(E'|F)P(F|E) \qquad (2)$$

where $\mathcal{C}$ is set of bilingual parallel corpora, and F is a foreign language phrase. Representing phrases as nodes, and viewing $P(E'|F)$ and $P(F|E)$ as transition probabilities of edges (F, E') and (E, F), we see that BCB is summing over the transition probabilities of all length-two paths between E and E'. All E' paraphrases of E can then be ranked in order of decreasing probability as given by Equation 2. The SBP system modifies Equation 2 to incorporate syntactic information, thus:

$$P(E'|E) \approx \frac{1}{|\mathcal{C}|} \sum_{C \in \mathcal{C}} \sum_{F \in C} P(E'|F, syn_E))P(F|E, syn_E) \qquad (3)$$

where syn_E is the syntax of phrase E, and $P(E'|F, syn_E)) = 0$ if E' is not of the same syntactic category. From Equation 3, we can see that SBP constrains E' to have the same syntactic structure as E. To obtain the syntactic structure of each English phrase, each English sentence in every parallel corpus has to be parsed to obtain its parse tree. An English phrase can have several syntactic structures because different parse trees can have the phrase as their leaves, and in each of these, SBP associates the phrase with all subtrees that have the phrase as their leaves. SBP thus offers several ways of choosing which syntactic structure a phrase should be associated with. In our experiments, we used the best performing method of averaging Equation 3 over all syntactic structures that E is associated with.

Table 2: Scoring Standards.

0	Clearly wrong; grammatically incorrect, or does not preserve meaning
1	Minor grammatical errors (e.g., subject-verb disagreement or wrong tense), or meaning is largely preserved but not completely
2	Totally correct; grammatically correct and meaning is preserved

4.3 Methodology

To evaluate performance, we used 33,216 English translations from the Linguistic Data Consortium's Multiple Translation Chinese (MTC) corpora (Huang et al., 2002). We randomly selected 100 1- to 4-grams that appeared in both Europarl and MTC sentences (excluding stop words, numbers, and phrases containing periods and commas). For each of those 100 phrases, we randomly selected a MTC sentence containing that phrase. We then replaced the phrase in the sentence with each paraphrase output by the systems, and evaluated the correctness of the paraphrase in the context of the sentence. We had two volunteers manually score the paraphrases on a 3-point scale (Table 2), using a simplified version of the scoring system used by Callison-Burch (2008). We deemed a paraphrase to be correct if it was scored 1 or 2, and wrong if it was scored 0. Evaluation was blind, and the paraphrases were presented randomly to the volunteers. The Kappa measure of inter-annotator agreement was 0.62, which indicates substantial agreement between the evaluators. We took the average score for each paraphrase.

The parameters used for HTP were as follows (see Table 1 for parameter descriptions): $d = 6, n = 50,000, m = 1,000,000, T = 10, \delta = 0.05, l = 20$, $f_{phrase} = 0.1, f_{ngram} = 0.1, f_{syntax} = 0.4, f_{substring} = 0.4$. ($\epsilon \leq 0.03$ with these values of n, m, T, and δ.)

Table 3: HTP vs. SBP.

	HTP	SBP
Correct top-1 paraphrases	71%	53%
Correct top-k paraphrases	54%	39%
Count of correct paraphrases	420	145
Correct paraphrases	43%	39%

Table 4: HTP vs. HTP without feature nodes.

	HTP	HTP-NoFeatNodes
Correct top-1 paraphrases	61%	41%
Correct top-k paraphrases	43%	29%
Count of correct paraphrases	420	283
Correct paraphrases	43%	29%

Table 5: HTP vs. HTP with bipartite graph.

	HTP	HTP-Bipartite
Correct top-1 paraphrases	62%	58%
Correct top-k paraphrases	46%	41%
Count of correct paraphrases	420	361
Correct paraphrases	43%	41%

4.4 Results

HTP versus SBP. Comparison between HTP and SBP is complicated by the fact that the two systems did not output the same number of paraphrases for the 100 query phrases. HTP output paraphrases for all the query phrases, but SBP only did so for 49 query phrases. Of those 49 query phrases, HTP returned at least as many paraphrases as SBP, and for many it returned more.

To provide a fair comparison, we present results both for these 49 query phrases, and for all paraphrases returned by each of the systems. The upper half of Table 3 shows results for the 49 query phrases. The first row of Table 3 reports the percentage of top-1 paraphrases from this set that are correct, while the second row reports the percentage of correct top-k paraphrases from this set, where k is the number of queries returned by SBP, and is limited to at most 10. The value of k may differ for each query: if SBP and HTP return 3 and 20 paraphrases respectively, we only consider the top 3. On the third and fourth rows, we present the number of correct paraphrases and the percentage of correct paraphrases among the top 10 paraphrases returned by HTP for all 100 queries and the corresponding figures for the 49 queries for SBP. (When a system returned fewer than 10 paraphrases for a query, we consider all the paraphrases for that query.) It is evident from Table 3 that HTP consistently outperforms SBP: not only does it return more correct paraphrases overall (420 versus 145), it also has higher precision (43% versus 39%)

HTP and SBP respectively took 48 and 468 seconds per query on a 3 GHz machine. The times are not directly comparable because the systems are implemented in different languages (HTP in C# and SBP in Java), and use different data structures.

HTP without Feature Nodes. Both HTP and HTP minus feature nodes output paraphrases for each of the 100 query phrases. Table 4 compares performance in the same manner as in Table 3, except that the “top-1” and “top-k” results are over all 100 query phrases. We see that feature nodes boost HTP’s performance, allowing HTP to return more correct paraphrases (420 versus 283), and at higher precision (43% versus 29%).

HTP with Bipartite Graph. Lastly, we investigate the contribution of alignments between foreign phrases to HTP’s performance. HTP-Bipartite refers to HTP that is given a set consisting only of English-foreign phrase alignment as input. HTP-Bipartite does not return paraphrases for 5 query phrases. Thus, in Table 5, the “top-1” and “top-k” results are for the 95 query phrases for which both systems return paraphrases. From the better performance of HTP, we see that the foreign phrase alignments help in finding English paraphrases.

5 Related Work

Random walks and hitting times have been successfully applied to a variety of applications. Brand (2005) has used hitting times for collaborative filtering, in which product recommendations to users are made based on purchase history. In computer vision, hitting times have been used to determine object shape from silhouettes (Gorelick et al., 2004), and for image segmentation (Grady and Schwartz, 2006). In social network analysis, Liben-Nowell and Kleinberg (2003) have investigated the use of hitting times for predicting relationships between entities. Recently, Mei et al. (2008) have used the hitting times of nodes in a bipartite graph created from search engine query logs to find related queries. They used an iterative algorithm to compute the hitting time, which converges slowly on large graphs. In HTP, we have sought to obviate this issue by using *truncated* hitting time that can be computed efficiently by sampling random walks.

Several approaches have been proposed to learn paraphrases. Barzilay and Mckeown (2001) acquire paraphrases from a monolingual parallel corpus using a co-training algorithm. Their co-trained classifier determines whether two phrases are paraphrases of one another using their surrounding contexts. Lin and Pantel (2001) learn paraphrases using the distributional similarity of paths in dependency trees. Ibrahim et al. (2003) generalize syntactic paths in aligned monolingual sentence pairs in order to generate paraphrases. Pang et al. (2003) merge parse trees of monolingual sentence pairs, and then compress the merged tree into a word lattice that can subsequently be used to generate paraphrases. Recently, Zhao et al. (2008) used dependency parses to learn paraphrase patterns that include part-of-speech slots. In other recent work, Das and Smith (2009) use a generative model for paraphrase detection. Rather than outputing paraphrases of an input phrase, their system detects whether two input sentences are paraphrases of one another.

6 Conclusion and Future Work

We have introduced HTP, a novel approach based on random walks and hitting times for the learning of paraphrases from bilingual parallel corpora. HTP works by converting aligned phrases into a graph, and finding paraphrases that are "close" to a phrase of interest. Compared to previous approaches, HTP is able to find more paraphrases by traversing paths of lengths longer than 2; utilizes information in the edges between foreign phrase nodes; and allows domain knowledge to be easily incorporated. Empirical results show its effectiveness in learning new paraphrases.

As future work, we plan to learn the distribution of weights on edges to phrase nodes and feature nodes automatically from data, rather than tuning them manually, and to develop a probabilistic model supporting HTP. We intend also to apply HTP to learning paraphrases in languages other than English and investigate the impact of the learned paraphrases on resource-sparse machine translation systems.

Training Paradigms for Correcting Errors in Grammar and Usage

Alla Rozovskaya and Dan Roth

Abstract

This paper proposes a novel approach to the problem of training classifiers to detect and correct grammar and usage errors in text by selectively introducing mistakes into the training data. When training a classifier, we would like the distribution of examples seen in training to be as similar as possible to the one seen in testing. In error correction problems, such as correcting mistakes made by second language learners, a system is generally trained on correct data, since annotating data for training is expensive. Error generation methods avoid expensive data annotation and create training data that resemble non-native data with errors.

We apply error generation methods and train classifiers for detecting and correcting article errors in essays written by non-native English speakers; we show that training on data that contain errors produces higher accuracy when compared to a system that is trained on clean native data. We propose several training paradigms with error generation and show that each such paradigm is superior to training a classifier on native data. We also show that the most successful error generation methods are those that use knowledge about the article distribution and error patterns observed in non-native text.

1 Introduction

This paper considers the problem of training classifiers to detect and correct errors in grammar and word usage in text. Both native and non-native speakers make a variety of errors that are not always easy to detect. Consider, for example, the problem of context-sensitive spelling correction (e.g., (Golding and Roth, 1996; Golding and Roth, 1999; Carlson et al., 2001)). Unlike spelling errors that result in non-words and are easy to detect, context-sensitive spelling correction task involves correcting spelling errors that result in legitimate words, such as confusing *peace* and *piece* or *your* and *you're*. The typical training paradigm for these context-sensitive ambiguities is to use text assumed to be error free, replacing each target word occurrence (e.g. *peace*) with a *confusion set* consisting of, say {*peace, piece*}, thus generating both positive and negative examples, respectively, from the same context.

This paper proposes a novel error generation approach to the problem of training classifiers for the purpose of detecting and correcting grammar and usage errors in text. Unlike previous work (e.g., (Sjöbergh and Knutsson, 2005; Brockett et al., 2006; Foster and Andersen, 2009)), we selectively introduce mistakes in an appropriate proportion. In particular, to create training data that closely resemble text with naturally occurring errors, we use error frequency information and error distribution statistics obtained from corrected non-native text. We apply the method to the problem of detecting and correcting article mistakes made by learners of English as a Second Language (ESL).

The problem of correcting article errors is generally viewed as that of article *selection*, cast as a classification problem and is trained as described above: a machine learning algorithm is used to train a classifier on native English data, where the possible selections are used to generate positive and negative

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 154–162,
Los Angeles, California, June 2010.

examples (e.g., (Izumi et al., 2003; Han et al., 2006; De Felice and Pulman, 2008; Gamon et al., 2008)). The classifier is then applied to non-native text to predict the correct article in context. But the article *correction* problem differs from the problem of article selection in that we know the original (*source*) article that the writer used. When proposing a correction, we would like to use information about the original article. One reason for this is that about 90% of articles are used correctly by ESL learners; this is higher than the performance of state-of-the-art classifiers for article selection. Consequently, not using the writer's article, when making a prediction, may result in making more mistakes than there are in the data. Another reason is that statistics on article errors (e.g., (Han et al., 2006; Lee and Seneff, 2008)) and in the annotation performed for the present study reveal that non-native English speakers make article mistakes in a consistent manner.

The system can consider the article used by the writer at evaluation time, by proposing a correction only when the confidence of the classifier is high enough, but the article cannot be used in training if the classifier is trained on clean native data that do not have errors. Learning Theory says that the distribution of examples seen in testing should be as similar as possible to the one seen in training, so one would like to train on errors similar to those observed in testing. Ideally, we would like to train using corrected non-native text. In that case, the original article of the writer can be used as a feature for the classifier and the correct article, as judged by a native English speaker, will be viewed as the label. However, obtaining annotated data for training is expensive and, since the native training data do not contain errors, we cannot use the writer's article as a feature for the classifier.

This paper compares the traditional training paradigm that uses native data to training paradigms that use data with artificial mistakes. We propose several methods of generating mistakes in native training data and demonstrate that they outperform the traditional training paradigm. We also show that the most successful error generation methods use knowledge about the article distribution and error patterns observed in the ESL data.

The rest of the paper is organized as follows. First, we discuss the baseline on the error correction task and show why the baselines used in selection tasks are not relevant for the error correction task. Next, we describe prior work in error generation and show the key difference of our approach. Section 4 presents the ESL data that we use and statistics on article errors. Section 5 describes training paradigms that employ error generation. In Sections 6 and 7 we present the results and discuss the results. The key findings are summarized in Table 7 in Section 6. We conclude with a brief discussion of directions for future work.

2 Measuring Success in Error Correction Tasks

The distinction between the selection and the error correction tasks alluded to earlier is important not only for training but also in determining an appropriate evaluation method.

The standard baseline used in selection tasks is the relative frequency of the most common class. For example, in word sense disambiguation, the baseline is the most frequent sense. In the task of article selection, the standard baseline used is to predict the article that occurs most frequently in the data (usually, it is the *zero* article, whose frequency is 60-70%). In this context, the performance of a state-of-the-art classifier (Knight and Chander, 1994; Minnen et al., 2000; Turner and Charniak, 2007; Gamon et al., 2008) whose accuracy is 85-87% is a significant improvement over the baseline. The majority has been used as the baseline also in the context-sensitive spelling task (e.g., (Golding and Roth, 1999)).

However, in article correction, spelling correction, and other text correction applications the split of the classes is not an appropriate baseline since the majority of the words in the confusion set are used correctly in the text. Han et al. (2006) report an average error rate of 13% on article data from TOEFL essays, which gives a baseline of 87%, versus the baseline of 60-70% used in the article selection task. Statistics on article mistakes in our data suggest a baseline of about 90%, depending on the source language of the writer. So the real baseline on the task is ”do nothing”. Therefore, to determine the baseline for a correction task, one needs to consider the error rate in the data.

Using the definitions of precision and recall and the "real" baseline, we can also relate the resulting accuracy of the classifier to the precision and recall on an error correction task as follows: Let P and R denote the precision and recall, respectively, of the system on an error correction task, and $Base$ denote the error rate in the data. Then the task baseline (i.e., accuracy of the data before running the system) is:

$$Baseline = 1 - Base$$

It can be shown that the error rate after running the classifier is:

$$Error = \frac{Base * (P + R - 2RP)}{P}$$

It follows that the accuracy of the system on the task is $1 - Error$.

For example, we can obtain a rough estimate on the accuracy of the system in Han et al. (2006), using precision and recall numbers by error type. Excluding the error type of category *other*, we can estimate that $Base = 0.1$, so the baseline is 0.9, average precision and recall are 0.85 and 0.25, respectively, and the resulting overall accuracy of the system is 92.2%.

3 Related Work

3.1 Generating Errors in Text

In text correction, adding mistakes in training has been explored before. Although the general approach has been to produce errors similar to those observed in the data to be corrected, mistakes were added in an ad-hoc way, without respecting the error frequencies and error patterns observed in non-native text. Izumi et al. (2003) train a maximum entropy model on error-tagged data from the Japanese Learners of English corpus (JLE, (Izumi et al., 2004)) to detect 8 error types in the same corpus. They show improvement when the training set is enhanced with sentences from the same corpus to which artificial article mistakes have been added. Though it is not clear in what proportion mistakes were added, it is also possible that the improvement was due to a larger training set. Foster and Andersen (2009) attempt to replicate naturally occurring learner mistakes in the Cambridge Learner Corpus (CLC)[1], but show a drop in accuracy when the original error-tagged data in training are replaced with corrected CLC sentences containing artificial errors.

Brockett et al. (2006) generate mass noun errors in native English data using relevant examples found in the Chinese Learners English Corpus (CLEC, (Gui and Yang, 2003)). Training data consist of an equal number of correct and incorrect sentences. Sjöbergh and Knutsson (2005) introduce split compound and agreement errors into native Swedish text: agreement errors are added in every sentence and for compound errors, the training set consists of an equal number of negative and positive examples. Their method gives higher recall at the expense of lower precision compared to rule-based grammar checkers.

To sum up, although the idea of using data with artificial mistakes is not new, the advantage of training on such data has not been investigated. Moreover, training on error-tagged data is currently unrealistic in the majority of error correction scenarios, which suggests that using text with artificial mistakes is the only alternative to using clean data. However, it has not been shown whether training on data with artificial errors is beneficial when compared to utilizing clean data. More importantly, error statistics have not been considered for error correction tasks. Lee and Seneff (2008) examine statistics on article and preposition mistakes in the JLE corpus. While they do not suggest a specific approach, they hypothesize that it might be helpful to incorporate this knowledge into a correction system that targets these two language phenomena.

3.2 Approaches to Detecting Article Mistakes

Automated methods for detecting article mistakes generally use a machine learning algorithm. Gamon et al. (2008) use a decision tree model and a 5-gram language model trained on the English Gigaword corpus (LDC2005T12) to correct errors in English article and preposition usage. Han et al. (2006) and De Felice and Pulman (2008) train a maximum entropy classifier. Yi et al. (2008) propose a web count-based system to correct determiner errors. In the above approaches, the classifiers are trained on native data. Therefore the classifiers cannot use the

[1] http://www.cambridge.org/elt

original article that the writer used as a feature. Han et al. (2006) use the *source* article at evaluation time and propose a correction only when the score of the classifier is high enough, but the *source* article is not used in training.

4 Article Errors in ESL Data

Article errors are one of the most common mistakes that non-native speakers make, especially those whose native language does not have an article system. For example, Han et al. (2006) report that in the annotated TOEFL data by Russian, Chinese, and Japanese speakers 13% of all noun phrases have an incorrect article. It is interesting to note that article errors are present even with very advanced speakers. While the TOEFL data include essays by students of different proficiency levels, we use data from very advanced learners and find that error rates on articles are similar to those reported by Han et al. (2006).

We use data from speakers of three first language backgrounds: Chinese, Czech, and Russian. None of these languages has an article system. The Czech and the Russian data come from the ICLE corpus (Granger et al., 2002), which is a collection of essays written by advanced learners of English. The Chinese data is a part of the CLEC corpus that contains essays by students of all levels of proficiency.

4.1 Data Annotation

A portion of data for each source language was corrected and error-tagged by native speakers. The annotation was performed at the sentence level: a sentence was presented to the annotator in the context of the entire essay. Essay context can become necessary, when an article is acceptable in the context of a sentence, but is incorrect in the context of the essay. Our goal was to correct all article errors, including those that, while acceptable in the context of the sentence, were not correct in the context of the essay. The annotators were also encouraged to propose more than one correction, as long as all of their suggestions were consistent with the essay context.

The annotators were asked to correct all mistakes in the sentence. The annotation schema included the following error types: mistakes in article and preposition usage, errors in *noun number*, *spelling*, *verb form*, and *word form*[2]. All other corrections were marked as *word replacement*, *word deletion*, and *word insertion*. For details about annotation and data selection, please refer to the companion paper (Rozovskaya and Roth, 2010).

4.2 Statistics on Article Errors

Traditionally, three article classes are distinguished: *the*, *a*(*an*)[3] and *None* (no article). The training and the test data are thus composed of two types of events:

1. All articles in the data

2. Spaces in front of a noun phrase if that noun phrase does not start with an article. To identify the beginning of a noun phrase, we ran a part-of-speech tagger and a phrase chunker[4] and excluded all noun phrases not headed[5] by a personal or demonstrative pronoun.

Table 1 shows the size of the test data by source language, proportion of errors and distribution of article classes before and after annotation and compares these distributions to the distribution of articles in English Wikipedia. The distribution before annotation shows statistics on article usage by the writers and the distribution after annotation shows statistics after the corrections made by the annotators were applied. As the table shows, the distribution of articles is quite different for native data (Wikipedia) and non-native text. In particular, non-native data have a lower proportion of *the*.

The annotation statistics also reveal that learners do not confuse articles randomly. From Table 2, which shows the distribution of article errors by type, we observe that the majority of mistakes are omissions and extraneous articles. Table 3 shows statistics on corrections by *source* and *label*, where *source* refers to the article used by the writer, and *label* refers to the article chosen by the annotator. Each entry in the table indicates $Prob(source =$

[2] Our classification, was inspired by the classification presented in Tetreault and Chodorow (2008)

[3] Henceforth, we will use *a* to refer to both *a* and *an*

[4] The tagger and the chunker are available at `http://L2R.cs.uiuc.edu/~cogcomp/software.php`

[5] We assume that the last word of the noun phrase is its head.

Source language	Number of test examples	Proportion of errors	Errors total	Article distribution	Classes		
					a	*the*	*None*
Chinese	1713	9.2%	158	Before annotation	8.5	28.2	63.3
				After annotation	9.9	24.9	65.2
Czech	1061	9.6%	102	Before annotation	9.1	22.9	68.0
				After annotation	9.9	22.3	67.8
Russian	2146	10.4%	224	Before annotation	10.5	21.7	67.9
				After annotation	12.5	20.1	67.4
English Wikipedia					9.6	29.1	61.4

Table 1: Statistics on articles in the annotated data before and after annotation.

Source language	Proportion of errors in the data	Errors total	Errors by Type			
			Extraneous	Missing a	Missing the	Confusion
Chinese	9.2%	158	57.0%	13.3%	22.8%	7.0%
Czech	9.6%	102	45.1%	14.7%	33.3%	6.9%
Russian	10.4%	224	41.5%	20.1%	25.5%	12.3%

Table 2: Distribution of article errors in the annotated data by error type. *Extraneous* refers to using *a* or *the* where *None* (no article) is correct. *Confusion* is using *a* instead of *the* or vice versa.

Label	Source language	Source		
		a	*the*	*None*
a	Chinese	81.7%	5.9%	12.4%
	Czech	81.0%	4.8%	14.3%
	Russian	75.3%	7.9%	16.9%
the	Chinese	0.2%	91.3%	8.5%
	Czech	0.9%	84.7%	14.4%
	Russian	1.9%	84.9%	13.2%
None	Chinese	0.6%	7.4%%	92.0%
	Czech	1.3%	5.2%	93.6%
	Russian	1.0%	5.4%%	93.6%

Table 3: Statistics on article corrections by the original article (*source*) and the annotator's choice (*label*). Each entry in the table indicates $Prob(source = s|label = l)$ for each article pair.

$s|label = l$) for each article pair. We can also observe specific error patterns. For example, *the* is more likely than *a* to be used superfluously.

5 Introducing Article Errors into Training Data

This section describes experiments with error generation methods. We conduct four sets of experiments. Each set differs in how article errors are generated in the training data. We now give a description of error generation paradigms in each experimental set.

5.1 Methods of error generation

We refer to the article that the writer used in the ESL data as *source*, and *label* refers to the article that the annotator chose. Similarly, when we introduce errors into the training data, we refer to the original article as *label* and to the replacement as *source*. This is because the original article is the correct article choice, and the replacement that the classifier will see as a feature can be an error. We call this feature *source* feature. In other words, both for training (native data) and test (ESL data), *source* denotes the form that the classifier sees as a feature (which could be an error) and *label* denotes the correct article. Below we describe how errors are generated in each set of experiments.

Method 1: General With probability x each article in the training data is replaced with a different article uniformly at random, and with probability $(1 - x)$ it remains unchanged. We build six classifiers, where $x \in \{5\%, 10\%, 12\%, 14\%, 16\%, 18\%\}$. We call this method *general* since it uses no information about article distribution in the ESL data.

Method 2: ArticleDistrBeforeAnnot We use the distribution of articles in the ESL data before the annotation to change the distribution of articles in the training. Specifically, we change the articles so that their distribution approximates the distribution of articles in the ESL data. For example, the relative frequency of *the* in English Wikipedia data is 29.1%, while in the writing by Czech speakers it is 22.3%. It should be noted that this method changes the distribution only of source articles, but the distribution of labels is not affected. An additional constraint that we impose is the minimum error rate r for each article class, so that $Prob(s|l) \geq r \; \forall l \in labels$. In this fashion, for each source language we train four classifiers, where we use article distribution from Chinese, Czech, and Russian, and where we set the minimum error rate r to be $\in \{2\%, 3\%, 4\%, 5\%\}$.

Method 3: ArticleDistrAfterAnnot This method is similar to the one above but we use the distribution of articles in the ESL data after the corrections have been made by the annotators.

Method 4: ErrorDistr This method uses information about error patterns in the annotated ESL data. For example, in the Czech annotated subcorpus, label *the* corresponds to source *the* in 85% of the cases and corresponds to source *None* in 14% of the cases. In other words, in 14% of the cases where the article *the* should have been used, the writer used no article at all. Thus, with probability 14% we change *the* in the training data to *None*.

6 Experimental Results

In this section, we compare the quality of the system trained on clean native English data to the quality of the systems trained on data with errors. The errors were introduced into the training data using error generation methods presented in Section 5.

In each training paradigm, we follow a discriminative approach, using an online learning paradigm and making use of the Averaged Perceptron Algorithm (Freund and Schapire, 1999) implemented within the Sparse Network of Winnow framework (Carlson et al., 1999) – we use the regularized version in Learning Based Java[6] (LBJ, (Rizzolo and Roth, 2007)). While classical Perceptron comes with generalization bound related to the margin of the data, Averaged Perceptron also comes with a PAC-like generalization bound (Freund and Schapire, 1999). This linear learning algorithm is known, both theoretically and experimentally, to be among the best linear learning approaches and is competitive with SVM and Logistic Regression, while being more efficient in training. It also has been shown to produce state-of-the-art results on many natural language applications (Punyakanok et al., 2008).

Since the methods of error generation described in Section 5 rely on the distribution of articles and article mistakes and these statistics are specific to the first language of the writer, we conduct evaluation separately for each source language. Thus, for each language group, we train five system types: one system is trained on clean English data without errors (the same classifier for the three language groups) and four systems are trained on data with errors, where errors are produced using the four methods described in Section 5. Training data are extracted from English Wikipedia.

All of the five systems employ the same set of features based on three tokens to the right and to the left of the target article. For each context word, we use its relative position, its part-of-speech tag and the word token itself. We also use the head of the noun phrase and the conjunctions of the pairs and triples of the six tokens and their part-of-speech tags[7]. In addition to these features, the classifiers trained on data with errors also use the *source* article as a feature. The classifier that is trained on clean English data cannot use the *source* feature, since in training the *source* always corresponds to the *label*. By contrast, when the training data contain mistakes, the *source* is not always the same as the *label*, the situation that we also have with the test (ESL) data.

We refer to the classifier trained on clean data as $TrainClean$. We refer to the classifiers trained on data with mistakes as TWE (TrainWithErrors). There are four types of TWE systems for each language group, one for each of the methods of error generation described in Section 5. All results are the averaged results of training on three random samples from Wikipedia with two million training examples on each round. All five classifiers are trained on exactly the same set of Wikipedia examples, except that we add article mistakes to the data used by the TWE systems. The $TrainClean$ system achieves an accuracy of 87.10% on data from English Wikipedia. This performance is state-of-the-

[6] LBJ code is available at `http://L2R.cs.uiuc.edu/~cogcomp/asoftware.php?skey=LBJ`

[7] Details about the features are given in the paper's web page, accessible from `http://L2R.cs.uiuc.edu/~cogcomp/`

art compared to other systems reported in the literature (Knight and Chander, 1994; Minnen et al., 2000; Turner and Charniak, 2007; Han et al., 2006; De Felice and Pulman, 2008). The best results of 92.15% are reported by De Felice and Pulman (2008). But their system uses sophisticated syntactic features and they observe that the parser does not perform well on non-native data.

As mentioned in Section 4, the annotation of the ESL data consisted of correcting all errors in the sentence. We exclude from evaluation examples that have spelling errors in the 3-word window around the target article and errors on words that immediately precede or immediately follow the article, as such examples would obscure the evaluation of the training paradigms.

Tables 4, 5 and 6 show performance by language group. The tables show the accuracy and the error reduction on the test set. The results of systems TWE (methods 2 and 3) that use the distribution of articles before and after annotation are merged and appear as $ArtDistr$ in the tables, since, as shown in Table 1, these distributions are very similar and thus produce similar results. Each table compares the performance of the $TrainClean$ system to the performance of the four systems trained on data with errors.

For all language groups, all classifiers of type TWE outperform the $TrainClean$ system. The reduction in error rate is consistent when the TWE classifiers are compared to the $TrainClean$ system.

Table 7 shows results for all three languages, comparing for each language group the $TrainClean$ classifier to the best performing system of type TWE.

Training paradigm	**Errors in training**	**Accuracy**	**Error reduction**
$TrainClean$	0.0%	91.85%	-2.26%
$TWE(General)$	10.0%	92.57%	6.78%
$TWE(ArtDistr)$	13.2%	92.67%	**8.33%**
$TWE(ErrorDistr)$	9.2%	92.31%	3.51%
Baseline		92.03%	

Table 4: **Chinese speakers**: Performance of the $TrainClean$ system (without errors in training) and of the best classifiers of type TWE. Rows 2-4 show the performance of the systems trained with error generation methods described in 5. *Error reduction* denotes the percentage reduction in the number of errors when compared to the number of errors in the ESL data.

Training paradigm	**Errors in training**	**Accuracy**	**Error reduction**
$TrainClean$	0.0%	91.82%	10.31%
$TWE(General)$	18.0%	92.22%	**14.69%**
$TWE(ArtDistr)$	21.6%	92.00%	12.28%
$TWE(ErrorDistr)$	10.2%	92.15%	13.93%
Baseline		90.88%	

Table 5: **Czech speakers**: Performance of the $TrainClean$ system (without errors in training) and of the best classifiers of type TWE. Rows 2-4 show the performance of the systems trained with error generation methods described in 5. *Error reduction* denotes the percentage reduction in the number of errors when compared to the number of errors in the ESL data.

Training paradigm	**Errors in training**	**Accuracy**	**Error reduction**
$TrainClean$	0.0%	90.62%	5.92%
$TWE(General)$	14.0%	91.25%	12.24%
$TWE(ArtDistr)$	18.8%	91.52%	14.94%
$TWE(ErrorDistr)$	10.7%	91.63%	**16.05%**
Baseline		90.03%	

Table 6: **Russian speakers**: Performance of the $TrainClean$ system (without errors in training) and of the best classifiers of type TWE. Rows 2-4 show the performance of the systems trained with error generation methods described in 5. *Error reduction* denotes the percentage reduction in the number of errors when compared to the number of errors in the ESL data.

7 Discussion

As shown in Section 6, training a classifier on data that contain errors produces better results when compared to the $TrainClean$ classifier trained on clean native data. The key results for all language groups are summarized in Table 7. It should be noted that the $TrainClean$ system also makes use of the article chosen by the author through a confidence threshold[8]; it prefers to keep the article chosen by the user. The difference is that the $TrainClean$ system does not consider the author's article in training. The results of training with error generation are better, which shows that training on automatically corrupted data indeed helps. While the performance is different by language group, there is an observable reduction in error rate for each language group when TWE systems are used compared to $TrainClean$ approach. The reduction in error rate

[8] The decision threshold is found empirically on a subset of the ESL data set aside for development.

achieved by the best performing TWE system when compared to the error rate of the $TrainClean$ system is 10.06% for Chinese, 4.89% for Czech and 10.77% for Russian, as shown in Table 7. We also note that the best performing TWE systems for Chinese and Russian speakers are those that rely on the distribution of articles (Chinese) and the distribution of errors (Russian), but for Czech it is the $General$ TWE system that performs the best, maybe because we had less data for Czech speakers, so their statistics are less reliable.

There are several additional observations to be made. First, training paradigms that use error generation methods work better than the training approach of using clean data. Every system of type TWE outperforms the $TrainClean$ system, as evidenced by Tables 4, 5, and 6. Second, the proportion of errors in the training data should be similar to the error rate in the test data. The proportion of errors in training is shown in Tables 4, 5 and 6 in column 2. Furthermore, TWE systems $ArtDistr$ and $ErrorDistr$ that use specific knowledge about article and error distributions, respectively, work better for Russian and Chinese groups than the $General$ method that adds errors to the data uniformly at random. Since $ArtDistr$ and $ErrorDistr$ depend on the statistics of learner mistakes, the success of the systems that use these methods for error generation depends on the accuracy of these statistics, and we only have between 100 and 250 errors for each language group. It would be interesting to see whether better results can be achieved with these methods if more annotated data are available. Finally, for the same reason, there is no significant difference in the performance of methods $ArtDistrBeforeAnnot$ and $ArtDistrAfterAnnot$: With small sizes of annotated data there is no difference in article distributions before and after annotation.

8 Conclusion and Future Work

We have shown that error correction training paradigms that introduce artificial errors are superior to training classifiers on clean data. We proposed several methods of error generation that account for error frequency information and error distribution statistics from non-native text and demonstrated that the methods that work best are those that result in a training corpus that statistically resembles the non-native text. Adding information about article distribution in non-native data and statistics on specific error types is even more helpful.

Source language	**Accuracy**		**Error reduction**
	$Train\ Clean$	TWE	
Chinese	91.85%	92.67%	**10.06%**
Czech	91.82%	92.22%	**4.89%**
Russian	90.62%	91.63%	**10.77%**

Table 7: **Improvement due to training with errors**. For each source language, the last column of the table shows the reduction in error rate achieved by the best performing TWE system when compared to the error rate of the $TrainClean$ system. The error rate for each system is computed by subtracting the accuracy achieved by the system, as shown in columns 2 and 3.

We have also argued that the baselines used earlier in the relevant literature – all based on the majority of the most commonly used class – suit selection tasks, but are inappropriate for error correction. Instead, the error rate in the data should be taken into account when determining the baseline.

The focus of the present study was on training paradigms. While it is quite possible that the article correction system presented here can be improved – we would like to explore improving the system by using a more sophisticated feature set – we believe that the performance gap due to the error driven training paradigms shown here will remain. The reason is that even with better features, some of the features that hold in the native data will not be active in in the ESL writing.

Finally, while this study focused on the problem of correcting article mistakes, we plan to apply the proposed training paradigms to similar text correction problems.

Using Mostly Native Data to Correct Errors in Learners' Writing: A Meta-Classifier Approach

Michael Gamon
Microsoft Research

mgamon@microsoft.com

Abstract

We present results from a range of experiments on article and preposition error correction for non-native speakers of English. We first compare a language model and error-specific classifiers (all trained on large English corpora) with respect to their performance in error detection and correction. We then combine the language model and the classifiers in a meta-classification approach by combining evidence from the classifiers and the language model as input features to the meta-classifier. The meta-classifier in turn is trained on error-annotated learner data, optimizing the error detection and correction performance on this domain. The meta-classification approach results in substantial gains over the classifier-only and language-model-only scenario. Since the meta-classifier requires error-annotated data for training, we investigate how much training data is needed to improve results over the baseline of not using a meta-classifier. All evaluations are conducted on a large error-annotated corpus of learner English.

1 Introduction

Research on the automatic correction of grammatical errors has undergone a renaissance in the past decade. This is, at least in part, based on the recognition that non-native speakers of English now outnumber native speakers by 2:1 in some estimates, so any tool in this domain could be of tremendous value. While earlier work in both native and non-native error correction was focused on the construction of grammars and analysis systems to detect and correct specific errors (see Heift and Schulze, 2005 for a detailed overview), more recent approaches have been based on data-driven methods.

The majority of the data-driven methods use a classification technique to determine whether a word is used appropriately in its context, continuing the tradition established for contextual spelling correction by Golding (1995) and Golding and Roth (1996). The words investigated are typically articles and prepositions. They have two distinct advantages as the subject matter for investigation: They are a closed class and they comprise a substantial proportion of learners' errors. The investigation of preposition corrections can even be narrowed further: amongst the more than 150 English prepositions, the usage of the ten most frequent prepositions accounts for 82% of preposition errors in the 20 million word *Cambridge University Press Learners' Corpus*. Learning correct article use is most difficult for native speakers of an L1 that does not overtly mark definiteness and indefiniteness as English does. Prepositions, on the other hand, pose difficulties for language learners from all L1 backgrounds (Dalgish, 1995; Bitchener et al., 2005).

Contextual classification methods represent the context of a preposition or article as a feature vector gleaned from a window of a few words around the preposition/article. Different systems typically vary along three dimensions: choice of features, choice of classifier, and choice of training data. Features range from words and morphological information (Knight and Chander, 1994) to the inclusion of part-of-speech tags (Minnen et al., 2000; Han et al., 2004, 2006; Chodorow et al., 2007; Gamon et al., 2008, 2009; Izumi et al., 2003, 2004; Tetrault and Chodorow, 2008) to features based on linguistic analysis and on WordNet (Lee, 2004; DeFelice and Pulman, 2007, 2008). Knight and Chander (1994) and Gamon et al. (2008) used decision tree classifiers but, in general, maximum entropy classifiers have become the classification

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 163–171,
Los Angeles, California, June 2010.

algorithm of choice. Training data are normally drawn from sizeable corpora of native English text (*British National Corpus* for DeFelice and Pulman (2007, 2008), *Wall Street Journal* in Knight and Chander (1994), a mix of *Reuters* and *Encarta* in Gamon et al. (2008, 2009). In order to partially address the problem of domain mismatch between learners' writing and the news-heavy data sets often used in data-driven NLP applications, Han et al. (2004, 2006) use 31.5 million words from the MetaMetrics corpus, a diverse corpus of fiction, non-fiction and textbooks categorized by reading level.

In addition to the classification approach to error detection, there is a line of research - going back to at least Atwell (1987) - that uses language models. The idea here is to detect errors in areas where the language model score is suspiciously low. Atwell (1987) uses a part-of-speech tag language model to detect errors, Chodorow and Leacock (2000) use mutual information and chi square statistics to identify unlikely function word and part-of-speech tag sequences, Turner and Charniak (2007) employ a language model based on a generative statistical parser, and Stehouwer and van Zaanen (2009) investigate a diverse set of language models with different backoff strategies to determine which choice, from a set of confusable words, is most likely in a given context. Gamon et al. (2008, 2009) use a combination of error-specific classifiers and a large generic language model with hand-tuned heuristics for combining their scores to maximize precision. Finally, Yi et al. (2008) and Hermet et al. (2008) use n-gram counts from the web as a language model approximation to identify likely errors and correction candidates.

2 Our Approach

We combine evidence from the two kinds of data-driven models that have been used for error detection and correction (error-specific classifiers and a language model) through a meta-classifier. We use the term *primary models* for both the initial error-specific classifiers and a large generic language model. The *meta-classifier* takes the output of the primary models (language model scores and class probabilities) as input. Using a meta-classifier for ensemble learning has been proven effective for many machine learning problems (see e.g. Dietterich 1997), especially when the combined models are sufficiently different to make distinct kinds of errors. The meta-classification approach also has an advantage in terms of data requirements: Our primary models are trained on large sets of widely available well-formed English text. The meta-classifier, in contrast, is trained on a smaller set of error-annotated learner data. This allows us to address the problem of domain mismatch: We can leverage large well-formed data sets that are substantially different from real-life learner language for the primary models, and then fine-tune the output to learner English using a much smaller set of expensive and hard-to-come-by annotated learner writing.

For the purpose of this paper, we restrict ourselves to article and preposition errors. The questions we address are:

1. How effective is the meta-classification approach compared to either a classifier or a language model alone?
2. How much error-annotated data are sufficient to produce positive results above the baseline of using either a language model or a classifier alone?

Our evaluation is conducted on a large data set of error-annotated learner data.

3 Experimental Design

3.1 Primary Models

Our error-specific primary models are maximum entropy classifiers (Rathnaparki 1997) for articles and for prepositions. Features include contextual features from a window of six tokens to the right and left, such as lexical features (word), part-of-speech tags, and a handful of "custom features", for example lexical head of governing VP or governed NP (as determined by part-of-speech-tag based heuristics). For both articles and prepositions, we employ two classifiers: the first determines the probability that a preposition/article is present in a given context (*presence classifier*), the second classifier determines the probability that a specific article or preposition is chosen (*choice classifier*). A training event for the presence classifier is any noun phrase boundary that is a potential location for a preposition or article. Whether a location is an NP boundary and a potential site for an article/preposition is determined by a simple heuristic based on part-of-speech tags.

The candidates for article choice are *the* and *a/an*, and the choice for prepositions is limited to twelve very frequent prepositions (*in, at, on, for, since, with, to, by, about, from, of, as*) which account for 86.2 % of preposition errors in our learner data. At prediction time, the presence and choice classifiers produce a list of potential changes in preposition/article usage for the given context. Since the application of our system consists of suggesting corrections to a user, we do not consider identity operations where the suggested word choice equals the actual word choice. For a potential preposition/article location where there is no preposition/article, each of the candidates is considered for an insertion operation. For a potential location that contains a preposition/article, the possible operations include deletion of the existing token or substitution with another preposition/article from the candidate set. Training data for the classifiers is a mix of primarily well-formed data sources: There are about 2.5 million sentences, distributed roughly equally across *Reuters* newswire, *Encarta* encyclopedia, UN proceedings, *Europarl* and web-scraped general domain data[1]. From the total set of candidate operations (substitutions, insertions, and deletions) that each combination of presence and choice classifier produces for prepositions, we consider only the top three highest-scoring operations[2].

Our language model is trained on the *Gigaword* corpus (Linguistic Data Consortium, 2003) and utilizes 7-grams with absolute discount smoothing (Gao, Goodman, and Miao, 2001; Nguyen, Gao, and Mahajan, 2007). Each suggested revision from the preposition/article classifiers (top three for prepositions, all revisions from the article classifiers) are scored by the language model: for each revision, the language model score of the original and the suggested rewrite is recorded, as is the language model entropy (defined as the language model probability of the sentence, normalized by sentence length).

3.2 Meta-Classifier

For the meta-classifier we chose to use a decision tree, trained with the WinMine toolkit (Chickering 2002). The motivation for this choice is that decision trees are well-suited for continuously valued features and for non-linear decision surfaces. An obvious alternative would be to use a support vector machine with non-linear kernels, a route that we have not explored yet. The feature set for the meta-classifier consists of the following scores from the primary models, including some arithmetic combinations of scores:

- Ratio and delta of Log LM score of the original word choice and the suggested revision (2 features)
- Ratio and delta of the LM entropy for original and suggested revision (2 features).
- Products of the above ratios/deltas and classifier choice/presence probabilities
- Type of operation: deletion, insertion, substitution (3 features)
- P(presence) (1 feature)
- For each preposition/article choice: P(choice): 13 features for prepositions (12 prepositions and *other* for a preposition not in that set), 2 for articles
- Original token: *none* (for insertion) or the original preposition/article (13 features for prepositions, 2 for articles)
- Suggested token: *none* (for deletion) or the suggested preposition/article (13 features for prepositions, 2 for articles)

The total number of features is 63 for prepositions and 36 for articles.

The meta-classifier is trained by collecting suggested corrections from the primary models on the error annotated data. The error-annotation provides the binary class label, i.e. whether the suggested revision is correct or incorrect. If the suggested revision matches an annotated correction, it counts as correct, if it does not match it counts as incorrect. To give an example, the top three preposition operations for the position before *this test* in the sentence *I rely to this test* are:

Change_to_on
Delete_to
Change_to_of

The class label in this example is "suggestion correct", assuming that the change of preposition is

[1] We are not able to train the error-specific classifiers on a larger data set like the one we use for the language model. Note that the 2.5 million sentences used in the classifier training already produce 16.5 million training vectors.

[2] This increases runtime performance because fewer calls need to be made to the language model which resides on a server. In addition, we noticed that overall precision is increased by not considering the less likely suggestions by the classifier.

annotated in the data. The operation *Change_to_on* in this example has the following feature values for the basic classifier and LM scores:

classifier P(choice): 0.755
classifier P(presence): 0.826
LM logP(original): -17.373
LM logP(rewrite): -14.184

An example of a path through the decision tree meta-classifier for prepositions is:

LMLogDelta is Not < -8.59 and
LMLogDelta is Not < -3.7 and
ProductRewriteLogRatioConf is Not < -0.00115 and
LMLogDelta is Not < -1.58 and
ProductOrigEntropyRatioChoiceConf is Not < -0.00443 and
choice_prob is Not < 0.206 and
Original_of is 0 and
choice_prob is Not < 0.329 and
to_prob is < 0.108 and
Suggested_on is 1 and
Original_in is 0 and
choice_prob is Not < 0.497 and
choice_prob is Not < 0.647 and
presence_prob is Not < 0.553

The leaf node at the end of this path has a 0.21 probability of changing “*to*” to “*on*” being a correct rewrite suggestion.

The features selected by the decision trees range across all of the features discussed above. For both the article and preposition meta-classifiers, the ranking of features by importance (as measured by how close to the root the decision tree uses the feature) follows the order in which features are listed.

3.3 Data

In contrast to the training data for the primary models, the meta-classifier is trained on error-annotated data from the *Cambridge University Press Learners’ Corpus* (CLC). The version of CLC that we have licensed currently contains a total of 20 million words from learner English essays written as part of one of *Cambridge’s English Language Proficiency Tests* (ESOL) – at all proficiency levels. The essays are annotated for error type, erroneous span and suggested correction.

We first perform a random split of the essays into 70% training, 20% test and 10% for parameter tuning. Next, we create error-specific training, tuning and test sets by performing a number of clean-up steps on the data. First, we correct all errors that were flagged as being spelling errors, since we presume that the user will perform a spelling check on the data before proceeding to grammatical proofing. Spelling errors that were flagged as morphology errors were left alone. By the same token, we corrected confused words that are covered by MS Word. We then revised British English spelling to American English spelling conventions. In addition, we eliminated all annotations for non-pertinent errors (i.e., non-preposition/article errors, or errors that do not involve any of the targeted prepositions), but we maintained the original (erroneous) text for these. This makes our task harder since we will have to learn how to make predictions in text containing multiple errors, but it also is a more realistic scenario given real learner writing. Finally, we eliminated sentences containing nested errors and immediately adjacent errors when they involve pertinent (preposition/article) errors. For example, an annotated error "*take a picture*" with the correction "*take pictures*" is annotated as two consecutive errors: "delete *a*" and "rewrite *picture* as *pictures*". Since the error involves operations on both the article and the noun, which our article correction module is not designed to cover, we eliminated the sentence from the data. (This last step eliminated 31% of the sentences annotated with preposition errors and 29% or the sentences annotated with article errors.) Sentences that were flagged for a replacement error but contained no replacement were also eliminated from the data.

The final training, tuning and test set sizes are as follows (note that for prepositions we had to reduce the size of the training set by an additional 20% in order to avoid memory limitations of our decision tree tools).

Prepositions:
train: 584,485 sentences, 68,806 prep errors
tuning: 105,166 sentences, 9918 prep errors
test: 208,724 sentences, 19,706 prep errors

Articles:
train: 737,091 sentences, 58,356 article errors
tuning: 106,052 sentences, 8341 article errors
test: 210,577 sentences, 16,742 article errors

This mix is strongly biased towards “correct” usage. After all, there are many more correct uses of articles and prepositions in the CLC data than incorrect ones. Again, this is likely to make our task harder, but more realistic, since both at training and test time we are working with the error distribution that is observed in learner data.

3.4 Evaluation

To evaluate, we run our meta-classifier system on the preposition and article test sets described in above and calculate precision and recall. Precision and recall for the overall system are controlled by thresholding the meta-classifier class probability. As a point of comparison, we also evaluate the performance of the primary models (the error-specific classifier and the language model) in isolation. Precision and recall for the error-specific classifier is controlled by thresholding class probability. To control the precision-recall tradeoff for the language model, we calculate the difference between the log probabilities of the original user input and the suggested correction. We then vary that difference across all observed values in small increments, which affects precision and recall: the higher the difference, the fewer instances we find, but the higher the reliability of these instances is.

This evaluation differs from many of the evaluations reported in the error detection/correction literature in several respects. First, the test set is a broad random sample across all proficiency levels in the CLC data. Second, it is far larger than any sets that have been so far to report results of preposition/article correction on learner data. Finally, we are only considering cases in which the system suggests a correction. In other words, we do not count as correct instances where the system's prediction matches a correct preposition/article.

This evaluation scheme, however, ignores one aspect of a real user scenario. Of all the suggested changes that are counted as wrong in our evaluation because they do not match an annotated error, some may in fact be innocuous or even helpful for a real user. Such a situation can arise for a variety of reasons: In some cases, there are legitimate alternative ways to correct an error. In other cases, the classifier has identified the location of an error although that error is of a different kind (which can be beneficial because it causes the user to make a correction - see Leacock et al., 2009). Gamon et al. (2009), for example manually evaluate preposition suggestions as belonging to one of three categories: (a) properly correcting an existing error, (b) offering a suggestion that neither improves nor degrades the user sentence, (c) offering a suggestion that would degrade the user input. Obviously, (c) is a more serious error than (b). Similarly, Tetrault and Chodorow (2008) annotate their test set with preposition choices that are valid alternatives. We do not have similar information in the CLC data, but we can perform a manual analysis of a random subset of test data to estimate an "upper bound" for our precision/recall curve. Our annotator manually categorized each suggested correction into one of seven categories.

Details of the distribution of suggested corrections into the seven categories are shown in Table 1.

Category	preps.	articles
Corrects a CLC error	32.87%	33.34%
Corrects an error that was not annotated as being that error type in CLC	11.67%	12.16%
Corrects a CLC error, but uses an alternative correction	3.62%	2.26%
Original and suggested correction are equally good	9.60%	11.30%
Error correctly detected, but the correction is wrong	8.73%	5.03%
Identifies an error site, but the actual error is not a preposition error	19.17%	12.64%
Introduces an error	14.65%	23.26%

Table 1: Manual analysis of suggested corrections on CLC data.

This analysis involves costly manual evaluation, so we only performed it at one point of the precision/recall curve (our current runtime system setting). The sample size was 6,000 sentences for prepositions and 5981 sentences for articles (half of the sentences were flagged as containing at least one article/preposition error while the other half were not). On this manual evaluation, we achieve 32.87% precision if we count all flags that do not perfectly match a CLC annotation as a false positive. Only counting the last category (introduction of an error) as a false positive, precision is at 85.34%. Similarly, for articles, the manual estimation arrives at 76.74% precision, where pure CLC annotation matching gives us 33.34%.

4 Results

Figure 1 and Figure 2 show the evaluation results of the meta-classifier for prepositions and articles, compared to the performance of the error-specific classifier and language model alone. For both prepositions and articles, the first notable observation is that the language model outperforms the classifier by a large margin. This came as a surprise to us, given the recent prevalence of classification approaches in this area of research and the fact that our classifiers produce state-of-the art performance when compared to other systems, on well-formed data. Second, the combination of scores from the classifier and language model through a meta-classifier clearly outperforms either one of them in isolation. This result, again, is consistent across prepositions and articles.

We had previously used a hand-tuned score combination instead of a meta-classifier. We also established that this heuristic performs worse than the language model for prepositions, and just about at the same level as the language model for articles. Note, though, that the manual tuning was performed to optimize performance against a different data set (the *Chinese Learners of English Corpus*: CLEC), so the latter point is not really comparable and hence is not included in the charts.

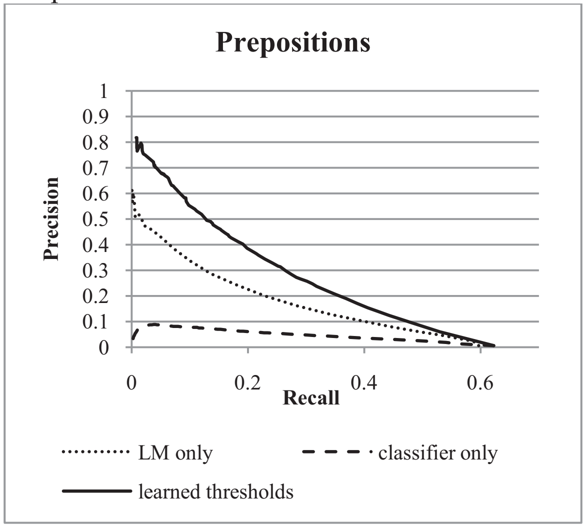

Figure 1: Precision and recall for prepositions.

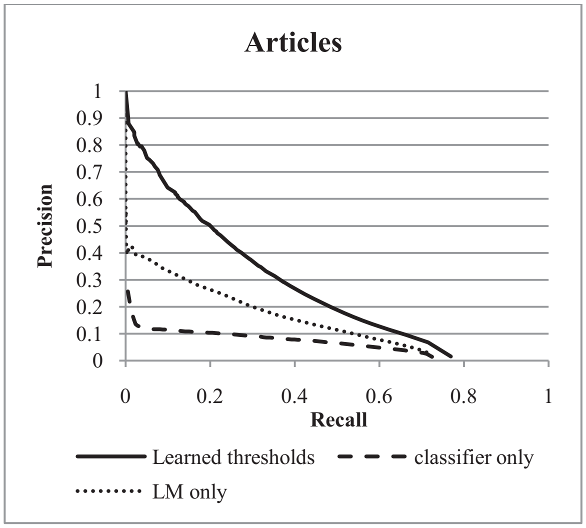

Figure 2: Precision and recall for articles.

We now turn to the question of the required amount of annotated training data for the meta-classifier. CLC is commercially available, but it is obvious that for many researchers such a corpus will be too expensive and they will have to create or license their own error-annotated corpus. Thus the question of whether one could use less annotated data to train a meta-classifier and still achieve reasonable results becomes important. Figure 3 and Figure 4 show results obtained by using decreasing amounts of training data. The dotted line shows the language model baseline. Any result below the language model performance shows that the training data is insufficient to warrant the use of a meta-classifier. In these experiments there is a clear difference between prepositions and articles. We can reduce the amount of training data for prepositions to 10% of the original data and still outperform the language model baseline. 10% of the data corresponds to 6,800 annotated preposition errors and 58,400 sentences. When we reduce the training data to 1% of the original amount (680 annotated errors, 5,800 sentences) we clearly see degraded results compared to the language model. With articles, the system is much less data-hungry. Reducing the training data to 1% (580 annotated errors, 7,400 sentences) still outperforms the language model alone. This result can most likely be explained by the different complexity of the preposition and article tasks. Article operations include only six distinct operations: deletion of *the*, deletion of *a/an*, insertion of *the*, insertion of *a/an*, change of *the* to *a/an*, and change of *a/an* to *the*. For the twelve prepositions that we work with, the total number of insertions, deletions and substitutions that require sufficient training events and might need different score combinations is 168, making the problem much harder.

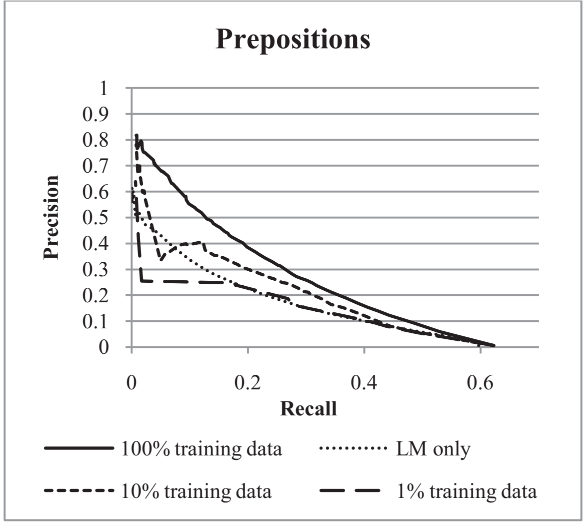

Figure 3: Using different amounts of annotated training data for the preposition meta-classifier.

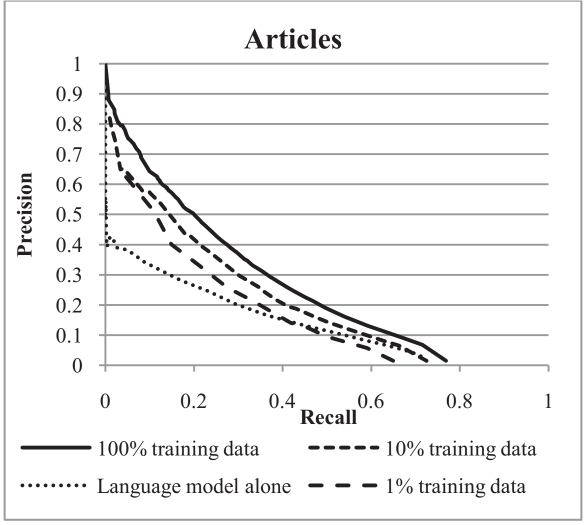

Figure 4: Using different amounts of annotated training data for the article meta-classifier.

To find out if it is possible to reduce the required amount of annotated preposition errors for a system that still covers more than one third of the preposition errors, we ran the same learning curve experiments but now only taking the four most frequent prepositions into account: *to*, *of*, *in*, *for*. In the CLC, these four prepositions account for 39.8% of preposition error flags. As in the previous experiments, however, we found that we are not able to outperform the baseline by using just 1% of annotated data.

5 Error Analysis

We have conducted a failure analysis on examples where the system produces a blatantly bad suggestion in order to see whether this decision could be attributed to the error-specific classifier or to the language model, or both, and what the underlying cause is. This preliminary analysis highlights two common causes for bad flags. One is that of frequent lower order n-grams that dominate the language model score. Consider the CLEC sentence *I get to know the world outside the campus* ***by*** *newspaper and television*. The system suggests deleting *by*. The cause of this bad decision is that the bigram *campus newspaper* is extremely likely, trumping all other n-grams, and leading to a high probability for the suggested string compared to the original: Log (P(original)) = -26.2 and Log (P(suggestion)) = -22.4. This strong imbalance of the language model score causes the meta-classifier to assign a relatively high probability to this being a correct revision, even though the error-specific classifier is on the right track and gives a relatively high probability for the presence of a preposition and the choice of *by*. A similar example, but for substitution, occurs in *They give discounts to their workers* ***on*** *books***.** Here the bigram *in books* has a very high probability and the system incorrectly suggests replacing *on* with *in*. An example for insertion is seen in *Please send me the letter* ***back*** *writing what happened.* Here, the bigram *back to* causes the bad suggestion of inserting *to* after *back*. Since the language model is generally more accurate than the error-specific classifier, the meta-classifier tends to trust its score more than that of the classifier. As a result we see this kind of error quite frequently.

Another common error class is the opposite situation: the language model is on the right track, but the classifier makes a wrong assessment. Consider *Whatever direction my leg fought to stretch*, with the suggested insertion of *on* before *my leg*. Here Log (P(original)) = -31.5 and Log (P(suggestion)) = -32.1, a slight preference for the original string. The error-specific classifier, however, assigns a probability of 0.65 for a preposition to be present, and 0.80 for that preposition to be *on*. The contextual features that are important in that decision are: the insertion site is between a pronoun and a noun, it is relatively close to the beginning of the sentence, and the head of the NP *my leg* has a possible mass noun sense. An example involving deletion is in *Someone came to sort **of** it.* While the language model assigns a high probability for deleting *of,* the error-specific classifier does not. Similarly, for substitution, in *Your experience is very interesting **for** our company,* the language model suggests substituting *for* with *to* while the classifier gives the substitution a very low probability.

As can be seen from the learner sentences cited above, often, even though the sentences are grammatical, they are not idiomatic, which can confuse all of the classifiers.

6 Conclusion and Future Work

We have addressed two questions in this paper:

1. How effective is a meta-classification approach that combines language modeling and error-specific classification to the detection and correction of preposition and article errors by non-native speakers?
2. How much error-annotated data is sufficient to produce positive results using that approach?

We have shown that a meta-classifier approach outperforms using a language model or a classifier alone. An interesting side result is that the language model solidly outperforms the contextual classifier for both article and preposition correction, contrary to current practice in the field. Training data requirements for the meta-classifier vary significantly between article and preposition error detection. The article meta-classifier can be trained with as few as 600 annotated errors, but the preposition meta-classifier requires more annotated data by an order of magnitude. Still, the overall amount of expensive error-annotated data is relatively small, and the meta-classification approach makes it possible to leverage large amounts of well-formed text in the primary models, tuning to the non-native domain in the meta-classifier.

We believe that the logical next step is to combine more primary models in the meta-classifier. Candidates for additional primary models include (1) more classifiers trained either on different data sets or with a different classification algorithm, and (2) more language models, such as skip models or part-of-speech n-gram language models.

Abstract

We propose the first unsupervised approach to the problem of modeling dialogue acts in an open domain. Trained on a corpus of noisy Twitter conversations, our method discovers dialogue acts by clustering raw utterances. Because it accounts for the sequential behaviour of these acts, the learned model can provide insight into the shape of communication in a new medium. We address the challenge of evaluating the emergent model with a qualitative visualization and an intrinsic conversation ordering task. This work is inspired by a corpus of 1.3 million Twitter conversations, which will be made publicly available. This huge amount of data, available only because Twitter blurs the line between chatting and publishing, highlights the need to be able to adapt quickly to a new medium.

1 Introduction

Automatic detection of dialogue structure is an important first step toward deep understanding of human conversations. **Dialogue acts**[1] provide an initial level of structure by annotating utterances with shallow discourse roles such as “statement”, “question” and “answer”. These acts are useful in many applications, including conversational agents (Wilks, 2006), dialogue systems (Allen et al., 2007), dialogue summarization (Murray et al., 2006), and flirtation detection (Ranganath et al., 2009).

Dialogue act tagging has traditionally followed an annotate-train-test paradigm, which begins with the design of annotation guidelines, followed by the collection and labeling of corpora (Jurafsky et al., 1997; Dhillon et al., 2004). Only then can one train a tagger to automatically recognize dialogue acts (Stolcke et al., 2000). This paradigm has been quite successful, but the labeling process is both slow and expensive, limiting the amount of data available for training. The expense is compounded as we consider new methods of communication, which may require not only new annotations, but new annotation guidelines and new dialogue acts. This issue becomes more pressing as the Internet continues to expand the number of ways in which we communicate, bringing us e-mail, newsgroups, IRC, forums, blogs, Facebook, Twitter, and whatever is on the horizon.

Previous work has taken a variety of approaches to dialogue act tagging in new media. Cohen et al. (2004) develop an inventory of dialogue acts specific to e-mail in an office domain. They design their inventory by inspecting a large corpus of e-mail, and refine it during the manual tagging process. Jeong et al. (2009) use semi-supervised learning to transfer dialogue acts from labeled speech corpora to the Internet media of forums and e-mail. They manually restructure the source act inventories in an attempt to create coarse, domain-independent acts. Each approach relies on a human designer to inject knowledge into the system through the inventory of available acts.

As an alternative solution for new media, we propose a series of **unsupervised** conversation models, where the discovery of acts amounts to clustering utterances with similar conversational roles. This avoids manual construction of an act inventory, and allows the learning algorithm to tell us something about how people converse in a new medium.

*This work was conducted at Microsoft Research.

[1] Also called “speech acts”

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 172–180,
Los Angeles, California, June 2010.

There is surprisingly little work in unsupervised dialogue act tagging. Woszczyna and Waibel (1994) propose an unsupervised Hidden Markov Model (HMM) for dialogue structure in a meeting scheduling domain, but model dialogue state at the word level. Crook et al. (2009) use Dirichlet process mixture models to cluster utterances into a flexible number of acts in a travel-planning domain, but do not examine the sequential structure of dialogue.[2]

In contrast to previous work, we address the problem of discovering dialogue acts in an informal, open-topic domain, where an unsupervised learner may be distracted by strong topic clusters. We also train and test our models in a new medium: Twitter. Rather than test against existing dialogue inventories, we evaluate using qualitative visualizations and a novel conversation ordering task, to ensure our models have the opportunity to discover dialogue phenomena unique to this medium.

2 Data

To enable the study of large-data solutions to dialogue modeling, we have collected a corpus of 1.3 million conversations drawn from the microblogging service, Twitter. [3] To our knowledge, this is the largest corpus of naturally occurring chat data that has been available for study thus far. Similar datasets include the NUS SMS corpus (How and Kan, 2005), several IRC chat corpora (Elsner and Charniak, 2008; Forsyth and Martell, 2007), and blog datasets (Yano et al., 2009; Gamon et al., 2008), which can display conversational structure in the blog comments.

As it characterizes itself as a micro-blog, it should not be surprising that structurally, Twitter conversations lie somewhere between chat and blogs. Like blogs, conversations on Twitter occur in a public environment, where they can be collected for research purposes. However, Twitter posts are restricted to be no longer than 140 characters, which keeps interactions chat-like. Like e-mail and unlike IRC, Twitter conversations are carried out by replying to specific posts. The Twitter API provides a link from each reply to the post it is responding to, allowing accurate thread reconstruction without requiring a conversation disentanglement step (Elsner and Charniak, 2008). The proportion of posts on Twitter that are conversational in nature are somewhere around 37% (Kelly, 2009).

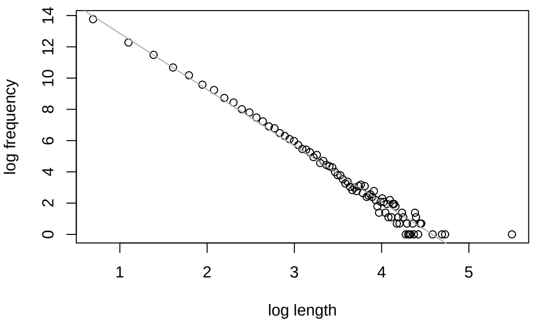

Figure 1: Conversation length versus frequency

To collect this corpus, we crawled Twitter using its publicly available API. We monitored the *public timeline*[4] to obtain a sample of active Twitter users. To expand our user list, we also crawled up to 10 users who had engaged in dialogue with each seed user. For each user, we retrieved all posts, retaining only those that were in reply to some other post. We recursively followed the chain of replies to recover the entire conversation. A simple function-word-driven filter was used to remove non-English conversations.

We crawled Twitter for a 2 month period during the summer of 2009. The resulting corpus consists of about 1.3 million conversations, with each conversation containing between 2 and 243 posts. The majority of conversations on Twitter are very short; those of length 2 (one status post and a reply) account for 69% of the data. As shown in Figure 1, the frequencies of conversation lengths follow a power-law relationship.

While the style of writing used on Twitter is widely varied, much of the text is very similar to SMS text messages. This is likely because many users access Twitter through mobile devices. Posts are often highly ungrammatical, and filled with spelling errors. In order to illustrate the spelling variation found on Twitter, we ran the Jcluster word clustering algorithm (Goodman, 2001) on our cor-

[2] The Crook et al. model should be able to be combined with the models we present here.

pus, and manually picked out clusters of spelling variants; a sample is displayed in Table 1.

Twitter's noisy style makes processing Twitter text more difficult than other domains. While moving to a new domain (e.g. biomedical text) is a challenging task, at least the new words found in the vocabulary are limited mostly to verbs and nouns, while function words remain constant. On Twitter, even closed-class words such as prepositions and pronouns are spelled in many different ways.

3 Dialogue Analysis

We propose two models to discover dialogue acts in an unsupervised manner. An ideal model will give insight into the sorts of conversations that happen on Twitter, while providing a useful tool for later processing. We first introduce the summarization technology we apply to this task, followed by two Bayesian extensions.

3.1 Conversation model

Our base model structure is inspired by the content model proposed by Barzilay and Lee (2004) for multi-document summarization. Their sentence-level HMM discovers the sequence of topics used to describe a particular type of news event, such as earthquakes. A news story is modeled by first generating a sequence of hidden topics according to a Markov model, with each topic generating an observed sentence according to a topic-specific language model. These models capture the sequential structure of news stories, and can be used for summarization tasks such as sentence extraction and ordering.

Our goals are not so different: we wish to discover the sequential dialogue structure of conversation. Rather than learning a disaster's location is followed by its death toll, we instead wish to learn that a question is followed by an answer. An initial conversation model can be created by simply applying the content modeling framework to conversation data. We rename the hidden states *acts*, and assume each post in a Twitter conversation is generated by a single act.[5] During development, we found that a unigram language model performed best as the act emission distribution.

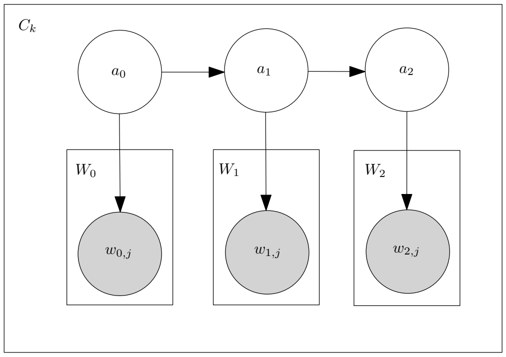

Figure 2: Conversation Model

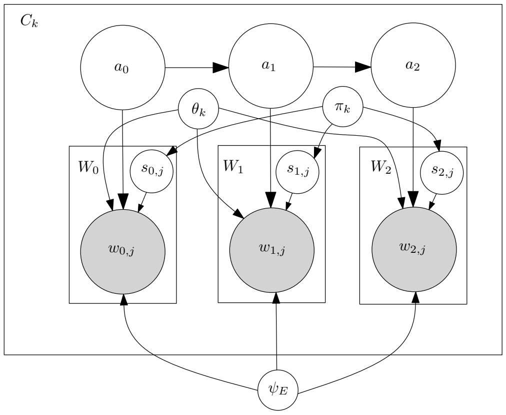

Figure 3: Conversation + Topic Model

The resulting conversation model is shown as a plate diagram in Figure 2. Each conversation C is a sequence of acts a, and each act produces a post, represented by a bag of words shown using the W plates. The number of acts available to the model is fixed; we experimented with between 5 and 40. Starting with a random assignment of acts, we train our conversation model using EM, with forward-backward providing act distributions during the expectation step. The model structure in Figure 2 is

Table 2: Example of a topical cluster discovered by the EM Conversation Model.

similar to previous HMMs for supervised dialogue act recognition (Stolcke et al., 2000), but our model is trained unsupervised.

3.2 Conversation + Topic model

Our conversations are not restricted to any particular topic: Twitter users can and will talk about anything. Therefore, there is no guarantee that our model, charged with discovering clusters of posts that aid in the prediction of the next cluster, will necessarily discover dialogue acts. The sequence model could instead partition entire conversations into topics, such as *food*, *computers* and *music*, and then predict that each topic self-transitions with high probability: if we begin talking about food, we are likely to continue to do so. Since we began with a content model, it is perhaps not surprising that our Conversation Model tends to discover a mixture of dialogue and topic structure. Several high probability posts from a topic-focused cluster discovered by EM are shown in Table 2. These clusters are undesirable, as they have little to do with dialogue structure.

In general, unsupervised sentence clustering techniques need some degree of direction when a particular level of granularity is desired. Barzilay and Lee (2004) mask named entities in their content models, forcing their model to cluster topics about earthquakes in general, and not instances of specific earthquakes. This solution is not a good fit for Twitter. As explained in Section 2, Twitter's noisiness resists off-the-shelf tools, such as named-entity recognizers and noun-phrase chunkers. Furthermore, we would require a more drastic form of preprocessing in order to mask all topic words, and not just alter the topic granularity. During development, we explored coarse methods to abstract away content while maintaining syntax, such as replacing tokens with either parts-of-speech or automatically-generated word clusters, but we found that these approaches degrade model performance.

Another approach to filtering out topic information leaves the data intact, but modifies the model to account for topic. To that end, we adopt a Latent Dirichlet Allocation, or LDA, framework (Blei et al., 2003) similar to approaches used recently in summarization (Daumé III and Marcu, 2006; Haghighi and Vanderwende, 2009). The goal of this extended model is to separate content words from dialogue indicators. Each word in a conversation is generated from one of three **sources**:

- The current post's dialogue act
- The conversation's topic
- General English

The extended model is shown in Figure 3.[6] In addition to act emission and transition parameters, the model now includes a conversation-specific word multinomial θ_k that represents the topic, as well as a universal general English multinomial ψ_E. A new hidden variable, s determines the source of each word, and is drawn from a conversation-specific distribution over sources π_k. Following LDA conventions, we place a symmetric Dirichlet prior over each of the multinomials. Dirichlet concentration parameters for act emission, act transition, conversation topic, general English, and source become the hyper-parameters of our model.

The multinomials θ_k, π_k and ψ_E create non-local dependencies in our model, breaking our HMM dynamic programing. Therefore we adopt Gibbs sampling as our inference engine. Each hidden variable is sampled in turn, conditioned on a complete assignment of all other hidden variables throughout the data set. Again following LDA convention, we carry out collapsed sampling, where the various multinomials are integrated out, and are never explicitly estimated. This results in a sampling sequence where for each post we first sample its act, and then sample a source for each word in the post. The hidden act and source variables are sampled according to the following transition distributions:

[6] This figure omits hyperparameters as well as act transition and emission multinomials to reduce clutter. Dirichlet priors are placed over all multinomials.

$$P_{trans}(a_i|\mathbf{a}_{-i}, \mathbf{s}, \mathbf{w}) \propto$$
$$P(a_i|\mathbf{a}_{-i}) \prod_{j=1}^{W_i} P(w_{i,j}|\mathbf{a}, \mathbf{s}, \mathbf{w}_{-(i,j)})$$

$$P_{trans}(s_{i,j}|\mathbf{a}, \mathbf{s}_{-(i,j)}, \mathbf{w}) \propto$$
$$P(s_{i,j}|\mathbf{s}_{-(i,j)})P(w_{i,j}|\mathbf{a}, \mathbf{s}, \mathbf{w}_{-(i,j)})$$

These probabilities can be computed analogously to the calculations used in the collapsed sampler for a bigram HMM (Goldwater and Griffiths, 2007), and those used for LDA (Griffiths and Steyvers, 2004).

Note that our model contains five hyperparameters. Rather than attempt to set them using an expensive grid search, we treat the concentration parameters as additional hidden variables and sample each in turn, conditioned on the current assignment to all other variables. Because these variables are continuous, we apply slice sampling (Neal, 2003). Slice sampling is a general technique for drawing samples from a distribution by sampling uniformly from the area under its density function.

3.3 Estimating Likelihood on Held-Out Data

In Section 4.2 we evaluate our models by comparing their probability on held-out test conversations. As computing this probability exactly is intractable in our model, we employ a recently proposed Chibb-style estimator (Murray and Salakhutdinov, 2008; Wallach et al., 2009). Chibb estimators estimate the probability of unseen data, $P(\mathbf{w})$ by selecting a high probability assignment to hidden variables $\mathbf{h}^*$, and taking advantage of the following equality which can be easily derived from the definition of conditional probability:

$$P(\mathbf{w}) = \frac{P(\mathbf{w}, \mathbf{h}^*)}{P(\mathbf{h}^*|\mathbf{w})}$$

As the numerator can be computed exactly, this reduces the problem of estimating $P(\mathbf{w})$ to the easier problem of estimating $P(\mathbf{h}^*|\mathbf{w})$. Murray and Salakhutdinov (2008) provide an unbiased estimator for $P(\mathbf{h}^*|\mathbf{w})$, which is calculated using the stationary distribution of the Gibbs sampler.

3.4 Bayesian Conversation model

Given the infrastructure necessary for the Conversation+Topic model described above, it is straightforward to also implement a Bayesian version of of the conversation model described in Section 3.1. This amounts to replacing the add-x smoothing of dialogue act emission and transition probabilities with (potentially sparse) Dirichlet priors, and replacing EM with Gibbs sampling. There is reason to believe that integrating out multinomials and using sparse priors will improve the performance of the conversation model, as improvements have been observed when using a Bayesian HMM for unsupervised part-of-speech tagging (Goldwater and Griffiths, 2007).

4 Experiments

Evaluating automatically discovered dialogue acts is a difficult problem. Unlike previous work, our model automatically discovers an appropriate set of dialogue acts for a new medium; these acts will not necessarily have a close correspondence to dialogue act inventories manually designed for other corpora. Instead of comparing against human annotations, we present a visualization of the automatically discovered dialogue acts, in addition to measuring the ability of our models to predict post order in unseen conversations. Ideally we would evaluate performance using an end-use application such as a conversational agent; however as this is outside the scope of this paper, we leave such an evaluation to future work.

For all experiments we train our models on a set of 10,000 randomly sampled conversations with conversation length in posts ranging from 3 to 6. Note that our implementations can likely scale to larger data by using techniques such as SparseLDA (Yao et al., 2009). We limit our vocabulary to the 5,000 most frequent words in the corpus.

When using EM, we train for 100 iterations, evaluating performance on the test set at each iteration, and reporting the maximum. Smoothing parameters are set using grid search on a development set.

When performing inference with Gibbs Sampling, we use 1,000 samples for burn-in and take 10 samples at a lag of 100. Although using multiple samples introduces the possibility of poor results due to "act drift", we found this not to be a problem in practice; in fact, taking multiple samples substantially improved performance during development.

Recall that we infer hyperparameters using slice sampling. The concentration parameters chosen in this manner were always sparse (< 1), which produced a moderate improvement over an uninformed prior.

4.1 Qualitative Evaluation

We are quite interested in what our models can tell us about how people converse on Twitter. To visualize and interpret our competing models, we examined act-emission distributions, posts with high-confidence acts, and act-transition diagrams. Of the three competing systems, we found the Conversation+Topic model by far the easiest to interpret: the 10-act model has 8 acts that we found intuitive, while the other 2 are used only with low probability. Conversely, the Conversation model, whether trained by EM or Gibbs sampling, suffered from the inclusion of general terms and from the conflation of topic and dialogue. For example, the EM-trained conversation model discovered an “act” that was clearly a collection of posts about food, with no underlying dialogue theme (see Table 2).

In the remainder of this section, we reproduce our visualization for the 10-act Conversation+Topic model. Word lists summarizing the discovered dialogue acts are shown in Table 3. For each act, the top 40 words are listed in order of decreasing emission probability. An example post, drawn from the set of highest-confidence posts for that act, is also included. Figure 4 provides a visualization of the matrix of transition probabilities between dialogue acts. An arrow is drawn from one act to the next if the probability of transition is above 0.15.[7] Note that a uniform model would transition to each act with probability 0.10. In both Table 3 and Figure 4, we use intuitive names in place of cluster numbers. These are based on our interpretations of the clusters, and are provided only to benefit the reader when interpreting the transition diagram.[8]

From inspecting the transition diagram (Figure 4), one can see that the model employs three distinct acts to initiate Twitter conversations. These initial acts are quite different from one another, and lead to different sets of possible responses. We discuss each of these in turn.

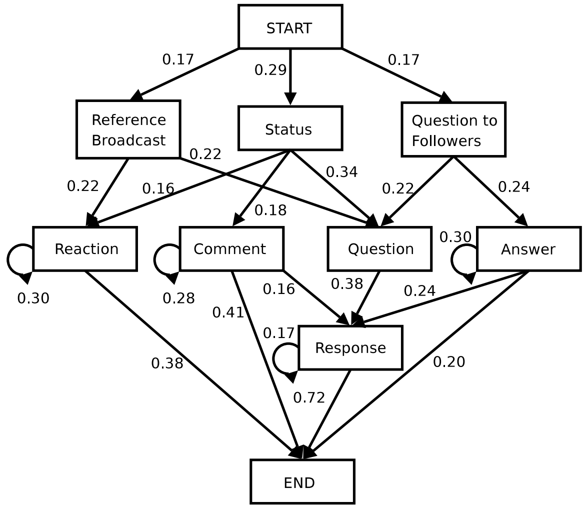

Figure 4: Transitions between dialogue acts. See table 3 for word lists and example posts for each act

The *Status* act appears to represent a post in which the user is broadcasting information about what they are currently doing. This can be seen by the high amount of probability mass given to words like *I* and *my*, in addition to verbs such as *go* and *get*, as well as temporal nouns such as *today*, *tomorrow* and *tonight*.

The *Reference Broadcast* act consists mostly of usernames and urls.[9] Also prominent is the word *rt*, which has special significance on Twitter, indicating that the user is re-posting another user’s post. This act represents a user broadcasting an interesting link or quote to their followers. Also note that this node transitions to the *Reaction* act with high probability. *Reaction* appears to cover excited or appreciative responses to new information, assigning high probability to *!*, *!!*, *!!!*, *lol*, *thanks*, and *haha*.

Finally *Question to Followers* represents a user asking a question to their followers. The presence of the question mark and WH question words indicate a question, while words like *anyone* and *know* indicate that the user is asking for information or an opinion. Note that this is distinct from the *Question* act, which is in response to an initial post.

Another interesting point is the alternation be-

[7] After setting this threshold, two Acts were cut off from the rest of the graph (had no incoming edges), and were therefore removed

[8] In some cases, the choice in name is somewhat arbitrary, ie: answer versus response, reaction versus comment.

[9] As part of the preprocessing of our corpus we replaced all usernames and urls with the special tokens *-usr-* and *-url-*.

Status	I . to ! my , is for up in ... and going was today so at go get back day got this am but Im now tomorrow night work tonight off morning home had gon need !! be just getting
	I just changed my twitter page bkgornd and now I can’t stop looking at it, lol!!
Question to Followers	? you is do I to -url- what -usr- me , know if anyone why who can “ this or of that how does - : on your are need any rt u should people want get did have would tell
	anyone using google voice? just got my invite, should i?? don’t know what it is? -url- for the video and break down
Reference Broadcast	-usr- ! -url- rt : -usr-: - “ my the , is (you new – ? !!) this for at in follow of on ¡ lol u are twitter your thanks via !!! by :) here 2 please check
	rt -usr-: -usr- word that mac lip gloss give u lock jaw! lol
Question	? you what ! are is how u do the did your that , lol where why or ?? hey about was have who it in so haha on doing going know good up get like were for there :) can
	DWL!! what song is that??
Reaction	! you I :) !! , thanks lol it haha that love so good too your thank is are u !!! was for :d me -usr- ¡ hope ? my 3 omg ... oh great hey awesome - happy now aww
	sweet! im so stoked now!
Comment	you I . to , ! do ? it be if me your know have we can get will :) but u that see lol would are so want go let up well need - come ca make or think them
	why are you in tx and why am I just now finding out about it?! i’m in dfw, till I get a job. i’ll have to come to Htown soon!
Answer	. I , you it “ that ? is but do was he the of a they if not would know be did or does think) like (as have what in are - no them said who say ‘
	my fave was “keeping on top of other week”
Response	. I , it was that lol but is yeah ! haha he my know yes you :) like too did well she so its ... though do had no - one as im thanks they think would not good oh
	nah im out in maryland, leaving for tour in a few days.

Table 3: Word lists and example posts for each Dialogue Act. Words are listed in decreasing order of probability given the act. Example posts are in *italics*.

tween the personal pronouns *you* and *I* in the acts due to the focus of conversation and speaker. The *Status* act generates the word *I* with high probability, whereas the likely response state *Question* generates *you*, followed by *Response* which again generates *I*.

4.2 Quantitative Evaluation

Qualitative evaluations are both time-consuming and subjective. The above visualization is useful for understanding the Twitter domain, but it is of little use when comparing model variants or selecting parameters. Therefore, we also propose a novel quantitative evaluation that measures the intrinsic quality of a conversation model by its ability to predict the ordering of posts in a conversation. This measures the model's predictive power, while requiring no tagged data, and no commitment to an existing tag inventory.

Our test set consists of 1,000 randomly selected conversations not found in the training data. For each conversation in the test set, we generate all $n!$ permutations of the posts. The probability of each permutation is then evaluated as if it were an unseen conversation, using either the forward algorithm (EM) or the Chibb-style estimator (Gibbs). Following work from the summarization community (Barzilay and Lee, 2004), we employ Kendall's τ to measure the similarity of the max-probability permutation to the original order.

The Kendall τ rank correlation coefficient measures the similarity between two permutations based on their agreement in pairwise orderings:

$$\tau = \frac{n_+ - n_-}{\binom{n}{2}}$$

where n_+ is the number of pairs that share the same order in both permutations, and n_- is the number that do not. This statistic ranges between -1 and +1, where -1 indicates inverse order, and +1 indicates identical order. A value greater than 0 indicates a positive correlation.

Predicting post order on open-domain Twitter conversations is a much more difficult task than on topic-focused news data (Barzilay and Lee, 2004). We found that a simple bigram model baseline does very poorly at predicting order on Twitter, achieving only a weak positive correlation of $\tau = 0.0358$ on our test data as compared with 0.19-0.74 reported by Barzilay and Lee on news data.

Note that τ is not a perfect measure of model quality for conversations; in some cases, multiple order-

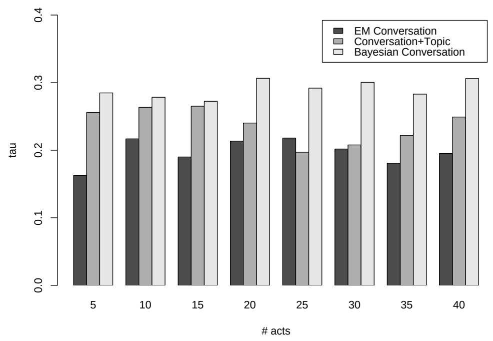

Figure 5: Performance at conversation ordering task.

ings of the same set of posts may form a perfectly acceptable conversation. On the other hand, there are often strong constraints on the type of response we might expect to follow a particular dialogue act; for example, answers follow questions. We would expect an effective model to use these constraints to predict order.

Performance at the conversation ordering task while varying the number of acts for each model is displayed in Figure 5. In general, we found that using Bayesian inference outperforms EM. Also note that the Bayesian Conversation model outperforms the Conversation+Topic model at predicting conversation order. This is likely because modeling conversation content as a sequence can in some cases help to predict post ordering; for example, adjacent posts are more likely to contain similar content words. Recall though that we found the Conversation+Topic model to be far more interpretable.

Additionally we compare the likelihood of these models on held out test data in Figure 6. Note that the Bayesian methods produce models with much higher likelihood.[10] For the EM models, likelihood tends to decrease on held out test data as we increase the number of hidden states, due to overfitting.

5 Conclusion

We have presented an approach that allows the unsupervised induction of dialogue structure from naturally-occurring open-topic conversational data.

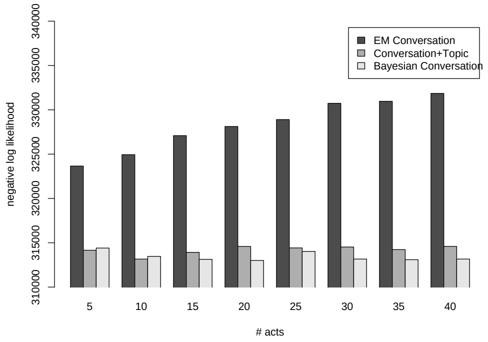

Figure 6: Negative log likelihood on held out test data (smaller values indicate higher likelihood).

By visualizing the learned models, coherent patterns emerge from a stew of data that human readers find difficult to follow. We have extended a conversation sequence model to separate topic and dialogue words, resulting in an interpretable set of automatically generated dialogue acts. These discovered acts have interesting differences from those found in other domains, and reflect Twitter's nature as a micro-blog.

We have introduced the task of conversation ordering as an intrinsic measure of conversation model quality. We found this measure quite useful in the development of our models and algorithms, although our experiments show that it does not necessarily correlate with interpretability. We have directly compared Bayesian inference to EM on our conversation ordering task, showing a clear advantage for Bayesian methods.

Finally, we have collected a corpus of 1.3 million Twitter conversations, which we will make available to the research community, and which we hope will be useful beyond the study of dialogue. In the future, we wish to scale our models to the full corpus, and extend them with more complex notions of discourse, topic and community. Ultimately, we hope to put the learned conversation structure to use in the construction of a data-driven, conversational agent.

Acknowledgements

We are grateful to everyone in the NLP and TMSN groups at Microsoft Research for helpful discussions and feedback. We thank Oren Etzioni, Michael Gamon, Mausam and Fei Wu, and the anonymous reviewers for helpful comments on a previous draft.

[10] Likelihood of the test data is estimated using the Chibb Style estimator described in (Murray and Salakhutdinov, 2008; Wallach et al., 2009). This method under-estimates likelihood in expectation. The maximum likelihood (EM) likelihoods are exact.

Abstract

With the recent rise in popularity and size of social media, there is a growing need for systems that can extract useful information from this amount of data. We address the problem of detecting new events from a stream of Twitter posts. To make event detection feasible on web-scale corpora, we present an algorithm based on locality-sensitive hashing which is able overcome the limitations of traditional approaches, while maintaining competitive results. In particular, a comparison with a state-of-the-art system on the first story detection task shows that we achieve over an order of magnitude speedup in processing time, while retaining comparable performance. Event detection experiments on a collection of 160 million Twitter posts show that celebrity deaths are the fastest spreading news on Twitter.

1 Introduction

In the recent years, the microblogging service Twitter has become a very popular tool for expressing opinions, broadcasting news, and simply communicating with friends. People often comment on events in real time, with several hundred micro-blogs (*tweets*) posted each second for significant events. Twitter is not only interesting because of this real-time response, but also because it is sometimes ahead of newswire. For example, during the protests following Iranian presidential elections in 2009, Iranian people first posted news on Twitter, where they were later picked up by major broadcasting corporations. Another example was the swine flu outbreak when the US Centre for disease control (CDC) used Twitter to post latest updates on the pandemic. In addition to this, subjective opinion expressed in posts is also an important feature that sets Twitter apart from traditional newswire.

New event detection, also known as first story detection (FSD)[1] is defined within the topic detection and tracking as one of the subtasks (Allan, 2002). Given a sequence of stories, the goal of FSD is to identify the first story to discuss a particular *event*. In this context, an event is taken to be something that happens at some specific time and place, e.g., an earthquake striking the town of L'Aquila in Italy on April 6th 2009. Detecting new events from tweets carries additional problems and benefits compared to traditional new event detection from newswire. Problems include a much higher volume of data to deal with and also a higher level of noise. A major benefit of doing new event detection from tweets is the added social component – we can understand the impact an event had and how people reacted to it.

The speed and volume at which data is coming from Twitter warrants the use of *streaming* algorithms to make first story detection feasible. In the streaming model of computation (Muthukrishnan, 2005), items (tweets in our case) arrive continuously in a chronological order, and we have to process each new one in bounded space and time. Recent examples of problems set in the streaming model include stream-based machine translation (Levenberg and Osborne, 2009), approximating kernel matrices of data streams (Shi et al., 2009), and topic modelling on streaming document collections (Yao et al., 2009). The traditional approach to FSD, where each new story is compared to all, or a constantly growing subset, of previously seen stories, does not scale to the Twitter streaming setting. We present a FSD system that works in the streaming model and takes constant time to process each new document, while also using constant space. Constant processing time is achieved by employing *locality sensitive hashing (LSH)* (Indyk and Motwani, 1998), a randomized technique that dramatically reduces the time needed

[1] We will be using the terms first story detection and new event detection interchangeably.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 181–189,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

to find a nearest neighbor in vector space, and the space saving is achieved by keeping the amount of stories in memory constant.

We find that simply applying pure LSH in a FSD task yields poor performance and a high variance in results, and so introduce a modification which virtually eliminates variance and significantly improves performance. We show that our FSD system gives comparable results as a state-of-the-art system on the standard TDT5 dataset, while achieving an order of magnitude speedup. Using our system for event detection on 160 million Twitter posts shows that i) the number of users that write about an event is more indicative than the volume of tweets written about it, ii) spam tweets can be detected with reasonable precision, and iii) news about deaths of famous people spreads the fastest on Twitter.

2 First Story Detection

2.1 Traditional Approach

The traditional approach to first story detection is to represent documents as vectors in term space, where coordinates represent the (possibly IDF-weighted) frequency of a particular term in a document. Each new document is then compared to the previous ones, and if its similarity to the closest document (or centroid) is below a certain threshold, the new document is declared to be a first story. For example, this approach is used in the UMass (Allan et al., 2000) and the CMU system (Yang et al., 1998). Algorithm 1 shows the exact pseudocode used by the UMass system. Note that $dis_{min}(d)$ is the novelty score assigned to document d. Often, in order to decrease the running time, documents are represented using only n features with the highest weights.

Algorithm 1: Traditional FSD system based on nearest-neighbor search.

```
foreach document d in corpus do
    foreach term t in d do
        foreach document d' that contains t do
            update distance(d, d')
        end
    end
    $dis_{min}(d) = \min_{d'}\{distance(d, d')\}$
    add d to inverted index
end
```

2.2 Locality Sensitive Hashing

The problem of finding the nearest neighbor to a given query has been intensively studied, but as the dimensionality of the data increases none of the current solutions provide much improvement over a simple linear search (Datar et al., 2004). More recently, research has focused on solving a relaxed version of the nearest neighbor problem, the *approximate nearest neighbor*, where the goal is to report any point that lies within $(1+\epsilon)r$ distance of the query point, where r is the distance to the nearest neighbor. One of the first approaches to solving the approximate-NN problem in sublinear time was described in Indyk and Motwani (1998), where the authors introduced a new method called *locality sensitive hashing (LSH)*. This method relied on hashing each query point into buckets in such a way that the probability of collision was much higher for points that are near by. When a new point arrived, it would be hashed into a bucket and the points that were in the same bucket were inspected and the nearest one returned.

Because we are dealing with textual documents, a particularly interesting measure of distance is the cosine between two documents. Allan et al. (2000) report that this distance outperforms the KL divergence, weighted sum, and language models as distance functions on the first story detection task. This is why in our work we use the hashing scheme proposed by Charikar (2002) in which the probability of two points colliding is proportional to the cosine of the angle between them. This scheme was used, e.g., for creating similarity lists of nouns collected from a web corpus in Ravichandran et al. (2005). It works by intersecting the space with random hyperplanes, and the buckets are defined by the subspaces formed this way. More precisely, the probability of two points x and y colliding under such a hashing scheme is

$$P_{coll} = 1 - \frac{\theta(x,y)}{\pi}, \tag{1}$$

where $\theta(x,y)$ is the angle between x and y. By using more than one hyperplane, we can decrease the probability of collision with a non-similar point. The number of hyperplanes k can be considered as a number of bits per key in this hashing scheme. In particular, if $x \cdot u_i < 0, i \in [1 \ldots k]$ for document x and hyperplane vector u_i, we set the i-th bit to 0, and 1 otherwise. The higher k is, the fewer collisions we will have in our buckets but we will spend more time computing the hash values.[2] However, increasing k also decreases the probability of collision with the nearest neighbor, so we need multiple hash tables (each with k independently chosen random hyperplanes) to increase the chance that the nearest neighbor will collide with our point in at least one of

[2] Probability of collision under k random hyperplanes will be P^k_{coll}.

them. Given the desired number of bits k, and the desired probability of missing a nearest neighbor δ, one can compute the number of hash tables L as

$$L = \log_{1-P_{coll}^{k}} \delta. \tag{2}$$

2.3 Variance Reduction Strategy

Unfortunately, simply applying LSH for nearest neighbor search in a FSD task yields poor results with a lot of variance (the exact numbers are given in Section 6). This is because LSH only returns the true near neighbor if it is reasonably close to the query point. If, however, the query point lies far away from all other points (i.e., its nearest neighbor is far away), LSH fails to find the true near neighbor. To overcome this problem, we introduce a strategy by which, if the LSH scheme declares a document new (i.e., sufficiently different from all others), we start a search through the inverted index, but only compare the query with a fixed number of most recent documents. We set this number to 2000; preliminary experiments showed that values between 1000 and 3000 all yield very similar results. The pseudocode shown in algorithm 2 summarizes the approach based on LSH, with the lines 11 and 12 being the variance reduction strategy.

Algorithm 2: Our LSH-based approach.

```
   input: threshold $t$
1  foreach document d in corpus do
2      add d to LSH
3      $S \leftarrow$ set of points that collide with d in LSH
4      $dis_{min}(d) \leftarrow 1$
5      foreach document d' in S do
6          c = distance(d, d')
7          if $c < dis_{min}(d)$ then
8              $dis_{min}(d) \leftarrow$ c
9          end
10     end
11     if $dis_{min}(d) >= t$ then
12         compare d to a fixed number of most
           recent documents as in Algorithm 1 and
           update $dis_{min}$ if necessary
13     end
14     assign score $dis_{min}(d)$ to d
15     add d to inverted index
16 end
```

3 Streaming First Story Detection

Although using LSH in the way we just described greatly reduces the running time, it is still too expensive when we want to deal with *text streams.* Text streams naturally arise on the Web, where millions of new documents are published each hour. Social media sites like Facebook, MySpace, Twitter, and various blogging sites are a particularly interesting source of textual data because each new document is timestamped and usually carries additional metadata like topic tags or links to author's friends. Because this stream of documents is unbounded and coming down at a very fast rate, there is usually a limit on the amount of space/time we can spend per document. In the context of first story detection, this means we are not allowed to store all of the previous data in main memory nor compare the new document to all the documents returned by LSH.

Following the previous reasoning, we present the following desiderata for a streaming first story detection system: we first assume that each day we are presented with a large volume of documents in chronological order. A streaming FSD system should, for each document, say whether it discusses a previously unseen event and give confidence in its decision. The decision should be made in bounded time (preferably constant time per document), and using bounded space (also constant per document). Only one pass over the data is allowed and the decision has to be made immediately after a new document arrives. A system that has all of these properties can be employed for finding first stories in real time from a stream of stories coming down from the Web.

3.1 A constant space and time approach

In this section, we describe our streaming FSD system in more depth. As was already mentioned in Section 2.2, we use locality sensitive hashing to limit our search to a small number of documents. However, because there is only a finite number of buckets, in a true streaming setting the number of documents in any bucket will grow without a bound. This means that i) we would use an unbounded amount of space, and ii) the number of comparisons we need to make would also grow without a bound. To alleviate the first problem, we limit the number of documents inside a single bucket to a constant. If the bucket is full, the oldest document in the bucket is removed. Note that the document is removed only from that single bucket in one of the L hash tables – it may still be present in other hash tables. Note that this way of limiting the number of documents kept is in a way topic-specific. Luo et al. (2007) use a global constraint on the documents they keep and show that around 30 days of data needs to be kept in order to achieve reasonable performance. While using this approach also ensures that the number of comparisons made is constant, this constant can be rather large. Theoretically, a new document can collide with all of the documents that are left, and this can be quite a large number (we have to keep a sufficient portion of the data in memory to make sure we have a representative sample of the stream to compare with). That is why, in addition to limiting the number of documents in a bucket, we also limit ourselves to making a constant number of comparisons. We do this by comparing each new document with at most 3L documents it collided with. Unlike Datar et al. (2004), where any 3L documents were used, we compare to the 3L documents that collide most frequently with the new document. That is, if S is the set of all documents that collided with a new document in all L hash tables, we order the elements of S according to the number of hash tables where the collision occurred. We take the top 3L elements of that ordered set and compare the new document only to them.

4 Detecting Events in Twitter Posts

While doing first story detection on a newspaper stream makes sense because all of the incoming documents are actual stories, this is not the case with Twitter posts (tweets). The majority of tweets are not real stories, but rather updates on one's personal life, conversations, or spam. Thus, simply running a first story detection system on this data would yield an incredible amount of new stories each day, most of which would be of no interest to anyone but a few people. However, when something significant happens (e.g., a celebrity dies), a lot of users write about this either to share their opinion or just to inform others of the event. Our goal here is to automatically detect these significant events, preferably with a minimal number of non-important events.

Threading. We first run our streaming FSD system and assign a novelty score to each tweet. In addition, since the score is based on a cosine distance to the nearest tweet, for each tweet we also output which other tweet it is most similar to. This way, we can analyze *threads* of tweets, i.e., a subset of tweets which all discuss the same topic (Nallapati et al., 2004). To explain how we form threads of tweets, we first introduce the *links* relation. We say that tweet a *links* to tweet b if b is the nearest neighbor of a and $1 - \cos(a, b) < t$, where t is a user-specified threshold. Then, for each tweet a we either assign it to an existing thread if its nearest neighbor is within distance t, or say that a is the first tweet in a new thread. If we assign a to an existing thread, we assign it to the same thread to which its nearest neighbor belongs. By changing t we can control the granularity of threads. If t is set very high, we will have few very big and broad threads, whereas setting t very low will result in many very specific and very small threads. In our experiments, we set $t = 0.5$. We experimented with different values of t and found that for $t \in [0.5, 0.6]$ results are very much the same, whereas setting t outside this interval starts to impact the results in the way we just explained.

Once we have threads of tweets, we are interested in which threads grow fastest, as this will be an indication that news of a new event is spreading. Therefore, for each time interval we only output the fastest growing threads. This growth rate also gives us a way to measure a thread's impact.

5 Related Work

In the recent years, analysis of social media has attracted a lot of attention from the research community. However, most of the work that uses social media focuses on blogs (Glance et al., 2004; Bansal and Koudas, 2007; Gruhl et al., 2005). On the other hand, research that uses Twitter has so far only focused on describing the properties of Twitter itself (Java et al., 2007; Krishnamurthy et al., 2008).

The problem of online new event detection in a large-scale streaming setting was previously addressed in Luo et al. (2007). Their system used the traditional approach to FSD and then employed various heuristics to make computation feasible. These included keeping only the first stories in memory, limiting the number of terms per document, limiting the number of total terms kept, and employing parallel processing. Our randomized framework gives us a principled way to work out the errors introduced and is more general than the previously mentioned approach because we could still use all the heuristics used by Luo et al. (2007) in our system. Finally, while Luo et al. (2007) achieved considerable speedup over an existing system on a TDT corpus, they never showed the utility of their system on a truly large-scale task.

The only work we are aware of that analyzes social media in a streaming setting is Saha and Getoor (2009). There, the focus was on solving the *maximum coverage* problem for a stream of blog posts. The maximum coverage problem in their setting, dubbed *blog watch*, was selecting k blogs that maximize the cover of interests specified by a user. This work differs from Saha and Getoor (2009) in many ways. Most notably, we deal with the problem of detecting new events, and determining who was the first to report them. Also, there is a difference in the type and volume of data – while Saha and Getoor (2009) use 20 days of blog data totalling two million posts, we use Twitter data from a timespan of six months, totalling over 160 million posts.

6 Experiments

6.1 TDT5 Experimental Setup

Baseline. Before applying our FSD system on Twitter data, we first compared it to a state-of-the-art FSD system on the standard TDT5 dataset. This way, we can test if our system is on par with the best existing systems, and also accurately measure the speedup that we get over a traditional approach. In particular, we compare our system with the UMass FSD system (Allan et al., 2000). The UMass system has participated in the TDT2 and TDT3 competitions and is known to perform at least as well as other existing systems who also took part in the competition (Fiscus, 2001). Note that the UMass system uses an inverted index (as shown in Algorithm 1) which optimizes the system for speed and makes sure a minimal number of comparisons is made. We compare the systems on the English part of the TDT5 dataset, consisting of $221,306$ documents from a time period spanning April 2003 to September 2003. To make sure that any difference in results is due to approximations we make, we use the same settings as the UMass system: 1-NN clustering, cosine as a similarity measure, and TFIDF weighted document representation, where the IDF weights are incrementally updated. These particular settings were found by Allan et al. (2000) to perform the best for the FSD task. We limit both systems to keeping only top 300 features in each document. Using more than 300 features barely improves performance while taking significantly more time for the UMass system.[3]

LSH parameters. In addition, our system has two LSH parameters that need to be set. The number of hyperplanes k gives a tradeoff between time spent computing the hash functions and the time spent computing the distances. A lower k means more documents per bucket and thus more distance computations, whereas a higher k means less documents per bucket, but more hash tables and thus more time spent computing hash functions. Given k, we can use equation (2) to compute L. In our case, we chose k to be 13, and L such that the probability of missing a neighbor within the distance of 0.2 is less than 2.5%. The distance of 0.2 was chosen as a reasonable estimate of the threshold when two documents are very similar. In general, this distance will depend on the application, and Datar et al. (2004) suggest guessing the value and then doing a binary search to set it more accurately. We set k to 13 because it achieved a reasonable balance between time spent computing the distances and the time spent computing the hash functions.

Evaluation metric. The official TDT evaluation requires each system to assign a confidence score for its decision, and this assignment can be made either immediately after the story arrives, or after a fixed number of new stories have been observed. Because we assume that we are working in a true streaming setting, systems are required to assign a confidence score as soon as the new story arrives. The actual performance of a system is measured in terms of *detection error tradeoff (DET)* curves and the *minimal normalized cost.* Evaluation is carried out by first sorting all stories according to their scores and then performing a threshold sweep. For each value of the threshold, stories with a score above the threshold are considered new, and all others are considered old. Therefore, for each threshold value, one can compute the probability of a *false alarm*, i.e., probability of declaring a story new when it is actually not, and the *miss probability*, i.e., probability of declaring a new story old (missing a new story). Having computed all the miss and false alarm probabilities, we can plot them on a graph showing the tradeoff between these two quantities – such graphs are called detection error tradeoff curves. The normalized cost C_{det} is computed as

$$C_{det} = C_{miss} * P_{miss} * P_{target} + C_{FA} * P_{FA} * P_{non-target},$$

where C_{miss} and C_{FA} are costs of miss and false alarm, P_{miss} and P_{FA} are probabilities of a miss and false alarm, and P_{target} and $P_{non-target}$ are the prior target and non-target probabilities. Minimal normalized cost C_{min} is the minimal value of C_{det} over all threshold values (a lower value of C_{min} indicates better performance).

6.2 TDT5 Results

All the results on the TDT5 dataset are shown in Table 1. In this section, we go into detail in explaining them. As was mentioned in Section 2.2, simply using LSH to find a nearest neighbor resulted in poor performance and a high variance of results. In particular, the mean normalized cost of ten runs of our system without the variance reduction strategy was 0.88, with a standard deviation of 0.046. When using the strategy explained in Section 2.2, the mean result dropped to 0.70, with a standard deviation of 0.004. Therefore, the results were significantly improved, while also reducing standard deviation by an order of magnitude. This shows that there is a clear advantage in using our variance reduction strategy,

[3] In other words, using more features only increases the advantage of our system over the UMass system.

Table 1: Summary of TDT5 results. Numbers next to LSH'_{ts} indicate the maximal number of documents in a bucket, measured in terms of percentage of the expected number of collisions.

	Baseline	Unbounded		Bounded			
		Pure	Variance Red.	Time	Space and Time		
System	UMass	LSH	LSH'	LSH'_t	LSH'_{ts} 0.5	LSH'_{ts} 0.3	LSH'_{ts} 0.1
C_{min}	0.69	0.88	0.70	0.71	0.76	0.75	0.73

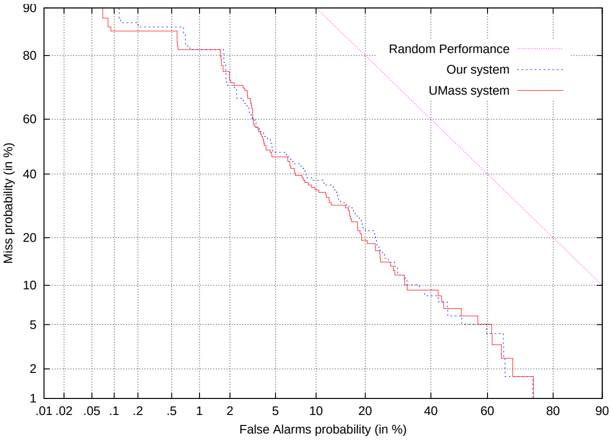

Figure 1: Comparison of our system with the UMass FSD system.

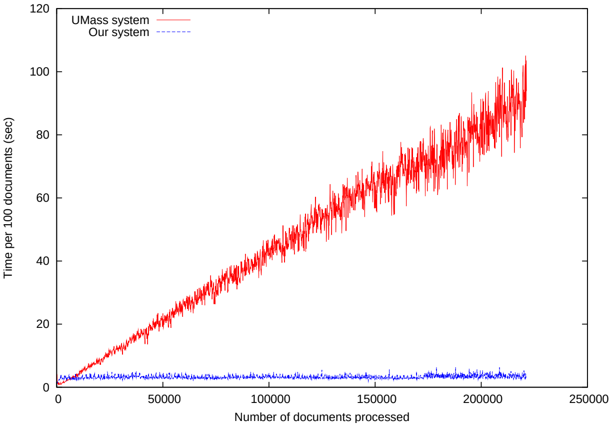

Figure 2: Comparison of processing time per 100 documents for our and the UMass system.

and all the following results we report were obtained from a system that makes use of it.

Figure 1 shows DET curves for the UMass and for our system. For this evaluation, our system was not limited in space, i.e., buckets sizes were unlimited, but the processing time per item was made constant. It is clear that UMass outperforms our system, but the difference is negligible. In particular, the minimal normalized cost C_{min} was 0.69 for the UMass system, and 0.71 for our system. On the other hand, the UMass system took 28 hours to complete the run, compared to two hours for our system. Figure 2 shows the time required to process 100 documents as a function of number of documents seen so far. We can see that our system maintains constant time, whereas the UMass system processing time grows without a bound (roughly linear with the number of previously seen documents).

The last three columns in Table 1 show the effect that limiting the bucket size has on performance. Bucket size was limited in terms of the percent of expected number of collisions, i.e., a bucket size of 0.5 means that the number of documents in a bucket cannot be more than 50% of the expected number of collisions. The expected number of collisions can be computed as $n/2^k$, where n is the total number of documents, and k is the LSH parameter explained earlier. Not surprisingly, limiting the bucket size reduced performance compared to the space-unlimited version, but even when the size is reduced to 10% of the expected number of collisions, performance remains reasonably close to the UMass system. Figure 3 shows the memory usage of our system on a month of Twitter data (more detail about the data can be found in Section 6.3). We can see that most of the memory is allocated right away, after which the memory consumption levels out. If we ran the system indefinitely, we would see the memory usage grow slower and slower until it reached a certain level at which it would remain constant.

6.3 Twitter Experimental Setup

Corpus. We used our streaming FSD system to detect new events from a collection of Twitter data gathered over a period of six months (April 1st 2009 to October 14th 2009). Data was collected through Twitter's streaming API.[4] Our corpus consists of 163.5 million timestamped tweets, totalling over 2 billion tokens. All the tweets in our corpus contain

[4] http://stream.twitter.com/

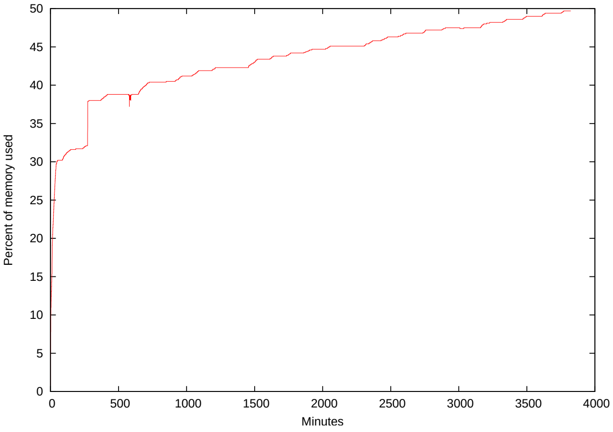

Figure 3: Memory usage on a month of Twitter data. X-axis shows how long the system has been running for.

only ASCII characters and we additionally stripped the tweets of words beginning with the @ or # symbol. This is because on Twitter words beginning with @ indicate a reply to someone, and words beginning with # are topic tags. Although these features would probably be helpful for our task, we decided not to use them as they are specific to Twitter and our approach should be independent of the stream type.

Gold standard. In order to measure how well our system performs on the Twitter data, we employed two human experts to manually label all the tweets returned by our system as either *Event, Neutral*, or *Spam*. Note that each tweet that is returned by our system is actually the first tweet in a thread, and thus serves as the representative of what the thread is about. Spam tweets include various advertisements, automatic weather updates, automatic radio station updates, etc. For a tweet to be labeled as an event, it had to be clear from the tweet alone what exactly happened without having any prior knowledge about the event, and the event referenced in the tweet had to be sufficiently important. Important events include celebrity deaths, natural disasters, major sports, political, entertainment, and business events, shootings, plane crashes and other disasters. Neutral tweets include everything not labeled as spam or event. Because the process of manual labeling is tedious and time-consuming, we only labeled the 1000 fastest growing threads from June 2009. Rate of growth of a thread is measured by the number of tweets that belong to that thread in a window of 100,000 tweets, starting from the beginning of the thread. Agreement between our two annotators, measured using Cohen's kappa coefficient, was substantial (kappa = 0.65). We use 820 tweets on which both annotators agreed as the gold standard.

Evaluation. Evaluation is performed by computing *average precision* (AP) on the gold standard sorted according to different criteria, where event tweets are taken to be relevant, and neutral and spam tweets are treated as non-relevant documents. Average precision is a common evaluation metric in tasks like ad-hoc retrieval where only the set of returned documents and their relevance judgements are available, as is the case here (Croft et al., 2009). Note that we are not evaluating our FSD system here. There are two main reasons for this: i) we already have a very good idea about the first story detection performance from the experiments on TDT5 data, and ii) evaluating a FSD system on this scale would be prohibitively expensive as it would involve human experts going through 30 million tweets looking for first stories. Rather, we are evaluating different methods of ranking threads which are output from a FSD system for the purpose of detecting important events in a very noisy and unstructured stream such as Twitter.

6.4 Twitter Results

Results for the average precisions are given in Table 2. Note that we were not able to compare our system with the UMass FSD system on the Twitter data, as the UMass system would not finish in any reasonable amount of time. Different rows of Table 2 correspond to the following ways of ranking the threads:

- Baseline – random ordering of threads
- Size of thread – threads are ranked according to number of tweets
- Number of users – threads are ranked according to number of unique users posting in a thread
- Entropy + users – if the entropy of a thread is < 3.5, move to the back of the list, otherwise sort according to number of unique users

Results show that ranking according to size of thread performs better than the baseline, and ranking according to the number of users is slightly better. However, a sign test showed that neither of the two ranking strategies is significantly better than the baseline. We perform the sign test by splitting the labeled data into 50 stratified samples and ranking each sample with different strategies. We then measure the number of times each strategy performed better (in terms of AP) and compute the significance levels based on these numbers. Adding the information about the entropy of the thread showed to be

Table 2: Average precision for *Events* vs. *Rest* and for *Events* and *Neutral* vs. *Spam*.

Ranking method	events vs. rest	spam vs. rest
Baseline	16.5	84.6
Size of thread	24.1	83.5
Number of users	24.5	83.9
Entropy + users	34.0	96.3

Table 3: Average precision as a function of the entropy threshold on the *Events* vs. *Rest* task.

Entropy	2	2.5	3	3.5	4	4.5
AP	24.8	27.6	30.0	34.0	33.2	29.4

very beneficial. Entropy of a thread is computed as

$$H_{thread} = -\sum_i \frac{n_i}{N} \log \frac{n_i}{N},$$

where n_i is the number of times word i appears in a thread, and $N = \sum_i n_i$ is the total number of words in a thread. We move the threads with low entropy (< 3.5) to the back of the list, while we order other threads by the number of unique users. A sign test showed this approach to be significantly better ($p \leq 0.01$) than all of the previous ranking methods. Table 3 shows the effect of varying the entropy threshold at which threads are moved to the back of the list. We can see that adding information about entropy improves results regardless of the threshold we choose. This approach works well because most spam threads have very low entropy, i.e., contain very little information.

We conducted another experiment where events and neutral tweets are considered relevant, and spam tweets non-relevant documents. Results for this experiment are given in the third column of Table 2. Results for this experiment are much better, mostly due to the large proportion of neutral tweets in the data. The baseline in this case is very strong and neither sorting according to the size of the thread nor according to the number of users outperforms the baseline. However, adding the information about entropy significantly ($p \leq 0.01$) improves the performance over all other ranking methods.

Finally, in Table 4 we show the top ten fastest growing threads in our data (ranked by the number of users posting in the thread). Each thread is represented by the first tweet. We can see from the table that events which spread the fastest on Twitter are mostly deaths of famous people. One spam thread that appears in the list has an entropy of 2.5 and doesn't appear in the top ten list when using the entropy + users ranking.

Table 4: Top ten fastest growing threads in our data.

# users	First tweet
7814	TMZ reporting michael jackson has had a heart attack. We r checking it out. And pulliing video to use if confirmed
7579	RIP Patrick Swayze...
3277	Walter Cronkite is dead.
2526	we lost Ted Kennedy :(

1220	LA Times reporting Manny Ramirez tested positive for performance enhancing drugs. To be suspended 50 games.
1057	A representative says guitar legend Les Paul has died at 94

7 Conclusion

We presented an approach to first story detection in a streaming setting. Our approach is based on locality sensitive hashing adapted to the first story detection task by introducing a backoff towards exact search. This adaptation greatly improved performance of the system and virtually eliminated variance in the results. We showed that, using our approach, it is possible to achieve constant space and processing time while maintaining very good results. A comparison with the UMass FSD system showed that we gain more than an order of magnitude speedup with only a minor loss in performance. We used our FSD system on a truly large-scale task of detecting new events from over 160 million Twitter posts. To the best of our knowledge, this is the first work that does event detection on this scale. We showed that our system is able to detect major events with reasonable precision, and that the amount of spam in the output can be reduced by taking entropy into account.

Acknowledgments

The authors would like to thank Donnla Osborne for her work on annotating tweets.

Abstract

In this paper we propose a novel general framework for unsupervised model adaptation. Our method is based on entropy which has been used previously as a regularizer in semi-supervised learning. This technique includes another term which measures the stability of posteriors w.r.t model parameters, in addition to conditional entropy. The idea is to use parameters which result in both low conditional entropy and also stable decision rules. As an application, we demonstrate how this framework can be used for adjusting language model interpolation weight for speech recognition task to adapt from Broadcast news data to MIT lecture data. We show how the new technique can obtain comparable performance to completely supervised estimation of interpolation parameters.

1 Introduction

All statistical and machine learning techniques for classification, in principle, work under the assumption that

1. A reasonable amount of training data is available.
2. Training data and test data are drawn from the same underlying distribution.

In fact, the success of statistical models is crucially dependent on training data. Unfortunately, the latter assumption is not fulfilled in many applications. Therefore, model adaptation is necessary when training data is not matched (not drawn from same distribution) with test data. It is often the case where we have plenty of labeled data for one specific domain/genre (source domain) and little amount of labeled data (or no labeled data at all) for the desired domain/genre (target domain). Model adaptation techniques are commonly used to address this problem. Model adaptation starts with trained models (trained on source domain with rich amount of labeled data) and then modify them using the available labeled data from target domain (or instead unlabeled data). A survey on different methods of model adaptation can be found in (Jiang, 2008).

Information regularization framework has been previously proposed in literature to control the label conditional probabilities via input distribution (Szummer and Jaakkola, 2003). The idea is that labels should not change too much in dense regions of the input distribution. The authors use the mutual information between input features and labels as a measure of label complexity. Another framework previously suggested is to use label entropy (conditional entropy) on unlabeled data as a regularizer to Maximum Likelihood (ML) training on labeled data (Grandvalet and Bengio, 2004).

Availability of resources for the target domain categorizes these techniques into either *supervised* or *unsupervised*. In this paper we propose a general framework for unsupervised adaptation using Shannon entropy and stability of entropy. The assumption is that in-domain and out-of-domain distributions are not too different such that one can improve the performance of initial models on in-domain data by little adjustment of initial decision boundaries (learned on out-of-domain data).

2 Conditional Entropy based Adaptation

In this section, conditional entropy and its relation to classifier performance are first described. Next, we introduce our proposed objective function for domain adaptation.

2.1 Conditional Entropy

Considering the classification problem where $\mathbf{X}$ and $\mathbf{Y}$ are the input features and the corresponding class labels respectively, the conditional entropy is a measure of the class overlap and is calculated as follows

$$H(\mathbf{Y}|\mathbf{X}) = E_{\mathbf{X}}[H(\mathbf{Y}|\mathbf{X}=x)] = \\ -\int p(x)\left(\sum_y p(y|x)\log p(y|x)\right)dx \quad (1)$$

Through *Fano's Inequality* theorem, one can see how conditional entropy is related to classification performance.

Theorem 1 (Fano's Inequality) *Suppose* $P_e = P\{\hat{\mathbf{Y}} \neq \mathbf{Y}\}$ *where* $\hat{\mathbf{Y}} = g(X)$ *are the assigned labels for the data points, based on the classification rule. Then*

$$P_e \geq \frac{H(\mathbf{Y}|\mathbf{X}) - 1}{\log(|\mathcal{Y}| - 1)}$$

where $\mathcal{Y}$ *is the number of possible classes and* $H(Y|X)$ *is the conditional entropy with respect to true distibution.*

The proof to this theorem can be found in (Cover and Thomas, 2006). This inequality indicates that $\mathbf{Y}$ can be estimated with low probability of error only if the conditional entropy $H(\mathbf{Y}|\mathbf{X})$ is small.

Although the above theorem is useful in a sense that it connects the classification problem to Shannon entropy, the true distributions are almost never known to us[1]. In most classification methods, a specific model structure for the distributions is assumed and the task is to estimate the model parameters within the assumed model space. Given the model structure and parameters, one can modify *Fano's Inequality* as follows,

Corollary 1

$$P_e(\theta) = P\{\hat{\mathbf{Y}} \neq \mathbf{Y} \mid \theta\} \geq \frac{H_\theta(\mathbf{Y}|\mathbf{X}) - 1}{\log(|\mathcal{Y}| - 1)} \quad (2)$$

where $P_e(\theta)$ *is the classifier probability of error given model parameters,* θ *and*

$$H_\theta(\mathbf{Y}|\mathbf{X}) = \\ -\int p(x)\left(\sum_y p_\theta(y|x)\log p_\theta(y|x)\right)dx$$

Here, $H_\theta(\mathbf{Y}|\mathbf{X})$ *is the conditional entropy imposed by model parameters.*

Eqn. 2 indicates the fact that models with low conditional entropy are preferable. However, a low entropy model does not necessarily have good performance (this will be reviewed later on) [2]

2.2 Objective Function

Minimization of conditional entropy as a framework in the classification task is not a new concept and has been tried by researchers. In fact, (Grandvalet and Bengio, 2004) use this along with the maximum likelihood criterion in a semi-supervised set up such that parameters with both maximum likelihood on labeled data and minimum conditional entropy on unlabeled data are chosen. By minimizing the entropy, the method assumes a prior which prefers minimal class overlap. Entropy minimization is used in (Li et al., 2004) as an unsupervised non-parametric clustering method and is shown to result in significant improvement over k-mean, hierarchical clustering and etc.

These methods are all based on the fact that models with low conditional entropy have their decision boundaries passing through low-density regions of the input distribution, $P(X)$. This is consistent with the assumption that classes are well separated so that one can expect to take advantage of unlabeled examples (Grandvalet and Bengio, 2004).

In many cases shifting from one domain to another domain, initial trained decision boundaries (on

[1] In fact, Theorem 1 shows how relevant the input features are for the classification task by putting a lower bound on the best possible classifier performance. As the overlap between features from different classes increases, conditional entropy increases as well, thus lowering the performance of the best possible classifier.

[2] Imagine a model which classifies any input as class 1. Clearly for this model $H_\theta(\mathbf{Y}|\mathbf{X}) = 0$.

out-of-domain data) result in high conditional entropy for the new domain, due to mismatch between distributions. Therefore, there is a need to adjust model parameters such that decision boundaries goes through low-density regions of the distribution. This motivates the idea of using minimum conditional entropy criterion for adapting to a new domain. At the same time, two domains are often close enough that one would expect that the optimal parameters for the new domain should not deviate too much from initial parameters. In order to formulate the technique mentioned in the above paragraph, let us define Θ_{init} to be the initial model parameters estimated on out-of-domain data (using labeled data). Assuming the availability of enough amount of unlabeled data for in-domain task, we try to minimize the following objective function w.r.t the parameters,

$$\theta_{\mathbf{new}} = \operatorname*{argmin}_{\theta} H_{\theta}(\mathbf{Y}|\mathbf{X}) + \lambda \left|\left|\theta - \theta_{\mathbf{init}}\right|\right|_p \tag{3}$$

where $||\theta - \theta_{\mathbf{init}}||_p$ is an L_p regularizer and tries to prevent parameters from deviating too much from their initial values[3].

Once again the idea here is to adjust the parameters (using unlabeled data) such that low-density separation between the classes is achieved. In the following section we will discuss the drawback of this objective function for adaptation in realistic scenarios.

3 Issues with Minimum Entropy Criterion

It is discussed in Section 2.2 that the model parameters are adapted such that a minimum conditional entropy is achieved. It was also discussed how this is related to finding decision boundaries through low-density regions of input distribution. However, the obvious assumption here is that the classes are well separated and there in fact exists low-density regions between classes which can be treated as boundaries. Although this is a suitable/ideal assumption for classification, in most practical problems this assumption is not satisfied and often classes overlap. Therefore, we can not expect the conditional entropy to be convex in this situation and to achieve minimization w.r.t parameters (other than the trivial solutions).

Let us clarify this through an example. Consider X to be generated by mixture of two 2-D Gaussians (each with a particular mean and covariance matrix) where each Gaussian corresponds to a particular class (binary class situation) . Also in order to have linear decision boundaries, let the Gaussians have same covariance matrix and let the parameter being estimated be the prior for class 1, $P(Y = 1)$. Fig. 1 shows two different situations with overlapping classes and non-overlapping classes. The left panel shows a distribution in which classes are well separated whereas the right panel corresponds to the situation where there is considerable overlap between classes. Clearly, in the later case there is no low-density region separating the classes. Therefore, as we change the parameter (here, the prior on the class $Y = 1$), there will not be any well defined point with minimum entropy. This can be seen from Fig. 2 where model conditional entropy is plotted vs. class prior parameter for both cases. In the case of no-overlap between classes, entropy is a convex function w.r.t the parameter (excluding trivial solutions which happens at $P(Y = 1) = 0, 1$) and is minimum at $P(Y = 1) = 0.7$ which is the true prior with which the data was generated.

We summarize issues with minimum entropy criterion and our proposed solutions as follows:

- Trivial solution: this happens when we put decision boundaries such that both classes are considered as one class (this can be avoided using the regularizer in Eqn. 3 and the assumption that initial models have a reasonable solution, e.g. close to the optimal solution for new domain)

- Overlapped Classes: As it was discussed in this section, if the overlap is considerable then the entropy will not be convex w.r.t to model parameters. We will address this issue in the next section by introducing the entropy-stability concept.

4 Entropy-Stability

It was discussed in the previous section that a minimum entropy criterion can not be used (by itself) in

[3] The other reason for using a regularizer is to prevent trivial solutions of minimum entropy criterion

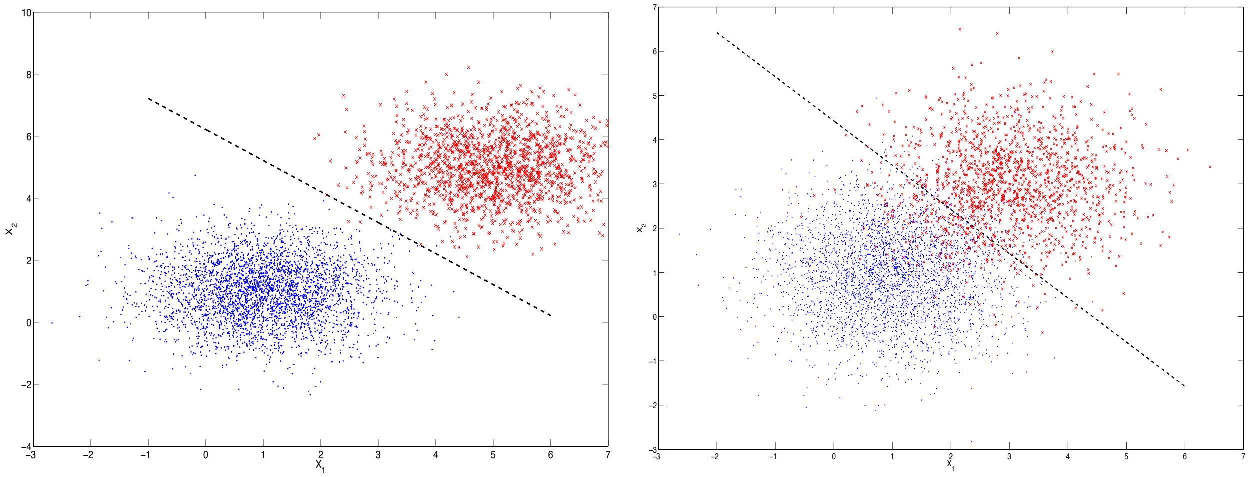

Figure 1: Mixture of two Gaussians and the corresponding Bayes decision boundary: (left) with no class overlap (right) with class overlap

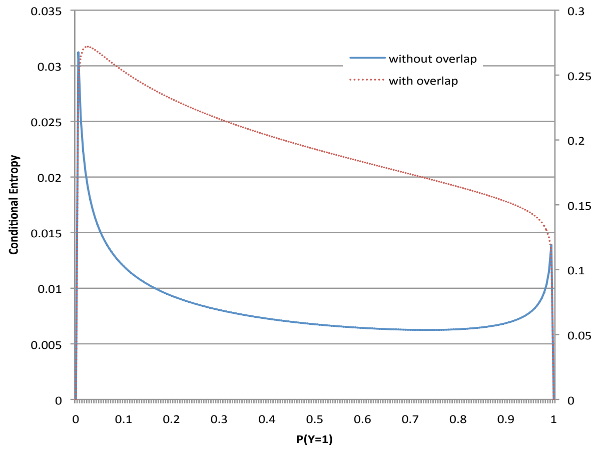

Figure 2: Condtional entropy vs. prior parameter, $P(Y = 1)$

situations where there is a considerable amount of overlap among classes. Assuming that class boundaries happen in the regions close to the tail of class distributions, we introduce the concept of *Entropy-Stability* and show how it can be used to detect boundary regions. Define *Entropy-Stability* to be the reciprocal of the following

$$\left|\left|\frac{\partial H_\theta(\mathbf{Y}|\mathbf{X})}{\partial\theta}\right|\right|_p = \left|\left|\int p(x)\frac{\partial\left(\sum_y p_\theta(y|x)\log p_\theta(y|x)\right)}{\partial\theta}dx\right|\right|_p \tag{4}$$

Recall: since θ is a vector of parameters, $\frac{\partial H_\theta(\mathbf{Y}|\mathbf{X})}{\partial\theta}$ will be a vector and by using L_p norm Entropy-stability will be a scalar.

The introduced concept basically measures the stability of label entropies w.r.t the model parameters. The idea is that we prefer models which not only have low-conditional entropy but also have stable decision rules imposed by the model. Next, we show through the following theorem how Entropy-Stability measures the stability over posterior probabilities (decision rules) of the model.

Theorem 2

$$\left|\left|\frac{\partial H_\theta(\mathbf{Y}|\mathbf{X})}{\partial\theta}\right|\right|_p = \left|\left|\int p(x)\left(\sum_y \frac{\partial p_\theta(y|x)}{\partial\theta}\log p_\theta(y|x)\right)dx\right|\right|_p$$

where the term inside the parenthesis is the weighted sum (by log-likelihood) over the gradient of posterior probabilities of labels for a given sample x

Proof The proof is straight forward and uses the fact that $\sum\frac{\partial p_\theta(y|x)}{\partial\theta} = \frac{\partial(\sum p_\theta(y|x))}{\partial\theta} = 0$.

Using Theorem 2 and Eqn. 4, it should be clear how Entropy-Stability measures the expected stability over the posterior probabilities of the model. A high value of $\left|\left|\frac{\partial H_\theta(\mathbf{Y}|\mathbf{X})}{\partial\theta}\right|\right|_p$ implies models with less stable decision rules. In order to explain how this is used for detecting boundaries (overlapped regions) we once again refer back to our mixture of Gaussians' example. As the decision boundary moves from class specific regions to overlapped regions (by changing the parameter which is here class prior probability) we expect the entropy to continuously decrease (due to the assumption that the overlaps occur at the tail of class distributions). However, as we get close to the overlapping regions the added data points from other class(es) will resist changes in the entropy. resulting in stability over the entropy until we enter the regions specific to other class(es).

In the following subsection we use this idea to propose a new objective function which can be used as an unsupervised adaptation method even for the case of input distribution with overlapping classes.

4.1 Better Objective Function

The idea here is to use the Entropy-Stability concept to accept only regions which are close to the overlapped parts of the distribution (based on our assumption, these are valid regions for decision boundaries) and then using the minimum entropy criterion we find optimum solutions for our parameters inside these regions. Therefore, we modify Eqn. 3 such that it also includes the Entropy-Stability term

$$\theta_{\mathbf{new}} = \underset{\theta}{\operatorname{argmin}} \Bigg(H_\theta(\mathbf{Y}|\mathbf{X}) + \gamma \left|\left| \frac{\partial H_\theta(\mathbf{Y}|\mathbf{X})}{\partial \theta} \right|\right|_{p'} + \lambda \left|\left|\theta - \theta_{\mathbf{init}}\right|\right|_p \Bigg) \tag{5}$$

The parameter γ and λ can be tuned using small amount of labeled data (Dev set).

5 Speech Recognition Task

In this section we will discuss how the proposed framework can be used in a speech recognition task. In the speech recognition task, Y is the sequence of words and X is the input speech signal. For a given speech signal, almost every word sequence is a possible output and therefore there is a need for a compact representation of output labels (words). For this, word graphs (Lattices) are generated during the recognition process. In fact, each lattice is an *acyclic directed graph* whose nodes correspond to particular instants of time, and arcs (edges connecting nodes) represent possible word hypotheses. Associated with each arc is an acoustic likelihood and language model likelihood scores. Fig. 3 shows an example of recognition lattice [4] (for the purpose of demonstration likelihood scores are not shown).

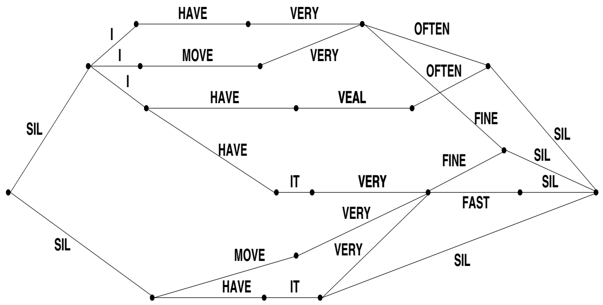

Figure 3: Lattice Example

Since lattices contain all the likely hypotheses (unlikely hypotheses are pruned during recognition and will not be included in the lattice), conditional entropy for any given input speech signal, x, can be approximated by the conditional entropy of the lattice. That is,

$$H_\theta(\mathbf{Y}|\mathbf{X} = x_i) = H_\theta(\mathbf{Y}|\mathcal{L}_i)$$

where $\mathcal{L}_i$ is the corresponding decoded lattice (given speech recognizer parameters) of utterance x_i.

For the calculation of entropy we need to know the distribution of X because $H_\theta(\mathbf{Y}|\mathbf{X}) = E_X[H_\theta(\mathbf{Y}|\mathbf{X} = x)]$ and since this distribution is not known to us, we use *Law of Large Numbers* to approximate it by the empirical average

$$H_\theta(\mathbf{Y}|\mathbf{X}) \approx -\frac{1}{N} \sum_{i=1}^{N} \sum_{y \in \mathcal{L}_i} p_\theta(y|\mathcal{L}_i) \log p_\theta(y|\mathcal{L}_i) \tag{6}$$

Here N indicates the number of unlabeled utterances for which we calculate the empirical value of conditional entropy. Similarly, expectation w.r.t input distribution in entropy-stability term is also approximated by the empirical average of samples.

Since the number of paths (hypotheses) in the lattice is very large, it would be computationally infeasible to compute the conditional entropy by enumerating all possible paths in the lattice and calculating

[4] The figure is adopted from (Mangu et al., 1999)

Element	$\langle p, r\rangle$
$\langle p_1, r_1\rangle \otimes \langle p_2, r_2\rangle$	$\langle p_1 p_2,\ p_1 r_2 + p_2 r_1\rangle$

0	$\langle 0, 0\rangle$
1	$\langle 1, 0\rangle$

Table 1: **First-Order (Expectation) semiring**: Defining *multiplication* and *sum* operations for first-order semirings.

their corresponding posterior probabilities. Instead we use Finite-State Transducers (FST) to represent the hypothesis space (lattice). To calculate entropy and the gradient of entropy, the weights for the FST are defined to be First- and Second-Order *semirings* (Li and Eisner, 2009). The idea is to use *semirings* and their corresponding operations along with the forward-backward algorithm to calculate first- and second-order statistics to compute entropy and the gradient of entropy respectively. Assume we are interested in calculating the entropy of the lattice,

$$\begin{aligned} H(p) &= -\sum_{d \in \mathcal{L}_i} \frac{p(d)}{Z} \log(\frac{p(d)}{Z}) \\ &= \log Z - \frac{1}{Z} \sum_{d \in \mathcal{L}_i} p(d) \log p(d) \\ &= \log Z - \frac{\bar{r}}{Z} \end{aligned} \quad (7)$$

where Z is the total probability of all the paths in the lattice (normalization factor). In order to do so, we need to compute $\langle Z, \bar{r}\rangle$ on the lattice. It can be proved that if we define the first-order semiring $\langle p_e, p_e \log p_e\rangle$ (p_e is the non-normalized score of each arc in the lattice) as our FST weights and define semiring operations as in Table. 1, then applying the forward algorithm will result in the calculation of $\langle Z, \bar{r}\rangle$ as the weight (semiring weight) for the final node.

The details for using Second-Order *semirings* for calculating the gradient of entropy can be found in (Li and Eisner, 2009). The same paper describes how to use the forward-backward algorithm to speed-up the this procedure.

6 Language Model Adaptation

Language Model Adaptation is crucial when the training data does not match the test data being decoded. This is a frequent scenario for all Automatic Speech Recognition (ASR) systems. The application domain very often contains named entities and N-gram sequences that are unique to the domain of interest. For example, conversational speech has a very different structure than class-room lectures. Linear Interpolation based methods are most commonly used to adapt LMs to a new domain. As explained in (Bacchiani et al., 2003), linear interpolation is a special case of Maximum A Posterior (MAP) estimation, where an N-gram LM is built on the adaptation data from the new domain and the two LMs are combined using:

$$p(w_i|h) = \lambda p_B(w_i|h) + (1-\lambda) p_A(w_i|h)$$
$$0 \le \lambda \le 1$$

where p_B refers to out-of-domain (background) models and p_A is the adaptation (in-domain) models. Here λ is the interpolation weight.

Conventionally, λ is calculated by optimizing perplexity (PPL) or Word Error Rate (WER) on some held-out data from target domain. Instead using our proposed framework, we estimate λ on enough amount of unlabeled data from target domain. The idea is that resources on the new domain have already been used to build domain specific models and it does not make sense to again use in-domain resources for estimating the interpolation weight. Since we are trying to just estimate one parameter and the performance of the interpolated model is bound by in-domain/out-of-domain models, there is no need to include a regularization term in Eqn. 5. Also $\left|\left|\frac{\partial H_\theta(\mathbf{Y}|\mathbf{X})}{\partial \theta}\right|\right|_p = |\frac{\partial H_\lambda(\mathbf{Y}|\mathbf{X})}{\partial \lambda}|$ because we only have one parameter. Therefore, interpolation weight will be chosen by the following criterion

$$\hat{\lambda} = \underset{0 \le \lambda \le 1}{\operatorname{argmin}} H_\lambda(\mathbf{Y}|\mathbf{X}) + \gamma |\frac{\partial H_\lambda(\mathbf{Y}|\mathbf{X})}{\partial \lambda}| \quad (8)$$

For the purpose of estimating one parameter λ, we use $\gamma = 1$ in the above equation

7 Experimental Setup

The large vocabulary continuous speech recognition (LVCSR) system used throughout this paper is based on the 2007 IBM Speech transcription system for GALE Distillation Go/No-go Evaluation (Chen et al., 2006). The acoustic models used in this system are state-of-the-art discriminatively trained models and are the same ones used for all experiments presented in this paper.

For LM adaptation experiments, the out-of-domain LM (p_B, Broadcast News LM) training text consists of 335M words from the following *broadcast news* (BN) data sources (Chen et al., 2006): 1996 CSR Hub4 Language Model data, EARS BN03 closed captions, GALE Phase 2 Distillation GNG Evaluation Supplemental Multilingual data, Hub4 acoustic model training transcripts, TDT4 closed captions, TDT4 newswire, and GALE Broadcast Conversations and GALE Broadcast News. This language model is of order 4-gram with Kneser-Ney smoothing and contains $4.6M$ n-grams based on a lexicon size of $84K$.

The second source of data is the MIT lectures data set (J. Glass, T. Hazen, S. Cyphers, I. Malioutov, D. Huynh, and R. Barzilay, 2007) . This serves as the target domain (in-domain) set for language model adaptation experiments. This set is split into 8 hours for in-domain LM building, another 8 hours served as unlabeled data for interpolation weight estimation using criterion in Eqn. 8 (we refer to this as unsupervised training data) and finally 2.5 hours Dev set for estimating the interpolation weight w.r.t WER (supervised tuning) . The lattice entropy and gradient of entropy w.r.t λ are calculated on the unsupervised training data set. The results are discussed in the next section.

8 Results

In order to optimize the interpolation weight λ based on criterion in Eqn. 8, we devide $[0, 1]$ to 20 different points and evaluate the objective function (Eqn. 8) on those points. For this, we need to calculate entropy and gradient of the entropy on the decoded lattices of the ASR system on 8 hours of MIT lecture set which is used as an unlabeled training data. Fig. 4 shows the value of the objective function against different values of model parameters (interpolation weight λ). As it can be seen from this figure just considering the conditional entropy will result in a non-convex objective function whereas adding the entropy-stability term will make the objective function convex. For the purpose of the evaluation, we show the results for estimating λ directly on the transcription of the 8 hour MIT lecture data and compare it to estimated value using our framework. The results are shown in Fig. 5. Using $\lambda = 0$ and $\lambda = 1$ the WERs are 24.7% and 21.1% respectively. Using the new proposed objective function, the optimal λ is estimated to be 0.6 with WER of 20.1% (Red circle on the figure). Estimating λ w.r.t 8 hour training data transcription (supervised adaptation) will result in $\lambda = 0.7$ (green circle) and WER of 20.0%. Instead $\lambda = 0.8$ will be chosen by tuning the interpolation weight on 2.5 hour Dev set with comparable WER of 20.1%. Also it is clear from the figure that the new objective function can be used to predict the WER trend w.r.t the interpolation weight parameter.

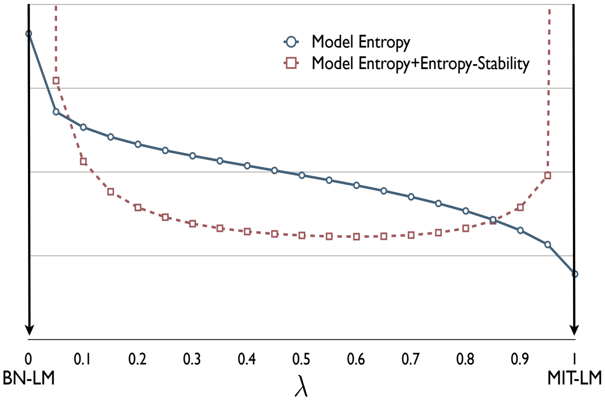

Figure 4: Objective function with and without including Entropy-Stability term vs. interpolation weight λ on 8 hours MIT lecture unlabeled data

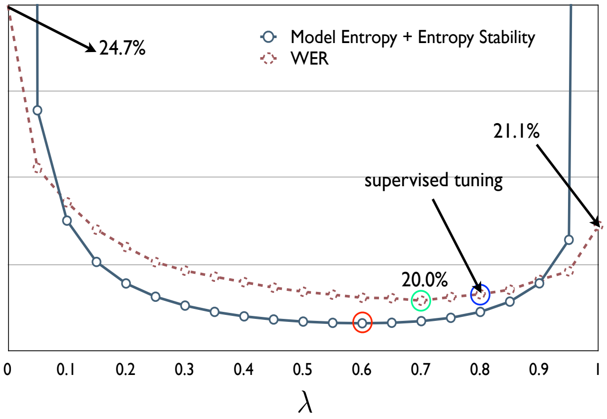

Figure 5: Estimating λ based on WER vs. the information-theoretic criterion

Therefore, it can be seen that the new unsupervised method results in the same performance as supervised adaptation in speech recognition task.

9 Conclusion and Future Work

In this paper we introduced the notion of entropy stability and presented a new criterion for unsupervised adaptation which combines conditional entropy minimization with entropy stability. The entropy stability criterion helps in selecting parameter settings which correspond to stable decision boundaries. Entropy minimization on the other hand tends to push decision boundaries into sparse regions of the input distributions. We show that combining the two criterion helps to improve unsupervised parameter adaptation in real world scenario where class conditional distributions show significant overlap. Although conditional entropy has been previously proposed as a regularizer, to our knowledge, the gradient of entropy (entropy-stability) has not been used previously in the literature. We presented experimental results where the proposed criterion clearly outperforms entropy minimization. For the speech recognition task presented in this paper, the proposed unsupervised scheme results in the same performance as the supervised technique.

As a future work, we plan to use the proposed criterion for adapting log-linear models used in Machine Translation, Conditional Random Fields (CRF) and other applications. We also plan to expand linear interpolation Language Model scheme to include history specific (context dependent) weights.

Formatting Time-Aligned ASR Transcripts for Readability

Maria Shugrina[*]
Google Inc.
New York, NY 10011
shumash@google.com

Abstract

We address the problem of formatting the output of an automatic speech recognition (ASR) system for readability, while preserving word-level timing information of the transcript. Our system enriches the ASR transcript with punctuation, capitalization and properly written dates, times and other numeric entities, and our approach can be applied to other formatting tasks. The method we describe combines hand-crafted grammars with a class-based language model trained on written text and relies on Weighted Finite State Transducers (WFSTs) for the preservation of start and end time of each word.

1 Introduction and Prior Work

The output of a typical ASR system lacks punctuation, capitalization and proper formatting of entities such as phone numbers, time expressions and dates. Even if such automatic transcript is free of recognition errors, it is difficult for a human to parse. The proper formatting of the transcript gains particular importance in applications where the user relies on ASR output for information and where information-rich numeric entities (e.g. time expressions, monetary amounts) are common. A good example of such application is a voicemail transcription system. The goal of our work is to transform the raw transcript into its proper written form in order to optimize it for the visual scanning task by the end user. We present quantitative and qualitative evaluation of our system with a focus on numeric entity formatting, punctuation and capitalization (See Fig. 1).

Apart from text, the ASR output usually contains word-level metadata such as time-alignment and confidence. Such quantities may be useful for a variety of applications. Although simple to recover via word alignment after some types of formatting, word-level quantities may be difficult to preserve if the original text has undergone a significant transformation. We present a formal and general augmentation of our WFST-based technique that preserves word-level timing and confidence information during arbitrary formatting.

Raw Transcript:
hi bill it's tracy at around three thirty P M just got an apartment for one thousand three thirty one thousand four hundred a month my number is five five five eight eight eight eight extension is three thirty bye

Our Result:
Hi Bill, it's Tracy at around 3:30 PM, just got an apartment for 1,330 1,400 a month. My number is 555-8888 extension is 330. Bye.

Figure 1: An example of a raw transcript with ambiguous written forms and the output of our formatting system.

The problems of sentence boundary detection and punctuation of transcripts have received a substantial amount of attention, e.g. (Beeferman et al., 1998; Shriberg et al., 2000; Christensen et al., 2001; Liu et al., 2006; Gravano et al., 2009). Capitalization of ASR transcripts received less attention (Brown and Coden, 2002; Gravano et al., 2009), but there has also been work on case restoration in the context of machine translation (Chelba and Acero, 2006; Wang et al., 2006). Our work does not propose competing methods for transcript punctuation and capitalization. Instead, we aim to provide a common framework for a wide range of formatting tasks. Our method extends the approach of Gravano et al. (2009) with a general WFST formulation suitable for formatting monetary amounts, time expressions, dates, phone numbers, honorifics and more, in addition to punctuation and capitalization.

To our knowledge, this scope of the problem has not been addressed in literature. Yet such formatting can have a high impact on transcript readability. In this paper we focus on numeric entity format-

ting. In general, context independent rules fail to adequately perform this task due to its inherent ambiguity (See Fig. 1). For example, the spoken words “three thirty” should be written differently in these three contexts:

- meet me at **3:30**
- you owe me **330**
- dinner for **three 30** minutes later

The proper written form of a numeric entity depends on its class (time, monetary amount, etc). In this sense, formatting is related to the problem of named entity (NE) detection and value extraction, as defined by MUC-7 (Chinchor, 1997). Several authors have considered the problem of NE value extraction from raw transcripts (Huang et al., 2001; Jansche and Abney, 2002; Béchet et al., 2004; Levit et al., 2004). This is an information extraction task that involves identifying transcript words corresponding to a particular NE class and extracting an unambiguous value of that NE (e.g. the value of the date NE “december first oh nine” is “12/01/2009”). Although relevant, this information extraction does not directly address the problem of proper formatting and ordinarily requires a tagged corpus for training.

A parallel corpus containing raw transcriptions and the corresponding formatted strings would facilitate the solution to the transcript formatting problem. However, there is no such corpus available. Therefore, we follow the approach of Gravano et al. and provide an approximation that exploits readily available written text instead. In section 2 we detail our method, provide a probabilistic interpretation and present a practical formulation of the solution in terms of WFSTs. Section 3 shows how to augment the WFST formulation to preserve word-level timing and confidence. Section 4 presents both qualitative and quantitative evaluation of our system.

2 Method

First, handwritten grammars are used to generate all plausible written forms. These variants are then scored with a language model (LM) approximating probability over written strings. To overcome data sparsity associated with written numeric strings, we introduce numeric classes into the LM. In section 2.1 we give a probabilistic formulation of this approach. In section 2.2 we comment on the handwritten grammars, and in section 2.3 we discuss the class-based language model used for scoring. Section 2.4 provides the WFST formulation of the solution.

2.1 Probabilistic Formulation

The problem of estimating the best written form $\hat{w}$ of a spoken sequence of words s can be formulated as a Machine Translation (MT) problem of translating a string s from the language of spoken strings into a language of written strings. From a statistical standpoint, $\hat{w}$ can be estimated as follows:

$$\hat{w} = \underset{w}{\operatorname{argmax}}\{P(w|s)\} \approx \underset{w}{\operatorname{argmax}}\{P'(s|w)P'(w)\},$$

where $P(\cdot)$ denotes probability, and $P'(\cdot)$ a probability approximation. The probability over written strings $P(w)$ can be estimated by training an n-gram language model on amply available written text. The absence of a parallel corpus containing sequences of spoken words and their written renditions makes the conditional distribution $P(s|w)$ impossible to estimate. An approximation $P'(s|w)$ can be obtained by defining handwritten grammars that generate multiple unweighted written variants for any spoken sequence. For a given s, a collection of grammars encodes a uniform probability distribution across the set of all written variants generated for s and assigns a zero probability to any string not in this set. Such grammar-based modeling of $P(s|w)$ combined with statistical estimation of $P(w)$ takes advantage of prior knowledge, but does not share the disadvantages of rigid, fully rule-based systems.

2.2 Handwritten Grammars

Handwritten grammars $G_1...G_m$ are used to generate unweighted written variants for a raw string s. In Gravano’s work (Gravano et al., 2009) the generated variants include optional punctuation between every two words and an optional capitalization for every word. Our system supports a wider range of variants, including but not limited to multiple variants of number formatting.

The handwritten grammars can be very restrictive or very liberal, depending on the application requirements. For example, a grammar we use to generate punctuation and capitalization only generates sentences with the first word capitalized. This enforces conventions and consistency, which the best scoring variant could occasionally violate. On the other

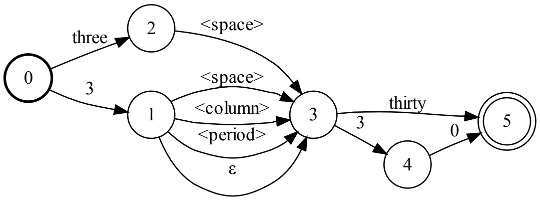

Figure 2: An FSA encoding all variants generated by the number grammar for a spoken string “three thirty”.

hand, the grammar for number formatting could be very liberal in producing written variants (See Fig. 2). Jansche and Abney (2002) observe that handwritten rules deterministically tagging numeric strings of certain length as phone numbers perform surprisingly well on phone number NE identification in voicemail. If appropriate to the task, deterministic grammars can be incorporated into the grammar stack. The unweighted written variants generated by applying $G_1 ... G_m$ to s are then scored with the language model.

2.3 Language Model

The probability distribution over written text $P(w)$ can be approximated by a Katz back-off n-gram language model trained on written text in a domain semantically similar to the domain for which the ASR engine is deployed. Unlike some of the approaches used for NE identification (Jansche and Abney, 2002; Levit et al., 2004) and sentence boundary detection (Christensen et al., 2001; Shriberg et al., 2000; Liu et al., 2006), LM-based scoring cannot exploit a larger context than n tokens or prosodic features. The advantage of the LM approach is the ease of applying it to new formatting tasks: no new tagged corpus, and only trivial changes to the preprocessing of the training text would be required.

If the LM is to score written numeric strings, care must be taken in modeling numbers. Representing each written number as a token (e.g. tokens “1,235”, “15”) during training results in a very large model and suffers from data sparsity even with very large training corpora. An alternative approach of modeling every digit as a token (e.g. “15” is comprised of tokens “1” and “2”) fails to model sufficient context for longer digit strings. A partially class-based LM remedies the drawbacks of both approaches, and has been used for tasks such as NE tagging (Béchet et al., 2004). The generalization provided by classes eliminates data sparsity, and is able to model sufficient context.

Class Set A	
Numeric range	*Interpretation*
2-9	single digits
10-12	up to hour in a 12-hour system
13-31	up to the largest day of the month
32-59	up to the largest minute in a time expression
other 2-digit	all other 2-digit numbers
other 3-digit	all 3-digit numbers
1900 - 2099	common year numbers
other 4-digit	all other 4-digit numbers
10000-99999	all 5-digit numbers; e.g. US zip-codes
$\geq$ 100000	all large numbers

Class Set B	
Numeric range	*Interpretation*
0-9	one digit string
10-99	two digit string
...	...
$10^9 - (10^{10} - 1)$	ten-digit string
$\geq 10^{10}$	longer digit string

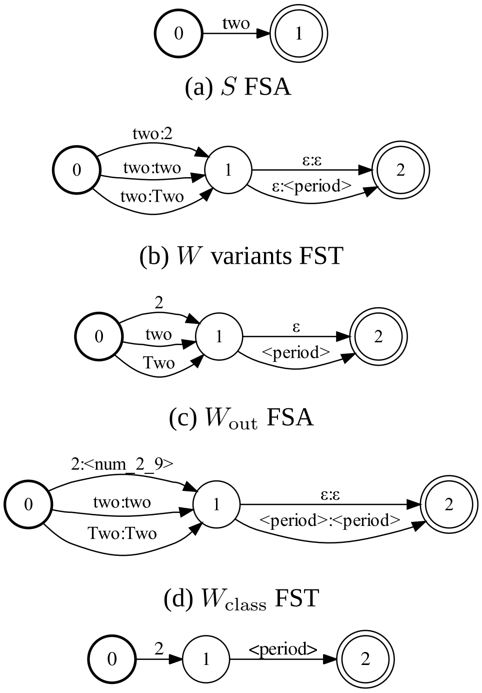
Table 1: Two sets of number classes used in our system. Each sequence of consecutive digit characters is mapped to the appropriate class. For example, “$1,235.12” would become “⟨dollar⟩ 1 ⟨comma⟩ ⟨num_100_999⟩ ⟨period⟩ ⟨num_10_12⟩” in Class Set A and “⟨dollar⟩ ⟨num_1D⟩ ⟨comma⟩ ⟨num_3D⟩ ⟨period⟩ ⟨num_2D⟩ in Class Set B.

We experiment with two sets of classes (See Table 1). Class Set B, based on (Béchet et al., 2004), marks strings of n consecutive digits as belonging to an n-digit class, assuming nothing about the number distribution. Class Set A is based on intuition about number distribution in text (See Table 1, *Interpretation*). In section 4.4 we show that Class Set A achieves better performance on number formatting. Now that it is established that the choice of classes affects performance, future research could focus on finding an optimal set of number classes automatically. Clustering techniques, often used to derive class definitions from training text, could be applied.

Although more punctuation marks could be considered, we focus on periods and commas. Similarly to Gravano et al. (2009), we map all other punctuation marks in the training text to these two. In many formatting scenarios (e.g. spelled out acronyms, numeric ranges), spaces are ambiguous and significant, and it is therefore important to consider whitespace when scoring the written variants. Because of this, we model space as a token in the LM.

2.4 WFST Formulation

The one-best[1] ASR output s can be represented by a Finite State Acceptor (FSA) S. We describe a series of standard WFST operations on S resulting in the FSA W_{best} encoding the best estimated formatted variant $\hat{w}$. Current section assumes familiarity with WFSTs; for background see (Mohri, 2009).



(a) S FSA

(b) W variants FST

(c) W_{out} FSA

(d) W_{class} FST

(e) W_{best} FSA

Figure 3: An example showing transducers produced during formatting.

We encode each grammar G_i as an unweighted FST T_i that transduces the raw transcript to its formatted versions. The necessity to encode them as FSTs restricts the set of grammars to regular grammars (Hopcroft and Ullman, 1979), sufficiently powerful for most formatting tasks. The back-off n-gram LM is naturally represented as a weighted deterministic FSA G with negative log probability weights (Mohri et al., 2008). The deterministic mapping of digit strings to number class tokens can also be accomplished by an unweighted transducer K, which passes all non-numeric strings unchanged.

Composing the input acceptor S with the grammar transducers T_i results in a transducer W with all written variants on the output. Projected onto its output labels, W becomes an acceptor W_{out}. W_{class}, the result of the composition of W_{out} with K, has all formatted written variants on the input side and the formatted variants with digit strings replaced by class tokens on the output. The output side of W_{class} can then be scored via composition with G to produce a weighted transducer W_{scored}. The shortest path in the Tropical Semiring on W_{scored} contains the estimate of the best written variant on the input side. This algorithm can be summarized as follows (See Fig. 3):

1. $W = S \circ T_1 \circ T_2 ... \circ T_m$
2. $W_{\text{out}} = \text{Proj}_{\text{out}}(W)$
3. $W_{\text{class}} = W_{\text{out}} \circ K$
4. $W_{\text{scored}} = W_{\text{class}} \circ G$
5. $W_{\text{best}} = \text{Proj}_{\text{in}}(\text{BestPath}(W_{\text{scored}}))$

where $\circ$ denotes FST composition, Proj_{in} and Proj_{out} denote projection on input and output labels respectively, and $\text{BestPath}(X)$ as a function returning an FST encoding the shortest path of X. The key Step 2 ensures that the target written variants are not consumed in the consequent composition operations. For efficiency reasons it is advisable to apply optimizations such as epsilon removal and determinization to the intermediate results. [2]

3 Preserving Word-Level Metadata

We extend the WFST formulation to preserve word-level timing and confidence information.

3.1 Background

A WFST is a finite set of states and transitions connecting them. Each transition has an input label, an output label and a weight in some semiring $\mathbb{K}$. A semiring is informally defined as a touple $(\mathbb{K}, \oplus, \otimes, \bar{0}, \bar{1})$, where $\mathbb{K}$ is the set of elements, $\oplus$ and $\otimes$ are the addition and multiplication operations, $\bar{0}$ is the additive identity and multiplicative annihilator, $\bar{1}$ is the multiplicative identity (See (Mohri,

[1] This WFST formulation can also be applied to the ASR lattice or n-best list with some modification to the scoring phase.

[2] Our system implements proper failure transitions available in the OpenFST Library (Allauzen et al., 2007).

2009)). By defining new semirings we can use standard FST operations to accomplish a wide range of goals.

3.2 Timing Semiring

In order to formulate time preservation within the FST formalism, we define the *timing semiring* $\mathbb{K}_t$ where each element is a pair (s, e) that can be interpreted as the start and end time of a word:

$$W_t = \{(s, e) : s, e \in \mathbb{R}^+ \cup \{0, \infty\}\}$$

$$(s_1, e_1) \oplus (s_2, e_2) = (max(s_1, s_2),\ min(e_1, e_2))$$

$$(s_1, e_1) \otimes (s_2, e_2) = (min(s_1, s_2),\ max(e_1, e_2))$$

$$\overline{0} = (0, \infty) \qquad \overline{1} = (\infty, 0)$$

Intuitively, the addition operation takes the largest interval contained by both operand intervals, while multiplication returns the smallest interval fully containing both operand intervals. [3] This definition fulfills all the semiring properties as defined in (Mohri, 2009). Note that encoding only the duration of each word is not sufficient, as there may be time gaps between the words due to the segmentation of the source audio. Let $\tilde{S}$ denote the Weighted Finite State Acceptor (WFSA) encoding the raw ASR output with the start and end time stored in the weight of each arc.

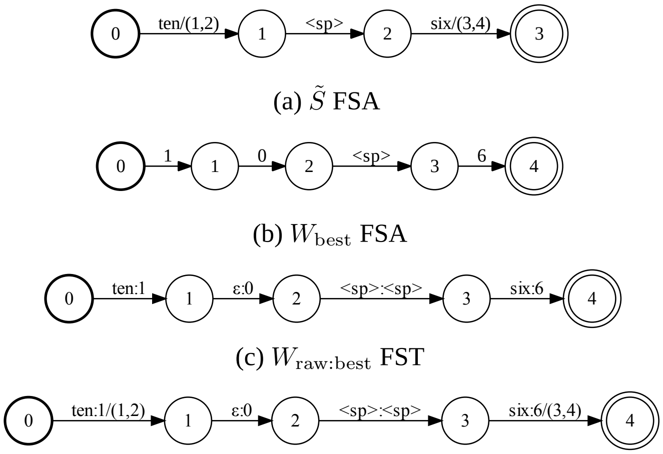
In order to preserve word-level confidence in addition to timing information, a Cartesian product of $\mathbb{K}_t$ and the Log semiring can be used to store both time and confidence in an arc weight.

3.3 Weight Synchronization

The goal is to associate the timing/confidence weights of $\tilde{S}$ with the word labels of W_{best}, the best formatted string (See Sec. 2.4). Because the weight of each transition in $\tilde{S}$ already expresses the timing/confidence corresponding to its word label, it is sufficient to associate the labels of $\tilde{S}$ with the labels of W_{best}. This is equivalent to identifying the output labels to which each input label is transduced during Step 1 in section 2.4. However, in general WFST operations may desynchronize input and output labels and weights, as the FST structure itself does not indicate a semantic correspondence between them. To alleviate this, we guarantee such a correspondence in our grammars by enforcing that for all paths in any grammar FST T_i:

- an input label appears before any of the corresponding output labels, and
- output labels corresponding to a given input label appear before the next input label.

In practice, these assumptions are usually met by handwritten grammars. Even if these assumptions are violated for a small number of paths, only small word-level timing discrepancies will be incurred. Each path in W can be thought of as a sequence of subpaths with only the first transition containing a non-ϵ input label. We say that the input label of each such subpath corresponds to that subpath's output labels.



(a) $\tilde{S}$ FSA

(b) W_{best} FSA

(c) $W_{\text{raw:best}}$ FST

(d) $\tilde{W}_{best}$ FST

Figure 4: A small example of time preservation section of the algorithm. Arcs with non-unity timing weights show parenthesized pair of start and end time.

The best path that has input labels corresponding to the raw ASR output can be obtained by composing the variants FST W with the best formatted FSA W_{best} and picking any path. The timing weights are restored to by composing the weighted $\tilde{S}$ with this result. To preserve timing we add two more steps to Steps 1–5 in section 2.4:

6. $W_{\text{raw:best}} = \text{RmEps}(\text{AnyPath}(W \circ W_{\text{best}}))$
7. $\tilde{W}_{\text{best}} = \tilde{S} \circ \text{Map}_{\text{t}}(W_{\text{raw:best}})$

where $\text{RmEps}(X)$ applies the epsilon-removal algorithm to X (Mohri, 2009), and $\text{Map}_{\text{t}}(X)$ maps

[3] Note that this is just a Cartesian product of min-max and max-min semirings. The elements of $\mathbb{K}_t$ are not proper intervals, as it is possible for s to exceed e.

all non-zero weights of X to the unity weight in the *timing semiring*. Because $\tilde{S}$ is an epsilon-free acceptor, the result $\tilde{W}_{\mathrm{best}}$ will contain the original weights of $\tilde{S}$ on the arcs with the corresponding input labels (See Fig. 4 for an example). The space-delimited words and the corresponding weights can then be read off by walking $\tilde{W}_{\mathrm{best}}$.

4 Evaluation

Section 4.1 presents our datasets and an evaluation metric specific to number formatting, and section 4.2 describes our experimental system. We present quantitative evaluation of capitalization/punctuation performance and number formatting performance separately in sections 4.3 and 4.4. Because the ultimate goal of our work is to improve the readability of ASR transcripts, we also present the result of a user study of transcript readability in section 4.5.

4.1 Data and Metrics

The training corpus contains 185M tokens of written text normalized to contain only comma and period punctuation marks. A set of 176M tokens (TRS) is used for training and a set of 7M tokens (PTS) is held back for testing punctuation and capitalization (See Table 3). To obtain a test input (NPTS) for our system, PTS is lowercased and all punctuation is removed.

	words	commas	periods	capitals
TRS	176M	10.6M	11.8M	24.3M
PTS	7M	420K	440K	880K

Table 3: Training set TRS and test set PTS.

Number formatting is evaluated on a manually formatted test set. We manually processed the set of raw manual transcripts (NNTS) from the LDC Voicemail Part I training set (Padmanabhan et al., 1998) to obtain a reference number formatting set (NTS). All numeric entities in NTS were formatted according to the following conventions:

- all quantities under 10 are spelled out
- time is written in a 12-hour system as “xx:xx” or “xx”
- dollar amounts are written as “$x,xxx.xx” with cents included if spoken
- US phone numbers are written as “(xxx) xxx-xxxx” or “xxx-xxxx”
- other phone numbers are written as digit strings
- decimals are written as “x.x”
- large amounts include commas: “x,xxx,xxx”

All contiguous sequences of words in NTS that could be a target for number formatting were marked as *numeric entities*, whether or not these words were formatted by the labeler (for example “six” is a *numeric entity*). To evaluate number formatting performance, we process NNTS with our full experimental system, then remove all capitalization and inter-word punctuation. This result is aligned with NTS, and each entity is scored separately as totally correct or totally incorrect (See Table 2), yielding:

$$\mathrm{Numeric\ Entity\ Error\ Rate} = 100 \cdot \frac{I}{N}$$

where I is the count of entities that did not match the reference entity string exactly and N is the total entity count. This error rate is independent of the numeric entity density in the test set. The errors are broken down into three types:

- incorrect formatting - when the system incorrectly formats an entity that is formatted in the reference
- overformatting - when the system formats an entity that stays unformatted in the reference
- underformatting - when the system does not format an entity formatted in the reference

Out of 1801 voicemail transcripts in NTS, 1347 contain at least one entity for a total of 3563 entities, signifying a frequent occurrence of numeric entities in voicemail. There is an average of 7 raw transcript words per entity, suggesting that in many cases entity formatting is non-trivial.

4.2 Experimental System

The experimental system includes a 5-gram LM trained on TRS with spaces treated as tokens. Number evaluation is performed with two sets of number classes, listed in Table 1. System A contains LM with classes from set A, and System B contains LM with classes from set B. The experimental setup also includes the following grammars:

- G_{phone} - deterministically formats as a phone number any string spoken like a US 7 or 10 digit phone number
- G_{number} - expands all spoken numbers to a full range of variants, with support for time expressions, ordinals, decimals, dollar amounts
- $G_{\mathrm{cap\_punct}}$ - generates all possible combinations of commas, periods and capitals; always capitalizes the first word of a sentence

Raw:	for	**six**	people at	**five five thirty**	cost is	**eleven hundred dollars**
Ref:	for	**six**	people at	**5 5:30**	cost is	**$1,100**
Hyp:	for	**6**	people at	**5 5:30**	cost is	**11 $100**
Score:	-	incorrect	-	correct	-	incorrect

Table 2: A example of a raw transcript, reference transcript with number formatting and the hypothesis produced by the system. The entities (bold) in reference and hypothesis are aligned and scored.

4.3 Evaluation of Punctuation

To evaluate the performance of capitalization and punctuation we run System A on NPTS with only the $G_{\mathrm{cap\_punct}}$ (in order not to introduce errors due to numeric formatting). The precision, recall and F-measure rates for periods, commas and capitals are computed using PTS as reference (See Fig. 5).

	Precision	Recall	F-Measure
Capitals	0.7902	0.5356	0.6385
Comma	0.5527	0.3129	0.3996
Period	0.6672	0.6783	0.6727

Figure 5: Punctuation and capitalization results.

It should be noted that a 5-gram language model that treats spaces as words models the same history as a 3-gram model that omits the spaces from training data. When this is taken into account, our results with a much smaller training set are comparable to Gravano et al. (2009). The F-measure scores for commas and periods are also comparable to the prosody-based work of (Christensen et al., 2001), with the precision of the period slightly lower, but compensated by recall. Thus, our system can perform additional formatting, while retaining a reasonable capitalization and punctuation performance.

4.4 Evaluation of Number Formatting

We evaluate number formatting performance of Systems A and B, which use different sets of classes for the language modeling (See Table 1). We process NNTS with both systems and score against the reference formatted set NTS to obtain Numeric Entity Error Rate (NEER). Class Set B naively breaks numbers into classes by digit count. System B using this class set performs worse than System A by 1.7% absolute (See Table 4). In particular, the overformatting rate (OFR) is higher by 1.2% absolute in System B than in System A. An example of overformatting is the mis-formatting of the English impersonal pronoun "one" as the digit "1". Such overformatting errors are much more noticeable than the underformatting errors, which are higher by 0.4% absolute in System A. This result shows that the choice of classes for the class-based LM significantly impacts number formatting performance. Superior overall performance of System A suggests that prior knowledge in the choice of classes favorably impacts performance.

	NEER	IFR	OFR	UFR
System A				
exact	16.1%	9.7%	5.4%	1.0%
ignore space	11.2%	4.9%	5.4%	1.0%
System B				
exact	17.8%	10.6%	6.6%	0.6%
ignore space	13.2%	6.0%	6.6%	0.6%

Table 4: The total NEER score, NEER due to incorrect formatting (IFR), NEER due to overformatting (OFR) and NEER due to underformatting (UFR); NEER rates with whitespace errors ignored are also listed.

In order to estimate the error rate not caused by whitespace errors, we also compute the NEER with whitespace errors ignored. It turns out that between 4 and 5% absolute of the errors are whitespace errors. Even if all whitespace errors are significant, the 83.9% of perfectly formatted entities suggests that the proposed formatting approach can achieve good performance on the number formatting task.

	entities	:	.	$	,
Reference totals	3563	310	50	39	17
System A correct	3161	232	36	33	10
System B correct	2923	204	35	31	5

Table 5: The count of formatted entities in NTS containing various formatting characters; the counts of these entities correctly formatted by the systems A and B.

To estimate how well the systems perform on specific number formatting tasks we count the number of reference entities containing certain formatting characters and compute the number of these entities correctly formatted by Systems A and B (See Table 5). The count of different formatting characters in NTS is small, but still provides an estimate of the number formatting performance for a real application like voicemail transcription. System A performs significantly better on the formatting of time expressions containing a colon, getting 74.8% correct. The NEER of System A for entities containing special formatting characters is under 28% for all formatting characters except comma, which is used inconsistently in training text.

4.5 Qualitative Evaluation

In addition to quantitative evaluation we have conducted a small-scale study of transcript readability. The study aims to compare raw ASR transcripts, ASR transcripts formatted by our system and raw manual transcripts. We have processed LDC Voicemail Part 1 with our ASR engine achieving an error rate of 30%, and have selected 50 voicemails with error rate under 30% and high informational content. Messages containing names, addresses and numbers were preferred. The word error rate on the selected voicemails is 20%. For each voicemail we have constructed three semantic multiple-choice questions, aimed at information extraction. We have asked each of 15 volunteers to answer all 3 questions about half of the voicemails. The questions were shown in sequence, while the transcript remained on the screen. The transcript for each voicemail was randomly selected to be ASR raw, ASR formatted or manual raw. The response time was measured individually for each question.

The analysis of the responses reveals a statistically significant difference in response time between formatted and raw ASR transcripts ($p = 0.02$, even allowing for per-item and per-subject effects; see also Fig. 6) and comparable accuracy. The response times for formatted ASR were comparable to the response times for manual unformatted transcripts. This suggests that for transcripts with low error rates the formatting of the ASR output significantly impacts readability. This disagrees with a similar study (Jones et al., 2003), which found no significant difference in the comprehension rates between raw ASR transcripts and capitalized, punctuated ASR output with disfluencies removed. This could be due to a number of factors, including a different type of transformation performed on the ASR transcript, a different corpus, and a lower word error rate of transcripts in our user study.

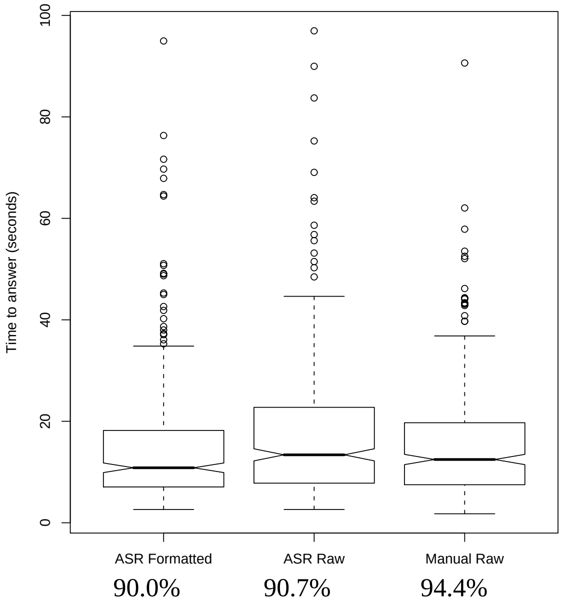


Figure 6: The standard R box plot of the response time for different transcript types and the corresponding accuracy.

5 Conclusion

We present a statistical approach suitable for a wide range of formatting tasks, including but not limited to punctuation, capitalization and numeric entity formatting. The average of 2 numeric entities per voicemail in the manually processed LDC Voicemail corpus shows that number formatting is important for applications such as voicemail transcription. Our best system achieves a Numeric Entity Error Rate of 16.1% on the ambiguous task of numeric entity formatting, while retaining capitalization and punctuation performance comparable to other published work. Our algorithm is concisely formulated in terms of WFSTs and is easily extended to new formatting tasks without the need for additional training data. In addition, the WFST formulation allows word-level timing and confidence to be retained during formatting. In order to overcome data sparsity associated with written numbers, we use a class-based language model and show that the choice of number classes significantly impacts number formatting performance. Finally, a statistically significant difference in question answering time for raw and formatted ASR transcripts in our user study demonstrates the positive impact of the transcript formatting on the readability of errorful ASR transcripts.

Cheap, Fast and Good Enough: Automatic Speech Recognition with Non-Expert Transcription

Scott Novotney and **Chris Callison-Burch**
Center for Language and Speech Processing
Johns Hopkins University
snovotne@bbn.com ccb@jhu.edu

Abstract

Deploying an automatic speech recognition system with reasonable performance requires expensive and time-consuming in-domain transcription. Previous work demonstrated that non-professional annotation through Amazon's Mechanical Turk can match professional quality. We use Mechanical Turk to transcribe conversational speech for as little as one thirtieth the cost of professional transcription. The higher disagreement of non-professional transcribers does not have a significant effect on system performance. While previous work demonstrated that redundant transcription can improve data quality, we found that resources are better spent collecting more data. Finally, we describe a quality control method without needing professional transcription.

1 Introduction

Successful speech recognition depends on huge investments in data collection. Even after training on 2000+ hours of transcribed conversational speech, over a billion words of language modeling text, and hand-crafted pronunciation dictionaries, state of the art systems still have an error rate of around 15% for English (Prasad et al., 2005) Transcribing the large volumes of data required for Large Vocabulary Continuous Speech Recognition (LVCSR) of new languages appears prohibitively expensive. Recent work has shown that Amazon's Mechanical Turk[1] can be used to cheaply create data for other natural language processing applications (Snow et al., 2008; Zaidan and Callison-Burch, 2009; McGraw et al., 2009). In this paper we focus on reducing the cost of transcribing conversational telephone speech (CTS) data. Previous measurements of Mechanical Turk stopped at agreement/disagreement with professional annotation. We take the next logical step and measure performance on systems trained with non-professional transcription.

Mechanical Turk is an online labor market where workers (or Turkers) perform simple tasks called Human Intelligence Tasks (HITs) for small amounts of money – frequently as little as $0.01 per HIT. Since HITs can be tasks that are difficult for computers, but easy for humans, they are ideal for natural language processing tasks (Snow et al., 2008). Mechanical Turk has even spawned a business that specializes in manual speech transcription.[2]

Automatic speech recognition (ASR) of conversational speech is an extremely difficult problem. Characteristics like rapid speech, phonetic reductions and speaking style limit the value of non-CTS data, necessitating in-domain transcription. Even a few hours of transcription is sufficient to bootstrap with unsupervised methods like self-training (Lamel et al., 2002). The speech community has built effective downstream solutions for the past twenty years despite imperfect recognition. In topic classification, 90% accuracy is possible on conversational data even with 80%+ word error rate

(WER) (Gillick et al., 1993). Other successful tasks include information retrieval from speech (Miller et al., 2007) and spoken dialogue processing (Young et al., 2007). Inexpensive transcription would quickly open new languages or domains (like meeting or lecture data) for automatic speech recognition.

In this paper, we make the following points:

- Quality control isn't necessary as a system built with non-professional transcription is only 6% worse for $\frac{1}{30}$ the cost of professional transcription.
- Resources are better spent collecting more data than improving data quality.
- Transcriber skill can be accurately estimated without gold standard data.

2 Related Work

Research into Mechanical Turk by the NLP community has largely focused on comparing the quality of annotations produced by non-expert Turkers against annotations created by experts. Snow et al. (2008) conducted a comprehensive study across a variety of NLP tasks. They showed that high agreement could be reached with gold-standard expert annotation for these tasks through a weighted combination of ten redundant annotations produced by Turkers.

Callison-Burch (2009) showed similar results for machine translation evaluation, and further showed that Turkers could accomplish complex tasks like translating Urdu or creating reading comprehension tests.

McGraw et al. (2009) used Mechanical Turk to improve an English isolated word speech recognizer by having Turkers listen to a word and select from a list of probable words at a cost of $20 per hour of transcription.

Marge et al. (2010) collected transcriptions of verbal instructions to robots with clean speech. By using five duplicate transcriptions, the average transcription disagreement with experts was reduced from 4% to 2%.

Previous efforts at reducing the cost of transcription include the EARS Fisher project (Cieri et al., 2004), which collected 2000+ hours of English CTS data – an order of magnitude more than had previously been transcribed. To speed transcription and lower costs, Kimball et al. (2004) created new transcription guidelines and used automatic segmentation. These improved the speed of transcription from fifty times real time to six times real time, and made it cost effective to transcribe 2000 hours at an average of $150 per hour. Models trained on the faster transcripts exhibited almost no degradation in performance, although discrimanitve training was sensitive to transcription errrors.

3 Experiment Description

3.1 Corpora

We conducted most experiments on a twenty hour subset of the English Switchboard corpus (Godfrey et al., 1992) where two strangers converse about an assigned topic. We used two sets of transcription as our gold standard: high quality transcription from the LDC and those following the Fisher quick transcription guidelines (Kimball et al., 2004) provided by a professional transcription company. All English ASR models were tested with the carefully transcribed three hour Dev04 test set from the NIST HUB5 evaluation.[3] A 75k word lexicon taken from the EARS Fisher training corpus covers the LDC training data and has a test OOV rate of 0.18%.

We also conducted experiments in Korean and collected Hindi and Tamil data from the Callfriend corpora [4]. Participants were given a free long distance phone call to talk with friends or family in their native language, although English frequently appears. Since Callfriend was originally intended for language identification, only the 27 hour Korean portion has been transcribed by the LDC.

3.2 LVCSR System

We used Byblos, a state-of-the-art multi-pass LVCSR system with state-clustered Gaussian tied-mixture acoustic models and modified Kneser-Ney smoothed language models (Prasad et al., 2005). While understanding the system

[3] http://www.itl.nist.gov/iad/mig/tests/ctr/1998/current-plan.html

[4] http://www.ldc.upenn.edu/CallFriend2/

details is not essential for this work, we provide a brief description for completeness.

Recognition begins with cepstral feature extraction using concatenated frames with cepstral mean subtraction and HLDA to reduce the feature dimension space. Vocal track length normalization follows. Decoding then requires three passes: a fast forward pass with coarse one-gaussian-per-phone models and bigram LM followed by a backward pass with triphone models and a trigram LM to generate word confusion lattices. The lattices are rescored with a more powerful quinphone cross-word acoustic model and trigram LM to extract the one best output. These three steps are repeated after unsupervised speaker adaptation with constrained MLLR. Decoding is around ten times real time.

3.3 Transcription Task

Using language-independent speaker activity detection models, we segmented each ten minute conversation into five second utterances, greatly simplifying the transcription task (Roy and Roy, 2009). Utterances were assigned in batches of ten per HIT and played with a simple flash player with a text box for entry. All non-empty HITs were approved and we did not award bonuses except as described in Section 5.1.

3.4 Measuring Annotation Quality

The usefullness of the transcribed data is ultimately measured by how much it benefits a speech recognition system. Factors that inflate disagreement (word error rate) between Turkers and professionals do not necessarily impact system performance. These include typographical mistakes, transcription inconsistencies (like improperly marking hesitations or the many variations of `um`) and spelling variations (`geez` or `jeez` are both valid spellings). Additionally, the gold standard is itself imperfect, with typical estimates of professional disagreement around five percent. Therefore, we judge the quality of Mechanical Turk data by comparing the performance of one LVCSR system trained on Turker annotation and another trained on professional transcriptions of the same dataset.

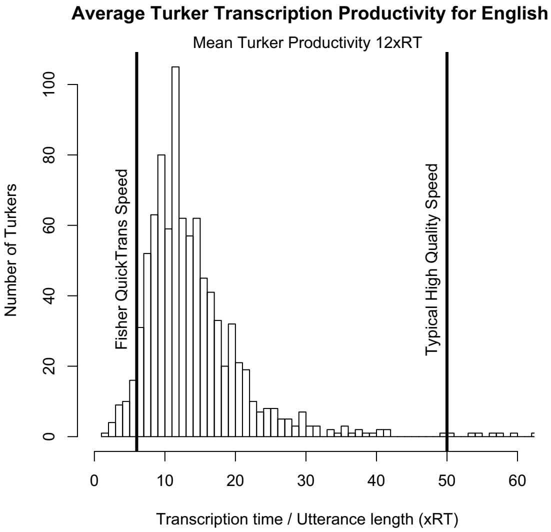

Figure 1: Histogram of per-turker transcription rate for twenty hours of English CTS data. Historical estimates for high quality transcription are 50xRT. The 2004 Fisher transcription effort achieved 6xRT and the average here is 11xRT.

4 Establishing Best Practices with English Switchboard

As an initial test to see how cheaply conversational data could be transcribed, we uploaded one hour of test data from Hub5 Dev04. We first paid $0.20 per HIT ($0.02 per utterance). This test finished quickly, and we measured the average disagreement with professionals at 17%. Next, we reduced payment to $0.10 per HIT and disagreement was again 17%. Finally, we pushed the price down to $0.05 per HIT or $5 per hour of transcription and again disagreement was nearly identical at 18%, although a few Turkers complained about the low pay.

Using this price, we then paid for the full twenty hours to be redundantly transcribed three times. 1089 Turkers participated in the task at an incoming rate of 10 hours of transcription per day. On average, each Turker transcribed 30 utterance (earning 15 cents) at an average professional disagreement of 23%. Transcribing one minute of audio required an average eleven minutes of effort (denoted 11xRT). 63 workers transcribed more than one hundred utterances and one prolific worker transcribed 1223 utterances.

4.1 Comparing Non-Professional to Professional Transcription

Table 1 details the results of different selection methods for redundant transcription. For each method of selection, we build an acoustic and language model and report WER on the heldout test set (transcribed at very high accuracy).

We first randomly selected one of the three transcriptions per utterance (as if the data were only tanscribed once) and repeated this three times with little variance. Selecting utterances randomly by *Turker* performed similarly. Performance of an LVCSR system trained on the non-professional transcription degrades by only 2.5% absolute (6% relative) despite a disagreement of 23%. This is without any quality control besides throwing out empty utterances. The degradation held constant as we swept the amount of training data frome one to twenty hours. Bot the acoustic and language models exhibited the log-linear relationship between WER and the amount of training data. Independent of the amount of training data, the acoustic model degraded by a nearly constant 1.7% and the language model by 0.8%.

To evaluate the benefit of multiple transcriptions, we built two oracle systems. The *Turker oracle* ranks Turkers by the average error rate of their transcribed utterances against the professionals and selects utterances by Turker until the twenty hours is covered (Section 4.3 discusses a fair way to rank Turkers). The *utterance oracle* selects the best of the three different transcriptions per utterance. The best of the three Turkers per utterance wrote the best transcription two thirds of the time.

The utterance oracle only recovered half of the degradation for using non-professional transcription. Cutting the disagreement in half (from 23% to 13%) reduced the WER gap by about half (from 2.5% to 1%). Using the standard system combination algorithm ROVER (Fiscus, 1997) to combine the three transcriptions per utterance only reduced disagreement from 23% to 21%. While previous work benefited from combining multiple annotations, this task shows little benefit.

Transcription	Disagreement with LDC	ASR WER
Random Utterance	23%	42.0%
Random Turker	20%	41.4%
Oracle Utterance	13%	40.9%
Oracle Turker	18%	41.1%
Contractor	< 5%	39.6%
LDC	-	39.5%

Table 1: Quality of Non-Professional Transcription on 20 hours of English Switchboard. Even though disagreement for random selection without quality control has 23% disagreement with professional transcription, an ASR system trained on the data is only 2.5% worse than using LDC transcriptions. The upper bound for quality control (row 3) recovers only 50% of the total loss.

4.2 Combining with External Sources

While in-domain speech transcription is typically the only effective way to improve the acoustic model, out-of-domain transcripts tend to be useful for language models of conversational speech. Broadcast News (BN) transcription is particularly well suited for English Switchboard data as the topics tend to cover news items like terrorism or politics. We built a small one million word language model (to simulate a resource-poor language) and interpolated it with varying amounts of LDC or Mechanical Turk transcriptions. Figure 2 details the results.

4.3 The Value of Quality Control

With a fixed transcription budget, should one even bother with redundant transcription to improve an ASR system? To find out, we transcribed 40 additional hours of Switchboard using Mechanical Turk. Disagreement to the LDC transcriptions was 24%, similar to the initial 20 hours. The two percent degradation of test WER when using Mechanical Turk compared to LDC held up with 40 and 60 hours of training.

Given a fixed budget of 60 hours of transcription, we compared the quality of 20 hours transcribed three times to 60 hours transcribed once. The best we could hope to recover from the three redundant transcriptions is the utterance oracle. Oracle and singly transcribed data had 13% and 24% disagreement with LDC respectively. System performance was 40.9% with 20 hours of

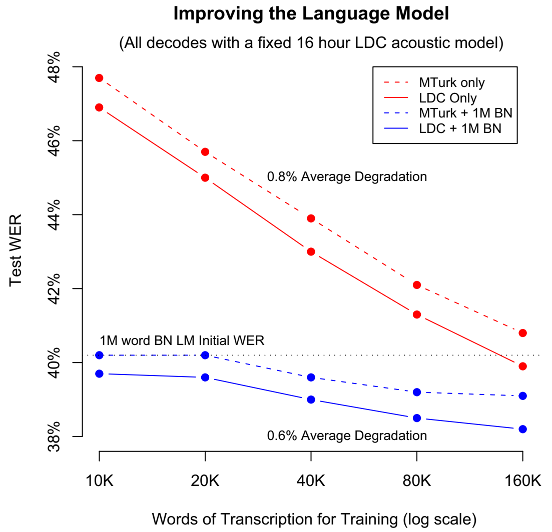

Figure 2: WER with a varied amount of LM training data and a fixed 16hr acoustic model. MTurk transcription degrades WER by 0.8% absolute across LM size. When interpolated with 1M words of broadcast news, this degradation shrinks to 0.6%.

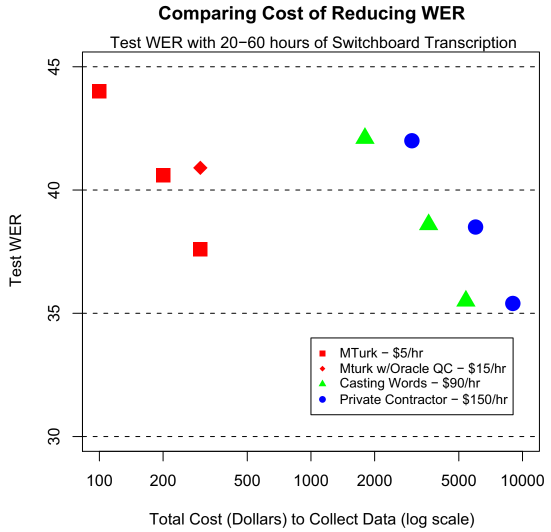

Figure 3: Historical cost estimates are $150 per hour of transcription (blue cirlces). The company Casting Words uses Turkers to transcribe English at $90 per hour which we estimated to be high quality (green triangles). Transcription without quality control on Mechanical Turk (red squares) is drastically cheaper at $5 per hour. With a fixed budget, it is better to transcribe more data at lower quality than to improve quality. Contrast the oracle WER for 20 hours transcribed three times (red diamond) with 60 hours transcribed once (bottom red square).

the former and 37.6% with 60 hours of the latter. Even though perfect selection cuts disagreement in half, three times as much data helps more.

The 2004 Fisher effort averaged a price of $150 per hour of English CTS transcription. The company CastingWords produces high quality (Passy, 2008) English transcription for $90 an hour using Mechanical Turk by a multi-pass process to collect and clean Turker-provided transcripts. While we did not use their service, we assume it is of comparable quality to the private contractor used earlier. The price for LDC transcription is not comparable here since it was intended for more precise linguistic tasks. Extrapolating from Figure 3, the entire 2000 Fisher corpus could be transcribed using Mechanical Turk at the same cost of collecting 60 hours of professional transcription.

5 Collection in Other Languages

To test the feasability of improving low-resource languages, we attempted to collect transcriptions for Korean, Hindi, Tamil CTS data. We built an LVCSR system in Korean since it is the only one with reference LDC transcriptions to use as a test set.

5.1 Korean

Korean is spoken by roughly 78 million speakers world wide and is written in Hangul, a phonetic orthography, although Chinese characters frequently appear in written text. Since Korean has essentially arbitrary spacing (Chong-Woo et al., 2001), we report Phoneme Error Rate (PER) instead of WER, which would be unfairly penalized. Both behave similarly as system performance improves. For comparison, an English WER of 39.5% has a PER of 34.8%.

We uploaded ten hours of audio to be transcribed once, again segmented into short snippets. Transcription was very slow at first and we had to pay $0.20 per HIT to attract workers. We posted a separate HIT to refer Korean transcribers, paying a 25% bonus of the income earned by referrals. This was quite successful as two referred Turkers contributed over 80% of the total transcription (at a cost of $25 per hour instead of $20). We collected three hours of transcriptions after five weeks, paying eight Turkers $113 at a transcription rate of 10xRT.

Average Turker disagreement to the LDC reference was 17% (computed at the character level). Using these transcripts to train an LVCSR system instead of those provided by LDC degraded PER by 0.8% from 51.3% to 52.1%. For comparison, a system trained on the entire 27 hours of LDC data had 41.2% PER.

Although performance seems poor, it is sufficiently good to bootstrap with acoustic model self-training (Lamel et al., 2002). The language model can be improved by finding 'conversational' web text found with n-gram queries extracted from the three hours of transcripts (Bulyko et al., 2003).

5.2 Hindi and Tamil

As a feasability experiment, we collected one hour of transcription in Hindi and Tamil, paying $20 per hour of transcription. Hindi and Tamil transcription finished in eight days, perhaps due to the high prevalence of Turkers in India (Ipeirotis, 2008). While we did not have any professional reference, Hindi speaking colleagues viewed some of the data and pointed out errors in English transliteration, but overall quality appeared fine. The true test will be to build an LVCSR system and report WER.

6 Quality Control sans Quality Data

Although we have shown that redundantly transcribing an entire corpus gives little gain, there is value in *some* amount of quality control. We could improve system performance by only rejecting Turkers with high disagreement, similar to confidence selection for active learning or unsupervised training (Ma and Schwartz,). But if we are transcribing a truly new domain, there is no gold-standard data to use as reference, so we must estimate disagreement against errorful reference. In this section we provide a practical use for quality control without gold standard reference data.

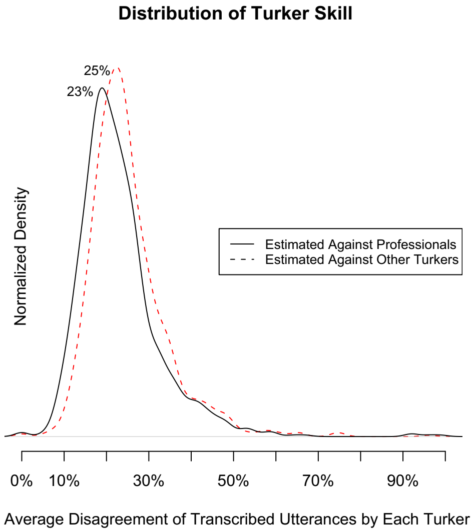

Figure 4: Each Turker was judged against professional and non-professional reference and assigned an overall disagreement. The distribution of Turker disagreement follows a gamma distribution, with a tight cluster of average Turkers and a long-tail of bad Turkers. Estimating with non-professionals (even though the reference is 23% wrong on average) is surprisingly well matched to professional estimate. Turker estimation over-estimated disagreement by only 2%.

6.1 Estimating Turker Skill

Using the twenty hour English transcriptions from Section 4, we computed disagreement for each Turker against the professional transcription for all utterances longer than four words. Note that each utterance was transcribed by three random turkers, so there is not one set of utterances which were transcribed by all turkers. Each Turker transcribed a different, partially overlapping, subset of the data.

For a particular Turker, we estimated the disagreement with other Turkers by using the two other transcripts as reference and taking the average. Figure 4 shows the density estimate of Turker disagreement when calculated against professional and non-professional transcription. On average, the non-professional estimate was 3% off from the professional disagreement.

Given that non-professional disagreement is a good estimate of professional disagreement

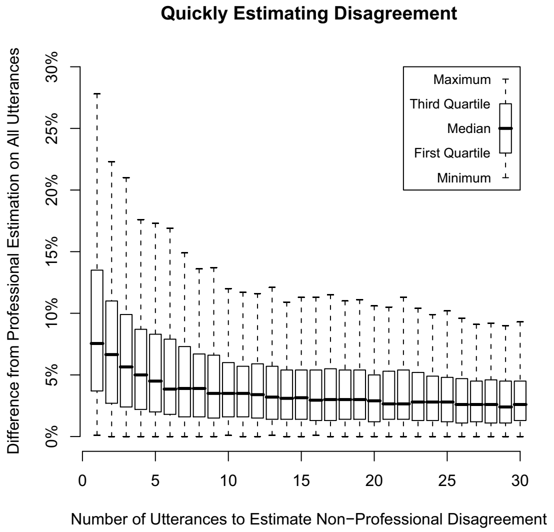

Figure 5: Boxplot of the difference of non-professional disagreement with a fixed number of utterances to professional disagreement over all utterances. While error is expectedly high with one utterance, 50% of the estimates are within 3% of the truth after ten utterances and 75% of the estimates are within 6% after fifteen utterances.

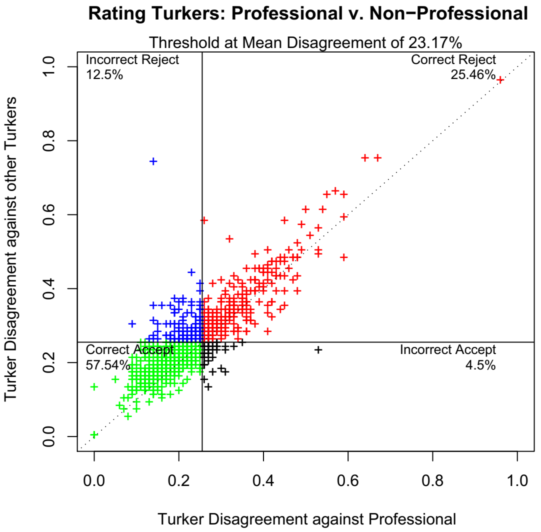

Figure 6: Each Turker is a point with professional (X axis) plotted against non-professional (Y axis) disagreement. The non-professional disagreement correlates surprisingly well with professional disagreement even though the transcripts used as reference are 23% wrong on average. By setting a selection threshold, the space is divided into four quadrants. The bottom left are correctly accepted: both non-professional and professional disagreement are below the threshold. The top left are incorrectly rejected: using their transcripts would have helped, but they don't hurt system performance, just waste money. The top right are correctly rejected for having high disagreement. The bottom right are the troublesome false positives that are included in training but actually may hurt performance. Luckily, the ratio of false negatives to false positives is usually much larger.

over all of a Turker's utterances, we wondered how few needed to be redundantly transcribed by other non-professionals. For each Turker, we started by randomly selecting one utterance and computed the non-professional disagreement. We compared the estimate to the true professional disagreement over all of the utterances and repeatedly sample 20 times. Then we increased the number of utterances used to estimate non-professional disagreement until all utterances by that Turker are selected.

Figure 5 shows a boxplot of the differences of non-professional to professional disagreement on *all* utterances. As few as fifteen utterances need to be redundantly transcribed to accurately estimate three out of four Turkers within 5% of the professional disagreement.

6.2 Finding the Right Turkers

Since we can accurately predict a Turker's skill with as few as fifteen utterances on average, we can rank Turkers by their professional and non-professional disagreeements. By thresholding on disagreement, we can either select good turkers or equivalently reject bad turkers. We can view the ranking as a precision/recall problem to select only the 'good' Turkers below the threshold. Figure 6 plots each Turker where the X axis is the professional disagreement and the Y axis is the non-professional disagreement. Sweeping the disagreement threshold from zero to one generates Figure 7, which reports F-score (the harmonic mean of precision and recall). This section suggests a concrete qualification test by first transcribing 15-30 utterance multiple times to create a gold standard. Using the transcription from the best Turker as reference, approve new Turkers with a WER less than the average WER from the initial set.

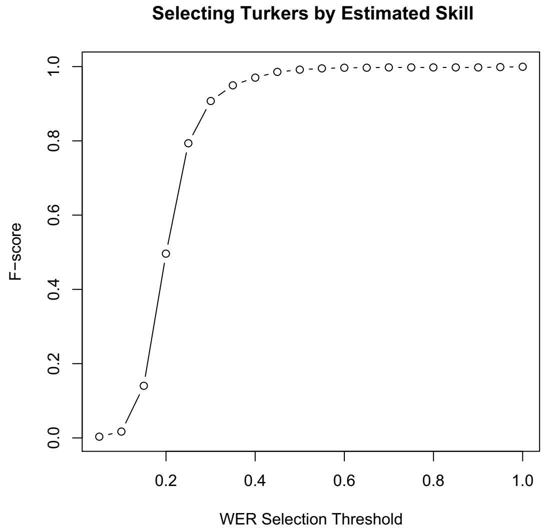

Figure 7: It is difficult to find only good Turkers since the false positives outnumber the few good workers. However, rejecting bad Turkers becomes very easy once past the mean error rate of 23%. It is better to use disagreement estimation to reject poor workers instead of finding good workers.

7 Experience with Mechanical Turk

We initially expected to invest most of our effort in managing Turker transcription. But the vast majority of Turkers completed the effort in good faith with few complaints about pay. Many left positive comments[5] despite the very difficult task. Indeed, the author's own disagreement on a few dozen English utterances were 17.7% and 26.8% despite an honest effort.

Instead, we spent most of our time normalizing the transcriptions for English acoustic model training. Every single misspelling or new word had to be mapped to a pronunciation in order to be used in training. We initially discarded any utterance with an out of vocabulary word, but after losing half of the data, we used a set of simple heuristics to produce pronunciations. Even though there were a few thousand of these errors, they were all singletons and had little effect on performance. Turkers sometimes left comments in the transcription box such as "no audio" or "man1: man2:". These errant transcriptions could be detected by force aligning the transcript with the audio and rejecting any with low scores (Lamel et al., 2000). Extending transcription to thousands of hours will require robust methods to automatically deal with errant transcripts and additionally run the risk of exhausting the available pool of workers.

Finding Korean transcribers required the most creativity. We found success in interacting with the transcribers, providing feedback, encouragement and paying bonuses for referring other workers. Cultivating workers for a new language is definitely a 'hands on' process.

For Hindi and Tamil, Turkers sometimes misinterpreted or ignored instructions and translated into English or transliterated into Roman characters. Additionally, *some* linguistic knowledge is required to classify phonemic categories (like fricative or sonorant) required for acoustic model training.

8 Conclusion

Unlike previous work which studied the quality of Mechanical Turk annotations alone, we judge its value in terms of the real task: improving system performance. Despite relatively high disagreement with professional transcription, data collected with Mechanical Turk was nearly as effective for training speech models. Since this degradation is so small, redundant annotation to improve quality is not worth the cost. Resources are better spent collecting more transcription. In addition to English, we demonstrated similar trends in Korean and also collected transcripts for Hindi and Tamil. Finally, we proposed an effective procedure to reduce costs by maintaining the quality of the annotator pool without needing high quality annotation.

Abstract

Out-of-vocabulary (OOV) words represent an important source of error in large vocabulary continuous speech recognition (LVCSR) systems. These words cause recognition failures, which propagate through pipeline systems impacting the performance of downstream applications. The detection of OOV regions in the output of a LVCSR system is typically addressed as a binary classification task, where each region is independently classified using local information. In this paper, we show that jointly predicting OOV regions, and including contextual information from each region, leads to substantial improvement in OOV detection. Compared to the state-of-the-art, we reduce the missed OOV rate from 42.6% to 28.4% at 10% false alarm rate.

1 Introduction

Even with a vocabulary of one hundred thousand words, a large vocabulary continuous speech recognition (LVCSR) system encounters out-of-vocabulary (OOV) words, especially in new domains or genres. New words often include named entities, foreign words, rare and invented words. Since these words were not seen during training, the LVCSR system has no way to recognize them.

OOV words are an important source of error in LVCSR systems for three reasons. First, OOVs can never be recognized by the LVCSR system, even if repeated. Second, OOV words contribute to recognition errors in surrounding words, which propagate into to later processing stages (translation, understanding, document retrieval, etc.). Third, OOVs are often information-rich nouns – mis-recognized OOVs can have a greater impact on the understanding of the transcript than other words.

One solution is to simply increase the LVCSR system's vocabulary, but there are always new words. Additionally, increasing the vocabulary size without limit can sometimes produce higher word error rates (WER), leading to a tradeoff between recognition accuracy of frequent and rare words.

A more effective solution is to detect the presence of OOVs directly. Once identified, OOVs can be flagged for annotation and addition to the system's vocabulary, or OOV segments can be transcribed with a phone recognizer, creating an open vocabulary LVCSR system. Identified OOVs prevent error propagation in the application pipeline.

In the literature, there are two basic approaches to OOV detection: 1) *filler* models, which explicitly represent OOVs using a filler, sub-word, or generic word model (Bazzi, 2002; Schaaf, 2001; Bisani and Ney, 2005; Klakow et al., 1999; Wang, 2009); and 2) confidence estimation models, which use different confidence scores to find unreliable regions and label them as OOV (Lin et al., 2007; Burget et al., 2008; Sun et al., 2001; Wessel et al., 2001).

Recently, Rastrow et al. (2009a) presented an approach that combined confidence estimation models and filler models to improve state-of-the-art results for OOV detection. This approach and other confidence based systems (Hazen and Bazzi, 2001; Lin et al., 2007), treat OOV detection as a binary classification task; each region is independently classified using local information as IV or OOV. This work moves beyond this independence assumption

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 216–224,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

that considers regions independently for OOV detection. We treat OOV detection as a sequence labeling problem and add features based on the local lexical context of each region as well as global features from a language model using the entire utterance. Our results show that such information improves OOV detection and we obtain large reductions in error compared to the best previously reported results. Furthermore, our approach can be combined with any confidence based system.

We begin by reviewing the current state-of-the-art results for OOV detection. After describing our experimental setup, we generalize the framework to a sequence labeling problem, which includes features from the local context, lexical context, and entire utterance. Each stage yields additional improvements over the baseline system. We conclude with a review of related work.

2 Maximum Entropy OOV Detection

Our baseline system is the Maximum Entropy model with features from filler and confidence estimation models proposed by Rastrow et al. (2009a). Based on filler models, this approach models OOVs by constructing a hybrid system which combines words and sub-word units. Sub-word units, or fragments, are variable length phone sequences selected using statistical methods (Siohan and Bacchiani, 2005). The vocabulary contains a word and a fragment lexicon; fragments are used to represent OOVs in the language model text. Language model training text is obtained by replacing low frequency words (assumed OOVs) by their fragment representation. Pronunciations for OOVs are obtained using grapheme to phoneme models (Chen, 2003).

This approach also includes properties from confidence estimation systems. Using a hybrid LVCSR system, they obtain *confusion networks* (Mangu et al., 1999), compact representations of the recognizer's most likely hypotheses. For an utterance, the confusion network is composed of a sequence of *confused regions*, indicating the set of most likely word/sub-word hypotheses uttered and their posterior probabilities[1] in a specific time interval.

Figure 1 depicts a confusion network decoded by the hybrid system for a section of an utterance in our test-set. Below the network we present the reference transcription. In this example, two OOVs were uttered: "slobodan" and "milosevic" and decoded as four and three in-vocabulary words, respectively. A *confused region* (also called "bin") corresponds to a set of competing hypothesis between two nodes. The goal is to correctly label each of the "bins" as OOV or IV. Note the presence of both fragments (e.g. `s_l_ow`, `l_aa_s`) and words in some of the hypothesis bins.

For any bin of the confusion network, Rastrow et al. combine features from that region using a binary Maximum Entropy classifier (White et al., 2007). Their most effective features were:

$$\begin{aligned}\text{Fragment-Posterior} &= \sum_{f \in t_j} p(f|t_j) \\ \text{Word-Entropy} &= -\sum_{w \in t_j} p(w|t_j) \log p(w|t_j)\end{aligned}$$

t_j is the current bin in the confusion network and f is a fragment in the hybrid dictionary.

We obtained confusion networks for a standard word based system and the hybrid system described above. We re-implemented the above features, obtaining nearly identical results to Rastrow et al. using Mallet's MaxEnt classifier (McCallum, 2002). [2] All real-valued features were normalized and quantized using the uniform-occupancy partitioning described in White et al. (2007).[3] The MaxEnt model is regularized using a Gaussian prior ($\sigma^2 = 100$), but we found results generally insensitive to σ.

3 Experimental Setup

Before we introduce and evaluate our context approach, we establish an experimental setup. We used the dataset constructed by Can et al. (2009) to evaluate Spoken Term Detection (STD) of OOVs; we refer to this corpus as OOVCORP. The corpus contains 100 hours of transcribed Broadcast News English speech emphasizing OOVs. There are 1290 unique OOVs in the corpus, which were selected with a minimum of 5 acoustic instances per word.

[1] $P(w_i|A)$: posterior probability of word i given the acoustics, which includes the language model and acoustic model scores, as described in (Mangu et al., 1999).

[2] Small differences are due to a change in MaxEnt library.

[3] All experiments use 50 partitions with a minimum of 100 training values per partition.

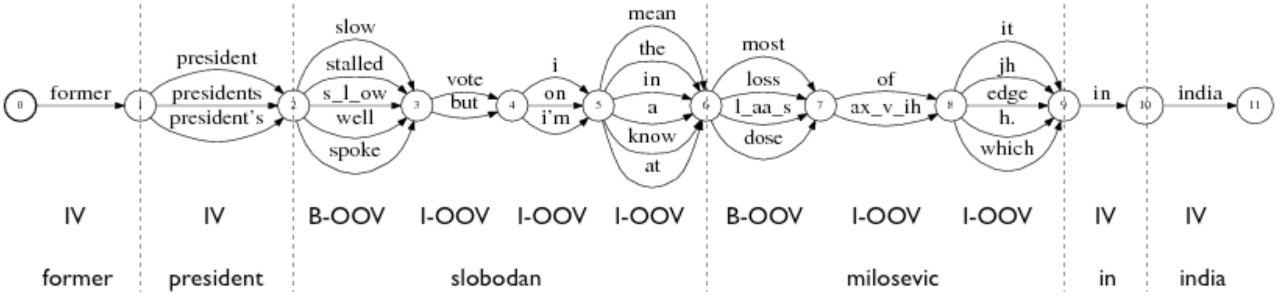

Figure 1: Example confusion network from the hybrid system with OOV regions and BIO encoding. Hypothesis are ordered by decreasing value of posterior probability. Best hypothesis is the concatenation of the top word/fragments in each bin. We omit posterior probabilities due to spacing.

Common English words were filtered out to obtain meaningful OOVs: e.g. NATALIE, PUTIN, QAEDA, HOLLOWAY. Since the corpus was designed for STD, short OOVs (less than 4 phones) were explicitly excluded. This resulted in roughly 24K (2%) OOV tokens.

For a LVCSR system we used the IBM Speech Recognition Toolkit (Soltau et al., 2005)[4] with acoustic models trained on 300 hours of HUB4 data (Fiscus et al., 1998) and excluded utterances containing OOV words as marked in OOVCORP. The language model was trained on 400M words from various text sources with a 83K word vocabulary. The LVCSR system's WER on the standard RT04 BN test set was 19.4%. Excluded utterances were divided into 5 hours of training and 95 hours of test data for the OOV detector. Both train and test sets have a 2% OOV rate. We used this split for all experiments. Note that the OOV training set is different from the LVCSR training set.

In addition to a word-based LVCSR system, we use a hybrid LVCSR system, combining word and sub-word (fragments) units. Combined word/subword systems have improved OOV Spoken Term Detection performance (Mamou et al., 2007; Parada et al., 2009), better phone error rates, especially in OOV regions (Rastrow et al., 2009b), and state-of-the-art performance for OOV detection. Our hybrid system's lexicon has 83K words and 20K fragments derived using Rastrow et al. (2009a). The 1290 excluded words are OOVs to both the word and hybrid systems.

Note that our experiments use a different dataset than Rastrow et. al., but we have a larger vocabulary (83K vs 20K), which is closer to most modern LVCSR system vocabularies; the resulting OOVs are more challenging but more realistic.

3.1 Evaluation

Confusion networks are obtained from both the word and hybrid LVCSR systems. In order to evaluate the performance of the OOV detector, we align the reference transcript to the audio. The LVCSR transcript is compared to the reference transcript at the confused region level, so each confused region is tagged as either OOV or IV. The OOV detector assigns a score/probability for IV/OOV to each of these regions.

Previous research reported OOV detection accuracy on all test data. However, once an OOV word has been observed in the training data for the OOV detector, even if it never appeared in the LVCSR training data, it is no longer truly OOV. The features used in previous approaches did not necessarily provide an advantage on observed versus unobserved OOVs, but our features do yield an advantage. Therefore, in the sections that follow we report unobserved OOV accuracy: OOV words that do not appear in either the OOV detector's or the LVCSR's training data. While this penalizes our results, it is a more informative metric of true system performance.

We present results using standard detection error tradeoff (DET) curves (Martin et al., 1997). DET

[4] We use the IBM system with speaker adaptive training based on maximum likelihood with no discriminative training.

curves measure tradeoffs between misses and false alarms and can be used to determine the optimal operating point of a system. The x-axis varies the false alarm rate (false positive) and the y-axis varies the miss (false negative) rate; lower curves are better.

4 From MaxEnt to CRFs

As a classification algorithm, Maximum Entropy assigns a label to each region independently. However, OOV words tend to be recognized as two or more IV words, hence OOV regions tend to co-occur. In the example of Figure 1, the OOV word "slobodan" was recognized as four IV words: "slow vote i mean". This suggests that sequence models, which jointly assign all labels in a sequence, may be more appropriate. Therefore, we begin incorporating context by moving from classification to sequence models.

MaxEnt classification models the target label as $p(y_i|\mathbf{x}_i)$, where y_i is a discrete variable representing the ith label ("IV" or "OOV") and $\mathbf{x}_i$ is a feature vector representing information for position i. The conditional distribution for y_i takes the form

$$p(y_i|\mathbf{x}_i) = \frac{1}{Z(\mathbf{x}_i)} \exp(\sum_{k=1}^{K} \lambda_k f_k(y_i, \mathbf{x}_i)) ,$$

$Z(\mathbf{x}_i)$ is a normalization term and $f(y_i, \mathbf{x}_i)$ is a vector of K features, such as those defined in Section 2. The model is trained discriminatively: parameters λ are chosen to maximize conditional data likelihood.

Conditional Random Fields (CRF) (Lafferty et al., 2001) generalize MaxEnt models to sequence tasks. While having the same model structure as Hidden Markov Models (HMMs), CRFs are trained discriminatively and can use large numbers of correlated features. Their primary advantage over MaxEnt models is their ability to find an optimal labeling for the entire sequence rather than greedy local decisions. CRFs have been used successfully used in numerous text processing tasks and while less popular in speech, still applied successfully, such as sentence boundary detection (Liu et al., 2005).

A CRF models the entire label sequence $\mathbf{y}$ as:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp(\lambda F(\mathbf{y}, \mathbf{x})) ,$$

where $F(\mathbf{y}, \mathbf{x})$ is a global feature vector for input sequence $\mathbf{x}$ and label sequence $\mathbf{y}$ and $Z(\mathbf{x})$ is a normalization term.[5]

5 Context for OOV Detection

We begin by including a minimal amount of local context in making OOV decisions: the predicted labels for adjacent confused regions (bins). This information helps when OOV bins occur in close proximity, such as successive OOV bins. This is indeed the case: in the OOV detector training data only 48% of OOV sequences contained a single bin; sequences were of length 2 (40%), 3 (9%) and 4 (2%). We found similar results in the test data. Therefore, we expect that even a minimal amount of context based on the labels of adjacent bins will help.

A natural way of incorporating contextual information is through a CRF, which introduces dependencies between each label and its neighbors. If a neighboring bin is likely an OOV, it increases the chance that the current bin is OOV.

In sequence models, another technique for capturing contextual dependence is the label encoding scheme. In information extraction, where sequences of adjacent tokens are likely to receive the same tag, the beginning of each sequence receives a different tag from words that continue the sequence. For example, the first token in a person name is labeled `B-PER` and all subsequent tokens are labeled `I-PER`. This is commonly referred to as BIO encoding (beginning, inside, outside). We applied this encoding technique to our task, labeling bins as either `IV` (in vocabulary), `B-OOV` (begin OOV) and `I-OOV` (inside OOV), as illustrated in Figure 1. This encoding allows the algorithm to identify features which might be more indicative of the beginning of an OOV sequence. We found that this encoding achieved a superior performance to a simple `IV`/`OOV` encoding. We therefore utilize the BIO encoding in all CRF experiments.

Another means of introducing context is through the order of the CRF model. A first order model ($n = 1$) adds dependencies only between neighboring labels, whereas an n order model creates dependencies between labels up to a distance of n positions. Higher order models capture length of label

[5] CRF experiments used the CRF++ package http://crfpp.sourceforge.net/

regions (up to length n). We experiment with both a first order and a second order CRF. Higher order models did not provide any improvements.

In order to establish a comparative baseline, we first present results using the same features from the system described in Section 2 (Word-Entropy and Fragment-Posterior). All real-valued features were normalized and quantized using the uniform-occupancy partitioning described in White et al. (2007).[6] Quantization of real valued features is standard for log-linear models as it allows the model to take advantage of non-linear characteristics of feature values and is better handled by the regularization term. As in White et. al. we found it improved performance.

Figure 2 depicts DET curves for OOV detection for the MaxEnt baseline and first and second order CRFs with BIO encoding on unobserved OOVs in the test data. We generated predictions at different false alarm rates by varying a probability threshold. For MaxEnt we used the predicted label probability and for CRFs the marginal probability of each bin's label. While the first order CRF achieves nearly identical performance to the MaxEnt baseline, the second order CRF shows a clear improvement. The second order model has a 5% absolute improvement at 10% false alarm rate, despite using the identical features as the MaxEnt baseline. Even a small amount of context as expressed through local labeling decisions improves OOV detection.

The quantization of the features yields quantized prediction scores, resulting in the non-smooth curves for the MaxEnt and 1st order CRF results. However, when using a second order CRF the OOV score varies more smoothly since more features (context labels) are considered in the prediction of the current label.

6 Local Lexical Context

A popular approach in sequence tagging, such as information extraction or part of speech tagging, is to include features based on local lexical content and context. In detecting a name, both the lexical form "John" and the preceding lexical context "Mr." provide clues that "John" is a name. While we do not

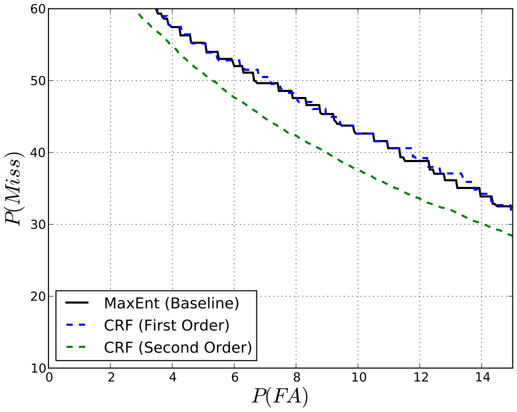

Figure 2: DET curves for OOV detection using a Maximum Entropy (MaxEnt) classifier and contextual information using a 1st order and 2nd order CRF. All models use the same baseline features (Section 2).

know the actual lexical items in the speech sequence, the speech recognizer output can be used as a best guess. In the example of Figure 1, the words "former president" are good indicators that the following word is either the word "of" or a name, and hence a potential OOV. Combining this lexical context with hypothesized words can help label the subsequent regions as OOVs (note that none of the hypothesized words in the third bin are "of", names, or nouns).

Words from the LVCSR decoding of the sentence are used in the CRF OOV detector. For each bin in the confusion network, we select the word with the highest probability (best hypothesis). We then add the best hypothesis word as a feature of the form: `current_word=X`. These features capture how the LVCSR system incorrectly recognizes OOV words. However, since detection is measured on unobserved OOVs, these features alone may not help.

Instead, we turn to lexical context, which includes correctly recognized IV words. We evaluate the following sets of features derived from lexical context:

- Current bin's best hypothesis. (Current-Word)
- Unigrams and bigrams from the best hypothesis in a window of 5 words around current bin. This feature ignores the best hypothesis in the current bin, i.e., `word[-2],word[-1]` is included, but `word[-1],word[0]` is not. (Context-Bigrams)

[6] All experiments use 50 partitions with a minimum of 100 training values per partition.

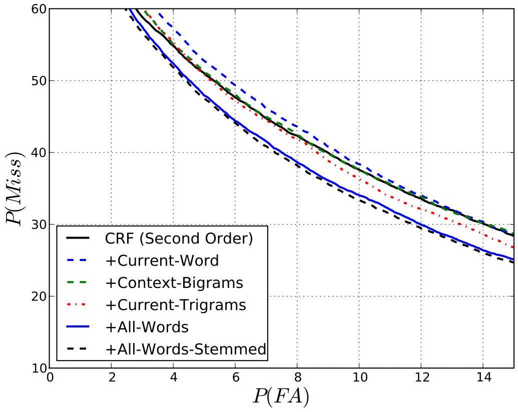

Figure 3: A second order CRF (Section 5) and additional features including including word identities from current and neighboring bins (Section 6).

- Unigrams, bigrams, and trigrams in a window of 5 words around and including current bin. (Current-Trigrams)

- All of the above features. (All-Words)

- All above features and their stems.[7] (All-Words-Stemmed)

We added these features to the second order CRF with BIO encoding and baseline features (Figure 3). As expected, the current words did not improve performance on unobserved OOVs. When the current words are combined with the lexical context and their lemmas, they give a significant boost in performance: a 4.2% absolute improvement at 10% false alarm rate over the previous CRF system, and 9.3% over the MaxEnt baseline. Interestingly, only combining context and current word gives a substantial gain. This indicates that OOVs tend to occur with certain distributional characteristics that are independent of the OOV word uttered (since we consider only unobserved OOVs), perhaps because OOVs tend to be named entities, foreign words, or rare nouns. The importance of distributional features is well known for named entity recognition and part of speech tagging (Pereira et al., 1993). Other features such as sub-strings or baseline features (Word-Entropy, Fragment-Posterior) from neighboring bins did not provide further improvement.

7 Global Utterance Context

We now include features that incorporate information from the entire utterance. The probability of an utterance as computed by a language model is often used as a measure of fluency of the utterance. We also observe that OOV words tend to take very specific syntactic roles (more than half of them are proper nouns), which means the surrounding context will have predictive lexical and *syntactic* properties. Therefore, we use a syntactic language model.

7.1 Language Models

We evaluated both a standard trigram language model and a syntactic language model (Filimonov and Harper, 2009a). The syntactic model estimates the joint probability of the word and its syntactic tag based on the preceding words and tags. The probability of an utterance w_1^n of length n is computed by summing over all latent syntactic tag assignments:

$$p(utt) = p(w_1^n) = \sum_{t_1 \ldots t_n} \prod_{i-1}^{n} p(w_i, t_i | w_1^{i-1}, t_1^{i-1}) \tag{1}$$

where w_i and t_i are the word and tag at position i, and w_1^{i-1} and t_1^{i-1} are sequences of words and tags of length $i-1$ starting a position 1. The model is restricted to a trigram context, i.e., $p(w_i, t_i | w_{i-2}^{i-1}, t_{i-2}^{i-1})$; experiments that increased the order yielded no improvement.

We trained the language model on 130 million words from Hub4 CSR 1996 (Garofolo et al., 1996). The corpus was parsed using a modified Berkeley parser (Huang and Harper, 2009) and tags extracted from parse trees incorporated the word's POS, the label of its immediate parent, and the relative position of the word among its siblings. [8] The parser required separated contractions and possessives, but we recombined those words after parsing to match the LVCSR tokenization, merging their tags. Since we are considering OOV detection, the language model was restricted to LVCSR system's vocabulary.

[7] To obtain stemmed words, we use the CPAN package: http://search.cpan.org/~snowhare/Lingua-Stem-0.83.

[8] The *parent* tagset of Filimonov and Harper (2009a).

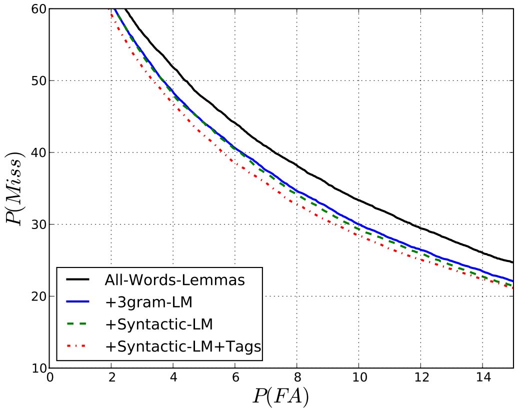

Figure 4: Features from a language model added to the best CRF from Section 6 (All-Words-Stemmed).

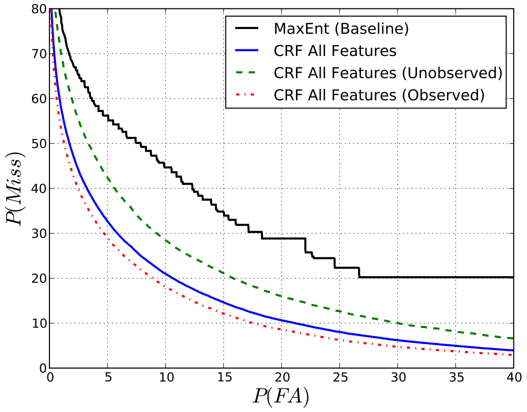

Figure 5: A CRF with all context features compared to the state-of-the-art MaxEnt baseline. Results for the CRF are shown for unobserved, observed and both OOVs.

We also used the standard trigram LM for reference. It was trained on the same data and with the same vocabulary using the SRILM toolkit. We used interpolated modified KN discounting.

7.2 Language Model Features

We designed features based on the entire utterance using the language model to measure how the utterance is effected by the current token: whether the utterance is more likely given the recognized word or some OOV word.

$$\begin{aligned}\text{Likelihood-ratio} &= \log \frac{p(utt)}{p(utt|w_i = \text{unknown})}\\ \text{Norm-LM-score} &= \frac{\log p(utt)}{length(utt)}\end{aligned}$$

where $p(utt)$ represents the probability of the utterance using the best path hypothesis word of the LVCSR system, and $p(utt|w_i = \text{unknown})$ is the probability of the entire utterance with the current word in the LVCSR output replaced by the token <unk>, used to represent OOVs. Intuitively, when an OOV word is recognized as an IV word, the fluency of the utterance is disrupted, especially if the IV is a function word. The Likelihood-ratio is designed to show whether the utterance is more fluent (more likely) if the current word is a misrecognized OOV. [9] The second feature (Norm-LM-score) is the normalized likelihood of the utterance. An unlikely utterance biases the system to predicting OOVs.

We evaluated a CRF with these features and all lexical context features (Section 6) using both the trigram model and the joint syntactic language model (Figure 4). Each model improved performance, but the syntactic model provided the largest improvement. At 10% false alarm rate it yields a 4% absolute improvement with respect to the previous best result (All-Words-Stemmed) and 13.3% over the MaxEnt baseline. Higher order language models did not improve.

7.3 Additional Syntactic Features

We explored other syntactic features; the most effective was the 5-tag window of POS tags of the best hypothesis.[10] The additive improvement of this feature is depicted in Figure 4 labeled "+Syntactic-LM+Tags." With this feature, we achieve a small additional gain. We tried other syntactic features without added benefit, such as the most likely POS tag for <unk>in the utterance.

[9] Note that in the standard n-gram LM the feature reduces to $\log \frac{\prod_{k=i}^{i+n-1} p(w_k|w_{k-n+1}^{k-1})}{\prod_{k=i}^{i+n-1} p(w_k|w_{k-n+1}^{k-1}, w_i{=}\text{unknown})}$, i.e., only n n-grams actually contribute. However, in the syntactic LM, the entire utterance is affected by the change of one word through the latent states (tags) (Eq. 1), thus making it a truly global feature.

[10] The POS tags were generated by the same syntactic LM (see Section 7.1) as described in (Filimonov and Harper, 2009b). In this case, POS tags include merged tags, i.e., the vocabulary word *fred's* may be tagged as NNP-POS or NNP-VBZ.

8 Final System

Figure 5 summarizes all of the context features in a single second order BIO encoded CRF. Results are shown for state-of-the-art MaxEnt (Rastrow et al., 2009a) as well as for the CRF on unobserved, observed and combined OOVs. For unobserved OOVs our final system achieves a 14.2% absolute improvement at 10% FA rate. The absolute improvement on all OOVs was 23.7%. This result includes *observed* OOVs: words that are OOV for the LVCSR but are encountered in the OOV detector's training data. MaxEnt achieved similar performance for observed and unobserved OOVs so we only include a single combined result.

Note that the MaxEnt curve flattens at 26% false alarms, while the CRF continues to decrease. The elbow in the MaxEnt curve corresponds to the probability threshold at which no other labeled OOV region has a non-zero OOV score (regions with zero entropy and no fragments). In this case, the CRF model can still rely on the context to predict a non-zero OOV score. This helps applications where misses are more heavily penalized than false alarms.

9 Related Work

Most approaches to OOV detection in speech can be categorized as filler models or confidence estimation models. Filler models vary in three dimensions: 1) The type of filler units used: variable-length phoneme units (as the baseline system) vs joint letter sound sub-words; 2) Method used to derive units: data-driven (Bazzi and Glass, 2001) or linguistically motivated (Choueiter, 2009); 3) The method for incorporating the LVCSR system: hierarchical (Bazzi, 2002) or flat models (Bisani and Ney, 2005). Our approach can be integrated with any of these systems.

We have shown that combining the presence of sub-word units with other measures of confidence can provided significant improvements, and other proposed local confidence measures could be included in our system as well. Lin et al. (2007) uses joint word/phone lattice alignments and classifies high local miss-alignment regions as OOVs. Hazen and Bazzi (2001) combines filler models with word confidence scores, such as the minimum normalized log-likelihood acoustic model score for a word and, the fraction of the N-best utterance hypotheses in which a hypothesized word appears.

Limited contextual information has been previously exploited (although maintaining independence assumptions on the labels). Burget et al. (2008) used a neural-network (NN) phone-posterior estimator as a feature for OOV detection. The network is fed with posterior probabilities from weakly-constrained (phonetic-based) and strongly-constrained (word-based) recognizers. Their system estimates frame-based scores, and interestingly, they report large improvements when using temporal context in the NN input. This context is quite limited; it refers to posterior scores from one frame on each side. Other features are considered and combined using a MaxEnt model. They attribute this gain to sampling from neighboring phonemes. Sun et al. (2001) combines a filler-based model with a confidence approach by using several acoustic features along with context based features, such as whether the next word is a filler, acoustic confidence features for next word, number of fillers, etc.

None of these approaches consider OOV detection as a sequence labeling problem. The work of Liu et al. (2005) is most similar to the approach presented here, but applies a CRF to sentence boundary detection.

10 Conclusion and Future Work

We have presented a novel and effective approach to improve OOV detection in the output confusion networks of a LVCSR system. Local and global contextual information is integrated with sub-word posterior probabilities obtained from a hybrid LVCSR system in a CRF to detect OOV regions effectively. At a 10% FA rate, we reduce the missed OOV rate from 42.6% to 28.4%, a 33.3% relative error reduction. Our future work will focus on additional features from the recognizer aside from the single best-hypothesis, as well as other applications of contextual sequence prediction to speech tasks.

Improved Extraction Assessment through Better Language Models

Arun Ahuja, Doug Downey

{arun.ahuja, ddowney}@eecs.northwestern.edu

Abstract

A variety of information extraction techniques rely on the fact that instances of the same relation are "distributionally similar," in that they tend to appear in similar textual contexts. We demonstrate that extraction accuracy depends heavily on the accuracy of the language model utilized to estimate distributional similarity. An unsupervised model selection technique based on this observation is shown to reduce extraction and type-checking error by 26% over previous results, in experiments with Hidden Markov Models. The results suggest that optimizing statistical language models over unlabeled data is a promising direction for improving weakly supervised and unsupervised information extraction.

1 Introduction

Many weakly supervised and unsupervised information extraction techniques assess the correctness of extractions using the *distributional hypothesis*—the notion that words with similar meanings tend to occur in similar contexts (Harris, 1985). A candidate extraction of a relation is deemed more likely to be correct when it appears in contexts similar to those of "seed" instances of the relation, where the seeds may be specified by hand (Paşca et al., 2006), taken from an existing, incomplete knowledge base (Snow et al., 2006; Pantel et al., 2009), or obtained in an unsupervised manner using a generic extractor (Banko et al., 2007). We refer to this technique as *Assessment by Distributional Similarity* (ADS).

Typically, distributional similarity is computed by comparing co-occurrence counts of extractions and seeds with various contexts found in the corpus. *Statistical Language Models* (SLMs) include methods for more accurately estimating co-occurrence probabilities via back-off, smoothing, and clustering techniques (e.g. (Chen and Goodman, 1996; Rabiner, 1989; Bell et al., 1990)). Because SLMs can be trained from only unlabeled text, they can be applied for ADS even when the relations of interest are not specified in advance (Downey et al., 2007). Unlabeled text is abundant in large corpora like the Web, making nearly-ceaseless automated optimization of SLMs possible. But how fruitful is such an effort likely to be—to what extent does optimizing a language model over a fixed corpus lead to improvements in assessment accuracy?

In this paper, we show that an ADS technique based on SLMs is improved substantially when the language model it employs becomes more accurate. In a large-scale set of experiments, we quantify how language model perplexity correlates with ADS performance over multiple data sets and SLM techniques. The experiments show that accuracy over unlabeled data can be used for selecting among SLMs—for an ADS approach utilizing Hidden Markov Models, this results in an average error reduction of 26% over previous results in extraction and type-checking tasks.

2 Extraction Assessment with Language Models

We begin by formally defining the extraction and typechecking tasks we consider, then discuss statistical language models and their utilization for extraction assessment.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 225–228,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

The extraction task we consider is formalized as follows: given a corpus, a target relation R, a list of seed instances S_R, and a list of candidate extractions U_R, the task is to order elements of U_R such that correct instances for R are ranked above extraction errors. Let U_{Ri} denote the set of the ith arguments of the extractions in U_R, and let S_{Ri} be defined similarly for the seed set S_R. For relations of arity greater than one, we consider the *typechecking* task, an important sub-task of extraction (Downey et al., 2007). The typechecking task is to rank extractions with arguments that are of the proper type for a relation above type errors. As an example, the extraction `Founded(Bill Gates, Oracle)` is type correct, but is not correct for the extraction task.

2.1 Statistical Language Models

A *Statistical Language Model* (SLM) is a probability distribution $P(\mathbf{w})$ over word sequences $\mathbf{w} = (w_1, ..., w_r)$. The most common SLM techniques are *n-gram models*, which are Markov models in which the probability of a given word is dependent on only the previous $n-1$ words. The accuracy of an n-gram model of a corpus depends on two key factors: the choice of n, and the *smoothing* technique employed to assign probabilities to word sequences seen infrequently in training. We experiment with choices of n from 2 to 4, and two popular smoothing approaches, Modified Kneser-Ney (Chen and Goodman, 1996) and Witten-Bell (Bell et al., 1990).

Unsupervised *Hidden Markov Models* (HMMs) are an alternative SLM approach previously shown to offer accuracy and scalability advantages over n-gram models in ADS (Downey et al., 2007). An HMM models a sentence $\mathbf{w}$ as a sequence of observations w_i each generated by a hidden state variable t_i. Here, hidden states take values from $\{1, \ldots, T\}$, and each hidden state variable is itself generated by some number k of previous hidden states. Formally, the joint distribution of a word sequence $\mathbf{w}$ given a corresponding state sequence $\mathbf{t}$ is:

$$P(\mathbf{w}|\mathbf{t}) = \prod_i P(w_i|t_i)P(t_i|t_{i-1}, \ldots, t_{i-k}) \quad (1)$$

The distributions on the right side of Equation 1 are learned from the corpus in an unsupervised manner using Expectation-Maximization, such that words distributed similarly in the corpus tend to be generated by similar hidden states (Rabiner, 1989).

2.2 Performing ADS with SLMs

The *Assessment by Distributional Similarity* (ADS) technique is to rank extractions in U_R in decreasing order of distributional similarity to the seeds, as estimated from the corpus. In our experiments, we utilize an ADS approach previously proposed for HMMs (Downey et al., 2007) and adapt it to also apply to n-gram models, as detailed below.

Define a *context* of an extraction argument e_i to be a string containing the m words preceding and m words following an occurrence of e_i in the corpus. Let $C_i = \{c_1, c_2, ..., c_{|C_i|}\}$ be the union of all contexts of extraction arguments e_i and seed arguments s_i for a given relation R. We create a *probabilistic context vector* for each extraction e_i where the j-th dimension of the vector is the probability of the context surrounding given the extraction, $P(c_j|e_i)$, computed from the language model. [1]

We rank the extractions in U_R according to how similar their arguments' contextual distributions, $P(c|e_i)$, are to those of the seed arguments. Specifically, extractions are ranked according to:

$$f(e) = \sum_{e_i \in e} KL(\frac{\sum_{w' \in S_{Ri}} P(c|w')}{|S_{Ri}|}, P(c|e_i)) \quad (2)$$

where KL represents KL Divergence, and the outer sum is taken over arguments e_i of the extraction e.

For HMMs, we alternatively rank extractions using the HMM *state distributions* $P(t|e_i)$ in place of the probabilistic context vectors $P(c|e_i)$. Our experiments show that state distributions are much more accurate for ADS than are HMM context vectors.

3 Experiments

In this section, we present experiments showing that SLM accuracy correlates strongly with ADS performance. We also show that SLM performance can be used for model selection, leading to an ADS technique that outperforms previous results.

3.1 Experimental Methodology

We experiment with a wide range of n-gram and HMM models. The n-gram models are trained using the SRILM toolkit (Stolcke, 2002). Evaluating a

[1] For example, for context c_j = "I visited ___ in July" and extraction e_i = "Boston," $P(c_j|e_i)$ is P("I visited Boston in July") / P("Boston"), where each string probability is computed using the language model.

LM	Unary	Binary	Wikipedia
HMM 1-5	-.911	-.361	-.994
HMM 2-5	-.856	.120	-.930
HMM 3-5	-.823	-.683	.922
HMM 1-10	-.916	-.967	-.905
HMM 2-10	-.877	-.797	-.963
HMM 3-10	-.957	-.669	-.924
HMM 1-25	-.933	-.850	-.959
HMM 1-50	-.942	-.942	-.947
HMM 1-100	-.896	-.877	-.942
N-Gram	-.512	-.999	.024

Table 1: Pearson Correlation value for extraction performance (in AUC) and SLM performance (in perplexity). Extraction accuracy increases as perplexity decreases, with an average correlation coefficient of -0.742. "HMM k-T" denotes an HMM model of order k, with T states.

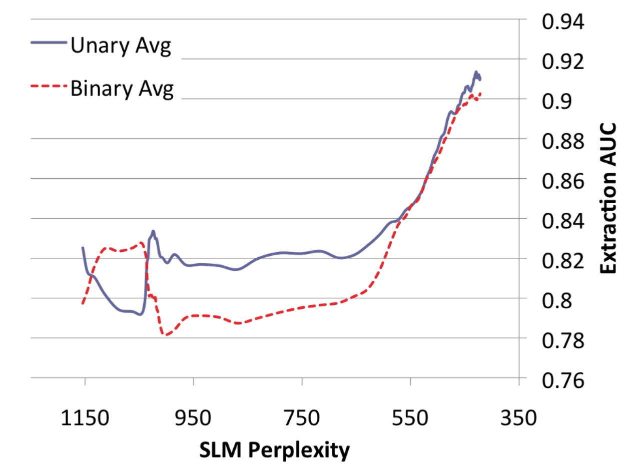

Figure 1: HMM 1-100 Performance. Information Extraction performance (in AUC) increases as SLM accuracy improves (perplexity decreases).

variety of HMM configurations over a large corpus requires a scalable training architecture. We constructed a parallel HMM codebase using the Message Passing Interface (MPI), and trained the models on a supercomputing cluster. All language models were trained on a corpus of 2.8M sentences of Web text (about 60 million tokens). SLM performance is measured using the standard perplexity metric, and assessment accuracy is measured using area under the precision-recall curve (AUC), a standard metric for ranked lists of extractions. We evaluated performance on three distinct data sets. The first two data sets evaluate ADS for unsupervised information extraction, and were taken from (Downey et al., 2007). The first, Unary, was an extraction task for unary relations (Company, Country, Language, Film) and the second, Binary, was a type-checking task for binary relations (Conquered, Founded, Headquartered, Merged). The 10 most frequent extractions served as bootstrapped seeds. The two test sets contained 361 and 265 extractions, respectively. The third data set, Wikipedia, evaluates ADS on weakly-supervised extraction, using seeds and extractions taken from Wikipedia 'List of' pages (Pantel et al., 2009). Seed sets of various sizes (5, 10, 15 and 20) were randomly selected from each list, and we present results averaged over 10 random samplings. Other members of the seed list were added to a test set as correct extractions, and elements from other lists were added as errors. The data set included 2264 extractions across 36 unary relations, including Composers and US Internet Companies.

3.2 Optimizing Language Models for IE

The first question we investigate is whether optimizing individual language models leads to better performance in ADS. We measured the correlation between SLM perplexity and ADS performance as training proceeds in HMMs, and as n and the smoothing technique vary in the n-gram models. Table 1 shows that as the SLM becomes more accurate (i.e. as perplexity decreases), ADS performance increases. The correlation is strong (averaging -0.742) and is consistent across model configurations and data sets. The low positive correlation for the n-gram models on Wikipedia is likely due to a "floor effect"; the models have low performance overall on the difficult Wikipedia data set. The lowest-perplexity n-gram model (Mod Kneser-Ney smoothing with n=3, KN3) does exhibit the best IE performance, at 0.039 (the *average* performance of the HMM models is more than twice this, at 0.084). Figure 1 shows the relationship between SLM and ADS performance in detail for the best-performing HMM configuration.

3.3 Model Selection

Different language models can be configured in different ways: for example, HMMs require choices for the hyperparameters k and T. Here, we show that

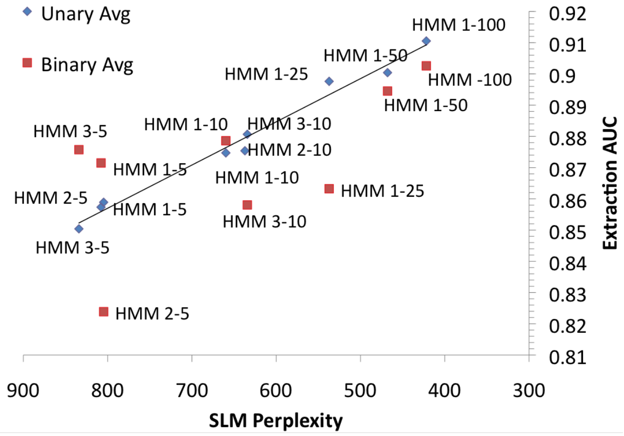

Figure 2: Model Selection for HMMs. SLM performance is a good predictor of extraction performance across model configurations.

Relation	HMM-T	Best HMM
Company	.966	**.985**
Country	.886	**.942**
Languages	**.936**	.914
Film	**.803**	.801
Unary Avg	.898	**.911**
Conquered	.917	**.923**
Founded	**.827**	.799
Merged	.920	**.925**
Headquartered	.734	**.964**
Binary Average	.849	**.903**

Table 2: Extraction Performance Results in AUC for Individual Relations. The lowest-perplexity HMM, 1-100, outperforms the HMM-T model from previous work.

SLM perplexity can be used to select a high-quality model configuration for ADS using only unlabeled data. We evaluate on the Unary and Binary data sets, since they have been employed in previous work on our corpora. Figure 2 shows that for HMMs, ADS performance increases as perplexity decreases across various model configurations (a similar relationship holds for n-gram models). A model selection technique that picks the HMM model with lowest perplexity (HMM 1-100) results in better ADS performance than previous results. As shown in Table 2, HMM 1-100 reduces error over the HMM-T model in (Downey et al., 2007) by 26%, on average. The experiments also reveal an important difference between the HMM and n-gram approaches. While KN3 is more accurate in SLM than our HMM models, it performs *worse* in ADS on average. For example, HMM 1-25 underperforms KN3 in perpexity, at 537.2 versus 227.1, but wins in ADS, 0.880 to 0.853. We hypothesize that this is because the latent state distributions in the HMMs provide a more informative distributional similarity measure. Indeed, when we compute distributional similarity for HMMs using probabilistic context vectors as opposed to state distributions, ADS performance for HMM 1-25 decreases to 5.8% *below* that of KN3.

4 Conclusions

We presented experiments showing that estimating distributional similarity with more accurate statistical language models results in more accurate extraction assessment. We note that significantly larger, more powerful language models are possible beyond those evaluated here, which (based on the trajectory observed in Figure 2) may offer significant improvements in assessment accuracy.

Language Identification: The Long and the Short of the Matter

Timothy Baldwin and **Marco Lui**

Dept of Computer Science and Software Engineering

tb@ldwin.net, saffsd@gmail.com

Abstract

Language identification is the task of identifying the language a given document is written in. This paper describes a detailed examination of what models perform best under different conditions, based on experiments across three separate datasets and a range of tokenisation strategies. We demonstrate that the task becomes increasingly difficult as we increase the number of languages, reduce the amount of training data and reduce the length of documents. We also show that it is possible to perform language identification without having to perform explicit character encoding detection.

1 Introduction

With the growth of the worldwide web, ever-increasing numbers of documents have become available, in more and more languages. This growth has been a double-edged sword, however, in that content in a given language has become more prevalent but increasingly hard to find, due to the web's sheer size and diversity of content. While the majority of (X)HTML documents declare their character encoding, only a tiny minority specify what language they are written in, despite support for language declaration existing in the various (X)HTML standards.[1] Additionally, a single encoding can generally be used to render a large number of languages such that the document encoding at best filters out a subset of languages which are incompatible with the given encoding, rather than disambiguates the source language. Given this, the need for automatic means to determine the source language of web documents is crucial for web aggregators of various types.

There is widespread misconception of language identification being a "solved task", generally as a result of isolated experiments over homogeneous datasets with small numbers of languages (Hughes et al., 2006; Xia et al., 2009). Part of the motivation for this paper is to draw attention to the fact that, as a field, we are still a long way off perfect language identification of web documents, as evaluated under realistic conditions.

In this paper we describe experiments on language identification of web documents, focusing on the broad question of what combination of tokenisation strategy and classification model achieves the best overall performance. We additionally evaluate the impact of the volume of training data and the test document length on the accuracy of language identification, and investigate the interaction between character encoding detection and language identification.

One assumption we make in this research, following standard assumptions made in the field, is that all documents are monolingual. This is clearly an unrealistic assumption when dealing with general web documents (Hughes et al., 2006), and we plan to return to investigate language identification over multilingual documents in future work.

Our contributions in this paper are: the demonstration that language identification is: (a) trivial over datasets with smaller numbers of languages and approximately even amounts of training data per language, but (b) considerably harder over datasets with larger numbers of languages with more skew in the amount of training data per language; byte-based tokenisation without character encoding detection is superior to codepoint-based tokenisation

with character encoding detection; and simple cosine similarity-based nearest neighbour classification is equal to or better than models including support vector machines and naive Bayes over the language identification task. We also develop datasets to facilitate standardised evaluation of language identification.

2 Background Research

Language identification was arguably established as a task by Gold (1967), who construed it as a closed class problem: given data in each of a predefined set of possible languages, human subjects were asked to classify the language of a given test document. It wasn't until the 1990s, however, that the task was popularised as a text categorisation task.

The text categorisation approach to language identification applies a standard supervised classification framework to the task. Perhaps the best-known such model is that of Cavnar and Trenkle (1994), as popularised in the `textcat` tool.[2] The method uses a per-language character frequency model, and classifies documents via their relative "out of place" distance from each language (see Section 5.1). Variants on this basic method include Bayesian models for character sequence prediction (Dunning, 1994), dot products of word frequency vectors (Darnashek, 1995) and information-theoretic measures of document similarity (Aslam and Frost, 2003; Martins and Silva, 2005). More recently, support vector machines (SVMs) and kernel methods have been applied to the task of language identification task with success (Teytaud and Jalam, 2001; Lodhi et al., 2002; Kruengkrai et al., 2005), and Markov logic has been used for joint inferencing in contexts where there are multiple evidence sources (Xia et al., 2009).

Language identification has also been carried out via linguistically motivated models. Johnson (1993) used a list of stop words from different languages to identify the language of a given document, choosing the language with the highest stop word overlap with the document. Grefenstette (1995) used word and part of speech (POS) correlation to determine if two text samples were from the same or different languages. Giguet (1995) developed a cross-language tokenisation model and used it to identify the language of a given document based on its tokenisation similarity with training data. Dueire Lins and Gonçalves (2004) considered the use of syntactically-derived closed grammatical-class models, matching syntactic structure rather than words or character sequences.

The observant reader will have noticed that some of the above approaches make use of notions such as "word", typically based on the naive assumption that the language uses white space to delimit words. These approaches are appropriate in contexts where there is a guarantee of a document being in one of a select set of languages where words are space-delimited, or where manual segmentation has been performed (e.g. interlinear glossed text). However, we are interested in language identification of web documents, which can be in any language, including languages that do not overtly mark word boundaries, such as Japanese, Chinese and Thai; while relatively few languages fall into this categories, they are among the most populous web languages and therefore an important consideration. Therefore, approaches that assume a language is space-delimited are clearly not suitable for our purposes. Equally, approaches which make assumptions about the availability of particular resources for each language to be identified (e.g. POS taggers, or the existence of precompiled stop word lists) cannot be used.

Language identification has been applied in a number of contexts, the most immediate application being in multilingual text retrieval, where retrieval results are generally superior if the language of the query is known, and the search is restricted to only those documents predicted to be in that language (McNamee and Mayfield, 2004). It can also be used to "word spot" foreign language terms in multilingual documents, e.g. to improve parsing performance (Alex et al., 2007), or for linguistic corpus creation purposes (Baldwin et al., 2006; Xia et al., 2009; Xia and Lewis, 2009).

3 Datasets

In the experiments reported in this paper, we employ three novel datasets, with differing properties relevant to language identification research:

[2] `http://www.let.rug.nl/vannoord/TextCat/`

Corpus	Documents	Languages	Encodings	Document Length (bytes)
EUROGOV	1500	10	1	17460.5±39353.4
TCL	3174	60	12	2623.2±3751.9
WIKIPEDIA	4963	67	1	1480.8±4063.9

Table 1: Summary of the three language identification datasets

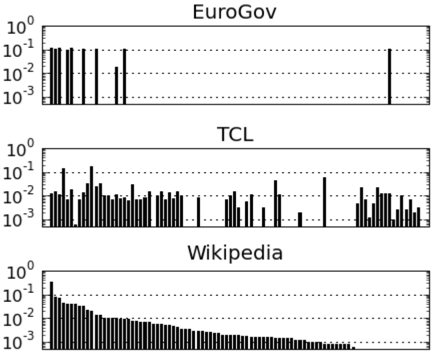

Figure 1: Distribution of languages in the three datasets (vector of languages vs. the proportion of documents in that language)

EUROGOV: longer documents, all in a single encoding, spread evenly across a relatively small number (10) of Western European languages; this dataset is comparable to the datasets conventionally used in language identification research. As the name would suggest, the documents were sourced from the EuroGOV document collection, as used in the 2005 WebCLEF task.

TCL: a larger number of languages (60) across a wider range of language families, with shorter documents and a range of character encodings (12). The collection was manually sourced by the Thai Computational Linguistics Laboratory (TCL) in 2005 from online news sources.

WIKIPEDIA: a slightly larger number of languages again (67), a single encoding, and shorter documents; the distribution of languages is intended to approximate that of the actual web. This collection was automatically constructed by taking the dumps of all versions of Wikipedia with 1000 or more documents in non-constructed languages, and randomly selecting documents from them in a bias-preserving manner (i.e. preserving the document distribution in the full collection); this is intended to represent the document language bias observed on the web. All three corpora are available on request.

We outline the characteristics of the three datasets in Table 1. We further detail the language distribution in Figure 1, using a constant vector of languages for all three datasets, based on the order of languages in the WIKIPEDIA dataset (in descending order of documents per language). Of note are the contrasting language distributions between the three datasets, in terms of both the languages represented and the relative skew of documents per language. In the following sections, we provide details of the corpus compilation and document sampling method for each dataset.

4 Document Representation

As we are interested in performing language identification over arbitrary web documents, we require a language-neutral document representation which does not make artificial assumptions about the source language of the document. Separately, there is the question of whether it is necessary to determine the character encoding of the document in order to extract out character sequences, or whether the raw byte stream is sufficient. To explore this question, we experiment with two document representations: (1) byte n-grams, and (2) codepoint n-grams. In both cases, a document is represented as a feature vector of token counts.

Byte n-grams can be extracted directly without explicit encoding detection. Codepoint n-grams, on the other hand, require that we know the character encoding of the document in order to perform tokenisation. Additionally, they should be based on a common encoding to prevent: (a) over-fragmenting the feature space (e.g. ending up with discrete feature spaces for `euc-jp`, `s-jis` and `utf-8` in the case of Japanese); and (b) spurious matches between encodings (e.g. Japanese hiragana and Korean hangul mapping onto the same codepoint in `euc-jp` and `euc-kr`, respectively). We use unicode as the common encoding for all documents.

In practice, character encoding detection is an issue only for TCL, as the other two datasets are in a single encoding. Where a character encoding was provided for a document in TCL and it was possible to transcode the document to unicode based on that encoding, we used the encoding information. In cases where a unique encoding was not provided, we used an encoding detection library based on the Mozilla browser.[3] Having disambiguated the encoding for each document, we transcoded it into unicode.

5 Models

In our experiments we use a number of different language identification models, as outlined below. We first describe the nearest-neighbour and nearest-prototype models, and a selection of distance and similarity metrics combined with each. We then present three standalone text categorisation models.

5.1 Nearest-Neighbour and Nearest-Prototype Models

The 1-nearest-neighbour (1NN) model is a common classification technique, whereby a test document D is classified based on the language of the closest training document D_i (with language $l(D_i)$), as determined by a given distance or similarity metric.

In nearest-neighbour models, each training document is represented as a single instance, meaning that the computational cost of classifying a test document is proportional to the number of training documents. A related model which aims to reduce this cost is nearest-prototype (AM), where each language is represented as a single instance, by merging all of the training instances for that language into a single centroid via the arithmetic mean.

For both nearest-neighbour and nearest-prototype methods, we experimented with three similarity and distance measures in this research:

Cosine similarity (COS): the cosine of the angle between two feature vectors, as measured by the dot product of the two vectors, normalised to unit length.

Skew divergence (SKEW): a variant of Kullback-Leibler divergence, whereby the second distribution (y) is smoothed by linear interpolation with the first (x) using a smoothing factor α (Lee, 2001):

$$s_\alpha(x, y) = D(x \mid\mid \alpha y + (1 - \alpha)x)$$

where:

$$D(x \mid\mid y) = \sum_i x_i(\log_2 x_i - \log_2 y_i)$$

In all our experiments, we set α to 0.99.

Out-of-place (OOP): a ranklist-based distance metric, where the distance between two documents is calculated as (Cavnar and Trenkle, 1994):

$$oop(D_x, D_y) = \sum_{t \in D_x \vee D_y} abs(R_{D_x}(t) - R_{D_y}(t))$$

$R_D(t)$ is the rank of term t in document D, based on the descending order of frequency in document D; terms not occurring in document D are conventionally given the rank $1 + \max_i R_D(t_i)$.

5.2 Naive Bayes (NB)

Naive Bayes is a popular text classification model, due to it being lightweight, robust and easy to update. The language of test document D is predicted by:

$$\hat{l}(D) = \arg\max_{l_i \in L} P(l_i) \prod_{j=1}^{|\mathscr{V}|} \frac{P(t_j|l_i)^{N_{D,t_j}}}{N_{D,t_j}!}$$

where L is the set of languages in the training data, N_{D,t_j} is the frequency of the jth term in D, $\mathscr{V}$ is the set of all terms, and:

$$P(t|l_i) = \frac{1 + \sum_{k=1}^{|\mathscr{D}|} N_{k,t} P(l_i|D_k)}{|\mathscr{V}| + \sum_{j=1}^{|\mathscr{V}|} \sum_{k=1}^{|\mathscr{D}|} N_{k,t_j} P(l_i|D_k)}$$

In this research, we use the `rainbow` implementation of multinominal naive Bayes (McCallum, 1996).

5.3 Support Vector Machines (SVM)

Support vector machines (SVMs) are one of the most popular methods for text classification, largely because they can automatically weight large numbers of features, capturing feature interactions in the process (Joachims, 1998; Manning et al., 2008). The basic principle underlying SVMs is to maximize the

[3] `http://chardet.feedparser.org/`

margin between training instances and the calculated decision boundary based on structural risk minimisation (Vapnik, 1995).

In this work, we have made use of `bsvm`,[4] an implementation of SVMs with multiclass classification support (Hsu et al., 2008). We only report results for multi-class bound-constrained support vector machines with linear kernels, as they were found to perform best over our data.

6 Experimental Methodology

We carry out experiments over the cross-product of the following options, as described above:

model (×7)**:** nearest-neighbour (COS$_{\text{1NN}}$, SKEW$_{\text{1NN}}$, OOP$_{\text{1NN}}$), nearest-prototype (COS$_{\text{AM}}$, SKEW$_{\text{AM}}$),[5] NB, SVM

tokenisation (×2)**:** byte, codepoint

n**-gram** (×3)**:** 1-gram, 2-gram, 3-gram

for a total of 42 distinct classifiers. Each classifier is run across the 3 datasets (EUROGOV, TCL and WIKIPEDIA) based on 10-fold stratified cross-validation.

We evaluate the models using micro-averaged precision ($\mathcal{P}_\mu$), recall ($\mathcal{R}_\mu$) and F-score ($\mathcal{F}_\mu$), as well as macro-averaged precision ($\mathcal{P}_M$), recall ($\mathcal{R}_M$) and F-score ($\mathcal{F}_M$). The micro-averaged scores indicate the average performance *per document*; as we always make a unique prediction per document, the micro-averaged precision, recall and F-score are always identical (as is the classification accuracy). The macro-averaged scores, on the other hand, indicate the average performance *per language*. In each case, we average the precision, recall and F-score across the 10 folds of cross validation.[6]

As a baseline, we use a majority class, or ZeroR, classifier (ZEROR), which assigns the language with highest prior in the training data to each of the test documents.

Table 2: Results for byte vs. codepoint (bigram) tokenisation over EUROGOV

7 Results

In our experiments, we first compare the different models for fixed n-gram order, then come back to vary the n-gram order. Subsequently, we examine the relative performance of the different models on test documents of differing lengths, and finally look into the impact of the amount of training data for a given language on the performance for that language.

7.1 Results for the Different Models and Tokenisation Strategies

First, we present the results for each of the classifiers in Tables 2–4, based on byte or codepoint tokenisation and bigrams. In each case, we present the best result in each column in **bold**.

The relative performance over EUROGOV and TCL is roughly comparable for all methods barring SKEW$_{\text{1NN}}$, with near-perfect scores over all 6 evaluation metrics. SKEW$_{\text{1NN}}$ is near-perfect over EUROGOV and TCL, but drops to baseline levels over WIKIPEDIA; we return to discuss this effect in Section 7.2.

In the case of EUROGOV, the near-perfect results are in line with our expectations for the dataset, based on its characteristics and results reported for comparable datasets. The results for WIKIPEDIA, however, fall off considerably, with the best model achieving an $\mathcal{F}_M$ of .671 and $\mathcal{F}_\mu$ of .869, due to

[4] `http://www.csie.ntu.edu.tw/~cjlin/bsvm/`

[5] We do not include the results for nearest-prototype classifiers with the OOP distance metric as the results were considerably lower than the other methods.

[6] Note that this means that the averaged $\mathcal{F}_M$ is not necessarily the harmonic mean of the averaged $\mathcal{P}_M$ and $\mathcal{R}_M$.

the larger number of languages, smaller documents, and skew in the amounts of training data per language. All models are roughly balanced in the relative scores they attain for $\mathcal{P}_M$, $\mathcal{R}_M$ and $\mathcal{F}_M$ (i.e. there are no models that have notably higher $\mathcal{P}_M$ relative to $\mathcal{R}_M$, for example).

The nearest-neighbour models outperform the corresponding nearest-prototype models to varying degrees, with the one exception of Skew$_{\text{1NN}}$ over Wikipedia. The nearest-prototype classifiers were certainly faster than the nearest-neighbour classifiers, by roughly an order of 10, but this is more than outweighed by the drop in classification performance. With the exception of Skew$_{\text{1NN}}$ over Wikipedia, all methods were well above the baselines for all three datasets.

The two methods which perform consistently well at this point are Cos$_{\text{1NN}}$ and SVM, with Cos$_{\text{1NN}}$ holding up particularly well under micro-averaged F-score while NB drops away over Wikipedia, the most skewed dataset; this is due to the biasing effect of the prior in NB.

Looking to the impact of byte- vs. codepoint-tokenisation on classifier performance over the three datasets, we find that overall, bytes outperform codepoints. This is most notable for TCL and Wikipedia, and the Skew$_{\text{1NN}}$ and NB models. Given this result, we present only results for byte-based tokenisation in the remainder of this paper.

The results for byte tokenisation of TCL are particularly noteworthy. The transcoding into unicode and use of codepoints, if anything, hurts performance, suggesting that implicit character encoding detection based on byte tokenisation is the best approach: it is both more accurate and simplifies the system, in removing the need to perform encoding detection prior to language identification.

7.2 Results for Differing n-gram Sizes

We present results with byte unigrams, bigrams and trigrams in Table 5 for Wikipedia.[7] We omit results for the other two datasets, as the overall trend is the same as for Wikipedia, with lessened relative differences between n-gram orders due to the relative simplicity of the respective classification tasks.

Skew$_{\text{1NN}}$ is markedly different to the other methods in achieving the best performance with unigrams, moving from the worst-performing method by far to one of the best-performing methods. This is the result of the interaction between data sparseness and heavy-handed smoothing with the α constant. Rather than using a constant α value for all n-gram orders, it may be better to parameterise it using an exponential scale such as $\alpha = 1 - \beta^n$ (with

[7] The results for OOP$_{\text{1NN}}$ over byte trigrams are missing due to the computational cost associated with the method, and our experiment hence not having run to completion at the time of writing. Extrapolating from the results for the other two datasets, we predict similar results to bigrams.

Table 5: Results for different n-gram orders over WIKIPEDIA

$\beta = 0.01$, e.g.), based on the n-gram order. We leave this for future research.

For most methods, bigrams and trigrams are better than unigrams, with the one notable exception of SKEW$_{1NN}$. In general, there is little separating bigrams and trigrams, although the best result for is achieved slightly more often for bigrams than for trigrams.

For direct comparability with Cavnar and Trenkle (1994), we additionally carried out a preliminary experiment with hybrid byte n-grams (all of 1- to 5-grams), combined with simple frequency-based feature selection of the top-1000 features for each n-gram order. The significance of this setting is that it is the strategy adopted by `textcat`, based on the original paper of Cavnar and Trenkle (1994) (with the one exception that we use 1000 features rather than 300, as all methods other than OOP$_{1NN}$ benefitted from more features). The results are shown in Table 6.

Compared to the results in Table 5, SKEW$_{1NN}$ and SKEW$_{AM}$ both increase markedly to achieve the best overall results. OOP$_{1NN}$, on the other hand, rises slightly, while the remaining three methods actually drop back slightly. Clearly, there is considerably more experimentation to be done here with mixed n-gram models and different feature selection methods, but the results indicate that some methods certainly benefit from n-gram hybridisation and feature selection, and also that we have been able to surpass the results of Cavnar and Trenkle (1994) with SKEW$_{1NN}$ in an otherwise identical framework.

7.3 Breakdown Across Test Document Length

To better understand the impact of test document size on classification accuracy, we divided the test documents into 5 equal-size bins according to their length, measured by the number of tokens. We then computed $\mathcal{F}_\mu$ individually for each bin across the 10 folds of cross validation. We present the breakdown of results for WIKIPEDIA in Figure 2.

WIKIPEDIA shows a pseudo-logarithmic growth in $\mathcal{F}_\mu$ (= $\mathcal{P}_\mu$ = $\mathcal{R}_\mu$) as the test document size increases. This fits with our intuition, as the model has progressively more evidence to base the classification on. It also suggests that performance over shorter documents appears to be the dominating factor in the overall ranking of the different methods. In particular, COS$_{1NN}$ and SVM appear to be able to classify shorter documents most reliably, leading to the overall result of them being the best-performing methods.

While we do not show the graph for reasons of space, the equivalent graph for EUROGOV displays a curious effect: $\mathcal{F}_\mu$ drops off as the test documents get longer. Error analysis of the data indicates that this is due to longer documents being more likely to be "contaminated" with either data from a second language or extra-linguistic data, such as large tables of numbers or chemical names. This suggests that all the models are brittle when the assump-

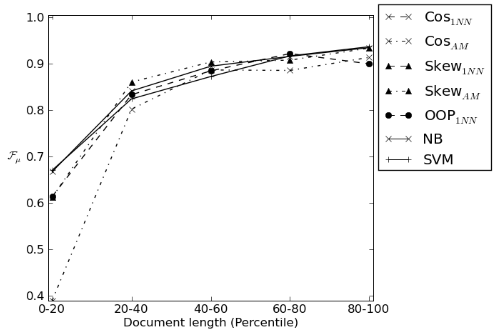

Figure 2: Breakdown of $\mathcal{F}_\mu$ over WIKIPEDIA for test documents of increasing length

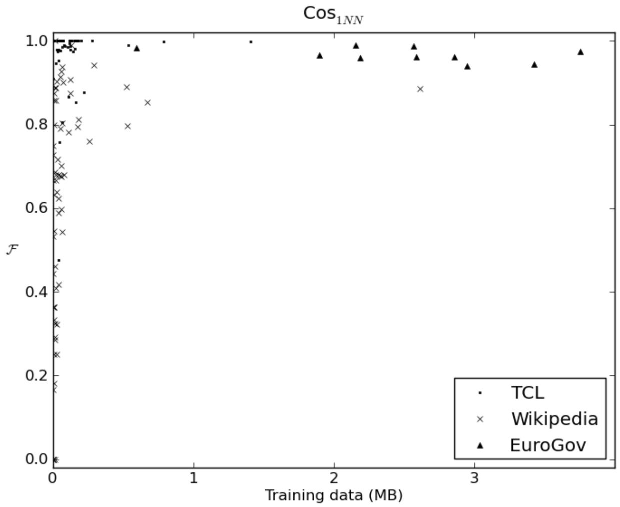

Figure 3: Per-language $\mathcal{F}_M$ for COS$_{\rm 1NN}$, relative to the training data size (in MB) for that language

tion of strict monolingualism is broken, or when the document is dominated by extra-linguistic data. Clearly, this underlines our assumption of monolingual documents, and suggests multilingual language identification is a fertile research area even in terms of optimising performance over our "monolingual" datasets.

7.4 Performance Relative to Training Data Size

As a final data point in our analysis, we calculated the $\mathcal{F}_M$ for each language relative to the amount of training data available for that language, and present the results in the form of a combined scatter plot for the three datasets in Figure 3. The differing distributions of the three datasets are self-evident, with most languages in EUROGOV (the squares) both having reasonably large amounts of training data and achieving high $\mathcal{F}_M$ values, but the majority of languages in WIKIPEDIA (the crosses) having very little data (including a number of languages with no training data, as there is a singleton document in that language in the dataset). As an overall trend, we can observe that the greater the volume of training data, the higher the $\mathcal{F}_M$ across all three datasets, but there is considerable variation between the languages in terms of their $\mathcal{F}_M$ for a given training data size (the column of crosses for WIKIPEDIA to the left of the graph is particularly striking).

8 Conclusions

We have carried out a thorough (re)examination of the task of language identification, that is predicting the language that a given document is written in, focusing on monolingual documents at present. We experimented with a total of 7 models, and tested each over two tokenisation strategies (bigrams vs. codepoints) and three token n-gram orders (unigrams, bigrams and trigrams). At the same time as reproducing results from earlier research on how easy the task can be over small numbers of languages with longer documents, we demonstrated that the task becomes much harder for larger numbers of languages, shorter documents and greater class skew. We also found that explicit character encoding detection is not necessary in language detection, and that the most consistent model overall is either a simple 1-NN model with cosine similarity, or an SVM with a linear kernel, using a byte bigram or trigram document representation. We also confirmed that longer documents tend to be easier to classify, but also that multilingual documents cause problems for the standard model of language identification.

Abstract

This paper describes an efficient sampler for synchronous grammar induction under a non-parametric Bayesian prior. Inspired by ideas from *slice sampling*, our sampler is able to draw samples from the posterior distributions of models for which the standard dynamic programing based sampler proves intractable on non-trivial corpora. We compare our sampler to a previously proposed Gibbs sampler and demonstrate strong improvements in terms of both training log-likelihood and performance on an end-to-end translation evaluation.

1 Introduction

Intractable optimisation algorithms abound in much of the recent work in Natural Language Processing. In fact, there is an increasing acceptance that solutions to many of the great challenges of NLP (e.g. machine translation, summarisation, question answering) will rest on the quality of approximate inference. In this work we tackle this problem in the context of inducing synchronous grammars for a machine translation system. We concern ourselves with the lack of a principled, and scalable, algorithm for learning a synchronous context free grammar (SCFG) from sentence-aligned parallel corpora.

The predominant approach for learning phrase-based translation models (both finite state or synchronous grammar based) uses a cascade of heuristics beginning with predicted word alignments and producing a weighted set of translation rules (Koehn et al., 2003). Alternative approaches avoid such heuristics, instead learning structured alignment models directly from sentence aligned data (e.g., (Marcu and Wong, 2002; Cherry and Lin, 2007; DeNero et al., 2008; Blunsom et al., 2009)). Although these models are theoretically attractive, inference is intractable (at least $\mathcal{O}(|\mathbf{f}|^3|\mathbf{e}|^3)$). The efficacy of direct estimation of structured alignment models therefore rests on the approximations used to make inference practicable – typically heuristic constraints or Gibbs sampling. In this work we show that naive Gibbs sampling (specifically, Blunsom et al. (2009)) is ineffectual for inference and reliant on a high quality initialisation, mixing very slowly and being easily caught in modes. Instead, blocked sampling over sentence pairs allows much faster mixing, but done in the obvious way (following Johnson et al. (2007)) would incur a $\mathcal{O}(|\mathbf{f}|^3|\mathbf{e}|^3)$ time complexity.

Here we draw inspiration from the work of Van Gael et al. (2008) on inference in infinite hidden Markov models to develop a novel algorithm for efficient sampling from a SCFG. We develop an auxiliary variable 'slice' sampler which can dramatically reduce inference complexity, and thereby make blocked sampling practicable on real translation corpora. Our evaluation demonstrates that our algorithm mixes more quickly than the local Gibbs sampler, and produces translation models which achieve state-of-the-art BLEU scores without using GIZA++ or symmetrisation heuristics for initialisation.

We adopt the generative model of Blunsom et al. (2009) which creates a parallel sentence pair by a sequence (derivation) of SCFG productions $\mathbf{d} = (r_1, r_2, ..., r_n)$. The tokens in each language can be read off the leaves of the derivation tree while their order is defined hierarchically by the productions in use. The probability of a derivation is defined as $p(\mathbf{d}|\theta) = \prod_{r \in \mathbf{d}} \theta_r$ where θ are the model parameters which are drawn from a Bayesian prior. We deviate from that models definition of the prior over phrasal translations, instead adopting the hierarchical Dirichlet process prior from DeNero et al. (2008), which incorporates IBM Model 1. Blunsom et al. (2009) describe a blocked sampler following Johnson et al. (2007) which uses the Metropolis-Hastings algorithm to correct proposal samples drawn from an approximating SCFG, however this is discounted as impractical due to the $\mathcal{O}(|\mathbf{f}|^3|\mathbf{e}|^3)$ complexity. Instead a Gibbs sampler is used which samples local updates to the derivation structure of each training instance. This avoids the dynamic program of the

Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

blocked sampler but at the expense of considerably slower mixing.

Recently Bouchard-Côté et al. (2009) proposed an auxialliary variable sampler, possibly complementary to ours, which was also evaluated on synchronous parsing. Rather than slice sampling derivations in a collapsed Bayesian model, this model employed a secondary proposal model (IBM Models) and sampled expectations over rule parameters.

2 Slice Sampling a SCFG

It would be advantageous to explore a middle ground where the scope of the dynamic program is limited to high probability regions, reducing the running time to an acceptable level. By employing the technique of *slice sampling* (Neal, 2003) we describe an algorithm which stochastically samples from a reduced space of possible derivations, while ensuring that these samples are drawn from the correct distribution. We apply the slice sampler to the approximating SCFG parameterised by θ, which requires samples from an *inside* chart $p(\mathbf{d}|\theta)$ (for brevity, we omit the dependency on θ in the following).

Slice sampling is an example of *auxiliary variable sampling* in which we make use of the fact that if we can draw samples from a joint distribution, then we can trivially obtain samples from the marginal distributions: $p(\mathbf{d}) = \sum_{\mathbf{u}} p(\mathbf{d}, \mathbf{u})$, where $\mathbf{d}$ is the variable of interest and $\mathbf{u}$ is an auxiliary variable. Using a Gibbs sampler we can draw samples from this joint distribution by alternately sampling from $p(\mathbf{d}|\mathbf{u})$ and $p(\mathbf{u}|\mathbf{d})$. The trick is to ensure that $\mathbf{u}$ is defined such that drawing samples from $p(\mathbf{d}|\mathbf{u})$ is more efficient than from $p(\mathbf{d})$.

We define the variable $\mathbf{u}$ to contain a slice variable u_s for every cell of a synchronous parse chart for every training instance:[1]

$$\mathcal{S} = \{(i, j, x, y) \mid 0 \leq i < j \leq |\mathbf{f}|, 0 \leq x < y \leq |\mathbf{e}|\}$$
$$\mathbf{u} = \{u_s \in \mathbb{R} \mid 0 < u_s < 1, s \in \mathcal{S}\}$$

These slice variables act as cutoffs on the probabilities of the rules considered in each cell s: rule applications r_s with $\theta_{r_s} \leq u_s$ will be pruned from the dynamic program.[2]

Sampling $p(\mathbf{u}|\mathbf{d})$ Unlike Van Gael et al. (2008), there is not a one-to-one correspondence between the spans of the rules in $\mathbf{d}$ and the set $\mathcal{S}$, rather the derivation's rule spans form a subset of $\mathcal{S}$. This complicates our definition of $p(\mathbf{u}|\mathbf{d})$; we must provide separate accounts of how each u_s is generated depending on whether there is a corresponding rule for s, i.e., $r_s \in \mathbf{d}$. We define $p(\mathbf{u}|\mathbf{d}) = \prod_s p(u_s|\mathbf{d})$, where:

$$p(u_s|\mathbf{d}) = \begin{cases} \frac{\mathbb{I}(u_s < \theta_{r_s})}{\theta_{r_s}} & \text{, if } r_s \in \mathbf{d} \\ \beta(u_s; a, b) & \text{, else} \end{cases} \quad (1)$$

which mixes a uniform distribution and a Beta distribution[3] depending on the existence of a rule r_s in the derivation $\mathbf{d}$.[4] Eq. 1 is constructed such that only rules with probability greater than the relevant threshold, $\{r_s \mid \theta_{r_s} > u_s\}$, could have feasibly been part of a derivation resulting in auxiliary variable $\mathbf{u}$. This is critical in reasoning over the reverse conditional $p(\mathbf{d}|\mathbf{u})$ which only has to consider the reduced space of rules (formulation below in (4)). Trivially, the conditioning derivation is recoverable, $\forall r_s \in \mathbf{d}, \theta_{r_s} \geq u_s$. We parameterise the β distribution in (1) with a heavy skew towards zero in order to limit the amount of pruning and thereby include many competing derivations.[5]

Sampling $p(\mathbf{d}|\mathbf{u})$ Recall the probability of a derivation, $p(\mathbf{d}) = \prod_{r_s \in \mathbf{d}} \theta_{r_s}$. We draw samples from the joint distribution, $p(\mathbf{d}, \mathbf{u})$, holding $\mathbf{u}$ fixed:

$$\begin{aligned} p(\mathbf{d}|\mathbf{u}) \propto p(\mathbf{d}, \mathbf{u}) &= p(\mathbf{d}) \times p(\mathbf{u}|\mathbf{d}) \\ &= \left(\prod_{r_s \in \mathbf{d}} \theta_{r_s}\right) \times \left(\begin{array}{r} \prod_{u_s : r_s \in \mathbf{d}} \frac{\mathbb{I}(u_s < \theta_{r_s})}{\theta_{r_s}} \\ \times \prod_{u_s : r_s \notin \mathbf{d}} \beta(u_s; a, b) \end{array}\right) \\ &= \prod_{u_s : r_s \in \mathbf{d}} \mathbb{I}\left(u_s < \theta_{r_s}\right) \prod_{u_s : r_s \notin \mathbf{d}} \beta(u_s; a, b) \quad (2) \\ &= \prod_{u_s : r_s \in \mathbf{d}} \frac{\mathbb{I}\left(u_s < \theta_{r_s}\right)}{\beta(u_s; a, b)} \prod_{u_s} \beta(u_s; a, b) \quad (3) \\ &\propto \prod_{u_s : r_s \in \mathbf{d}} \frac{\mathbb{I}\left(u_s < \theta_{r_s}\right)}{\beta(u_s; a, b)} \quad (4) \end{aligned}$$

In step (2) we cancel the θ_{r_s} terms while in step (3) we introduce $\beta(u_s; a, b)$ terms to the numerator and denominator for $u_s : r_s \in \mathbf{d}$ to simplify the range

[1] The dependence on training instances is omitted here and subsequently for simplicity. Each instance is independent, and therefore this formulation can be trivially applied to a set.

[2] Alternatively, we could naively sample from a pruned chart using a fixed beam threshold. However, this would not produce samples from $p(\mathbf{d})$, but some other unknown distribution.

[3] Any distribution defined over $\{x \in \mathbb{R} \mid 0 \leq x \leq 1\}$ may be used in place of β, however this may affect the efficiency of the sampler.

[4] $\mathbb{I}(\cdot)$ returns 1 if the condition is true and 0 otherwise.

[5] We experiment with a range of $a < 1$ while fixing $b = 1$.

Table 1: IWSLT Chinese to English translation.

of the second product. The last step (4) discards the term $\prod_{u_s} \beta(u_s; a, b)$ which is constant wrt $\mathbf{d}$. The net result is a formulation which factors with the derivation structure, thereby eliminating the need to consider all $\mathcal{O}(|\mathbf{e}|^2|\mathbf{f}|^2)$ spans in $\mathcal{S}$. Critically $p(\mathbf{d}|\mathbf{u})$ is zero for all spans failing the $\mathbb{I}\left(u_s < \theta_{r_s}\right)$ condition.

To exploit the decomposition of Equation 4 we require a parsing algorithm that only explores chart cells whose child cells have not already been pruned by the slice variables. The standard approach of using synchronous CYK (Wu, 1997) doesn't posses this property: all chart cells would be visited even if they are to be pruned. Instead we use an agenda based parsing algorithm, in particular we extend the algorithm of Klein and Manning (2004) to synchronous parsing.[6] Finally, we need a Metropolis-Hastings acceptance step to account for intra-instance dependencies (the 'rich-get-richer' effect). We omit the details, save to state that the calculation cancels to the same test as presented in Johnson et al. (2007).[7]

3 Evaluation

In the following experiments we compare the slice sampler and the Gibbs sampler (Blunsom et al., 2009), in terms of mixing and translation quality. We measure mixing in terms of training log-likelihood (LLH) after a fixed number of sampling iterations. Translations are produced using Moses (Koehn et al., 2007), initialised with the word alignments from the final sample, and are evaluated using BLEU(Papineni et al., 2001). The slice sampled models are restricted to learning binary branching one-to-one (or null) alignments,[8] while no restriction is placed on the Gibbs sampler (both use the same model, so have comparable LLH). Of particular interest is how the different samplers perform given initialisations of varying quality. We evaluate three initialisers: **M4**: the symmetrised output of GIZA++ factorised into ITG form (as used in Blunsom et al. (2009)); **M1**: the output of a heavily pruned ITG parser using the IBM Model 1 prior for the rule probabilities;[9] and **LB**: left-branching monotone derivations.[10]

We experiment with the Chinese→English translation task from IWSLT, as used in Blunsom et al. (2009).[11] Figure 1 shows LLH curves for the samplers initialised with the M1 and LB derivations, plus the curve for Gibbs sampler with the M4 initialiser.[12] Table 1 gives BLEU scores on Test-05 for phrase-based translation models built from the 1500^{th} sample for the various models along with the average time per sample and their final log-likelihood.

4 Discussion

The results are particularly encouraging. The slice sampler uniformly finds much better solutions than the Gibbs sampler regardless of initialisation. In particular, the slice sampled model initialised with the naive LB structure achieves a higher likelihood than the M4 initialised model, although this is not reflected in their relative BLEU scores. In contrast the Gibbs sampler is more significantly affected by its initialisation, only deviating slightly before becoming trapped in a mode, as seen in Fig. 1. With sufficient (infinite) time both sampling strategies will converge on the true posterior regardless of initialisation, however the slice sampler appears to be converging much faster than the Gibbs sampler.

Interestingly, the initialisation heuristics (M1 and M4) outperform the default heuristics (Koehn et al., 2007) by a considerable margin. This is most likely because the initialisation heuristics force the alignments to factorise with an ITG, resulting in more aggressive pruning of spurious alignments which in turn allows for more and larger phrase pairs.

[6] Moreover, we only sample values for u_s as they are visited by the parser, thus avoiding the quartic complexity.

[7] Acceptance rates averaged above 99%.

[8] This restriction is not strictly necessary, however it greatly simplifies the implementation and increases efficiency.

[9] The following beam heuristics are employed: alignments to null are only permitted on the longer sentence side; words are only allowed to align to those whose relative sentence position is within ± 3 words.

[10] Words of the longer sentence are randomly assigned to null.

[11] We limit the maximum training sentence length to 40, resulting in $\sim 40k$ training sentences.

[12] The GIZA++ M4 alignments don't readily factorise to word-based ITG derivations, as such we haven't produced results for this initialiser using the slice sampler.

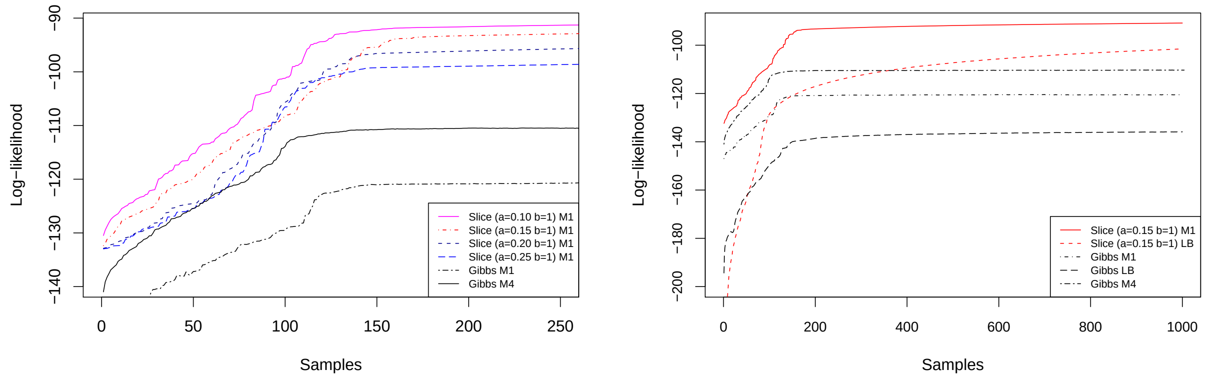

Figure 1: Training log-likelihood as a function of sampling iteration for Gibbs and slice sampling.

While the LLHs for the slice sampled models and their BLEU scores appear correlated, this doesn't extend to comparisons with the Gibbs sampled models. We believe that this is because the GIZA++ initialisation alignments also explain the data well, while not necessarily obtaining a high LLH under the ITG model. Solutions which score highly in one model score poorly in the other, despite both producing good translations.

The slice sampler is slower than the local Gibbs sampler, its speed depending on the parameterisation of the Beta distribution (affecting the width of the beam). In the extreme, exhaustive search using the full dynamic program is intractable on current hardware,[13] and therefore we have achieved our aim of mediating between local and blocked inference.

This investigation has established the promise of the SCFG slice sampling technique to provide a scalable inference algorithm for non-parametric Bayesian models. With further development, this work could provide the basis for a family of principled inference algorithms for parsing models, both monolingual and synchronous, and other models that prove intractable for exact dynamic programming.

Task-based Evaluation of Multiword Expressions: a Pilot Study in Statistical Machine Translation

Abstract

We conduct a pilot study for task-oriented evaluation of Multiword Expression (MWE) in Statistical Machine Translation (SMT). We propose two different integration strategies for MWE in SMT, which take advantage of different degrees of MWE semantic compositionality and yield complementary improvements in SMT quality on a large-scale translation task.[1]

1 Introduction

A multiword expression (MWE) generally refers to a multiword unit or a collocation of words that co-occur together statistically more than chance. A MWE is a cover term for different types of collocations which vary in their transparency and fixedness. Identifying MWEs and understanding their meaning is considered essential to language understanding, and of crucial importance for any Natural Language Processing (NLP) applications that aim at handling robust language meaning and use. In fact, the seminal paper (Sag et al., 2002) refers to this problem as a key issue for the development of high-quality NLP applications. (Villavicencio et al., 2005) identify Machine Translation as an application of particular interest since “ recognition of MWEs is necessary for systems to preserve the meaning and produce appropriate translations and avoid the generation of unnatural or nonsensical sentences in the target language.”

However, statistical machine translation (SMT) typically does not model MWEs explicitly. SMT units are typically phrasal translations, defined without any direct syntactic or lexical semantic motivation: they are simply n-grams that are consistently translated in parallel corpora. Phrasal translations might indirectly capture MWEs, but they are not distinguished from any other n-gram.

As a result, the usefulness of explicitly modeling MWEs in the SMT framework has not yet been studied systematically. Previous work has focused on automatically learning and integrating translations of very specific MWE categories, such as, for instance, idiomatic Chinese four character expressions (Bai et al., 2009) or domain specific MWEs (Ren et al., 2009). MWEs have also been defined not from a lexical semantics perspective but from a SMT error reduction perspective, as phrases that are hard to align during SMT training (Lambert and Banchs, 2005). For each of these particular cases, translation quality improved by augmenting the SMT translation lexicon with the learned bilingual MWEs either directly or through improved word alignments.

In this paper, we consider a more general problem: we view SMT as an extrinsic evaluation of the usefulness of monolingual MWEs as used pervasively in natural language regardless of domain, idiomaticity and compositionality. A MWE is compositional if its meaning as a unit can be predicted from the meaning of its component words such as in *make a decision* meaning *to decide*. Some MWEs are more predictable than others, for instance, *kick the bucket*, when used idiomatically to mean *to die*, has nothing in common with the literal meaning of either *kick* or *bucket*, while *make a decision* is very clearly related to *to decide*. These expressions are

Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

both considered MWEs but have varying degrees of compositionality and predictability.

We explore strategies for integrating all MWEs along this continuum in SMT. Given a monolingual MWE lexicon, we propose (1) a **static integration** strategy that segments training and test sentences according to the MWE vocabulary, and (2) a **dynamic integration** strategy that adds a new MWE-based feature in SMT translation lexicons.

In a pilot study of the impact of WordNet MWEs on a large-scale English to Arabic SMT system, we show that static and dynamic strategies both improve translation quality and that their impact is not the same for different types of MWEs. This suggests that the proposed framework would be an interesting testbed for a task-driven evaluation of automatic MWE extraction.

2 Static integration of MWE in SMT

The first strategy for integration can be seen as a generalization of word segmentation for MWEs. Given a MWE lexicon, we identify MWEs in running text and turn them into a single unit by underscoring. We call this integration method **static**, since, once segmented, all MWEs are considered frozen from the perspective of the SMT system. During training and decoding, MWEs are handled as distinct words regardless of their compositionality, and all knowledge of the MWE components is lost.

3 Dynamic integration of MWE in SMT

The second strategy attempts to encourage cohesive translations of MWEs without ignoring their components. Word alignment and phrasal translation extraction are conducted without any MWE knowledge, so that the SMT system can learn word-for-word translations from consistently translated compositional MWEs. MWE knowledge is integrated as a feature in the translation lexicon. For each entry, in addition to the standard phrasal translation probabilities, we define a count feature that represents the number of MWEs in the input language phrase.

We refer to this integration strategy as **dynamic**, because the SMT system decides at decoding time how to segment the input sentence. The MWE feature biases the system towards using phrases that do not break MWEs. This can be seen as a generalization of the binary MWE feature in (Ren et al., 2009), repurposed for monolingual MWEs.

4 Empirical Evaluation

We evaluate the impact of MWEs in SMT on a large-scale English-Arabic translation task.

Using two languages from different families is a challenging testbed for MWEs in SMT. In contrast, very closely related languages such as English and French might present less divergence in lexicalization.

In addition, Arabic-English is a well-studied language pair in SMT, with large amounts of data available. However, we tackle the less common English to Arabic direction in order to take advantage of the rich lexical resources available for English on the input side.

Our test set consists of the 813 newswire sentences of the 2008 NIST Open Machine Translation Evaluation, which is standard evaluation data for Arabic-English translation. The first English reference translation is used as the input to our SMT system, and the single Arabic translation is used as the unique reference[2]. Translation quality is evaluated using two automatic evaluation metrics: (1) BLEUr1n4 (Papineni et al., 2002), which is based on n-gram precisions for $n = 1..4$, and (2) Translation Edit Rate (TER) (Snover et al., 2006), which generalizes edit distance beyond single-word edits.

4.1 SMT system

We use the open-source Moses toolkit (Koehn et al., 2007) to build a standard phrase-based SMT system.

Our training data consists of 2.5M sentence pairs from mostly newswire parallel corpora distributed by the Linguistic Data Consortium. The English side is tokenized using simple punctuation-based rules. The Arabic side is segmented according to the Arabic Treebank v3 tokenization scheme using the MADA+TOKAN morphological analyzer and tokenizer (Habash et al., 2009).

The parallel corpus is word-aligned using GIZA++ in both translation directions, which are

[2] We exclude weblog text since it consists of an informal mix of Modern Standard Arabic and Dialectal Arabic which is suboptimal as a reference translation.

combined by intersection and the grow-diag-final-and heuristic (Koehn et al., 2007). Phrase translations of up to 10 words are extracted in the Moses phrase-table. We use a 5-gram language model with modified Kneser-Ney smoothing. Feature weights are tuned on NIST-MT06.

4.2 English MWE

Our main source of English MWE is the WordNet 3.0 lexical database (Fellbaum, 1998). We use simple rules to augment WordNet entries with morphological variations (e.g., *keep one's eyes peeled* is expanded into *keep her eyes peeled*, etc.). In addition when marking MWEs in text, we allow matches not only with surface forms, but also with lemmatized forms (Schmid, 1994) to account for inflections. This results in a total of about 900 MWE tokens and 500 types in our evaluation test set. MWE identification in running text is performed using a straightforward maximum forward match algorithm.

Second, in order to contrast the impact of MWEs with that of frequent collocations in our dynamic integration strategy, we consider the top 500 most frequent n-grams from the SMT test set, so that the same number of n-gram types and WordNet MWEs are marked in the test set. Unlike WordNet MWEs, these n-gram represent cohesive units, but are not necessarily frozen or even a single concept. We consider n-grams up to length 10 from the phrase-table, and compute their frequency in the English side of the parallel corpus. The top 500 most frequent n-grams and the WordNet MWEs yield two very different lexicons. Only the following 10 entries appear in both: *at the same time, deputy prime minister, for the first time, in the south, in the wake of, international atomic energy agency, islamic resistance movement, on the other hand, osama bin laden, secretary of state*.

5 Static MWE Integration Improves SMT

As seen in Table 1, the static integration of the WordNet MWE lexicon by segmentation of English training and test sentences improves BLEU and TER compared to the SMT baseline. This suggests that WordNet MWEs represent useful units of meaning for alignment and translation into Arabic despite the fact that they are monolingually defined.

MWE	**integration**	**TER**	**BLEU**
Baseline	—	59.43	30.49
Top 500 n-grams	dynamic	59.07	30.98
WordNet MWE	dynamic	58.89	31.07
WordNet MWE	static	58.98	31.27

Table 1: Impact of MWE integration measured on NIST MT08

Consider, for instance, the following input sentence: *the special envoy of the secretary-general will submit an oral report to the international security council rather than a written report*. With static integration, the MWE *written report* is correctly translated as *tqryrA mktwbA*, while the baseline produces the incorrect translation *ktb Altqryr* (*writing the report* or *book of report*).

6 Dynamic MWE Integration Improves SMT

Dynamic integration of the WordNet MWE lexicon and the top 500 n-grams both improve BLEU and TER (Table 1), but WordNet MWEs yield slightly better scores. This confirms the ability of the dynamic integration method to handle compositional MWEs, since the most frequent n-grams are highly compositional by definition.

7 Discussion

At the corpus-level, static integration yields a slightly better BLEU score than dynamic with WordNet MWEs, while the opposite effect is observed on TER. This suggests that the two integration strategies impact translation in different ways. Sentence-level scores indeed reveal that dynamic and static integration strategies have an opposite impact on 27% of the test set (Table 2).

For instance, the dynamic approach fails for phrasal verbs such as *take out*. In *who were then allowed to take out as many unsecured loans as they wanted*, *take out* is realized as *b+ AlHSwl* (*acquire*) with the static approach, while it is entirely dropped from the dynamic translation.

In the static approach, translation quality is often degraded when our simple dictionary matching approach incorrectly detects MWE. For instance, in the sentence *the perpetration of this heinous act on our*

Dynamic integration	helps	hurts
Static integration		
helps	45%	**16%**
hurts	**11%**	28%

Table 2: Percentage of sentences where each integration strategy helps or hurts both BLEU and TER compared to the baseline SMT system.

soil, *act on* is incorrectly identified as a MWE which degrades translation fluency. This suggests that further gains in translation quality could be obtained with a more sophisticated MWE detection method.

8 Conclusion

We have proposed a framework of two complementary integration strategies for MWEs in SMT, which allows extrinsic evaluation of the usefulness of MWEs of varying degree of compositionality. We conducted a pilot study using manually defined WordNet MWE and a dictionary matching approach to MWE detection. This simple model improves English-Arabic translation quality, even on a large SMT system trained on more than 2 Million sentence pairs.

This result suggests that standard SMT phrases do not implicitly capture all useful MWE information. It would therefore be interesting to conduct this study on a larger scale, using more general MWE definitions such as automatically learned collocations (Smadja, 1993) or verb-noun constructions (Diab and Bhutada, 2009).

Abstract

Semantic role labeling (SRL) not only needs lexical and syntactic information, but also needs word sense information. However, because of the lack of corpus annotated with both word senses and semantic roles, there is few research on using word sense for SRL. The release of OntoNotes provides an opportunity for us to study how to use word sense for SRL. In this paper, we present some novel word sense features for SRL and find that they can improve the performance significantly.

1 Introduction

Semantic role labeling (SRL) is a kind of shallow sentence-level semantic analysis and is becoming a hot task in natural language processing. SRL aims at identifying the relations between the predicates in a sentence and their associated arguments. At present, the main stream researches are focusing on feature engineering or combination of multiple results.

Word senses are important information for recognizing semantic roles. For example, if we know “cat” is an “agent” of the predicate “eat” in a sentence, we can guess that “dog” can also be an “agent” of “eat”. Word sense has been successfully used in many natural language processing tasks, such as machine translation (Chan et al., 2007; Carpuat and Wu, 2007). CoNLL 2008 shared task (Surdeanu et al., 2008) first introduced the predicate classification task, which can be regarded as the predicate sense disambiguation. Meza-Ruiz and Riedel (2009) has shown that the predicate sense can improve the final SRL performance. However, there is few discussion about the concrete influence of all word senses, i.e. the words besides predicates. The major reason is lacking the corpus, which is both annotated with all word senses and semantic roles.

The release of OntoNotes corpus provides an opportunity for us to verify whether all word senses can help SRL. OntoNotes is a large corpus annotated with constituency trees (based on Penn Treebank), predicate argument structures (based on Penn PropBank) and word senses. It has been used in some natural language processing tasks, such as joint parsing and named entity recognition (Finkel and Manning, 2009) and word sense disambiguation (Zhong et al., 2008).

In this paper, we regard the word sense information as additional SRL features. We compare three categories of word sense features (subtree-word related sense, predicate sense, and sense path) and find that the subtree-word related sense feature is ineffective, however, the predicate sense and the sense path features can improve the SRL performance significantly.

2 Data Preparation

In our experiments, we use the OntoNotes Release 2.0[1] corpus (Hovy et al., 2006). The OntoNotes project leaders describe it as “a large, multilingual richly-annotated corpus constructed at 90% internanotator agreement.” The corpus has been annotated with multiple levels of annotation, including constituency trees, predicate argument structure, word senses, co-reference, and named entities. For this work, we focus on the constituency trees, word senses, and predicate argument structures. The corpus has English and Chinese portions, and we just use the English portion, which has been split into seven sections: ABC, CNN, MNB, NBC, PRI, VOA, and WSJ. These sections represent a mix of speech and newswire data.

Because we used SRL system based on dependence syntactic trees, we convert the constituency

[1] http://www.ldc.upenn.edu/Catalog/CatalogEntry.jsp?catalogId=LDC2008T04

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 246–249,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

trees into dependence trees with an Constituent-to-Dependency Conversion Tool[2]. In addition, we also convert the OntoNotes sense of each polysemant into WordNet sense using sense inventory file provided by OntoNotes 2.0. For an OntoNotes sense with more than one WordNet sense, we simply use the foremost (more popular) one.

3 Semantic Role Labeling System

Our baseline is a state-of-the-art SRL system based on dependency syntactic tree (Che et al., 2009). A maximum entropy (Berger et al., 1996) classifier is used to predict the probabilities of a word in the sentence to be each semantic role. A virtual role "NULL" (presenting none of roles is assigned) is added to the roles set, so it does not need semantic role identification stage anymore. For a predicate, two classifiers (one for noun predicates, and the other for verb predicates) predict probabilities of each word in a sentence to be each semantic role (including virtual role "NULL"). The features used in this stage are listed in Table 1.

Feature	Description
FirstwordLemma	The lemma of the first word in a subtree
HeadwordLemma	The lemma of the head word in a subtree
HeadwordPOS	The POS of the head word in a subtree
LastwordLemma	The lemma of the last word in a subtree
POSPath	The POS path from a word to a predicate
PathLength	The length of a path
Position	The relative position of a word with a predicate
PredicateLemma	The lemma of a predicate
RelationPath	The dependency relation path from a word to a predicate

Table 1: Features that are used in SRL.

4 Word Sense for Semantic Role Labeling

From Table 1, we can see that there are lots of lemma or POS related features. However, the lemma feature is very sparse and may result in data sparseness problem. As for the POS, it represents the syntactic information, but is not enough to distinguish different semantic roles. Therefore, we need a kind of new feature, which is general than the lemma and special than the POS.

The word sense just satisfies the requirement. Thus, we will add some new features related with word sense for SRL. Generally, the original features can be classified into three categories:

1. Subtree-word related: FirstwordLemma, LastwordLemma, HeadwordLemma, and HeadwordPOS
2. Predicate related: PredicateLemma
3. Word and predicate related: POSPath, RelationPath, PathLenght, and Position

Correspondingly, we add three categories of word sense features by replacing Lemma or POS into Sense, i.e.

1. Subtree-word related sense: FirstwordSense, LastwordSense, and HeadwordSense
2. Predicate related sense: PredicateSense
3. Word and predicate related sense: SensePath

Three strategies are designed to adopt these senses:

1. Lemma+Sense: It is the original word sense representation in OntoNotes, such as "dog.n.1". In fact, This is a specialization of the lemma.
2. Hypernym(n): It is the hypernym of a word sense, e.g. the hypernym of "dog.n.1" is "canine.n.1". The n means the level of the hypernym. With the increasing of n, the sense becomes more and more general. In theory, however, this strategy may result in inconsistent sense, e.g. word "dog" and "canine" have different hypernyms. The same problem occurs with Basic Concepts method (Izquierdo et al., 2007).
3. Root_Hyper(n): In order to extract more consistent sense, we use the hypernym of a word sense counting from the root of a sense tree, e.g. the root hypernym of "dog.n.1" is "entity.n.1". The n means the level of the root hypernym. With the increasing of n, the sense

[2] http://nlp.cs.lth.se/software/treebank_converter/

becomes more and more special. Thus, word "dog" and "canine" have the same Root_Hyper: "entity", "physical_entity", and "object" with n = 1, 2, and 3 respectively.

5 Experiments

We will do our experiments on seven of the OntoNotes English datasets described in Section 2. For each dataset, we aimed for roughly a 60% train / 20% development / 20% test split. See Table 2 for the detailed statistics. In order to examine the influence of word senses in isolation, we use the human annotated POS, parse trees, and word senses provided by OntoNotes. The lemma of each word is extracted using WordNet tool.

	Training	Developing	Testing
ABC	669 (0001-0040)	163 (0041-0054)	138 (0057-0069)
CNN	1,691 (0001-0234)	964 (0235-0331)	1,146 (0333-0437)
MNB	381 (0001-0015)	130 (0016-0020)	125 (0021-0025)
NBC	351 (0001-0025)	129 (0026-0032)	86 (0033-0039)
PRI	1,205 (0001-0067)	384 (0068-0090)	387 (0091-0112)
VOA	1,238 (0001-0159)	325 (0160-0212)	331 (0213-0264)
WSJ	8,592 (0020-1446)	2,552 (1447-1705)	3,432 (1730-2454)
All	14,127	4,647	5,645

Table 2: Training, developing and testing set sizes for the seven datasets in sentences. The file ranges (in parenthesis) refer to the numbers within the names of the original OntoNotes files.

The baseline SRL system without sense information is trained with all the training corpus as described in Section 3. Its performance on the development data is F1 = 85.48%.

Table 3 shows the performance (F1) comparison on the development data among different sense extracting strategies with different feature categories. The numbers are the parameter n used in Hypernym and Root_Hyper strategies.

From Table 3, we can find that:

1. Both of the predicate sense feature and the sense path feature can improve the performance. For the predicate sense feature, we arrive at the same conclusion with Meza-Ruiz and Riedel (2009). As for the sense path feature, it is more special than the POS, therefore, it can enhance the precision.

2. The subtree-word related sense is almost useless. The reason is that the original lemma and POS features have been able to describe the subtree-word related information. This kind of sense features is just reduplicate.

3. For different sense feature categories (columns), the performance is not very seriously affected by different sense extracting strategies (rows). That is to say, once the sense of a word is disambiguated, the sense expressing form is not important for SRL.

		Subtree-word related sense	Predicate sense	Sense path
Lemma+Sense		85.34%	86.16%	85.69%
Hypernym(n)	1	85.41%	86.12%	85.74%
	2	85.48%	86.10%	85.74%
	3	85.38%	86.10%	85.69%
Root_Hyper(n)	1	85.35%	86.07%	85.96%
	2	85.45%	86.13%	85.86%
	3	85.46%	86.05%	85.91%

Table 3: The performance comparison on the development data among different sense extracting strategies with different feature categories.

In order to further improve the performance, we add the predicate sense and the sense path features simultaneously. Here, we select the Lemma+Sense strategy for the predicate sense and the Root_Hyper(1) strategy for the sense path. The final performance achieves F1 = 86.44%, which is about 1% higher than the baseline (F1 = 85.48%).

Finally, we compare the baseline (without sense) result with the word sense result on the test data. In order to see the contribution of correct word senses, we introduce a simple sense determining strategy, which use the first (the most popular) WordNet sense for each word. The final detailed comparison results are listed in Table 4.

Averagely, both of the methods with the first sense and the correct sense can perform better than the baseline. However, the improvement of the method with the first sense is not significant (χ^2-test[3] with

	word sense	88.84	83.37	86.02

Table 4: The testing performance comparison among the baseline without (w/o) sense information, the method with the first sense, and the method with the correct word sense.

$\rho < 0.01$). Especially, for some sections, such as ABC and MNB, it is harmful to the performance. In contrast, the correct word sense can improve the performance significantly (χ^2-test with $\rho < 0.01$)and consistently. These can further prove that the word sense can enhance the semantic role labeling.

6 Conclusion

This is the first effort to adopt the word sense features into semantic role labeling. Experiments show that the subtree-word related sense features are ineffective, but the predicate sense and the sense path features can improve the performance significantly. In the future, we will use an automatic word sense disambiguation (WSD) system to obtain word senses and study the function of WSD for SRL.

Abstract

This paper presents METEOR-NEXT, an extended version of the METEOR metric designed to have high correlation with post-editing measures of machine translation quality. We describe changes made to the metric's sentence aligner and scoring scheme as well as a method for tuning the metric's parameters to optimize correlation with human-targeted Translation Edit Rate (HTER). We then show that METEOR-NEXT improves correlation with HTER over baseline metrics, including earlier versions of METEOR, and approaches the correlation level of a state-of-the-art metric, TER-plus (TERp).

1 Introduction

Recent focus on the need for accurate automatic metrics for evaluating the quality of machine translation output has spurred much development in the field of MT. Workshops such as WMT09 (Callison-Burch et al., 2009) and the MetricsMATR08 challenge (Przybocki et al., 2008) encourage the development of new MT metrics and reliable human judgment tasks.

This paper describes our work extending the METEOR metric to improve correlation with human-targeted Translation Edit Rate (HTER) (Snover et al., 2006), a semi-automatic post-editing based metric which measures the distance between MT output and a targeted reference. We identify several limitations of the original METEOR metric and describe our modifications to improve performance on this task. Our extended metric, METEOR-NEXT, is then tuned to maximize segment-level correlation with HTER scores and tested against several baseline metrics. We show that METEOR-NEXT outperforms earlier versions of METEOR when tuned to the same HTER data and approaches the performance of a state-of-the-art TER-based metric, TER-plus.

2 The METEOR-NEXT Metric

2.1 Traditional METEOR Scoring

Given a machine translation hypothesis and a reference translation, the traditional METEOR metric calculates a lexical similarity score based on a word-to-word alignment between the two strings (Banerjee and Lavie, 2005). When multiple references are available, the hypothesis is scored against each and the reference producing the highest score is used. Alignments are built incrementally in a series of stages using the following METEOR matchers:

Exact: Words are matched if and only if their surface forms are identical.

Stem: Words are stemmed using a language-appropriate Snowball Stemmer (Porter, 2001) and matched if the stems are identical.

Synonym: Words are matched if they are both members of a synonym set according to the WordNet (Miller and Fellbaum, 2007) database. This matcher is limited to translations into English.

At each stage, one of the above matchers identifies all possible word matches between the two translations using words not aligned in previous stages. An alignment is then identified as the largest subset of these matches in which every word in each sentence aligns to zero or one words in the other sen-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 250–253,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

tence. If multiple such alignments exist, the alignment is chosen that best preserves word order by having the fewest crossing alignment links. At the end of each stage, matched words are fixed so that they are not considered in future stages. The final alignment is defined as the union of all stage alignments.

Once an alignment has been constructed, the total number of unigram matches (m), the number of words in the hypothesis (t), and the number of words in the reference (r) are used to calculate precision ($P = m/t$) and recall ($R = m/r$). The parameterized harmonic mean of P and R (van Rijsbergen, 1979) is then calculated:

$$F_{mean} = \frac{P \cdot R}{\alpha \cdot P + (1 - \alpha) \cdot R}$$

To account for differences in word order, the minimum number of "chunks" (ch) is calculated where a chunk is defined as a series of matched unigrams that is contiguous and identically ordered in both sentences. The fragmentation ($frag = ch/m$) is then used to calculate a fragmentation penalty:

$$Pen = \gamma \cdot frag^{\beta}$$

The final METEOR score is then calculated:

$$Score = (1 - Pen) \cdot F_{mean}$$

The free parameters α, β, and γ can be tuned to maximize correlation with various types of human judgments (Lavie and Agarwal, 2007).

2.2 Extending the METEOR Aligner

Traditional METEOR is limited to unigram matches, making it strictly a word-level metric. By focusing on only one match type per stage, the aligner misses a significant part of the possible alignment space. Further, selecting partial alignments based only on the fewest number of per-stage crossing alignment links can in practice lead to missing full alignments with the same number of matches in fewer chunks. Our extended aligner addresses these limitations by introducing support for multiple-word phrase matches and considering all possible matches in a single alignment stage.

We introduce an additional **paraphrase** matcher which matches *phrases* (one or more successive words) if one phrase is considered a paraphrase of the other by a paraphrase database. For English, we use the paraphrase database developed by Snover et al. (2009), using techniques presented by Bannard and Callison-Burch (2005).

The extended aligner first constructs a search space by applying all matchers in sequence to identify all possible matches between the hypothesis and reference. To reduce redundant matches, stem and synonym matches between pairs of words which have already been identified as exact matches are not considered. Matches have start positions and *lengths* in both sentences; a word occurring less than *length* positions after a match start is said to be *covered* by the match. As exact, stem, and synonym matches will always have length one in both sentences, they can be considered phrase matches of length one. Since other matches can cover phrases of different lengths in the two sentences, matches are now said to be one-to-one at the *phrase* level rather than the *word* level.

Once all possible matches have been identified, the aligner identifies the final alignment as the largest subset of these matches meeting the following criteria in order of importance:

1. Each word in each sentence is covered by zero or one matches

2. Largest number of covered words across both sentences

3. Smallest number of chunks, where a chunk is now defined as a series of matched phrases that is contiguous and identically ordered in both sentences

4. Smallest sum of absolute distances between match start positions in the two sentences (prefer to align words and phrases that occur at similar positions in both sentences)

The resulting alignment is selected from the full space of possible alignments and directly optimizes the statistics on which the the final score will be calculated.

2.3 Extended METEOR Scoring

Once an alignment has been chosen, the METEOR-NEXT score is calculated using extended versions of the traditional METEOR statistics. We also introduce a tunable weight vector used to dictate the relative contribution of each match type. The extended METEOR score is calculated as follows.

The number of words in the hypothesis (t) and reference (r) are counted. For each of the matchers (m_i), count the number of words covered by matches of this type in the hypothesis ($m_i(t)$) and reference ($m_i(r)$) and apply the appropriate module weight (w_i). The weighted Precision and Recall are then calculated:

$$P = \frac{\sum_i w_i \cdot m_i(t)}{t} \qquad R = \frac{\sum_i w_i \cdot m_i(r)}{r}$$

The minimum number of chunks (ch) is then calculated using the new chunk definition. Once P, R, and ch are calculated, the remaining statistics and final score can be calculated as in Section 2.1.

3 Tuning for Post-Editing Measures of Quality

Human-targeted Translation Edit Rate (HTER) (Snover et al., 2006), is a semi-automatic assessment of machine translation quality based on the number of edits required to correct translation hypotheses. A human annotator edits each MT hypothesis so that it is meaning-equivalent with a reference translation, with an emphasis on making the minimum possible number of edits. The Translation Edit Rate (TER) is then calculated using the human-edited translation as a targeted reference for the MT hypothesis. The resulting scores are shown to correlate well with other types of human judgments (Snover et al., 2006).

3.1 Tuning Toward HTER

The GALE (Olive, 2005) Phase 2 unsequestered data includes HTER scores for multiple Arabic-to-English and Chinese-to-English MT systems. We used HTER scores for 10838 segments from 1045 documents from this data set to tune both the original METEOR and METEOR-NEXT. Both were exhaustively tuned to maximize the length-weighted segment-level Pearson's correlation with the HTER scores. This produced globally optimal α, β, and γ values for METEOR and optimal α, β, γ values plus stem, synonym, and paraphrase match weights for METEOR-NEXT (with the weight of exact matches fixed at 1). Table 1 compares the new HTER parameters to those tuned for other tasks including adequacy and fluency (Lavie and Agarwal, 2007) and ranking (Agarwal and Lavie, 2008).

Task	α	β	γ
Adequacy & Fluency	0.81	0.83	0.28
Ranking	0.95	0.50	0.50
HTER	0.70	1.95	0.50
HTER (extended)	0.65	1.95	0.45
	Stem	Syn	Par
	0	0.4	0.9

Table 1: Parameter values for various METEOR tasks for translations into English.

As observed by Snover et al. (2009), HTER prefers metrics which are more balanced between precision and recall: this results in the lowest values of α for any task. Additionally, non-exact matches receive lower weights, with stem matches receiving zero weight. This reflects a weakness in HTER scoring where words with matching stems are treated as completely dissimilar, requiring full word substitutions (Snover et al., 2006).

4 Experiments

The GALE (Olive, 2005) Phase 3 unsequestered data includes HTER scores for Arabic-to-English MT output. We created a test set from HTER scores of 2245 segments from 195 documents in this data set. Our evaluation metric (METEOR-NEXT-hter) was tested against the following established metrics: BLEU (Papineni et al., 2002) with a maximum N-gram length of 4, TER (Snover et al., 2006), versions of METEOR based on release 0.7 tuned for adequacy and fluency (METEOR-0.7-af) (Lavie and Agarwal, 2007), ranking (METEOR-0.7-rank) (Agarwal and Lavie, 2008), and HTER (METEOR-0.7-hter). Also included is the HTER-tuned version of TER-plus (TERp-hter), a metric with state-of-the-art performance in recent evaluations (Snover et al., 2009). Length-weighted Pearson's and Spearman's correlation are shown for all metrics at both the segment (Table 2) and document level (Table 3). System level correlations are not shown as the Phase 3 data only contained the output of 2 systems.

Metric	Pearson's r	Spearman's ρ
BLEU-4	-0.496	-0.510
TER	0.539	0.510
METEOR-0.7-af	-0.573	-0.561
METEOR-0.7-rank	-0.561	-0.556
METEOR-0.7-hter	-0.574	-0.562
METEOR-NEXT-hter	-0.600	-0.581
TERp-hter	0.627	0.610

Table 2: Segment level correlation with HTER.

Metric	Pearson's r	Spearman's ρ
BLEU-4	-0.689	-0.686
TER	0.675	0.679
METEOR-0.7-af	-0.696	-0.699
METEOR-0.7-rank	-0.691	-0.693
METEOR-0.7-hter	-0.704	-0.705
METEOR-NEXT-hter	-0.719	-0.713
TERp-hter	0.738	0.747

Table 3: Document level correlation with HTER.

METEOR-NEXT-hter outperforms all baseline metrics at both the segment and document level. Bootstrap sampling indicates that the segment-level correlation improvements of 0.026 in Pearson's r and 0.019 in Spearman's ρ over METEOR-0.7-hter are statistically significant at the 95% level. TERp's correlation with HTER is still significantly higher across all categories. Our metric does run significantly faster than TERp, scoring approximately 120 segments per second to TERp's 3.8.

5 Conclusions

We have presented an extended METEOR metric which shows higher correlation with HTER than baseline metrics, including traditional METEOR tuned on the same data. Our extensions are not specific to HTER tasks; improved alignments and additional features should improve performance on any task having sufficient tuning data. Although our metric does not outperform TERp, it should be noted that HTER incorporates TER alignments, providing TER-based metrics a natural advantage. Our metric also scores segments relatively quickly, making it a viable choice for tuning MT systems.

Testing a Grammar Customization System with Sahaptin

Scott Drellishak
University of Washington
Seattle, WA, USA
sfd@u.washington.edu

Abstract

I briefly describe a system for automatically creating an implemented grammar of a natural language based on answers to a web-based questionnaire, then present a grammar of Sahaptin, a language of the Pacific Northwest with complex argument-marking and agreement patterns, that was developed to test the system. The development of this grammar has proved useful in three ways: (1) verifying the correct functioning of the grammar customization system, (2) motivating the addition of a new pattern of agreement to the system, and (3) making detailed predictions that uncovered gaps in the linguistic descriptions of Sahaptin.

1 Introduction

The **LinGO Grammar Matrix** (Bender et al., 2002) is a resource for building implemented precision HPSG (Pollard and Sag, 1994) grammars of natural languages. Grammars based on the Matrix are expressed in the Type Description Language (TDL) (Krieger and Schäfer, 1994), are interpretable by the Linguistic Knowledge Building system (LKB) (Copestake, 2002) (a software tool for developing constraint-based grammars), and have semantic representations that are compatible with Minimal Recursion Semantics (MRS) (Copestake et al., 2005). The Grammar Matrix project, in particular the customization system described below, has drawn on the linguistics and linguistic typology literature during its development; the system is now complex enough that it is capable making contributions back to linguistics.

1.1 Matrix Customization System

In its earliest form, the Matrix provided a set of predefined types intended to give grammar engineers a head start, allowing them to avoid duplicating the effort required to develop analyses of linguistic structures thought to occur in all languages. However, there exist many linguistic phenomena that are widespread, but not universal. If the Matrix were restricted to supporting only what is truly universal, it would be a much less useful resource for grammar-writers working on languages containing such non-universal phenomena. Our solution has been to provide the **Matrix customization system**, which presents a linguist with a web-based typological questionnaire designed to elicit a description of a target language and, based on it, automatically produce a grammar that parses and generates the target language.[1] The grammars produced are not encumbered by phenomena that do not occur in the target language; rather, they contain just enough complexity to model it as described. Although the grammars produced by the customization system are intended as a starting point for further grammar engineering, that starting point is now far enough along that even without enhancement the grammars can be used for interesting linguistic work.

The customization system is conceived of as consisting of a set of **libraries**, each of which supports a particular linguistic phenomenon, and includes a section of the questionnaire and a syntactic analysis of the target phenomenon that can be

[1] A frozen version of the customization system as described here can be found on the Web at depts.washington.edu/uwcl/matrix/sfddiss/.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 254–262,
Los Angeles, California, June 2010.

customized and included in output grammars. Recently, I have added three new libraries to the system (Drellishak, 2009). A library for case-marking supports a variety of patterns for the marking of up to two mandatory verbal arguments, including the nominative-accusative, ergative-absolutive, and tripartite patterns, as well as various split-ergative systems and Austronesian alignment (see Blake (2001) for definitions of these terms). A library for agreement supports agreement in syntactic and semantic features between verbs and their arguments. Finally, a library for so-called direct-inverse argument marking supports languages in which the marking of verbs and verbal arguments is conditioned on a grammatical scale—for example, languages in which clauses with a first person subject and a second person object are marked differently than clauses with a second person subject and a first person object. Languages can contain none, some, or all of these phenomena, and the customization system must produce consistent grammars for every combination.

1.2 Testing the Customization System

Work to add new libraries to the customization system is ongoing. Since the grammatical analyses of different phenomena can interact in unexpected ways, we utilize a system of regression testing to verify that the implementation new libraries does not break older libraries.

A customization system regression test consists of three parts. First, each test includes a stored set of answers to the questionnaire describing a language that illustrates one or more linguistic phenomena; this can be fed into the customization system to create a grammar. Second, each test has a list of strings, some grammatical and some ungrammatical in the test's language, that probe the behavior of the grammar with respect to the phenomena in question. Third, each test has the expected results, including semantic representations in the format of Oepen (2001), that are produced by the grammar when it parses the test sentences.

At the time of this writing, the regression test suite includes 112 tests that fall roughly into two categories. The first category contains small artificial languages that illustrate a single phenomenon (e.g. nominative-accusative case marking or a particular word order). The second category contains larger grammars based on natural languages that illustrate a wider range of phenomena, and therefore test the interaction of the associated libraries. The largest and most complex test in the latter category is the regression test for Sahaptin.

2 Sahaptin

Sahaptin [uma] (Penutian) is a family of closely related dialects spoken in Washington, Idaho, and Oregon. The details of Sahaptin grammar are drawn primarily from a description of the language by Rigsby and Rude (1996) (henceforth R&R). It happens that Sahaptin contains extremely complex argument marking and agreement patterns that illustrate, in a single grammar, a number of phenomena covered by my recently-implemented Matrix libraries, including:

- Case marking on verbal arguments.
- Argument marking sensitive to a grammatical scale, including patterns analyzed here as proximate and obviative marking on third-person nominals.
- Two loci of agreement (a verbal prefix and a second-position enclitic) with both the subject and the object.
- A distinction in number between singular, dual, and plural on nominals, but only between singular and plural on agreement morphology.
- An inclusive/exclusive distinction in person reflected only in the second-position enclitic.

2.1 Sahaptin Grammar

This section contains a brief sketch of the structure of Sahaptin sentences. Consider the following simple sentence:

(1) *ín=aš á-tux̣nana yáamaš-na*
I=1SG 3ABS-shot mule.deer-OBJ
'I shot the mule deer.' [uma]
(Rigsby and Rude, 1996, 676)

In (1) the first word consists of the first person singular pronoun in its unmarked form, the nominative, followed by a second-position enclitic that agrees with the pronoun. The second word is the verb, consisting of a verbal prefix appropriate to the person and number of the subject and object (glossed by

R&R as 3ABS, but see §3.6 below for a different analysis) and the verb stem. The third word consists of the noun stem meaning ‘mule deer’ and a suffix marking the objective case.

R&R describe several cases in Sahaptin, including an unmarked “nominative” case, a marked “objective” case, an “inverse ergative” case, and an “obviative ergative” case. In spite of their use of the term “ergative”, R&R make it clear that the subject generally appears in the nominative case in both transitive and intransitive clauses, and that the object consistently appears in the objective case in transitive clauses. The “inverse ergative” and “obviative ergative” forms only occur with third person singular nominals, both nouns and pronouns, in addition to the subject and object forms, and they are used to distinguish the subject from the object in transitive clauses.

In addition to case marking on nominals, Sahaptin has two ways to cross-reference the arguments of verbs: a verbal prefix and a second-position enclitic that attaches to whichever word comes first in the sentence. R&R characterize the prefixes and enclitics in two ways: first, they provide a general description of the distribution of each; second, they provide detailed paradigms of intransitive and transitive sentence patterns that cover most, but not all, of the logical combinations.

Enclitic	Description
=naš ∼ *=aš* ∼ *=š*	“first-person singular”
=na	“first-person plural inclusive”
=nataš ∼ *=ataš* ∼ *=taš*	“first-person plural exclusive”
=nam ∼ *=am* ∼ *=m*	“second-person singular”
=pam	“second-person plural”
=maš	“second-person object with first-person subject (both singular)”
=mataš	“second-person object with first-person subject (one or both plural)”

Table 1: Sahaptin enclitics (Rigsby and Rude, 1996, 675)

R&R describe Sahaptin’s second-position enclitics as shown in Table 1. Notice in particular that several of the enclitics are associated with a person and number, but R&R do not mention whether those values are associated with the subject or the object. The reason for this becomes clear when we examine the full paradigm of clauses. The enclitic *=nataš*, for example, occurs with first person plural exclusive subjects in intransitive clauses; in transitive clauses, however, it occurs when one argument is first person plural exclusive and the other is third person, regardless of which is the subject and which is the object. A similar pattern can be observed for *=na* and *=naš*. This variant of scale-sensitive argument marking motivated an enhancement to the customization system described in §5 below.

Prefix	Description
i-	“third-person nominative”
pa-	“third-person plural nominative”
á- ∼ *áw-*	“third-person absolutive”
pá-	“inverse”
patá- ∼ *patáw-*	“third-person plural subject with third-person object”

Table 2: Sahaptin prefixes (Rigsby and Rude, 1996, 675)

As for Sahaptin’s verbal prefixes, R&R describe them as shown in Table 2.[2] These descriptions are less straightforward than those for the enclitics. In particular, the description of *á-* ∼ *áw-* as “absolutive” is misleading. Regarding that prefix, R&R write, “...this pronominal marks subjects in intransitive clauses when they are possessors, and objects in transitive clauses when the subject is first or second person.” (675) In other words, it does not occur in all transitive clauses, and only in those intransitive clauses where the subject is possessive. Furthermore, all the prefixes above appear on the verb, not the nominal arguments, as one might expect for an “absolutive” affix. In spite of the use of the term “absolutive”, the distribution of the prefix *á-* ∼ *áw-* does not give evidence of ergative alignment in Sahaptin. Similarly, although there is evidence of argument marking sensitive to a grammatical scale, the description of *pá-* as “inverse” is misleading, since that prefix does not appear if and only if the object outranks the subject.

[2] There are three further verbal prefixes in Sahaptin that mark reflexives and reciprocals, but there is currently no support for these phenomena in the customization system.

3 Sahaptin Test Case

The phenomena described above make Sahaptin an excellent test case for demonstrating the flexibility and expressive power of the customization system. In this section, I will show how a significant fragment of Sahaptin can be described in the customization system questionnaire, producing a grammar that correctly models some of the complexity of Sahaptin morphosyntax.

It should be noted that some aspects of Sahaptin are beyond the current capabilities of the customization system, so some simplifying assumptions were necessary. For instance, the customization system models complex morphosyntax but not complex morphophonology. In effect, the grammars it outputs expect a morpheme-by-morpheme gloss as input rather than orthography, leaving the problem of morphological analysis to other systems.[3] The Sahaptin test grammar therefore uses only a single spelling for each stem and morpheme, and the morphemes are separated by '-' or '=' characters. The facts of Sahaptin word order are also too complex for the customization system; in particular, it cannot model truly free word order (i.e., discontinuous noun phrases), and the attachment behavior of the second-position enclitic is similarly beyond its capability. However, given these simplifying assumptions, the customization system is capable of modeling all the agreement and marking patterns of Sahaptin intransitive and transitive clauses shown in Tables 7 and 8 in R&R (1996, 676).

After the design and implementation of the libraries for case, direct-inverse languages, and agreement were completed, the construction of the Sahaptin test case took only about 80 hours of work, including the creation of test sentences (described in more detail in §4 below), a linguistic analysis of Sahaptin, filling out the questionnaire to reflect that analysis, and debugging the answers to the questionnaire.

3.1 Word Order

In the test grammar, I treat Sahaptin as a VSO language, and the enclitic as a suffix on verbs. This means that the sentences recognized and generated by the grammar are in a legal word order—VSO sentences with the verb followed by the second-position enclitic are grammatical in Sahaptin—but there are other legal word orders that the test grammar will not accept. The analysis of the enclitic is therefore limited by the current capabilities of the customization system's word order library; however, if that library is enhanced in the future to support second-position clitics, the analysis presented below should transfer straightforwardly.

3.2 Number

I analyze Sahaptin as having three values of number: singular (sg), dual (du), and plural (pl). All three values are distinguished on pronouns, as shown in Table 3; however, agreement with enclitics and verbal prefixes only shows a singular/plural distinction (with dual pronouns agreeing with the plural morpheme). It will be necessary in several places for the grammar to refer to a non-singular category covering *du* and *pl*. The questionnaire allows the explicit description of such a category; however, it also allows the user to select multiple values for a feature, and from those values infers the existence of categories like *non-singular*. I have made use of the latter mechanism in this grammar.

Table 3 shows the Sahaptin pronoun forms that distinguish singular, dual, and plural; in the questionnaire, therefore, I specified a number value on each. So-called plural agreement morphemes, on the other hand, do not distinguish between the dual and plural so are simply specified as covering both values.

3.3 Person

Sahaptin distinguishes three values of person: first, second, and third. The enclitics (but, interestingly, not the pronouns) further distinguish a first person inclusive and first person exclusive. I filled out the person section of the questionnaire with answers reflecting the presence of an inclusive/exclusive distinction.

3.4 Case

As described above, Sahaptin has a nominative case that marks intransitive and transitive subjects and an objective case that marks transitive objects. This

[3] The construction of such systems is well-understood (Beesley and Karttunen, 2003), as is the method for hooking up such a system to the LKB.

	Singular		Dual		Plural	
	Subject	**Object**	**Subject**	**Object**	**Subject**	**Object**
1	*ín*	*ináy*	*napiiní*	*napiinamanáy*	*náma*	*naamanáy*
2	*ím*	*imanáy*	*imiiní*	*imiinamanáy*	*imáy*	*imaamanáy*
3	*pɨ́n*	*paanáy*	*piiní*	*piinamanáy*	*pmáy*	*paamanáy*
3 obv erg	*piiní*					
3 inv erg	*pnɨ́m*					

Table 3: Umatilla Sahaptin Pronouns (Rigsby and Rude, 1996, 682–683)

is the common nominative-accusative pattern, so in the case section of the questionnaire I describe it as such. Note that I do *not* analyze the inverse ergative and obviative ergative as case; see §3.6 for details.

3.5 Direct-Inverse

I analyze Sahaptin as a direct-inverse language—that is, a language whose argument marking is sensitive to a grammatical scale—though one that lacks clear direct or inverse forms of the verb, with the exception of the *pá-* prefix. The scale I propose for Sahaptin is:

(2) 1P $>$ 2P $>$ 3P topic $>$ 3P non-topic

The customization system interprets this scale, creating a series of rules that constrain the value of a feature DIRECTION on verbs. This feature takes the values *direct* and *inverse* and can be used to constrain the form either of verbs themselves or of their arguments.

3.6 Other Features

I use two additional features in my analysis of Sahaptin: a semantic TOPICALITY feature and a syntactic PROXIMITY feature, both on nominals.

Marking of Sahaptin transitive clauses distinguishes between topical and non-topical third person arguments. There is no overt marking of topicality on nominals, but clausal marking is conditioned on pragmatic distinctions that influence the felicity of the sentence in different discourse contexts. In order to systematically test this aspect of Sahaptin grammar in terms of string grammaticality, I introduced an artificial mark on topical noun phrases, the suffix *-TOP*. This suffix constrains the value of the TOPICALITY feature on nominal indices.

I use the syntactic PROXIMITY feature to model the "inverse ergative" and "obviative ergative" forms of nominals. In Sahaptin transitive clauses, the inverse ergative occurs precisely when the subject is third person singular and the clause is inverse (that is, the object is higher on the scale). The obviative ergative occurs in exactly one case: when the subject is third person singular and the object is a topical third person singular. These "ergative" forms function very much like the so-called proximate and obviative forms in Algonquian languages. However, in contrast to those languages, I analyze Sahaptin as having three values of the PROXIMITY feature rather than two: *proximate*, corresponding to the inverse ergative *-nɨ́m*, which promotes the marked nominal up the scale; *obviative*, corresponding to the obviative ergative *-in*, which demotes the marked nominal down the scale; and *neutral*, the unmarked form, which does not affect the nominal's position on the scale.[4]

3.7 Lexicon

Having defined the necessary features and values, we can now describe the lexicon of the Sahaptin grammar, which includes lexical types and inflectional morphemes. In the questionnaire, inflectional morphology is described as a series of slots, each attaching to one or more lexical types or other slots, and each containing one or more morphemes, each of which in turn specifies features. In order to prevent spurious ambiguity, the features on each set of morphemes are specified in such a way that no morpheme overlaps another, but also so that no legal combination of features goes unexpressed.

The simplest grammars are those that do not resort to homophony—that is, they do not have multiple lexical items or morphemes with the same

[4] Note that, for consistency with R&R's description, I nonetheless continue to refer to the marked forms as the "inverse ergative" and "obviative ergative".

spelling but different semantics or features. It is often possible to avoid homophony by adding complexity to feature hierarchies, but overly complex hierarchies can be as difficult to manage as extensive homophony. In the Sahaptin grammar, I have attempted to strike a balance between homophony and hierarchy complexity. For example, to make the grammar easier for users to understand, I segregated verbal prefixes and enclitics each into two classes: those attaching to intransitive stems and those attaching to transitive stems. This produced two homophonous variants of the prefixes *i-* and *pa-*, and of the enclitics *=naš*, *=na*, *=nataš*, *=nam*, and *=pam*. Furthermore, the distributions of two transitive prefixes (*pá-* and the null variant) and of three transitive enclitics (*=nam*, *=pam*, and *=mataš*) were easier to model using homophonous variants. Finally, the third person singular obviative pronoun and the third person dual subject pronoun are both *piiní* (as shown in Table 3) and it seemed simplest to represent these using two separate lexical entries. The grammar, then, contains 22 lexical items, of which only two are homophonous, and 24 non-null inflectional morphemes representing 12 distinctly spelled prefixes and enclitics.

A full description of the morphosyntactic details of the Sahaptin test grammar would be too long for this paper; instead, I will provide a summary.[5] The lexicon of the test grammar contains six inflectional slots: a slot for the topic morpheme described above that attaches to nominals; a slot for verbal prefixes that attach to intransitive verbs; a slot for verbal prefixes that attach to transitive verbs; a slot for enclitics that attach to intransitive verbs; a slot for enclitics that attach to transitive verbs; and a slot that contains no overt morphemes, but is used to produce lexical rules that constrain the appearance of topic, proximate, and obviative on a verb's nominal arguments. Each of these slots contains morphemes, on which are specified values for one or more features. To give an idea of what this looks like, Table 4 shows the features that are defined for the most complex of these slots, the one that contains transitive prefixes.

4 Testing the Sahaptin Grammar

In order to test the correctness of the Sahaptin grammar, it was necessary to create a suite of test sentences, some grammatical and some not, that probe its expected lexical and grammatical coverage. I started with the sentence patterns in R&R's Tables 7 and 8 (Rigsby and Rude, 1996, 676); from each, I created a sentence with the appropriate prefix, verb, enclitic, subject, and object. In every case where a plural argument was called for, I actually created two sentences, one with a dual argument—and in cases with two plural arguments, I created four: *du/du*, *du/pl*, *pl/du*, and *pl/pl*.

All these sentences were expected to be grammatical based on the descriptions in R&R. To generate ungrammatical sentences, I initially permuted the grammatical sentences in the following ways:

1. For each grammatical sentence with a prefix, I created an ungrammatical variant with the prefix missing.
2. For each grammatical sentence with an enclitic, I created an ungrammatical variant with the enclitic missing.
3. For each grammatical sentence, I created variants that contained every incorrect prefix and variants that contained every incorrect enclitic.

After duplicates were removed, this produced a list of 89 grammatical and 220 ungrammatical sentences, for a total of 309.

The permutation of the grammatical sentences as described above was sufficient to test the phenomena of interest for intransitive sentences, producing ungrammatical sentences consisting of correctly-formed words in the correct basic word order but with an ungrammatical agreement pattern, and this permutation was a small enough job to perform by hand. For transitive sentences, though, there is a much larger space of sentences with the right word order but wrong agreement, so in order to test the grammar thoroughly, I decided to supplement the ungrammatical sentences I created by hand by writing a small program to generate every sentence containing the verb *q̓ínun* 'see' that followed the pattern:

[5] The full details of the Sahaptin grammar can be found in my dissertation (Drellishak, 2009). How the questionnaire can be filled out to model Sahaptin can be seen by visiting the customization system web site at `depts.washington.edu/uwcl/matrix/sfddiss/` and clicking the Umatilla Sahaptin link at the bottom of the main page, which fills out the questionnaire automatically.

Transitive	**Subject**	**Subject**	**Object**	**Object**
prefix	PERNUM	TOPICALITY	PERNUM	TOPICALITY
i-	*3sg*			*non-topic*
pa-	*3du, 3pl*			*non-topic*
á-	*1st, 2nd*		*3rd*	
pá-	*2sg*		*1sg*	
pá-	*3sg*	*non-topic*	*3sg*	*topic*
patá-	*3du, 3pl*	*non-topic*	*3sg*	*topic*
∅	*1st*		*2nd*	
∅	*2du, 2pl*		*1st*	
∅	*2sg*		*1du, 1pl*	

Table 4: Morphemes appearing in the transitive prefix slot

(3) **prefix-***q̇ínun***=enclitic subject object**

The possible fillers for each position in (3) are shown in Table 5:

prefix	*i-*, *pa-*, *á-*, *pá-*, *patá-*, and ∅
enclitic	*=naš, =na, =nataš, =nam, =pam, =maš, =mataš*, and ∅
subject	subject forms in Table 3
object	object forms in Table 3

Table 5: Fillers for positions in (3)

As mentioned above, the lexicon of the Sahaptin grammar, and consequently the test sentences, uses the various forms of the personal pronoun to represent the possible person, number, case, and proximity values of subject and object noun phrases. In addition to plain case-marked pronouns, the subject and object positions may also contain third person pronouns marked as the topic with *-TOP*.

Generating every sentence that followed the pattern in (3) produced 6048 sentences, but some additional filtering was required. First, since it appears that topic marking is only relevant when disambiguating third person arguments, I removed all sentences where the *-TOP* suffix appeared with a first or second person pronoun. Second, 192 of the permutations of (3) are actually duplicates of the ungrammatical transitive test sentences created by hand above, so I removed those as well. After filtering, a total of 5856 programmatically-generated sentences remained. Added to the aforementioned 309 examples, this made 6165 unique test sentences.

After using the customization system to generate a grammar of Sahaptin, I used that grammar to attempt to parse every test sentence. All 89 sentences corresponding to R&R's grammatical transitive and intransitive patterns parsed and were assigned exactly one analysis.[6] Among the ungrammatical sentences, 5848 out of 5856 failed to parse, as expected. To my surprise, however, eight of the sentences did parse. These sentences were:

(4) a. *i-q̇ínun pɨ́n-TOP piinamanáy*
3SG-see 3SG.NOM-TOP 3DU.OBJ
'He saw them (DU).'
b. *i-q̇ínun pɨ́n-TOP paamanáy*
3SG-see 3SG.NOM-TOP 3PL.OBJ
'He saw them.'
c. *pa-q̇ínun piiní paanáy*
3NONSG-see 3DU.NOM 3SG.OBJ
'They (DU) saw him.'
d. *pa-q̇ínun pmáy paanáy*
3NONSG-see 3PL.NOM 3SG.OBJ
'They saw him.'
e. *pa-q̇ínun piiní-TOP piinamanáy*
3NONSG-see 3DU.NOM-TOP 3DU.OBJ
'They (DU) saw them (DU).'
f. *pa-q̇ínun piiní-TOP paamanáy*
3NONSG-see 3DU.NOM-TOP 3PL.OBJ
'They (DU) saw them.'
g. *pa-q̇ínun pmáy-TOP piinamanáy*
3NONSG-see 3PL.NOM-TOP 3DU.OBJ
'They saw them (DU).'
h. *pa-q̇ínun pmáy-TOP paamanáy*
3NONSG-see 3PL-TOP.NOM 3PL.OBJ
'They saw them.'

[6] Multiple analyses would not necessarily have been wrong—some sentences in some languages are structurally ambiguous—but the grammatical Sahaptin sentences in the test suite are marked explicitly enough for agreement that none was ambiguous.

Notice that the eight sentences fall into three patterns. The first two sentences have a third person singular topical subject and a third person non-singular non-topical object, the next two have a third person non-singular non-topical subject and a third person singular non-topical object, and the last four have a third person non-singular topical subject and a third person non-topical object. These are precisely the patterns that are absent from R&R's Table 8; corresponding sentences were therefore not included in the list of 89 grammatical sentences. In developing the Sahaptin grammar, I had, without considering these eight patterns, defined the prefixes in such a way that the grammar expected *i-* to appear in the first two sentences and *pa-* in the last six.

In order to determine whether this analysis was correct, Sharon Hargus presented the Yakima Sahaptin equivalents of the sentences in (4) by telephone to Virginia Beavert, a native speaker of that dialect, who accepted all eight of them with the readings shown in (4). Note that, in order for these sentences to be acceptable, they had to be cast in the past tense, a feature not modeled in my Sahaptin grammar fragment. Note also that Dr. Beavert considered sentence (4c) somewhat less acceptable, saying that it is "[a] little awkward, but has meaning."

The Sahaptin grammar, then, which was created using the customization system and based on its support for case, direct-inverse languages, and agreement, correctly analysed all 6165 of the test sentences, including eight that fell outside of the patterns described in the linguistic literature.

5 Summary and Discussion

Based on these results, I conclude that even Sahaptin, a language with extremely complex argument marking morphology, can be modeled using the customization system. Note that the system was not designed with the facts of Sahaptin in mind, and with two exceptions, the system did not need to be modified to enable it to handle Sahaptin.

One of the exceptions was trivial: formerly, grammars produced by the system treated '=' as punctuation, stripping it out and breaking words containing it. The other exception concerns an unusual agreement pattern I first encountered in Sahaptin: morphemes that agree, not with the subject or the object of a verb, but with the nominal argument that is more highly ranked on the direct-inverse scale. Supporting this agreement pattern proved worthwhile later, when it was used again in a test grammar for Plains Cree [crk] (Algonquian), another direct-inverse language. Although this latter change was a substantive one that allows grammars to be described more compactly, it did not increase the descriptive power of the system—languages showing that pattern of agreement could still be modeled using duplicated, homophonous morphemes. Such an enhancement to the system is an example of the feedback loop between grammar engineering and customization system development, where new languages with new phenomena (or new variations of old phenomena) inform the design and, in some cases, the descriptive power of the system.

After constructing the Sahaptin grammar and test suite described here, it was natural to include it in two places in the customization system. First, it is now one of the regression tests that is regularly run to ensure that future enhancement of the system does not break earlier features. Second, Sahaptin has been added to the list of sample grammars accessible from the main page of the questionnaire—by clicking on links in this list, users can see detailed examples of how the questionnaire can be filled out to model a target language.

The Sahaptin grammar, developed using the customization system, has proved itself useful—not only to the Grammar Matrix project, where it inspired the addition of support for scale-sensitive agreement and serves as a regression test of the correct functioning of the system, but also to the field of linguistics. By analyzing Sahaptin in the precise detail required by the customization system, I found unnoticed gaps in linguistic descriptions of the language, and in collaboration with linguists studying the language was able to help resolve those gaps.

Two monolingual parses are better than one (synchronous parse)*

Abstract

We describe a synchronous parsing algorithm that is based on two successive *monolingual* parses of an input sentence pair. Although the worst-case complexity of this algorithm is and must be $O(n^6)$ for binary SCFGs, its average-case run-time is far better. We demonstrate that for a number of common synchronous parsing problems, the two-parse algorithm substantially outperforms alternative synchronous parsing strategies, making it efficient enough to be utilized without resorting to a pruned search.

1 Introduction

Synchronous context free grammars (SCFGs) generalize monolingual context-free grammars to generate strings concurrently in pairs of languages (Lewis and Stearns, 1968) in much the same way that finite state transducers (FSTs) generalize finite state automata (FSAs).[1] *Synchronous parsing* is the problem of finding the best derivation, or forest of derivations, of a source and target sentence pair $\langle \mathbf{f}, \mathbf{e} \rangle$ under an SCFG, $\mathcal{G}$.[2] Solving this problem is necessary for several applications, for example, optimizing how well an SCFG translation model fits parallel training data. Wu (1997) describes a bottom-up $O(n^6)$ synchronous parsing algorithm for ITGs, a binary SCFG with a restricted form. For general grammars, the situation is even worse: the problem has been shown to be NP-hard (Satta and Peserico, 2005). Even if we restrict ourselves to binary ITGs, the $O(n^6)$ run-time makes large-scale learning applications infeasible. The usual solution is to use a heuristic search that avoids exploring edges that are likely (but not guaranteed) to be low probability (Zhang et al., 2008; Haghighi et al., 2009). In this paper, we derive an alternative synchronous parsing algorithm starting from a conception of parsing with SCFGs as a composition of binary relations. This enables us to factor the synchronous parsing problem into two successive *monolingual* parses. Our algorithm runs more efficiently than $O(n^6)$ with many grammars (including those that required using heuristic search with other parsers), making it possible to take advantage of synchronous parsing without developing search heuristics; and the SCFGs are not required to be in a normal form, making it possible to easily parse with more complex SCFG types.

2 Synchronous parsing

Before presenting our algorithm, we review the $O(n^6)$ synchronous parser for binary ITGs.[3]

2.1 ITG synchronous parsing algorithm

Wu (1997) describes a bottom-up synchronous parsing algorithm that can be understood as a generalization of the CKY algorithm. CKY defines a table consisting of n^2 cells, with each cell corresponding to a span $[i, j]$ in the input sentence; and the synchronous variant defines a table in 4 dimensions, with cells corresponding to a source span $[s, t]$ *and* a target span $[u, v]$. The bottom of the chart is initialized first, and pairs of items are combined from bottom to top. Since combining items from the n^4 cells involves considering two split points (one source, one target), it is not hard to see that this algorithm runs in time $O(n^6)$.

[1] SCFGs have enjoyed a resurgence in popularity as the formal basis for a number of statistical translation systems, e.g. Chiang (2007). However, translation requires only the manipulation of SCFGs using monolingual parsing algorithms.

[2] It is assumed that $n = |\mathbf{f}| \approx |\mathbf{e}|$.

[3] Generalizing the algorithm to higher rank grammars is possible (Wu, 1997), as is converting a grammar to a weakly equivalent binary form in some cases (Huang et al., 2009).

Los Angeles, California, June 2010.

2.2 Parsing, intersection, and composition

We motivate an alternative conception of the synchronous parsing problem as follows. It has long been appreciated that monolingual parsing computes the intersection of an FSA and a CFG (Bar-Hillel et al., 1961; van Noord, 1995). That is, if S is an FSA encoding some sentence **s**, intersection of S with a CFG, $\mathcal{G}$, results in a parse forest which contains all and only derivations of **s**, that is $L(S) \cap L(\mathcal{G}) \in \{\{\mathbf{s}\}, \emptyset\}$.[4] Crucially for our purposes, the resulting parse forest *is also itself a CFG*.[5] Figure 1 illustrates, giving two equivalent representations of the forest $S \cap \mathcal{G}$, once as a directed hypergraph and once as a CFG. While $S \cap \mathcal{G}$ appears similar to $\mathcal{G}$, the non-terminals (NTs) of the resulting CFG are a cross product of pairs of states from S and NTs from $\mathcal{G}$.[6]

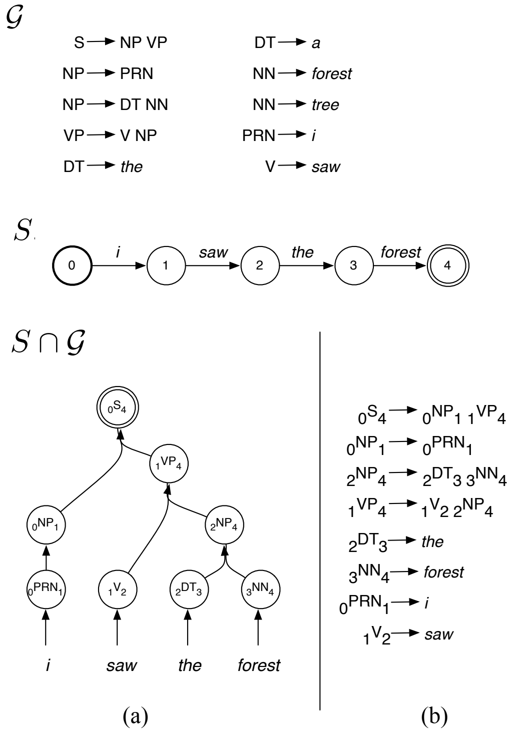

Figure 1: A CFG, $\mathcal{G}$, an FSA, S, encoding a sentence, and two equivalent representations of the parse forest $S \cap \mathcal{G}$, (a) as a directed hypergraph and (b) as a CFG.

When dealing with SCFGs, rather than intersection, parsing computes a related operation, *composition*.[7] The standard MT decoding-by-parsing task can be understood as computing the composition of an FST,[8] F, which encodes the source sentence **f** with the SCFG, $\mathcal{G}$, representing the translation model. The result is the translation forest, $F \circ \mathcal{G}$, which encodes all translations of **f** licensed by the translation model. While $\mathcal{G}$ can generate a potentially infinite set of strings in the source and target languages, $F \circ \mathcal{G}$ generates *only* **f** in the source language (albeit with possibly infinitely many derivations), but any number of different strings in the target language. It is not hard to see that a second composition operation of an FST, E, encoding the target string **e** with the e-side of $F \circ \mathcal{G}$ (again using a monolingual parsing algorithm), will result in a parse forest that exactly derives $\langle \mathbf{f}, \mathbf{e} \rangle$, which is the goal of synchronous composition. Figure 2 shows an example. In $F \circ \mathcal{G} \circ E$ the NTs (nodes) are the cross product of pairs of states from E, the NTs from $\mathcal{G}$, and pairs of states in F.

Thus, synchronous parsing is the task of computing $F \circ \mathcal{G} \circ E$. Since composition is associative, we can compute this quantity either as $(F \circ \mathcal{G}) \circ E$ or $F \circ (\mathcal{G} \circ E)$. Alternatively, we can use an algorithm that performs 3-way composition directly.

2.3 The two-parse algorithm[9]

The *two-parse algorithm* refers to performing a synchronous parse by computing either $(F \circ \mathcal{G}) \circ E$ or $F \circ (\mathcal{G} \circ E)$. Each composition operation is carried out using a standard monolingual parsing algorithm, such as Earley's or CKY. In the experiments below, since we use ϵ-free grammars, we use a variant of CKY for unrestricted CFGs (Chiang, 2007).

Once the first composition is done, the resulting parse forest must be converted into a CFG representation that the second parser can utilize. This is straightforward to do: each node becomes a unique non-terminal symbol, with its incoming edges corresponding to different ways of rewriting it. Tails of edges are non-terminal variables in the RHS of these rewrites. A single bottom-up traversal of the forest is sufficient to perform the conversion. Since

[4] $L(x)$ denotes the set of strings generated by the grammar/automaton x. In future mentions of intersection and composition operations, this will be implicit.

[5] The forest grammar derives only **s**, but using possibly many derivations.

[6] Each pair of states from the FSA corresponds to a span $[i, j]$ in a CKY table.

[7] Intersection is a special case of composition where the input and output labels on the transducers are identical (Mohri, 2009).

[8] FSTs used to represent the source and target sentences have identical input and output labels on every transition.

[9] Satta (submitted) has independently derived this algorithm.

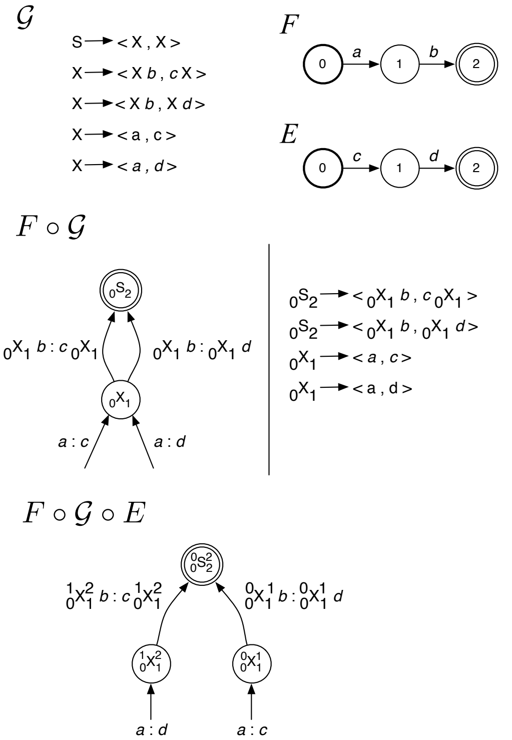

Figure 2: An SCFG, $\mathcal{G}$, two FSAs, E and F, and two equivalent representations of $F \circ \mathcal{G}$. The synchronous parse forest of the pair $\langle ab, cd \rangle$ with $\mathcal{G}$ is given under $F \circ \mathcal{G} \circ E$.

our parser operates more efficiently with a determinized grammar, we left-factor the grammar during this traversal as well.

Analysis. Monolingual parsing runs in worst case $O(|\mathcal{G}| \cdot n^3)$ time, where n is the length of the input being parsed and $|\mathcal{G}|$ is a measure of the size of the grammar (Graham et al., 1980). Since the grammar term is constant for most typical parsing applications, it is generally not considered carefully; however, in the two-parse algorithm, the size of the grammar term for the second parse is not $|\mathcal{G}|$ but $|F \circ \mathcal{G}|$, which clearly depends on the size of the input F; and so understanding the impact of this term is key to understanding the algorithm's run-time.

If $\mathcal{G}$ is an ϵ-free SCFG with non-terminals N and maximally two NTs in a rule's right hand side, and n is the number of states in F (corresponding to the number of words in the $\mathbf{f}$ in a sentence pair $\langle \mathbf{f}, \mathbf{e} \rangle$), then the number of nodes in the parse forest $F \circ \mathcal{G}$ will be $O(|N| \cdot n^2)$. This can be shown easily since by stipulation, we are able to use CKY+ to perform the parse, and there will be maximally as many nodes in the forest as there are cells in the CKY chart times the number of NTs. The number of edges will be $O(|N| \cdot n^3)$, which occurs when every node can be derived from all possible splits. This bound on the number of edges implies that $|F \circ \mathcal{G}| \in O(n^3)$.[10] Therefore, the worst case run-time of the two-parse algorithm is $O(|N| \cdot n^3 \cdot n^3 + |\mathcal{G}| \cdot n^3) = O(|N| \cdot n^6)$, the same as the bound on the ITG algorithm. We note that while the ITG algorithm requires that the SCFGs be rank-2 and in a normal form, the two-parse algorithm analysis holds as long as the grammars are rank-2 and ϵ-free.[11]

3 Experiments

We now describe two different synchronous parsing applications, with different classes of SCFGs, and compare the performance of the two-parse algorithm with that of previously used algorithms.

Phrasal ITGs. Here we compare performance of the two-parse algorithm and the $O(n^6)$ ITG parsing algorithm on an Arabic-English phrasal ITG alignment task. We used a variant of the phrasal ITG described by Zhang et al. (2008).[12] Figure 3 plots the average run-time of the two algorithms as a function of the Arabic sentence length. The two-parse approach is far more efficient. In total, aligning the 80k sentence pairs in the corpus completed in less than 4 hours with the two-parse algorithm but required more than 1 week with the baseline algorithm.[13]

"Hiero" grammars. An alternative approach to computing a synchronous parse forest is based on *cube pruning* (Huang and Chiang, 2007). While more commonly used to integrate a target m-gram LM during decoding, Blunsom et al. (2008), who required synchronous parses to discriminatively train

[10] How tight these bounds are depends on the ambiguity in the grammar w.r.t. the input: to generate n^3 edges, every item in every cell must be derivable by every combination of its subspans. Most grammars are substantially less ambiguous.

[11] Since many widely used SCFGs meet these criteria, including hierarchical phrase-based translation grammars (Chiang, 2007), SAMT grammars (Zollmann and Venugopal, 2006), and phrasal ITGs (Zhang et al., 2008), a detailed analysis of ϵ-containing and higher rank grammars is left to future work.

[12] The restriction that phrases contain exactly a single alignment point was relaxed, resulting in much larger and more ambiguous grammars than those used in the original work.

[13] A note on implementation: our ITG aligner was minimal; it only computed the probability of the sentence pair using the inside algorithm. With the two-parse aligner, we stored the complete forest during both the first and second parses.

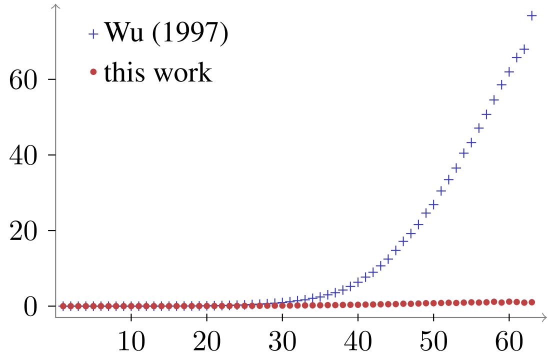

Figure 3: Average synchronous parser run-time (in seconds) as a function of Arabic sentence length (in words).

an SCFG translation model, repurposed this algorithm to discard partial derivations during translation of **f** if the derivation yielded a target m-gram not found in **e** (p.c.). We replicated their BTEC Chinese-English baseline system and compared the speed of their 'cube-parsing' technique and our two-parse algorithm.[14] The SCFG used here was extracted from a word-aligned corpus, as described in Chiang (2007).[15] The following table compares the average per sentence synchronous parse time.

Algorithm	avg. run-time (sec)
Blunsom et al. (2008)	7.31
this work	0.20

4 Discussion

Thinking of synchronous parsing as two composition operations has both conceptual and practical benefits. The two-parse strategy can outperform both the ITG parsing algorithm (Wu, 1997), as well as the 'cube-parsing' technique (Blunsom et al., 2008). The latter result points to a connection with recent work showing that determinization of edges before LM integration leads to fewer search errors during decoding (Iglesias et al., 2009).

Our results are somewhat surprising in light of work showing that 3-way composition algorithms for FSTs operate far more efficiently than performing successive pairwise compositions (Allauzen and Mohri, 2009). This is certainly because the 3-way algorithm used here (the ITG algorithm) does an exhaustive search over all n^4 span pairs without awareness of any top-down constraints. This suggests that faster composition algorithms that incorporate top-down filtering may still be discovered.

[14] To the extent possible, the two experiments were carried out using the exact same code base, which was a C++ implementation of an SCFG-based decoder.

[15] Because of the mix of terminal and non-terminal symbols, such grammars cannot be used by the ITG synchronous parsing algorithm.

Abstract

A variety of query systems have been developed for interrogating parsed corpora, or treebanks. With the arrival of efficient, wide-coverage parsers, it is feasible to create very large databases of trees. However, existing approaches that use in-memory search, or relational or XML database technologies, do not scale up. We describe a method for storage, indexing, and query of treebanks that uses an information retrieval engine. Several experiments with a large treebank demonstrate excellent scaling characteristics for a wide range of query types. This work facilitates the curation of much larger treebanks, and enables them to be used effectively in a variety of scientific and engineering tasks.

1 Introduction

The problem of representing and querying linguistic annotations has been an active area of research for several years. Much of the work has grown from efforts to curate large databases of annotated text such as *treebanks*, for use in developing and testing language technologies (Marcus et al., 1993; Abeillé, 2003; Hockenmaier and Steedman, 2007). At least a dozen linguistic tree query languages have been developed for interrogating treebanks (see §2).

While high quality syntactic parsers are able to efficiently annotate large quantities of English text (Clark and Curran, 2007), existing approaches to query do not work on the same scale. Many existing systems load the entire corpus into memory and check a user-supplied query against every tree. Others avoid the memory limitation, and use relational or XML database systems. Although these have built-in support for indexes, they do not scale up either (Ghodke and Bird, 2008; Zhang et al., 2001)).

The ability to interrogate large collections of parsed text has important practical applications. First, it opens the way to a new kind of information retrieval (IR) that is sensitive to syntactic information, permitting users to do more focussed search. At the simplest level, an ambiguous query term like *wind* or *park* could be disambiguated with the help of a POS tag (e.g. `wind/N`, `park/V`). (Existing IR engines already support query with part-of-speech tags (Chowdhury and McCabe, 1998)). More complex queries could stipulate the syntactic category of *apple* is in subject position.

A second benefit of large scale tree query is for natural language processing. For example, we might compute the likelihood that a given noun appears as the agent or patient of a verb, as a measure of animacy. We can use features derived from syntactic trees in order to support semantic role labeling, language modeling, and information extraction (Chen and Rambow, 2003; Collins et al., 2005; Hakenberg et al., 2009). A further benefit for natural language processing, though not yet realized, is for a treebank and query engine to provide the underlying storage and retrieval for a variety of linguistic applications. Just as a relational database is present in most business applications, providing reliable and efficient access to relational data, such a system would act as a repository of annotated texts, and expose an expressive API to client applications.

A third benefit of large scale tree query is to support syntactic investigations, e.g. for develop-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 267–275,

ing syntactic theories or preparing materials for language learners. Published treebanks will usually not attest particular words in the context of some infrequent construction, to the detriment of syntactic studies that make predictions about such combinations, and language learners wanting to see instances of some construction involving words from some specialized topic. A much larger treebank alleviates these problems. To improve recall performance, multiple parses for a given sentence could be stored (possibly derived from different parsers).

A fourth benefit for large scale tree query is to support the curation of treebanks, a major enterprise in its own right (Abeillé, 2003). Manual selection and correction of automatically generated parse trees is a substantial part of the task of preparing a treebank. At the point of making such decisions, it is often helpful for an annotator to view existing annotations of a given construction which have already been manually validated (Hiroshi et al., 2005). Occasionally, an earlier annotation decision may need to be reconsidered in the light of new examples, leading to further queries and to corrections that are spread across the whole corpus (Wallis, 2003; Xue et al., 2005).

This paper explores a new methods for scaling up tree query using an IR engine. In §2 we describe existing tree query systems, elaborating on the design decisions, and on key aspects of their implementation and performance. In §3 we describe a method for indexing trees using an IR engine, and discuss the details of our open source implementation. In §4 we report results from a variety of experiments involving two data collections. The first collection contains of 5.5 million parsed trees, two orders of magnitude larger than those used by existing tree query systems, while the second collection contains 26.5 million trees.

2 Treebank Query

A tree query system needs to be able to identify trees having particular properties. On the face of it, this should be possible to achieve by writing simple programs over treebank files on disk. The programs would match tree structures using regular expression patterns, possibly augmented with syntax for matching tree structure. However, tree query is a more complex and interesting task, due to several factors which we list below.

Structure of the data: There are many varieties of treebank. Some extend the nested bracketing syntax to store morphological information. Others store complex attribute-value matrices in tree nodes or have tree-valued attributes (Oepen et al., 2002), or store dependency structures (Čmejrek et al., 2004), or categorial grammar derivations (Hockenmaier and Steedman, 2007). Others store multiple overlapping trees (Cassidy and Harrington, 2001; Heid et al., 2004; Volk et al., 2007).

Form of results: Do we want entire trees, or matching subtrees, or just a count of the number of results? Do we need some indication of why the query matched a particular tree, perhaps by showing how query terms relate to a hit, cf. document snippets and highlighted words in web search results? Do we want to see multiple hits when a query matches a particular tree in more than one place? Do we want to see tree diagrams, or some machine-readable tree representation that can be used in external analysis? Can a query serve to update the treebank, cf. SQL update queries?

Number of results: Do we want all results, or the first n results in document order, or the “best” n results, where our notion of best might be based on representativeness or distinctiveness.

Description language: Do we prefer to describe trees by giving examples of tree fragments, replacing some nodes replaced with wildcards (Hiroshi et al., 2005; Ichikawa et al., 2006; Mírovský, 2006)? Or do we prefer a path language (Rohde, 2005; Lai and Bird, 2010)? Or perhaps we prefer a language involving variables, quantifiers, boolean operators, and negation (König and Lezius, 2001; Kepser, 2003; Pajas and Štěpánek, 2009)? What built-in tree relations are required, beyond the typical parent/child, ancestor/descendent, sibling and temporal relations? (E.g. last child, leftmost descendent, parent’s following sibling, pronoun’s antecedent.) Do we need to describe tree nodes using regular expressions, or attributes and values? Do we need a type system, a pattern language, or boolean logic for talking about attribute values? The expressive requirements of the query language have been discussed at length elsewhere (Lai and Bird, 2004; Mírovský, 2008), and we will not consider them further here.

Performance: What performance is acceptable, especially as the data size grows? Do we want to optimize multiple reformulations of a query, for users who iteratively refine a query based on query results? Do we want to optimize certain query types? Are queries performed interactively or in batch mode? Is the treebank stable, or being actively revised, in which case indexes need to be easily updatable? Do we expect logically identical queries to have the same performance, so that users do not have to rewrite their queries for efficiency? Key performance measures are index size and search times.

Architecture: Is the query system standalone, or does it exist in a client-server architecture? Is there a separate user-interface layer that interacts with a data server using a well-defined API, or is it a monolithic system? Should it translate queries into another language, such as SQL (Bird et al., 2006; Nakov et al., 2005), or XQuery (Cassidy, 2002; Mayo et al., 2006), or to automata (Maryns and Kepser, 2009), in order to benefit from the performance optimizations they provide

Indexing. The indexing methods used in individual systems are usually not reported. Many systems display nearly constant time for querying a database, regardless of the selectivity of a query, a strong indicator that no indexes are being used. For example, Emu performs all queries in memory with no indexes, and several others are likely to be the same (Cassidy and Harrington, 2001; König and Lezius, 2001; Heid et al., 2004). TGrep2 (Rohde, 2005) uses a custom corpus file and processes it sentence by sentence at query execution time. Other tree query systems use hashed indexes or other types of in-memory indexes. However, a common drawback of these systems is that they are designed for treebanks that are at most a few million words in size, and do not scale well to much larger treebanks.

There are many positions to be taken on the above questions. Our goal is not to argue for a particular data format or query style, but rather to demonstrate a powerful technique for indexing and querying treebanks which should be applicable to most of the above scenarios.

3 Indexing Trees

In this section we discuss two methods of storing and indexing trees. The first uses a relational database and linguistic queries are translated into SQL, while the second uses an inverted index approach based on an open source IR engine, Lucene.[1] Relational databases are a mature technology and are known to be efficient at performing joins and accessing data using indexes. Information retrieval engines using term vectors, on the other hand, efficiently retrieve documents relevant to a query. IR engines are known to scale well, but they do not support complex queries. A common feature of both the IR and database approaches is the adoption of so-called "tree labeling" schemes.

3.1 Tree labeling schemes

Tree queries specify node labels ("value constraints") and structural relationships between nodes of interest ("structural constraints"). A simple value constraint could look for a *wh noun phrase* by specifying the `WHNP`; such queries are efficiently implemented using indexes. Structural relationships cannot be indexed like node labels. A term in a sentence will have multiple relationships with other terms in the same sentence. Indexing all pairs of terms that exist in a given structural relationship results in an explosion in the index size. Instead, the standard approach is to store position information with each occurrence of a term, using a table or a term vector, and then use the position information to find structural matches. Many systems use this approach, from early object databases such as Lore (McHugh et al., 1997), to relational representation of tree data (Bird et al., 2006) and XISS/R (Harding et al., 2003), and native XML databases such as eXist (Meier, 2003). Here, the position is encoded via node labeling schemes, and is designed so it can support efficient testing of a variety of structural relations.

A labeling scheme based on pre-order and post-order labeling of nodes is the foundation for several extended schemes. It can be used for efficiently detecting that two nodes are in a hierarchical (or inclusion) relationship. Other labeling schemes are based on the Dewey scheme, in which each node contains

[1] http://lucene.apache.org/

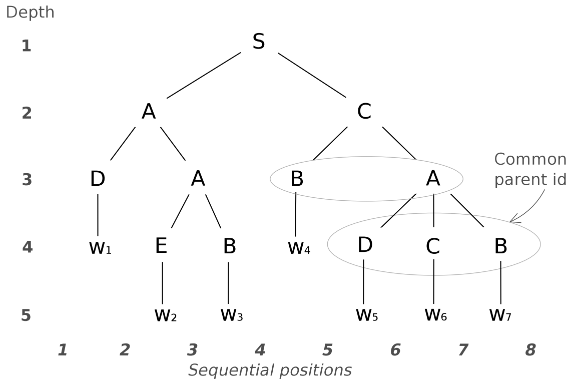

Figure 1: Generating node labels

a hierarchical label in which numbers are separated by periods (Tatarinov et al., 2002). A child node gets its label by appending its position relative to its siblings to its parent's label. This scheme can be used for efficiently detecting that two nodes are in a hierarchical or sequential (temporal) relationship.

The LPath numbering scheme assigns four integer labels to each node (Bird et al., 2006). The generation of these labels is explained with the help of an example. Figure 1 is the graphical representation of a parse tree for a sentence with 7 words, $w_1 \cdots w_7$. Let *A*, *B*, *C*, *D*, *E*, and *S* represent the annotation tags. Some nodes at different positions in the tree share a common name.

The first step in labeling is to identify the sequential positions between words, as shown beneath the parse tree in Figure 1. The left id of a terminal node is the sequence position immediately to the left of a node, while its right id is the one to its immediate right. The left id of a non-terminal node is the left id of its leftmost descendant, and the right id is the right id of its rightmost descendant. In most cases the ancestor-descendant and preceding-following relationships between two elements can be evaluated using the left and right ids alone. The sequential ids do not differentiate between two nodes where one is the lone child of the other. The depth id is therefore required in such cases and to identify the child node (depth values are shown on the left side of Figure 1). In order to check if two given nodes are siblings, the above three ids will not suffice. We therefore assign a common parent id label to siblings. These four identifiers together enable us to identify relationships between elements without traversing trees.

Node	Left	Right	Depth	Parent
A	2	4	3	2
A	1	4	2	6
A	5	8	3	8
B	3	4	4	4
B	4	5	3	8
B	7	8	4	10

Table 1: Node labels

Table 1 illustrates the node labels assigned to *A* and *B* nodes in Figure 1. We can see that the parent id of the third *A* and second *B* are equal because they are siblings.

Once these numbers are assigned to each node, the nodes can be stored independently without loss of any structural information (in either a relational database or an inverted index). At query execution time, the set of elements on either side of an operator are extracted and only those node numbers that satisfy the operator's specification are selected as the result. For example, if the operator is the child relation, and the operands are *A* and *B*, then there are two matches: $B\{3,4,4,4\}$, child of $A\{2,4,3,2\}$ and, $B\{7,8,4,10\}$, child of $A\{5,8,3,8\}$.[2] This process of finding the elements of a document that match operators is nothing other than the standard join operation (and it is implemented differently in relational databases and IR engines).

3.2 Relational database approach

Tree nodes can be stored in a relational database using a table structure (Bird et al., 2006). Each treebank would have a single table for all nodes where each node's information is stored in a tuple. The node name is stored along with other position information and the sentence id. Every node tuple also has a unique primary key. The parent id column is a foreign key, referencing the parent node's id, speeding up parent/child join operations. In practice, queries are translated from higher level linguistic query languages such as LPath into SQL automatically, allowing users to use a convenient syntax, rather than query using SQL.

Previous research on a similar database structure for containment queries in XML databases showed

[2] The node labels are represented as an ordered set here for brevity. Their positions match the headings in Table 1.

that databases are generally slower than specialised IR indexes (Zhang et al., 2001). In that work, the authors provide results comparing their IR join algorithm, the multi-predicate merge join (MPMGJN), with two standard relational join algorithms. They consider the number of comparisons performed in the standard merge join and the index nested loop join, and contrast these with their IR join algorithm. They show that the IR algorithm performs fewer comparisons than a standard merge join but greater than the index nested loop join.

The multi-predicate merge join exploits the fact that nodes are encountered in document order (i.e. a node appears before its descendents). Search within a document can be aborted as soon as it is clear that further searching will not yield further results. Importantly, this IR join algorithm is faster than both relational join algorithms in practice, since it makes much better use of the hardware disk cache. Our own experiments with a large treebank stored in an Oracle database have demonstrated that this shortcoming of relational query relative to IR query exists in the linguistic domain (Ghodke and Bird, 2008).

3.3 IR engine approach

We transform the task of searching treebanks into a conventional document retrieval task in which each sentence is treated as a document. Tree node labels are stored in inverted indexes just like words in a text index. We require two types of indexes, for frequency and position. The frequency index for a node label contains a list of sentence ids and, for each one, a count indicating the frequency of the node label in the sentence. (Labels with a frequency of zero do not appear in this index.) The position index is used to store node numbers for each occurrence of the node label. The numbers at each position are read into memory as objects only when required (at other times, the byte numbers are skipped over for efficiency). During query processing, the frequency indexes are first traversed sequentially to find a document that contains all the required elements in the query. Once a document is found, the structural constraints are checked using the data stored in the position index for that document. The document itself does not need to be loaded.

Using an inverted index for searching structured data is not new, and several XML databases already use this method to index XML elements (Meier, 2003). However, linguistic query systems are special purpose applications where the unit of retrieval is usually a sentence. A given tree may satisfy a query in multiple places, but we only identify which sentences are relevant. Finding all matches within a sentence requires further processing. [3]

Our approach has been to process each sentence as a document. By fixing the unit of retrieval to be the sentence, we are able to greatly reduce the size of intermediate results when performing a series of joins. The task is then to simply check whether a sentence satisfies a query or not. This can be done using substantially less resources than is needed for finding sets of nodes, the unit of retrieval for relational and XML databases. When processing a series of joins, we use a single buffer to store the node positions required to perform the next join in the series. After computing that join and processing another operator in the query, the buffer contents is replaced with a new set of nodes, discarding the intermediate information.

4 Experiments with IR Engine

4.1 Data

We used two data collections in our experiments. The first collection is a portion of the English Gigaword Corpus, parsed in the Penn Treebank format. We used the TnT tagger and the DBParser trained on the Wall Street Journal section of the Penn Treebank to parse sentences in the corpus. The total size of the corpus is about 5.5 million sentences. The TGrep2 corpus file for this corpus is about 1.8 GB and the Lucene index is 4 GB on disk. The second data collection is a portion of English Wikipedia, again tagged and parsed using TnT tagger and DBParser, respectively. This collection contains 26.5 million parsed sentences. The TGrep2 corpus file corresponding to this collection is about 6.6 GB and the Lucene index is 14 GB on disk.

[3] Several alternate path joins and improvements to the MPMGJN algorithm have been proposed over the years to overcome the problem of large number of intermediate nodes and to reduce unnecessary joins (Al-Khalifa et al., 2002; Li and Moon, 2001). Bruno *et al.*'s work on twig joins further improved on those efforts by processing an entire query twig in a holistic fashion (Bruno et al., 2002), and has since been further optimized.

Query	Selectivity	Data Collection 1 (5.5M sentences)					Data Collection 2 (26.5M sentences)

Table 2: Execution times (in seconds) for queries of varying selectivity

4.2 Types of queries

Query performance depends largely on the nature of the individual queries, therefore we present a detailed analysis of the query types and their corresponding results in this section.

Selectivity: A query term that has few corresponding hits in the corpus will be considered to have high selectivity. The selectivity of whole queries depends not only on the selectivity of their individual elements, but also on how frequently these terms satisfy the structural constraints specified by the query.

Table 2 gives execution times for queries with varying selectivity, using our system. We assign a selectivity measure for the operator based on how often the two operands satisfy the structural condition. It is clear that when elements are very common and they frequently satisfy the structural constraints of the operator, there are bound to be more run-time structural checks and the performance deteriorates. This is demonstrated by the time taken by the first query. Note the relatively small difference in the execution time between the second and third queries. The third query contains a high selectivity element and even returns fewer matches compared to the second, but takes almost as long. This may be due to the relative frequency of the tags within each sentence, which we have not controled in this experiment. If there are several LST tags in the sentences where it appears, there are likely to be greater number of searches within each sentence. A better join algorithm would improve the performance in such cases.

A multiple regression analysis of the full search (cold start) times for collection 2 shows that low-selectivity labels contribute 9.5 seconds, and a low-selectivity operator contributes 6.7 seconds, and that this accounts for most of the variability in the timing data ($t = -1.53 + 9.51 * N_1 + 6.72 * op + 9.44 * N_2, R^2 = 0.8976$). This demonstrates that the distribution of full search (cold start) times is mostly accounted for by the index load time, with the time for computing a large join being a secondary cost. The full search (warm start) times in Table 2 pay a lesser index loading cost.

Query length: It is evident that the system must retrieve and process more term vectors as we increase the number of elements in a query. To find out exactly how the query length affects processing, we ran tests with three sets of queries. In each set we varied the number of elements in a dominance relationship with another node of the same name. The number of terms in the dominance relationship was varied from 1 to 6, where the first case is equivalent to just finding all terms with that name. In the first set, queries search for nested noun phrases (`NP`), while the second and third look for adjective phrases (`ADJP`) and list elements (`LST`) respectively.

These terms have been chosen to simultaneously study the effects of selectivity and query length, with `NP` being the least selective (or most common), followed by `ADJP`, then with `LST` being the most selective (or least common). `NP` is also more frequently self-nested than the others. Figure 2 plots query length (x-axis) against query execution time (y-axis, log scale) for the three sets, using our system. With

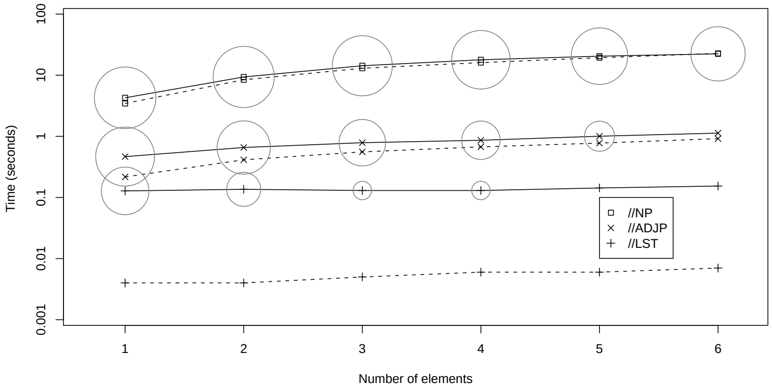

Figure 2: Variation of query execution time with query length in data collection 1

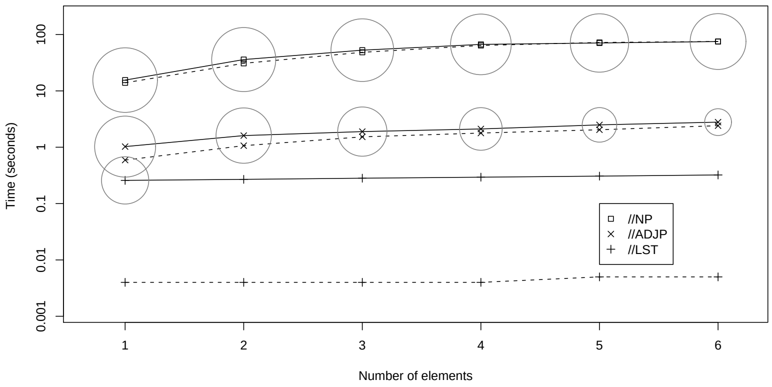

Figure 3: Variation of query execution time with query length in data collection 2

each step on the x-axis, a query will have an extra descendant node. For example, at position 3 for element `A`, the query would be `//A//A//A`.

The circles on the plot are proportional to the log of the result set size. The biggest circle is for `//NP` which is of the order of 5.4 million, while there are only 4 trees in which `LST` is nested 4 times. `LST` is not nested 5 or more times. Similarly, `ADJP` returns 0 results for the 6th test query and hence there are no circles at these locations. The thick lines on the plot indicate the average cold start run time over three runs, while the dashed line shows the minimum average run time of 4 sets, with the query executed 5 times in each set. Together, the pairs of unbroken and dashed lines indicate the variation in run time depending on the state of the system. [4]

4.3 Measurement techniques

The measurement techniques vary for TGrep and the IR based approach. In TGrep the corpus file is loaded each time during query processing, but in the IR approach an index once loaded can operate faster than a cold start.

In order to understand the variations in the operating speed we plot the variation in times from a cold start to a repeat query, as shown in Table 3.

[4] We can observe from the results that the variation between cold start and warm start correlates with query length. The length experiment here use a single term repeated multiple times. However, there is a possibility that the results may vary when the terms are different, because it would involve additional time to load the term vectors of distinct elements into memory.

Query	Data collection 1		Data collection 2	
	TGrep2	IR	TGrep2	IR
//NP	25.28	8.15	89.35	15.53

Table 3: Comparison of TGrep2 and IR Engine cold start query times (seconds)

5 Conclusions

We have shown how an IR engine can be used to build a high performance tree query system. It outperforms existing approaches using indexless in-memory search, or custom indexes, or relational database systems, or XML database systems. We reported the results of a variety of experiments to demonstrate the efficiency of query for a variety of query types on two treebanks consisting of around 5 and 26 million sentences, more than two orders of magnitude larger than what existing systems support. The approach is quite general, and not limited to particular treebank formats or query languages. This work suggests that web-scale tree query may soon be feasible. This opens the door to some interesting possibilities: augmenting web search with syntactic constraints, the ability discover rare examples of particular syntactic constructions, and as a technique for garnering better statistics and more sensitive features for the purpose of constructing language models.

Abstract

The use of well-nested linear context-free rewriting systems has been empirically motivated for modeling of the syntax of languages with discontinuous constituents or relatively free word order. We present a chart-based parsing algorithm that asymptotically improves the known running time upper bound for this class of rewriting systems. Our result is obtained through a linear space construction of a binary normal form for the grammar at hand.

1 Introduction

Since its earliest years, one of the main goals of computational linguistics has been the modeling of natural language syntax by means of formal grammars. Following results by Huybregts (1984) and Shieber (1985), special attention has been given to formalisms that enlarge the generative power of context-free grammars, but still remain below the full generative power of context-sensitive grammars. On this line of investigation, *mildly context-sensitive grammar formalisms* have been introduced (Joshi, 1985), including, among several others, the tree adjoining grammars (TAGs) of Joshi et al. (1975).

Linear context-free rewriting system (LCFRS), introduced by Vijay-Shanker et al. (1987), is a mildly context-sensitive formalism that allows the derivation of tuples of strings, i.e., discontinuous phrases. This feature has been used to model phrase structure treebanks with discontinuous constituents (Maier and Søgaard, 2008), as well as to map non-projective dependency trees into discontinuous phrase structures (Kuhlmann and Satta, 2009).

Informally, in an LCFRS G, each nonterminal can generate string tuples with a fixed number of components. The *fan-out* of G is defined as the maximum number of tuple components generated by G. During a derivation of an LCFRS, tuple components generated by the nonterminals in the right-hand side of a production are concatenated to form new tuples, possibly adding some terminal symbols. The only restriction applying to these generalized concatenation operations is linearity, that is, components cannot be duplicated or deleted.

The freedom in the rearrangement of components has specific consequences in terms of the computational and descriptional complexity of LCFRS. Even for grammars with bounded fan-out, the universal recognition problem is NP-hard (Satta, 1992), and these systems lack Chomsky-like normal forms for fixed fan-out (Rambow and Satta, 1999) that are especially convenient in tabular parsing. This is in contrast with other mildly context-sensitive formalisms, and TAG in particular: TAGs can be parsed in polynomial time both with respect to grammar size and string size, and they can be cast in normal forms having binary derivation trees only.

It has recently been argued that LCFRS might be too powerful for modeling languages with discontinuous constituents or with relatively free word order, and that additional restrictions on the rearrangement of components might be needed. More specifically, analyses of both dependency and constituency treebanks (Kuhlmann and Nivre, 2006; Havelka, 2007; Maier and Lichte, 2009) have shown that rearrangements of argument tuples almost always satisfy the so-called *well-nestedness condition*, a generalization

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 276–284,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

of the standard condition on balanced brackets. This condition states that any two components x_1, x_2 of some tuple will never be composed with any two components y_1, y_2 of some other tuple in such a way that a 'crossing' configuration is realized.

In this paper, we contribute to a better understanding of the formal properties of well-nested LCFRS. We show that, when fan-out is bounded by any integer $\varphi \geq 1$, these systems can always be transformed, in an efficient way, into a specific normal form with no more than two nonterminals in their productions' right-hand sides. On the basis of this result, we then develop an efficient parsing algorithm for well-nested LCFRS, running in time $\mathcal{O}(\varphi \cdot |G| \cdot |w|^{2\varphi+2})$, where G and w are the input grammar and string, respectively. Well-nested LCFRS with fan-out $\varphi = 2$ are weakly equivalent to TAG, and our complexity result reduces to the well-known upper bound $\mathcal{O}(|G| \cdot |w|^6)$ for this class. For $\varphi > 2$, our upper bound is asymptotically better than the one obtained from existing parsing algorithms for general LCFRS or equivalent formalisms (Seki et al., 1991).

Well-nested LCFRS are generatively equivalent to (among others) coupled context-free grammars (CCFG), introduced by Hotz and Pitsch (1996). These authors also provide a normal form and develop a parsing algorithm for CCFGs. One difference with respect to our result is that the normal form for CCFGs allows more than two nonterminals to appear in the right-hand side of a production, even though no nonterminal may contribute more than two tuple components. Also, the construction in (Hotz and Pitsch, 1996) results in a blow-up of the grammar that is exponential in its fan-out, and the parsing algorithm that is derived runs in time $\mathcal{O}(4^\varphi \cdot |G| \cdot |w|^{2\varphi+2})$. Our result is therefore a considerable asymptotic improvement over the CCFG result, both with respect to the normal form construction and the parsing efficiency. Finally, under a practical perspective, our parser is a simple chart-based algorithm, while the algorithm in (Hotz and Pitsch, 1996) involves two passes and is considerably more complex to analyze and to implement than ours.

Kanazawa and Salvati (2010) mention a normal form for well-nested multiple context-free grammars.

Structure In Section 2, we introduce LCFRS and the class of well-nested LCFRS that is the focus of this paper. In Section 3, we discuss the parsing complexity of LCFRS, and show why grammars using our normal form can be parsed efficiently. Section 4 presents the transformation of a well-nested LCFRS into the normal form. Section 5 concludes the paper.

2 Linear Context-Free Rewriting Systems

We write $[n]$ to denote the set of positive integers up to and including n: $[n] = \{1, \ldots, n\}$.

2.1 Linear, non-erasing functions

Let Σ be an alphabet. For integers $m \geq 0$ and $k_1, \ldots, k_m, k \geq 1$, a total function

$$f : (\Sigma^*)^{k_1} \times \cdots \times (\Sigma^*)^{k_m} \to (\Sigma^*)^k$$

is called a *linear, non-erasing function* over Σ with type $k_1 \times \cdots \times k_m \to k$, if it can be defined by an equation of the form

$$f(\langle x_{1,1}, \ldots, x_{1,k_1} \rangle, \ldots, \langle x_{m,1}, \ldots, x_{m,k_m} \rangle) = \vec{\alpha}\,,$$

where $\vec{\alpha}$ is a k-tuple of strings over the variables on the left-hand side of the equation and Σ with the property that each variable occurs in $\vec{\alpha}$ exactly once. The values m and k are called the *rank* and the *fan-out* of f, and denoted by $\rho(f)$ and $\varphi(f)$.

2.2 Linear Context-Free Rewriting Systems

For the purposes of this paper, a *linear context-free rewriting system*, henceforth LCFRS, is a construct $G = (N, T, P, S)$, where N is an alphabet of nonterminal symbols in which each symbol A is associated with a positive integer $\varphi(A)$ called its *fan-out*, T is an alphabet of terminal symbols, $S \in N$ is a distinguished start symbol with $\varphi(S) = 1$; and P is a finite set of productions of the form

$$p \;=\; A \to f(A_1, \ldots, A_m)\,,$$

where $m \geq 0$, $A, A_1, \ldots, A_m \in N$, and f is a linear, non-erasing function over the terminal alphabet T with type $\varphi(A_1) \times \cdots \times \varphi(A_m) \to \varphi(A)$, called the *composition operation* associated with p. The *rank* of G and the *fan-out* of G are defined as the maximal rank and fan-out of the composition operations of G, and are denoted by $\rho(G)$ and $\varphi(G)$.

The sets of *derivation trees* of G are the smallest indexed family of sets D_A, $A \in N$, such that, if

$$p \;=\; A \to f(A_1, \ldots, A_m)$$

$$N = \{S, R\}\,,\ T = \{a, b, c, d\}\,,\ P = \{\, p_1 = S \to f_1(R),\ p_2 = R \to f_2(R),\ p_3 = R \to f_3 \,\}\,,$$
$$\text{where: } f_1(\langle x_{1,1}, x_{1,2}\rangle) = \langle x_{1,1}\, x_{1,2}\rangle\,,\ f_2(\langle x_{1,1}, x_{1,2}\rangle) = \langle a\, x_{1,1}\, b, c\, x_{1,2}\, d\rangle\,,\ f_3 = \langle \varepsilon, \varepsilon\rangle\,.$$

Figure 1: An LCFRS that generates the string language $\{\, a^n b^n c^n d^n \mid n \geq 0 \,\}$.

is a production of G and $t_i \in D_{A_i}$ for all $i \in [m]$, then $t = p(t_1, \dots, t_m) \in D_A$. By interpreting productions as their associated composition operations in the obvious way, a derivation tree $t \in D_A$ evaluates to a $\varphi(A)$-tuple of strings over T; we denote this tuple by $\mathit{val}(t)$. The *string language* generated by G, denoted by $L(G)$, is then defined as

$$L(G) \;=\; \{\, w \in T^* \mid t \in D_S,\ \langle w\rangle = \mathit{val}(t) \,\}\,.$$

Two LCFRS are called *weakly equivalent*, if they generate the same string language.

Example Figure 1 shows a sample LCFRS G with $\rho(G) = 1$ and $\varphi(G) = 2$. The sets of its derivation trees are $D_R = \{\, p_2^n(p_3) \mid n \geq 0 \,\}$ and $D_S = \{\, p_1(t) \mid t \in D_R \,\}$. The string language generated by G is $\{\, a^n b^n c^n d^n \mid n \geq 0 \,\}$.

2.3 Characteristic strings

In the remainder of this paper, we use the following convenient syntax for tuples of strings. Instead of

$$\langle v_1, \dots, v_k\rangle\,, \quad \text{we write} \quad v_1 \,\$\, \cdots \,\$\, v_k\,,$$

using the \$-symbol to mark the component boundaries. We call this the *characteristic string* of the tuple, and an occurrence of the symbol \$ a *gap marker*. We also use this notation for composition operations. For example, the characteristic string of the operation

$$f(\langle x_{1,1}, x_{1,2}\rangle, \langle x_{2,1}\rangle) \;=\; \langle a\, x_{1,1}\, x_{2,1}, x_{1,2}\, b\rangle$$

is $a\, x_{1,1}\, x_{2,1} \,\$\, x_{1,2}\, b$. If we assume the variables on the left-hand side of an equation to be named according to the schema used in Section 2.1, then the characteristic string of a composition operation determines that operation completely. We will therefore freely identify the two, and write productions as

$$p \;=\; A \to [v_1 \,\$\, \cdots \,\$\, v_k](A_1, \dots, A_m)\,,$$

where the string inside the brackets is the characteristic string of some composition operation. The substrings $v_1, \dots, v_k$ are called the *components* of the characteristic string. Note that the characteristic string of a composition operation with type $k_1 \times \cdots \times k_m \to k$ is a sequence of terminal symbols, gap markers, and variables from the set $\{\, x_{i,j} \mid i \in [m],\ j \in [k_i] \,\}$ in which the number of gap markers is $k-1$, and each variable occurs exactly once. When in the context of such a composition operation we refer to 'a variable of the form $x_{i,j}$', then it will always be the case that $i \in [m]$ and $j \in [k_i]$.

The identification of composition operations and their characteristic strings allows us to construct new operations by string manipulations: if, for example, we delete some variables from a characteristic string, then the resulting string still defines a composition operation (after a suitable renaming of the remaining variables, which we leave implicit).

2.4 Canonical LCFRS

To simplify our presentation, we will assume that LCFRS are given in a certain canonical form. Intuitively, this canonical form requires the variables in the characteristic string of a composition operation to be ordered in a certain way.

Formally, the defining equation of a composition operation f with type $k_1 \times \cdots \times k_m \to k$ is called *canonical*, if (i) the sequence obtained from f by reading variables of the form $x_{i,1}$ from left to right has the form $x_{1,1} \cdots x_{m,1}$; and (ii) for each $i \in [m]$, the sequence obtained from f by reading variables of the form $x_{i,j}$ from left to right has the form $x_{i,1} \cdots x_{i,k_i}$. An LCFRS is called *canonical*, if each of its composition operations is canonical.

We omit the proof that every LCFRS can be transformed into a weakly equivalent canonical LCFRS. However, we point out that both the normal form and the parsing algorithm that we present in this paper can be applied also to general LCFRS. This is in contrast to some left-to-right parsers in the literature on LCFRS and equivalent formalisms (de la Clergerie, 2002; Kallmeyer and Maier, 2009), which actually depend on productions in canonical form.

2.5 Well-nested LCFRS

We now characterize the class of *well-nested LCFRS* that are the focus of this paper. Well-nestedness was first studied in the context of dependency grammars (Kuhlmann and Möhl, 2007). Kanazawa (2009) defines well-nested multiple context-free grammars, which are weakly equivalent to well-nested LCFRS.

A composition operation is called *well-nested*, if it does not contain a substring of the form

$$x_{i,i_1} \cdots x_{j,j_1} \cdots x_{i,i_2} \cdots x_{j,j_2}\,, \quad \text{where } i \neq j\,.$$

For example, the operation $x_{1,1}\, x_{2,1} \$ x_{2,2}\, x_{1,2}$ is well-nested, while $x_{1,1}\, x_{2,1}\ \$\ x_{1,2}\, x_{2,2}$ is not. An LCFRS is called well-nested, if it contains only well-nested composition operations.

The class of languages generated by well-nested LCFRS is properly included in the class of languages generated by general LCFRS; see Kanazawa and Salvati (2010) for further discussion.

3 Parsing LCFRS

We now discuss the parsing complexity of LCFRS, and motivate our interest in a normal form for well-nested LCFRS.

3.1 General parsing schema

A bottom-up, chart-based parsing algorithm for the class of (not necessarily well-nested) LCFRS can be defined by using the formalism of parsing schemata (Sikkel, 1997). The parsing schemata approach considers parsing as a deduction process (as in Shieber et al. (1995)), generating intermediate results called *items*. Starting with an initial set of items obtained from each input sentence, a parsing schema defines a set of *deduction steps* that can be used to infer new items from existing ones. Each item contains information about the sentence's structure, and a successful parsing process will produce at least one *final item* containing a full parse for the input.

The item set used by our bottom-up algorithm to parse an input string $w = a_1 \cdots a_n$ with an LCFRS $G = (N, T, P, S)$ will be

$$\mathcal{I} = \{[A, (l_1, r_1), \ldots, (l_k, r_k)] \mid A \in N \quad \wedge \\ 0 \leq l_i \leq r_i \leq n \quad \forall i \in [k]\},$$

where an item $[A, (l_1, r_1), \ldots, (l_k, r_k)]$ can be interpreted as the set of those derivation trees $t \in D_A$ of G for which

$$\mathit{val}(t) \;=\; a_{l_1+1} \cdots a_{r_1}\ \$ \cdots \$\ a_{l_k+1} \cdots a_{r_k}\,.$$

The set of final items is thus $\mathcal{F} = \{[S, (0, n)]\}$, containing full derivation trees that evaluate to w.

For simplicity of definition of the sets of initial items and deduction steps, let us assume that productions of rank > 0 in our grammar do not contain terminal symbols in their right-hand sides. This can be easily achieved from a starting grammar by creating a nonterminal A_a for each terminal $a \in T$, a corresponding rank-0 production $p_a = A_a \to [a]()$, and then changing each occurrence of a in the characteristic string of a production to the single variable associated with the fan-out 1 nonterminal A_a. With this, our initial item set for a string $a_1 \cdots a_n$ will be

$$\mathcal{H} = \{[A_{a_i}, (i-1, i)] \mid i \in [n]\}\,,$$

and each production $p = A_0 \to f(A_1, \ldots, A_m)$ of G (excluding the ones we created for the terminals) will produce a deduction step of the form given in Figure 2a, where the indexes are subject to the following constraints, imposed by the semantics of f.

1. If the kth component of the characteristic string of f starts with $x_{i,j}$, then $l_{0,k} = l_{i,j}$.
2. If the kth component of the characteristic string of f ends with $x_{i,j}$, then $r_{0,k} = r_{i,j}$.
3. If $x_{i,j} x_{i',j'}$ is an infix of the characteristic string of f, then $r_{i,j} = l_{i',j'}$.
4. If the kth component of the characteristic string of f is the empty string, then $l_{0,k} = r_{0,k}$.

3.2 General complexity

The time complexity of parsing LCFRS with respect to the length of the input can be analyzed by counting the maximum number of indexes that can appear in an instance of the inference rule above. Although the total number of indexes is $\sum_{i=0}^{m} 2 \cdot \varphi(A_i)$, some of these indexes are equated by the constraints.

To count the number of independent indexes, consider all the indexes of the form $l_{0,i}$ (corresponding to the left endpoints of each component of the characteristic string of f) and those of the form $r_{j,k}$ for $j > 0$ (corresponding to the right endpoints of each variable in the characteristic string). By the constraints above, these indexes are mutually independent, and it is easy to check that any other index is equated to one of these: indexes $r_{0,i}$ are equated to the index $r_{j,k}$ corresponding to the last variable $x_{j,k}$ of the ith component of the characteristic string, or to $l_{0,i}$ if there is no such variable; while indexes $l_{j,k}$ with $j > 0$ are equated to an index $l_{0,i}$ if the variable $x_{j,k}$ is at the beginning of a component of the characteristic string, or to an index $r_{j',k'}(j' > 1)$ if the variable $x_{j,k}$ follows another variable $x_{j',k'}$.

$$\frac{[A_1,(l_{1,1},r_{1,1}),\ldots,(l_{1,\varphi(A_1)},r_{1,\varphi(A_1)})] \qquad \cdots \qquad [A_m,(l_{m,1},r_{m,1}),\ldots,(l_{m,\varphi(A_m)},r_{m,\varphi(A_m)})]}{[A_0,(l_{0,1},r_{0,1}),\ldots,(l_{0,\varphi(A_0)},r_{0,\varphi(A_0)})]}$$

(a) The general rule for a parsing schema for LCFRS

$$\frac{[B,(l_1,r_1),\ldots,(l_m,r_m)] \qquad [C,(l'_1,r'_1),\ldots(l'_n,r'_n)]}{[A,(l_1,r_1),\ldots,(l_m,r'_1),\ldots(l'_n,r'_n)]}\; r_m = l'_1$$

(b) Deduction step for concatenation

$$\frac{[B,(l_1,r_1),\ldots,(l_m,r_m)] \qquad [C,(l'_1,r'_1),\ldots(l'_n,r'_n)]}{[A,(l_1,r_1),\ldots,(l_i,r'_1),\ldots(l'_n,r_{i+1}),\ldots,(l_m,r_m)]}\; r_i = l'_1, r'_n = l_{i+1}$$

(c) Deduction step for wrapping

Figure 2: Deduction steps for parsing LCFRS.

Thus, the *parsing complexity* (Gildea, 2010) of a production $p = A_0 \to f(A_1,\ldots,A_m)$ is determined by $\varphi(A_0)$ l-indexes and $\sum_{i\in[m]}\varphi(A_i)$ r-indexes, for a total complexity of

$$\mathcal{O}(|w|^{\varphi(A_0)+\sum_{i\in[m]}\varphi(A_i)})$$

where $|w|$ is the length of the input string. The parsing complexity of an LCFRS will correspond to the maximum parsing complexity among its productions. Note that this general complexity matches the result given by Seki et al. (1991).

In an LCFRS of rank ρ and fan-out φ, the maximum possible parsing complexity is $\mathcal{O}(|w|^{\varphi(\rho+1)})$, obtained by applying the above expression to a production of rank ρ and where each nonterminal has fan-out φ. The asymptotic time complexity of LCFRS parsing is therefore exponential both in its rank and its fan-out. This means that it is interesting to transform LCFRS into equivalent forms that reduce their rank while preserving the fan-out. For sets of LCFRS that can be transformed into a *binary* form (i.e., such that all its rules have rank at most 2), the ρ factor in the complexity is reduced to a constant, and complexity is improved to $\mathcal{O}(|w|^{3\varphi})$ (see Gómez-Rodríguez et al. (2009) for further discussion). Unfortunately, it is known by previous results (Rambow and Satta, 1999) that it is not always possible to convert an LCFRS into such a binary form without increasing the fan-out. However, we will show that it is always possible to build such a binarization for *well-nested* LCFRS. Combining this result with the inference rule and complexity analysis given above, we would obtain a parser for well-nested LCFRS running in $\mathcal{O}(|w|^{3\varphi})$ time. But the construction of our binary normal form additionally restricts binary composition operations in the binarized LCFRS to be of two specific forms, *concatenation* and *wrapping*, which further improves the parsing complexity to $\mathcal{O}(|w|^{2\varphi+2})$, as we will see below.

3.3 Concatenation and wrapping

A composition operation is called a *concatenation operation*, if its characteristic string has the form

$$x_{1,1}\,\$\cdots\$\,x_{1,m}\,x_{2,1}\,\$\cdots\$\,x_{2,n}\,,$$

where $m,n \geq 1$. Intuitively, such an operation corresponds to the bottom-up combination of two adjacent discontinuous constituents into one. An example of a concatenation operation is the binary parsing rule used by the standard CKY parser for context-free grammars, which combines continuous constituents (represented as 1-tuples of strings in the LCFRS notation). In the general case, a concatenation operation will take an m-tuple and an n-tuple and return an $(m+n-1)$-tuple, as the joined constituents may have gaps that will also appear in the resulting tuple.

If we apply the general parsing rule given in Figure 2a to a production $A \to \mathit{conc}(B,C)$, where *conc* is a concatenation operation, then we obtain the deduction step given in Figure 2b. This step uses $2m$ different l- and r-indexes, and $2n-1$ different l'- and r'-indexes (excluding l'_1 which must equal r_m), for a total of $2m+2n-1 = 2(m+n-1)+1$ indexes. Since $m+n-1$ is the fan-out of the nonterminal A, we conclude that the maximum number of indexes in the step associated with a concatenation operation in an LCFRS of fan-out φ is $2\varphi+1$.

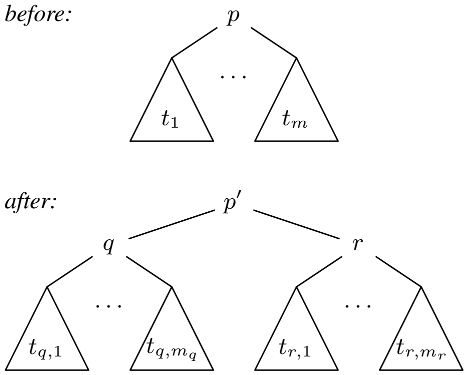

Figure 3: Transformation of derivation trees

A linear, non-erasing function is called a *wrapping operation*, if its characteristic string has the form

$$x_{1,1}\,\$\cdots\$\,x_{1,i}\,x_{2,1}\,\$\cdots\$\,x_{2,n}\,x_{1,i+1}\,\$\cdots\$\,x_{1,m}\,,$$

where $m, n \geq 1$ and $i \in [m-1]$. Intuitively, such an operation wraps the tuple derived from a nonterminal B around the tuple derived from a nonterminal C, filling the ith gap in the former. An example of a wrapping operation is the adjunction of an auxiliary tree in tree-adjoining grammar. In the general case, a wrapping operation will take an m-tuple and an n-tuple and return an $(m+n-2)$-tuple of strings: the gaps of the argument tuples appear in the obtained tuple, except for one gap in the tuple derived from B which is filled by the tuple derived from C.

By applying the general parsing rule in Figure 2a to a production $A \to \mathit{wrap}_i(B, C)$, where wrap_i is a wrapping operation, then we obtain the deduction step given in Figure 2c. This step uses $2m$ different l- and r-indexes, and $2n-2$ different l'- and r'-indexes (discounting l'_1 and r'_n which are equal to other indexes), for a total of $2m+2n-2 = 2(m+n-2)+2$ indexes. Since the fan-out of A is $m+n-2$, this means that a wrapping operation needs at most $2\varphi+2$ indexes for an LCFRS of fan-out φ.

From this, we conclude that an LCFRS of fan-out φ in which all composition operations are either concatenation operations, wrapping operations, or operations of rank 0 or 1, can be parsed in time $\mathcal{O}(|w|^{2\varphi+2})$. In particular, nullary and unary composition operations do not affect this worst-case complexity, since their associated deduction steps can never have more than 2φ indexes.

4 Transformation

We now show how to transform a well-nested LCFRS into the normal form that we have just described.

4.1 Informal overview

Consider a production $p = A \to f(A_1, \ldots, A_m)$, where $m \geq 2$ and f is neither a concatenation nor a wrapping operation. We will construct new productions p', q, r such that every derivation that uses p can be rewritten into a derivation that uses the new productions, and the new productions do not license any other derivations. Formally, this can be understood as implementing a *tree transformation*, where the input trees are derivations of the original grammar, and the output trees are derivations of the new grammar. The situation is illustrated in Figure 3. The tree on top represents a derivation in the original grammar; this derivation starts with the rewriting of the nonterminal A using the production p, and continues with the subderivations $t_1, \ldots, t_m$. The tree at the bottom represents a derivation in the transformed grammar. This derivation starts with the rewriting of A using the new production p', and continues with two independent subderivations that start with the new productions q and r, respectively. The sub-derivations $t_1, \ldots, t_m$ have been partitioned into two sequences

$$t_{1,1}, \ldots, t_{1,m_1} \quad \text{and} \quad t_{2,1}, \ldots, t_{2,m_2}\,.$$

The new production p' will be either a concatenation or a wrapping operation, and the rank of both q and r will be strictly smaller than the rank of p. The transformation will continue with q and r, unless these have rank one. By applying this strategy exhaustively, we will thus eventually end up with a grammar that only has productions with rank at most 2, and in which all productions with rank 2 are either concatenation or wrapping operations.

4.2 Constructing the composition operations

To transform the production p, we first factorize the composition operation f associated with p into three new composition operations f', g, h as follows. Recall that we represent composition operations by their characteristic strings.

In the following, we will assume that no characteristic string starts or ends with a gap marker, or contains immediate repetitions of gap markers. This property can be ensured, without affecting the asymptotic complexity, by adding intermediate steps to the transformation that we report here; we omit the details due to space reasons. When this property holds, we are left with the following two cases. Let us call a sequence of variables *joint*, if it contains all and only variables associated with a given nonterminal.

Case 1 $f \;=\; x_1\, f_1\, x_2 \cdots x_{k-1}\, f_{k-1}\, x_k\, f^*$, where $k \geq 1$, $x_1, \dots, x_k$ are joint variables, and the suffix f^* contains at least one variable. Let

$$g \;=\; x_1\, f_1\, x_2 \cdots x_{k-1}\, f_{k-1}\, x_k\,,$$

let $h = f^*$, and let $f' = \mathit{conc}$. As f is well-nested, both g and h define well-nested composition operations. By the specific segmentation of f, the ranks of these operations are strictly smaller than the rank of f. Furthermore, we have $\varphi(f) \;=\; \varphi(g) + \varphi(h) - 1$.

Case 2 $f \;=\; x_1\, f_1\, x_2 \cdots x_{k-1}\, f_{k-1}\, x_k$, where $k \geq 2$, $x_1, \dots, x_k$ are joint variables, and there exist at least one i such that the sequence f_i contains at least one variable. Choose an index j as follows: if there is at least one i such that f_i contains at least one variable and one gap marker, let j be the minimal such i; otherwise, let j be the minimal i such that f_i contains at least one variable. Now, let

$$g \;=\; x_1\, f_1\, x_2 \cdots x_j\, \$\, x_{j+1} \cdots x_{k-1}\, f_{k-1}\, x_k\,,$$

let $h = f_j$, and let $f' = \mathit{wrap}_j$. As in Case 1, both g and h define well-nested composition operations whose ranks are strictly smaller than the rank of f. Furthermore, we have $\varphi(f) \;=\; \varphi(g) + \varphi(h) - 2$.

Note that at most one of the two cases can apply to f. Furthermore, since f is well-nested, it is also true that at least one of the two cases applies. This is so because for two distinct nonterminals $A_i, A_{i'}$, either all variables associated with $A_{i'}$ precede the leftmost variable associated with A_i, succeed the rightmost variable associated with A_i, or are placed between two variables associated with A_i without another variable associated with A_i intervening. (Here, we have left out the symmetric cases.)

4.3 Constructing the new productions

Based on the composition operations, we now construct three new productions p', q, r as follows. Let B and C be two fresh nonterminals with $\varphi(B) = \varphi(g)$ and $\varphi(C) = \varphi(h)$, and let $p' = A \to f'(B, C)$. The production p' rewrites A into B and C and combines the two subderivations that originate at these nonterminals using either a concatenation or a wrapping operation. Now, let $A_{q,1}, \dots, A_{q,m_q}$ and $A_{r,1}, \dots, A_{r,m_r}$ be the sequences of nonterminals that are obtained from the sequence $A_1, \dots, A_m$ by deleting those nonterminals that are not associated with any variable in g or h, respectively. Then, let

$$q = B \to g(A_{q,1}, \dots, A_{q,m_q}) \quad \text{and}$$
$$r = C \to h('A_{r,1}, \dots, A_{r,m_r})\,.$$

4.4 Example

We now illustrate the transformation using the concrete production $p = A \to f(A_1, A_2, A_3)$, where

$$f \;=\; x_{1,1}\, x_{2,1}\, \$\, x_{1,2}\, \$\, x_{3,1}\,.$$

Note that this operation has rank 3 and fan-out 3.

The composition operations are constructed as follows. The operation f matches the pattern of Case 1, and hence induces the operations

$$g_1 = x_{1,1}\, x_{2,1}\, \$\, x_{1,2}\,, \quad h_1 = \; \$\, x_{3,1}\,, \quad f'_1 = \mathit{conc}\,.$$

The productions constructed from these are

$$p'_1 = A \to \mathit{conc}(B_1, C_1)\,,$$
$$q_1 = B_1 \to g_1(A_1, A_2)\,, \quad r_1 = C_1 \to h_1(A_3)\,.$$

where B_1 and C_1 are fresh nonterminals with fan-out 2. The production r_1 has rank one, so it does not require any further transformations. The transformation thus continues with q_1. The operation g_1 matches the pattern of Case 2, and induces the operations

$$g_2 = x_{1,1}\, \$\, x_{1,2}\,, \quad h_2 = x_{2,1}\$\,, \quad f'_2 = \mathit{wrap}_1\,.$$

The productions constructed from these are

$$p'_2 = B_1 \to \mathit{wrap}_1(B_2, C_2)\,,$$
$$q_2 = B_2 \to g_2(A_1)\,, \quad r_2 = C_2 \to h_2(A_2)\,,$$

where B_2 and C_2 are fresh nonterminals with fan-out 2. At this point, the transformation terminates. We can now delete p from the original grammar, and replace it with the productions $\{p'_1, r_1, p'_2, q_2, r_2\}$.

4.5 Correctness

To see that the transformation is correct, we need to verify that each production of the original grammar is transformed into a set of equivalent normal-form productions, and that the fan-out of the new grammar does not exceed the fan-out of the old grammar.

For the first point, we note that the transformation preserves well-nestedness, decreases the rank of a production, and is always applicable as long as the rank of a production is at most 2 and the production does not use a concatenation or wrapping operation. That the new productions are equivalent to the old ones in the sense of Figure 3 can be proved by induction on the length of a derivation in the original and the new grammar, respectively.

Let us now convince ourselves that the fan-out of the new grammar does not exceed the fan-out of the old grammar. This is clear in Case 1, where

$$\varphi(f) \;=\; \varphi(g) + \varphi(h) - 1$$

implies that both $\varphi(g) \leq \varphi(f)$ and $\varphi(h) \leq \varphi(f)$. For Case 2, we reason as follows. The fan-out of the operation h, being constructed from an infix of the characteristic string of the original operation f, is clearly bounded by the fan-out of f. For g, we have

$$\varphi(g) \;=\; \varphi(f) - \varphi(h) + 2\,,$$

Now suppose that the index j was chosen according to the first alternative. In this case, $\varphi(h) \geq 2$, and

$$\varphi(g) \;\leq\; \varphi(f) - 2 + 2 \;=\; \varphi(f)\,.$$

For the case where j was chosen according to the second alternative, $\varphi(f) < k$ (since there are no immediate repetitions of gap markers), $\varphi(h) = 1$, and $\varphi(g) \leq k$. If we assume that each nonterminal is productive, then this means that the underlying LCFRS has at least one production with fan-out k or more; therefore, the fan-out of g does not increase the fan-out of the original grammar.

4.6 Complexity

To conclude, we now briefly discuss the space complexity of the normal-form transformation. We measure it in terms of the *length* of a production, defined as the length of its string representation, that is, the string $A \to [v_1 \,\$ \cdots \$\, v_k](A_1, \ldots, A_m)$.

Looking at Figure 3, we note that the normal-form transformation of a production p can be understood as the construction of a (not necessarily complete) binary-branching tree whose leaves correspond to the productions obtained by splitting the characteristic string of p and whose non-leaf nodes are labeled with concatenation and wrapping operations. By construction, the sum of the lengths of leaf-node productions is $\mathcal{O}(|p|)$. Since the number of inner nodes of a binary tree with n leaves is bounded by $n - 1$, we know that the tree has $\mathcal{O}(\rho(p))$ inner nodes. As these nodes correspond to concatenation and wrapping operations, each inner-node production has length $\mathcal{O}(\varphi(p))$. Thus, the sum of the lengths of the productions created from $|p|$ is $\mathcal{O}(|p| + \rho(p)\varphi(p))$. Since the rank of a production is always smaller than its length, this is reduced to $\mathcal{O}(|p|\varphi(p))$.

Therefore, the size of the normal-form transformation of an LCFRS G of fan-out φ is $\mathcal{O}(\varphi|G|)$ in the worst case, and linear space in practice, since the fan-out is typically bounded by a small integer. Taking the normal-form transformation into account, our parser therefore runs in time $\mathcal{O}(\varphi \cdot |G| \cdot |w|^{2\varphi+2})$ where $|G|$ is the original grammar size.

5 Conclusion

In this paper, we have presented an efficient parsing algorithm for well-nested linear context-free rewriting systems, based on a new normal form for this formalism. The normal form takes up linear space with respect to grammar size, and the algorithm is based on a bottom-up process that can be applied to any LCFRS, achieving $\mathcal{O}(\varphi \cdot |G| \cdot |w|^{2\varphi+2})$ time complexity when applied to LCFRS of fan-out φ in our normal form. This complexity is an asymptotic improvement over existing results for this class, both from parsers specifically geared to well-nested LCFRS or equivalent formalisms (Hotz and Pitsch, 1996) and from applying general LCFRS parsing techniques to the well-nested case (Seki et al., 1991).

The class of well-nested LCFRS is an interesting syntactic formalism for languages with discontinuous constituents, providing a good balance between coverage of linguistic phenomena in natural language treebanks (Kuhlmann and Nivre, 2006; Maier and Lichte, 2009) and desirable formal properties (Kanazawa, 2009). Our results offer a further argument in support of well-nested LCFRS: while the complexity of parsing general LCFRS depends on two dimensions (rank and fan-out), this bidimensional hierarchy collapses into a single dimension in the well-nested case, where complexity is only conditioned by the fan-out.

Abstract

We describe a utility evaluation to determine whether cross-document information extraction (IE) techniques measurably improve user performance in news summary writing. Two groups of subjects were asked to perform the same time-restricted summary writing tasks, reading news under different conditions: with no IE results at all, with traditional single-document IE results, and with cross-document IE results. Our results show that, in comparison to using source documents only, the quality of summary reports assembled using IE results, especially from cross-document IE, was significantly better and user satisfaction was higher. We also compare the impact of different user groups on the results.

1 Introduction

Information Extraction (IE) is a task of identifying 'facts' (entities, relations and events) within unstructured documents, and converting them into structured representations (e.g., databases). IE techniques have been effectively applied to different domains (e.g. daily news, Wikipedia, biomedical reports, financial analysis and legal documentations) and different languages. Recently we described a new cross-document IE task (Ji et al., 2009) to extract events across-documents and track them on a time line. Compared to traditional single-document IE, this new task can extract more salient, accurate and concise event information.

However, a significant question remains: will the events extracted by IE, especially this new cross-document IE task, actually help end-users to make better use of the large volumes of news? In order to investigate whether we have reached this goal, we performed an extrinsic utility (i.e., usefulness) and usability evaluation on IE results. Two groups of subjects were asked to perform the same time-restricted summary writing tasks, reading news under different conditions: with no IE results at all, with traditional single-document IE results, and with cross-document IE results. Our results show that, in comparison to using source documents only, the quality of summary reports assembled using IE techniques, especially from cross-document IE, was significantly better. Also, as extraction quality increases from no IE at all to single-document IE and then to cross-document IE, user satisfaction increases. We also compare the impact of different user groups on the results. To the best of our knowledge, this is the first systematic evaluation of cross-document IE from a usability perspective.

2 Overview of IE Systems

We applied the English single-document IE system (Ji and Grishman, 2008) and cross-document IE system presented in (Ji et al., 2009). Both systems were developed for the ACE program[1].

The single-document IE system can extract events from individual documents. The core stages include entity extraction, time expression extraction and normalization, relation extraction and event extraction. Events include the 33 distinct types defined in ACE05. The extraction results are presented in tabular form.

The cross-document IE system can identify important person entities which are frequently in-

volved in events as 'centroid entities'; and then for each centroid entity, link and order the events centered around it on a time line and associate them to a geographical map. The event chains are presented in a user-friendly graphical interface (Ji and Chen, 2009). Both systems link the events back to their context documents.

3 Evaluation Methods

3.1 Study Execution

Our measurement challenge is to assess how IE techniques affect users' abilities to perform real-world tasks. We followed the summary writing task described in the Integrated Feasibility Experiment of the DARPA TIDES program (Colbath and Kubala, 2003) and the daily task conducted by intelligence analysts (Bodnar, 2003). Each task in our evaluation is based on writing a summary of ACE-type events involving a specific centroid entity, using one of three levels of support:

- Level (I): Read the news articles, with assistance of keyword based sentence search;
- Level (II): (I) + with assistance from single-document IE results;
- Level (III): (I) + with assistance from cross-document IE results.

The summary writing task for each entity using any level should be finished in 10 minutes. The users can choose to trust the IE results to create new sentences or select relevant sentences from the source documents. The IE systems were applied to a corpus of 106 articles from ACE 2005 training data.

3.2 Summary Scoring

We measure user responses in three aspects:

- *Observer-based Quantity* -- How many sentences are extracted in each summary? How many of them are uniquely correct?
- *Observer-based Quality*-- How fluent and coherent are the sentences in each summary?
- *User-based Usability* -- How does the user feel about the system?

3.3 User Group Selection

We selected user groups based on the principles that we should run as many tests as we can afford (Nielsen, 1994), and at least 5 to insure that we detect any major usability problems (Faulkner, 2003). Two different groups of users were asked to conduct the evaluation:

(1) Hallway Evaluation

We chose the first group of users with a "Hallway Testing" user-study method described in (Nielsen, 1994). We randomly asked 11 PhD students in the field of natural language processing to conduct the evaluation. In order to evaluate these three levels independently, each student was asked to write at most one summary, using one of the three levels, for any single centroid entity. To avoid the impact of diverse text comprehension abilities, each student was involved in all of these three levels for different centroid entities.

(2) Remote Evaluation

An effective utility evaluation will require users with a diversity of prior knowledge and computer experience. Therefore we asked the second group of 11 users in a remote usability testing mode (Hammontree et al., 1994). We sent out the request to university-wide undergraduate student mailing lists and found 11 users to work on the evaluation. The evaluation procedure follows the Hallway Testing method, except that the tests are carried out in the user's own environment (rather than labs) helping further simulate real-life scenario testing. Also the users didn't meet with the observers and thus they were not aware of any expectations for results.

4 Evaluation Results

In this section we will focus on reporting the results from Hallway Evaluation, while providing comparisons with Remote Evaluation.

4.1 Observer-based Quantity

The summaries were judged by two annotators and the judgements reconciled. A summary sentence is judged as uniquely correct if it: (1) includes relevant events involving the centroid entity; and (2) the same information was not included in previous sentences in the current summary. This metric can be considered as an approximate com bination of the "content responsiveness", "non-redundancy"and "focus" criteria in the NIST TAC summarization track[2]. Table 1 presents the

[2] http://www.nist.gov/tac/2009/Summarization/update.summ.09.guidelines.html

Centroid	(I)	(II)	(III)	Centroid	(I)	(II)	(III)	Centroid	(I)	(II)	(III)
Bush	3/1/0	5/1/2	6/0/0	Al-douri	4/3/3	4/2/0	6/0/1	Ba'asyir	3/1/0	3/0/0	5/0/0
Ibrahim	4/0/1	5/0/0	8/0/0	Giuliani	2/0/0	3/2/0	5/0/0	Erdogan	1/0/1	4/0/0	4/0/0
Toefting	0/0/0	7/1/0	4/0/0	Blair	2/0/1	3/0/0	5/0/0	Diller	3/0/0	4/1/0	3/0/0
Putin	2/1/0	4/3/2	7/1/1	Pasko	3/0/0	3/0/0	2/0/0	**Overall**	**27/6/6**	**45/10/5**	**55/1/2**

Table 1. # (uniquely correct sentences)/ #(redundant correct sentences)/ #(spurious sentences) in a summary in Hallway Evaluation

quantified Hallway Testing results for each centroid separately and the overall score. It shows that overall Level (II) contained 18 more correct sentences than the baseline (I), while (III) achieved 11 further correct sentences. (I) obtained significantly fewer sentences without assistance from IE tools. We conducted the Wilcoxon Matched-Pairs Signed-Ranks Test on a query entity basis for accuracy - number of (uniquely correct sentences)/number of (total extracted sentences in a summary). The results show that (III) is significantly better than (I) at a 99.2% confidence level, and better than (II) at a 96.9% confidence level. (II) is not significantly better than (I).

We can also see that for some centroid entities such as “Putin”, “Al-douri” and “Giuliani”, (II) generated more sentences but also introduced more redundant information. The user feedback has indicated that they did not have enough time to remove redundancy. In contrast, (III) yielded much less redundant information. In fact, the average time the users spent using (III) was only about 7.2 minutes. Therefore we can conclude that cross-document IE can produce more informative summaries in a more efficient way.

Error analysis showed that the major error types propagated from IE to summaries are as follows.

1. Event time errors. For example, the summary sentence “Toefting was convicted in September 2001 of assaulting a pair of restaurant workers in the capital” was judged as incorrect because the time argument should be “October 2002”.

2. Pronoun resolution errors. When a pronoun is mistakenly linked to an entity, incorrect event arguments will be included in the summaries.

3. Event type errors. When an event is misclassified, the users tend to use incorrect templates and thus generate wrong summaries.

4. Negative events. Sometimes the event attribute classifier makes mistakes and the users include negative events in the summaries.

4.2 Impact of User Groups

In the Remote Testing, the accuracy results from the three levels are as follows: 21/37, 28/37 and 31/36. Thus both user groups benefited from using IE techniques, but the enhancements vary a lot. In the Hallway Testing, the users were better trained and more familiar with IE tools (including the graphical interface of cross-document IE); and thus they can benefit more from the IE techniques. In contrast, in the Remote Evaluation, the users had quite diverse knowledge backgrounds. For example, one remote user was only able to find 1-2 sentences using any of the three levels; while another, more skilled remote user found more than 5 sentences with any level. However the Remote Evaluation is important to gather the feedback of the more subjective usability evaluation in section 4.4. Because the users in Hallway Testing may be aware of the observations that the observer is hoping to achieve, they may provide potentially biased feedback.

4.3 Observer-based Quality

The evaluation also showed that (III) produced summaries with better quality. We asked the observers to give a score between [1, 10] to each summary according to the following TAC summarization quality criteria: Readability/Fluency, Referential Clarity and Structure/Coherence. Table 2 shows the evaluation results for the three different methods.

Criteria	(I)	(II)	(III)
Readability/Fluency	9.4	8.5	8.2
Referential Clarity	6.1	8.3	8.7
Structure/Coherence	7.1	7.6	8.5

Table 2. Observer-based Average Quality

In their detailed feedback, the users indicated that (III) has the following advantages: (1) Better pronoun resolution; (2) More complete and accurate temporal order because (III) Can recover unknown time arguments using cross-document inference. (3) Can generate abstractive summaries. For the biographical events (e.g. employment), some users were able to use specific templates such as "PER was hired by ORG at TIME" to write summaries. For example, a sentence "Bush and Blair met at Camp David and the UK three times in March 2003" was derived from three different "Contact-Meeting" events in the event chains. (4) Can connect related events into more concise summaries. For example, several events were connected to generate the following sentences "Pasko was appealed for treason crime on April 16, 2003 *and then* released on June 15, 2003". The readability scores in Table 2 also indicate that a more effective template generation method should be developed to produce more fluent summaries based on IE results.

4.4 User-based Usability

The user feedback from both evaluations also showed that (II) and (III) results were trusted almost equally, and (III) was claimed to provide the most useful functions. The positive comments about (III) include "Temporal Linking allows logical reasoning and generalization", "Centroid search helps to focus immediately", "Spatial Linking allows to browse all the places which a person has visited", "Name disambiguation helps to filter irrelevant information", "Can find key information from event chains", "Timeline helps correlate events"; and the negative comments include "Sometimes IE errors mislead locating the sentences", "No support of name pair search for meeting events", "No color emphasis of events on the original documents" and "No suggestions of templates to compose summary sentences".

5 Conclusion and Future Work

Through a utility evaluation on summary writing we have proved that IE techniques, especially cross-document IE, can aid news browsing, search and analysis. In particular, temporal event tracking across documents helps users perform better at fact-gathering than they do without IE. Users also produced more informative summaries with cross-document IE than with traditional single-document IE. We also compared and analyzed the differences between two user groups. Such measures of the benefits to the eventual end users also provided feedback on what works well and identified additional research problems, such as to expand the centroid to a pair of entities and to provide confidence metrics in the interface. In the future we aim to set up an online news article analysis system and perform larger and regular utility evaluations.

Evaluation Metrics for the Lexical Substitution Task

Sanaz Jabbari Mark Hepple Louise Guthrie

{S.Jabbari,M.Hepple,L.Guthrie}@dcs.shef.ac.uk

Abstract

We identify some problems of the evaluation metrics used for the English Lexical Substitution Task of SemEval-2007, and propose alternative metrics that avoid these problems, which we hope will better guide the future development of lexical substitution systems.

1 Introduction

The English Lexical Substitution task at SemEval-2007 (here called ELS07) requires systems to find substitutes for target words in a given sentence (McCarthy & Navigli, 2007: M&N). For example, we might replace the target word *match* with *game* in the sentence *they lost the* <u>*match*</u>. System outputs are evaluated against a set of candidate substitutes proposed by human subjects for test items. Targets are typically *sense ambiguous* (e.g. *match* in the above example), and so task performance requires a combination of *word sense disambiguation* (by exploiting the given sentential context) and (near) *synonym generation*. In this paper, we discuss some problems of the evaluation metrics used in ELS07, and then propose some alternative measures that avoid these problems, and which we believe will better serve to guide the development of lexical substitution systems in future work.[1] The subtasks within ELS07 divide into two groups, in terms of whether they focus on a system's 'best' answer for a test item, or address the broader set of answer candidates a system can produce. In what follows, we address these two cases in separate sections, and then present some results for applying our new metrics for the second case. We begin by briefly introducing the test materials that were created for the ELS07 evaluation.

2 Evaluation Materials

Briefly stated, the ELS07 dataset comprises around 2000 sentences, providing 10 test sentences each for some 201 preselected target words, which were required to be sense ambiguous and have at least one synonym, and which include nouns, verbs, adjectives and adverbs. Five human annotators were asked to suggest up to three substitutes for the target word of each test sentence, and their collected suggestions serve as the gold standard against which system outputs are compared. Around 300 sentences were distributed as development data, and the remainder retained for the final evaluation.

To assist defining our metrics, we formally describe this data as follows.[2] For each sentence t_i in the test data ($1 \leq i \leq N$, N the number of test items), let H_i denote the set of human proposed substitutes. A key aspect of the data is the *count* of human annotators that proposed each candidate (since a term appears a stronger candidate if proposed by annotators). For each t_i, there is a function freq_i which returns this count for each term within H_i (and 0 for any other term), and a value $\mathit{maxfreq}_i$ corresponding to the maximal count for any term in H_i. The pairing of H_i and freq_i in effect provides a *multiset* representation of the human answer set. We

[1] We consider here only the case of substituting for single word targets. Subtasks of ELS07 involving multi-word substitutions are not addressed.

[2] For consistency, we also restate the original ELS07 metrics in these terms, whilst preserving their essential content.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 289–292,
Los Angeles, California, June 2010.

use $|S|^i$ in what follows to denote the *multiset cardinality* of S according to $freq_i$, i.e. $\Sigma_{a \in S} freq_i(a)$. Some of the ELS07 metrics use a notion of *mode* answer m_i, which exists only for test items that have a single most-frequent human response, i.e. a ***unique*** $a \in H_i$ such that $freq_i(a) = maxfreq_i$. To adapt an example from M&N, an item with target word *happy* (adj) might have human answers $\{glad, merry, sunny, jovial, cheerful\}$ with counts (3,3,2,1,1) respectively. We will abbreviate this answer set as $H_i = \{G{:}3,M{:}3,S{:}2,J{:}1,Ch{:}1\}$ where it is used later in the paper.

3 Best Answer Measures

Two of the ELS07 tasks address how well systems are able to find a 'best' substitute for a test item, for which individual test items are scored as follows:

$$best(i) = \frac{\sum_{a \in A_i} freq_i(a)}{|H_i|^i \times |A_i|}$$

$$mode(i) = \begin{cases} 1 & \text{if } bg_i = m_i \\ 0 & \text{otherwise} \end{cases}$$

For the first task, a system can return a *set* of answers A_i (the answer set for item i), but since the score achieved is divided by $|A_i|$, returning multiple answers only serves to allow a system to 'hedge its bets' if it is uncertain which candidate is really the best. The optimal score on a test item is achieved by returning a single answer whose count is $maxfreq_i$, with proportionately lesser credit being received for any answer in H_i with a lesser count. For the second task, which uses the *mode* metric, only a single system answer – its 'best guess' bg_i – is allowed, and the score is simply 0 or 1 depending on whether the best guess is the mode. Overall performance is computed by averaging across a broader set of test items (which for the second task includes only items having a mode value). M&N distinguish two overall performance measures: *Recall*, which averages over all relevant items, and *Precision*, which averages only over those items *for which the system gave a non-empty response*.

We next discuss these measures and make an alternative proposal. The task for the first measure seems a reasonable one, i.e. assessing the ability of systems to provide a 'best' answer for a test item, but allowing them to offer multiple candidates (to 'hedge their bets'). However, the metric is unsatisfactory in that a system that performs optimally in terms of this task (i.e. which, for every test item, returns a single correct 'most frequent' response) will get a score that is well below 1, because the score is also divided by $|H_i|^i$, the multiset cardinality of H_i, whose size varies between test items (being a consequence of the number of alternatives suggested by the human annotators), but which is typically larger than the numerator value $maxfreq_i$ of an optimal answer (unless H_i is singleton). This problem is fixed in the following modified metric definition, by dividing instead by $maxfreq_i$, as then a response containing a single optimal answer will score 1.

$$best(i) = \frac{\sum_{a \in A_i} freq_i(a)}{maxfreq_i \times |A_i|} \qquad best_1(i) = \frac{freq_i(bg_i)}{maxfreq_i}$$

With $H_i = \{G{:}3,M{:}3,S{:}2,J{:}1,Ch{:}1\}$, for example, an optimal response $A_i = \{M\}$ receives score 1, where the original metric gives score 0.3. Singleton responses containing a correct but non-optimal answer receive proportionately lower credit, e.g. for $A_i = \{S\}$ we score 0.66 (vs. 0.2 for the original metric). For a non-singleton answer set including, say, a correct answer and an incorrect one, the credit for the correct answer will be halved, e.g. for $A_i = \{S, X\}$ we score 0.33.

Regarding the second task, we think it reasonable to have a task where systems may offer only a single 'best guess' response, but argue that the *mode* metric used has two key failings: it is too *brittle* in being applicable only to items that have a mode answer, and it *loses information* valuable to system ranking, in assigning no credit to a response that might be good but not optimal. We propose instead the $best_1$ metric above, which assigns score 1 to a best guess answer with count $maxfreq_i$, but applies to *all* test items irrespective of whether or not they have a unique mode. For answers having lesser counts, proportionately less credit is assigned. This metric is equivalent to the new *best* metric shown beside it for the case where $|A_i| = 1$.

For assessing overall performance, we suggest just taking the average of scores across *all* test items, c.f. M&N's Recall measure. Their Precision metric is presumably intended to favour a system that can tell whether it does or does not have any good answers to return. However, the ability to draw a boundary between good vs. poor candidates will be reflected widely in a system's performance and captured elsewhere (not least by the coverage metrics discussed later) and so, we argue, does not need to be separately assessed in this way. Furthermore, the fact that a system does not return any answers may have other causes, e.g. that its lexical resources have failed to yield *any* substitution candidates for a term.

4 Measures of Coverage

A third task of ELS07 assesses the ability of systems to field a wider set of good substitution candidates for a target, rather than just a 'best' candidate. This 'out of ten' (*oot*) task allows systems to offer a set A_i of *upto 10* guesses per item i, and is scored as:

$$oot(i) = \frac{\sum_{a \in A_i} freq_i(a)}{|H_i|^i}$$

Since the score is *not* divided by the answer set size $|A_i|$, no benefit derives from offering less than 10 candidates.[3] When systems are asked to field a broader set of candidates, we suggest that evaluation should assess if the response set is *good* in containing as many correct answers as possible, whilst containing as few incorrect answers as possible. In general, systems will tackle this problem by combining a means of ranking candidates (drawn from lexical resources) with a means of drawing a boundary between good and bad candidates, e.g. threshold setting.[4] Since the *oot* metric does not penalise incorrect answers, it does not encourage systems to develop such boundary methods, even though this is important to their ultimate practical utility.

The view of a 'good' answer set described above suggests a comparison of A_i to H_i using versions of 'recall' and 'precision' metrics, that incorporate the 'weighting' of human answers via $freq_i$. Let us begin by noting the obvious definitions for recall and precision metrics *without* count-weighting:

$$R(i) = \frac{|H_i \cap A_i|}{|H_i|} \qquad P(i) = \frac{|H_i \cap A_i|}{|A_i|}$$

Our definitions of these metrics, given below, *do* include count-weighting, and require some explanation. The numerator of our recall definition is $|A_i|^i$ not $|H_i \cap A_i|^i$ as $|A_i|^i = |H_i \cap A_i|^i$ (as $freq_i$ assigns 0 to any term not in H_i), an observation which also affects the numerator of our P definition. Regarding the latter's denominator, merely dividing by $|A_i|^i$ would not penalise incorrect terms (as, again, $freq_i(a) = 0$ for any $a \notin H_i$), so this is done directly by adding $k|A_i - H_i|$, where $|A_i - H_i|$ is the number of incorrect answers, and k some *penalty factor*, which might be $k = 1$ in the simplest case. (Note that our weighted R metric is in fact equivalent to the *oot* definition above.) As usual, an F-score can be computed as the harmonic mean of these values (i.e. $F = 2PR/(P + R)$). For assessing overall performance, we might average P, R and F scores across all test items.

$$R(i) = \frac{|A_i|^i}{|H_i|^i} \qquad P(i) = \frac{|A_i|^i}{|A_i|^i + k|A_i - H_i|}$$

With H_i = {*G:3,M:3,S:2,J:1,Ch:1*}, for example, the perfect response set $A_i = \{G, M, S, J, Ch\}$ gives P and R scores of 1. The response $A_i = \{G, M, S, J, Ch, X, Y, Z, V, W\}$, containing all correct answers plus 5 incorrect ones, gets $R = 1$, but only $P = 0.66$ (assuming $k = 1$, giving $10/(10 + 5)$). The response $A_i = \{G, S, J, X, Y\}$, with 3 out of 5 correct answers, plus 2 incorrect ones, gets $R = 0.6$ $(6/10)$ and $P = 0.75$ $(6/6 + 2))$

5 Applying the Coverage measure

Although the 'best guess' task is a valuable indicator of the likely utility of a lexical substitution system within various broader applications, we would argue that the *core* task for lexical substitution is *coverage*, i.e. the ability to field a broad set of correct substitution candidates. This task requires systems both to field and rank promising candidates, and to have a means of drawing a boundary between the good and bad candidates, i.e. a *boundary strategy*.

In this section, we apply the coverage metrics to the outputs of some lexical substitution systems, and

[3] We do not consider here a related task which assesses whether the *mode* answer m_i is found within an answer set of up to 10 guesses. We do not favour the use of this metric for reasons parallel to those discussed for the *mode* metric of the previous section, i.e. *brittleness* and *information loss*.

[4] In Jabbari *et al.* (2010), we define a metric that directly addresses the ability of systems to achieve good ranking of substitution candidates. This is not itself a measure of lexical substitution task performance, but addresses a component ability that is key to the achievement of lexical substitution tasks.

Model	1	2	3	4	5	6	7	8	9	10

cmlc	.414	.404	.447	.311	.534
KU	.462	.408	.511	.398	.567

Table 1: Out-of-ten recall scores for all the systems (with a subdivision by *pos* of target item).

	All	*By part-of-speech*			
Model	*words*	nouns	adj	verb	adv
bow	.298	.315	.302	.189	.422
lm	.371	.35	.408	.24	.539
cmlc	.395	.383	.419	.31	.506
KU	.435	.379	.477	.385	.536

Table 2: *Optimal* F-scores (macro-avgd) for coverage, computed over the (oot) ranked outputs of the systems (with *penalty factor* $k = 1$).

compare the indication it provides of relative system performance to that of the *oot* metric. We consider three systems described in Jabbari (2010), developed as part of an investigation into the means and benefits of combining models of lexical context: (i) *bow*: a system using a bag-of-words model to rank candidates, (ii) *lm*: using a (simple) n-gram language model, and (iii) *cmlc*: using a model that combines *bow* and *lm* models into one. We also consider the system KU, which uses a very large language model and an advanced treatment of smoothing, and which performed well at ELS07 (Yuret, 2007).[5] Table 1 shows the *oot* scores for these systems, including a breakdown by part-of-speech, which indicate a performance ranking: *bow* $<$ *lm* $<$ *cmlc* $<$ KU

Our first problem is that these systems are developed for the *oot* task, not coverage, so after ranking their candidates, they do not attempt to draw a boundary between the candidates worth returning and those not. Instead, we here use the *oot* outputs to compute an *optimal* performance for each system, i.e. we find, for the ranked candidates of each question, the cut-off position giving the highest F-score, and then average these scores across questions, which tells us the F-score the system could achieve if it had an *optimal boundary strategy*. These scores, shown in Table 2, indicate a ranking of systems in line with that in Table 1, which is not surprising as both will ultimately reflect the quality of candidate ranking achieved by the systems.

Table 3 shows the coverage results achieved by applying a naive boundary strategy to the system outputs. The strategy is just to always return the top n candidates for each question, for a fixed value n. Again, performance correlates straightforwardly with the underlying quality of ranking. Comparing tables, we see, for example, that by always returning 6 candidates, the system KU could achieve a coverage of .32 as compared to the .435 optimal score.

Abstract

We consider the problem of predicting a movie's opening weekend revenue. Previous work on this problem has used metadata about a movie—e.g., its genre, MPAA rating, and cast—with very limited work making use of text *about* the movie. In this paper, we use the text of film critics' reviews from several sources to predict opening weekend revenue. We describe a new dataset pairing movie reviews with metadata and revenue data, and show that review text can substitute for metadata, and even improve over it, for prediction.

1 Introduction

Predicting gross revenue for movies is a problem that has been studied in economics, marketing, statistics, and forecasting. Apart from the economic value of such predictions, we view the forecasting problem as an application of NLP. In this paper, we use the text of critics' reviews to predict opening weekend revenue. We also consider metadata for each movie that has been shown to be successful for similar prediction tasks in previous work.

There is a large body of prior work aimed at predicting gross revenue of movies (Simonoff and Sparrow, 2000; Sharda and Delen, 2006; *inter alia*). Certain information is used in nearly all prior work on these tasks, such as the movie's genre, MPAA rating, running time, release date, the number of screens on which the movie debuted, and the presence of particular actors or actresses in the cast. Most prior text-based work has used automatic text analysis tools, deriving a small number of aggregate statistics. For example, Mishne and Glance (2006) applied sentiment analysis techniques to pre-release and post-release blog posts about movies and showed higher correlation between actual revenue and sentiment-based metrics, as compared to mention counts of the movie. (They did not frame the task as a revenue prediction problem.) Zhang and Skiena (2009) used a news aggregation system to identify entities and obtain domain-specific sentiment for each entity in several domains. They used the aggregate sentiment scores and mention counts of each movie in news articles as predictors.

While there has been substantial prior work on using critics' reviews, to our knowledge all of this work has used polarity of the review or the number of stars given to it by a critic, rather than the review text directly (Terry et al., 2005).

Our task is related to sentiment analysis (Pang et al., 2002) on movie reviews. The key difference is that our goal is to predict a *future* real-valued quantity, restricting us from using any post-release text data such as user reviews. Further, the most important clues about revenue may have little to do with whether the reviewer *liked* the movie, but rather what the reviewer found worth mentioning. This paper is more in the tradition of Ghose et al. (2007) and Kogan et al. (2009), who used text regression to directly quantify review "value" and make predictions about future financial variables, respectively.

Our aim in using the full text is to identify particular words and phrases that predict the movie-going tendencies of the public. We can also perform syntactic and semantic analysis on the text to identify richer constructions that are good predictors. Furthermore, since we consider multiple reviews for each movie, we can compare these features across reviews to observe how they differ both in frequency and predictive performance across different media outlets and individual critics.

In this paper, we use linear regression from text and non-text (meta) features to directly predict gross revenue aggregated over the opening weekend, and the same averaged per screen.

Table 1: Total number of reviews from each domain for the training, development and test sets.

2 Data

We gathered data for movies released in 2005–2009. For these movies, we obtained metadata and a list of hyperlinks to movie reviews by crawling MetaCritic (`www.metacritic.com`). The metadata include the name of the movie, its production house, the set of genres it belongs to, the scriptwriter(s), the director(s), the country of origin, the primary actors and actresses starring in the movie, the release date, its MPAA rating, and its running time. From The Numbers (`www.the-numbers.com`), we retrieved each movie's production budget, opening weekend gross revenue, and the number of screens on which it played during its opening weekend. Only movies found on both MetaCritic and The Numbers were included.

Next we chose seven review websites that most frequently appeared in the review lists for movies at Metacritic, and obtained the text of the reviews by scraping the raw HTML. The sites chosen were the *Austin Chronicle*, the *Boston Globe*, the *LA Times*, *Entertainment Weekly*, the *New York Times*, *Variety*, and the *Village Voice*. We only chose those reviews that appeared on or before the release date of the movie (to ensure that revenue information is not present in the review), arriving at a set of 1718 movies with at least one review. We partitioned this set of movies temporally into training (2005–2007), development (2008) and test (2009) sets. Not all movies had reviews at all sites (see Table 1).

3 Predictive Task

We consider two response variables, both in U.S. dollars: the total revenue generated by a movie during its release weekend, and the *per screen* revenue during the release weekend. We evaluate these predictions using (1) mean absolute error (MAE) in U.S. dollars and (2) Pearson's correlation between the actual and predicted revenue.

We use linear regression to directly predict the opening weekend gross earnings, denoted y, based on features $\boldsymbol{x}$ extracted from the movie metadata and/or the text of the reviews. That is, given an input feature vector $\boldsymbol{x} \in \mathbb{R}^p$, we predict an output $\hat{y} \in \mathbb{R}$ using a linear model: $\hat{y} = \beta_0 + \boldsymbol{x}^\top \boldsymbol{\beta}$. To learn values for the parameters $\boldsymbol{\theta} = \langle \beta_0, \boldsymbol{\beta} \rangle$, the standard approach is to minimize the sum of squared errors for a training set containing n pairs $\langle \boldsymbol{x}_i, y_i \rangle$ where $\boldsymbol{x}_i \in \mathbb{R}^p$ and $y_i \in \mathbb{R}$ for $1 \leq i \leq n$:

$$\hat{\boldsymbol{\theta}} = \operatorname*{argmin}_{\boldsymbol{\theta}=(\beta_0,\boldsymbol{\beta})} \frac{1}{2n} \sum_{i=1}^{n} \Big(y_i - (\beta_0 + \boldsymbol{x}_i^\top \boldsymbol{\beta}) \Big)^2 + \lambda P(\boldsymbol{\beta})$$

A penalty term $P(\boldsymbol{\beta})$ is included in the objective for regularization. Classical solutions use an ℓ_2 or ℓ_1 norm, known respectively as ridge and lasso regression. Introduced recently is a mixture of the two, called the elastic net (Zou and Hastie, 2005):

$$P(\boldsymbol{\beta}) = \textstyle\sum_{j=1}^{p} \left(\frac{1}{2}(1-\alpha)\beta_j^2 + \alpha|\beta_j| \right)$$

where $\alpha \in (0, 1)$ determines the trade-off between ℓ_1 and ℓ_2 regularization. For our experiments we used the elastic net and specifically the `glmnet` package which contains an implementation of an efficient coordinate ascent procedure for training (Friedman et al., 2008).

We tune the α and λ parameters on our development set and select the model with the $\langle \alpha, \lambda \rangle$ combination that yields minimum MAE on the development set.

4 Experiments

We compare predictors based on metadata, predictors based on text, and predictors that use both kinds of information. Results for two simple baselines of predicting the training set mean and median are reported in Table 2 (Pearson's correlation is undefined since the standard deviation is zero).

4.1 Metadata Features

We considered seven types of metadata features, and evaluated their performance by adding them to our pool of features in the following order: whether the film is of U.S. origin, running time (in minutes), the logarithm of its budget, # opening screens, genre (e.g., Action, Comedy) and MPAA rating (e.g., G, PG, PG-13), whether the movie opened on a holiday weekend or in summer months, total count as well as of presence of individual Oscar-winning actors and directors and high-grossing actors. For the first task of predicting the total opening weekend revenue of a movie, the best-performing feature set in terms of MAE turned out to be all the features. However, for the second task of predicting the *per screen* revenue, addition of the last feature subset consisting of information related to the actors and directors hurt performance (MAE increased). Therefore, for the second task, the best performing set contained only the first six types of metadata features.

4.2 Text Features

We extract three types of text features (described below). We only included feature instances that occurred in at least five different movies' reviews. We stem and downcase individual word components in all our features.

I. n-grams. We considered unigrams, bigrams, and trigrams. A 25-word stoplist was used; bigrams and trigrams were only filtered if all words were stopwords.

II. Part-of-speech n-grams. As with words, we added unigrams, bigrams, and trigrams. Tags were obtained from the Stanford part-of-speech tagger (Toutanova and Manning, 2000).

III. Dependency relations. We used the Stanford parser (Klein and Manning, 2003) to parse the critic reviews and extract syntactic dependencies. The dependency relation features consist of just the relation part of a dependency triple ⟨relation, head word, modifier word⟩.

We consider three ways to combine the collection of reviews for a given movie. The first ("$-$") simply concatenates all of a movie's reviews into a single document before extracting features. The second ("$+$") conjoins each feature with the source site (e.g., *New York Times*) from whose review it was extracted. A third version (denoted "B") combines both the site-agnostic and site-specific features.

	Features	**Site**	**Total**		**Per Screen**	
			MAE ($M)	r	**MAE ($K)**	r
	Predict mean		11.672	–	6.862	–
	Predict median		10.521	–	6.642	–
meta	Best		5.983	0.722	6.540	0.272
text	I	$-$	8.013	0.743	6.509	0.222
		$+$	7.722	0.781	6.071	0.466
	see Tab. 3	B	7.627	0.793	6.060	0.411
	I ∪ II	$-$	8.060	0.743	6.542	0.233
		$+$	**7.420**	0.761	6.240	0.398
		B	7.447	0.778	6.299	0.363
	I ∪ III	$-$	8.005	0.744	6.505	0.223
		$+$	7.721	0.785	6.013	**0.473**
		B	7.595	**0.796**	†**6.010**	0.421
meta ∪ text	I	$-$	5.921	**0.819**	6.509	0.222
		$+$	5.757	0.810	6.063	0.470
		B	5.750	**0.819**	6.052	0.414
	I ∪ II	$-$	5.952	0.818	6.542	0.233
		$+$	5.752	0.800	6.230	0.400
		B	5.740	**0.819**	6.276	0.358
	I ∪ III	$-$	5.921	**0.819**	6.505	0.223
		$+$	**5.738**	0.812	6.003	**0.477**
		B	5.750	**0.819**	†**5.998**	0.423

Table 2: Test-set performance for various models, measured using mean absolute error (MAE) and Pearson's correlation (r), for two prediction tasks. Within a column, **boldface** shows the best result among "text" and "meta ∪ text" settings. †Significantly better than the meta baseline with $p < 0.01$, using the Wilcoxon signed rank test.

4.3 Results

Table 2 shows our results for both prediction tasks. For the total first-weekend revenue prediction task, metadata features baseline result ($r^2 = 0.521$) is comparable to that reported by Simonoff and Sparrow (2000) on a similar task of movie gross prediction ($r^2 = 0.446$). Features from critics' reviews by themselves improve correlation on both prediction tasks, however improvement in MAE is only observed for the *per screen* revenue prediction task.

A combination of the meta and text features achieves the best performance both in terms of MAE and r. While the text-only models have some high negative weight features, the combined models do not have any negatively weighted features and only a very few metadata features. That is, the text is able to substitute for the other metadata features.

Among the different types of text-based features that we tried, lexical n-grams proved to be a strong baseline to beat. None of the "I ∪ $*$" feature sets are significantly better than n-grams alone, but adding the dependency relation features (set III) to the n-grams does improve the performance enough to make it significantly better than the metadata-only baseline for per screen revenue prediction.

Salient Text Features: Table 3 lists some of the highly weighted features, which we have categorized manually. The features are from the text-only model annotated in Table 2 (total, not per screen). The feature weights can be directly interpreted as U.S. dollars contributed to the predicted value $\hat{y}$ by each occurrence of the feature. Sentiment-related features are not as prominent as might be expected, and their overall proportion in the set of features with non-zero weights is quite small (estimated in preliminary trials at less than 15%). Phrases that refer to metadata are the more highly weighted and frequent ones. Consistent with previous research, we found some positively-oriented sentiment features to be predictive. Some other prominent features not listed in the table correspond to special effects ("*Boston Globe*: of_the_art", "and_cgi"), particular movie franchises ("shrek_movies", "*Variety*: chronicle_of", "voldemort"), hype/expectations ("blockbuster", "anticipation"), film festival ("*Variety*: canne" with negative weight) and time of release ("summer_movie").

	Feature	**Weight ($M)**

Table 3: Highly weighted features categorized manually. ^ and $ denote sentence boundaries. "brittany" frequently refers to Brittany Snow and Brittany Murphy. "^_producer_brian" refers to producer Brian Grazer (*The Da Vinci Code*, among others).

5 Conclusion

We conclude that text features from pre-release reviews can substitute for and improve over a strong metadata-based first-weekend movie revenue prediction. The dataset used in this paper has been made available for research at `http://www.ark.cs.cmu.edu/movie$-data`.

Using Gaussian Mixture Models to Detect Figurative Language in Context

Linlin Li and Caroline Sporleder
Saarland University, Postfach 15 11 50
66041 Saarbrücken, Germany
{linlin, csporled}@coli.uni-saarland.de

Abstract

We present a Gaussian Mixture model for detecting different types of figurative language in context. We show that this model performs well when the parameters are estimated in an unsupervised fashion using EM. Performance can be improved further by estimating the parameters from a small annotated data set.

1 Introduction

Figurative language employs words in a way that deviates from their normal meaning. It includes idiomatic usage, metaphor, metonymy or other types of creative language. Being able to detect figurative language is important for a number of NLP applications, e.g., machine translation.

Simply checking the input against an idiom dictionary does not solve the problem. While some expressions (e.g., *trip the light fantastic*) are always used idiomatically, many expressions (e.g., *spill the beans*), can take on a literal meaning as well. Whether such expression is used idiomatically or not has to be inferred from the discourse context. Likewise, simple dictionary look-up would not work for truly creative, one-off usages; these can neither be found in a dictionary nor can they be detected by standard idiom extraction methods, which apply statistical measures to accumulated corpus evidence for an expression to assess its 'idiomaticity'. An example of a fairly creative usage can be found in (1), which is a variation of the idiom *put a sock in*.

(1) **Take the sock out of your mouth** and create a brand-new relationship with your mom.

We propose a method for detecting figurative language in context. Because we use context information rather than corpus statistics, our approach works also for truly creative usages.

2 Related Work

Most studies on the detection of idioms and other types of figurative language focus on one of three aspects: type-based extraction (detect idioms on the type level), token-based classification (given a potentially idiomatic phrase in context, decide whether it is used idiomatically), token-based detection (detect figurative expressions in running text).

Type-based extractions exploit the fact that idioms have many properties which differentiate them from other expressions, e.g., they often exhibit a degree of syntactic and lexical fixedness. These properties can be used to identify potential idioms, for instance, by employing measures of association strength between the elements of an expression (Lin, 1999).

Type-based approaches are unsuitable for expressions which can be used both figuratively and literally. These have to be disambiguated in context. *Token-based classification* aims to do this. A number of token-based approaches have been proposed: supervised (Katz and Giesbrecht, 2006), weakly supervised (Birke and Sarkar, 2006), and unsupervised (Fazly et al., 2009; Sporleder and Li, 2009).

Finally, *token-based detection* can be viewed as a two stage task which is the combination of type-based extraction and token-based classification. There has been relatively little work on this so far. One exception are Fazly et al. (2009) who detect idiom types by using statistical methods that model the general idiomaticity of an expression and then combine this with a simple second-stage process that detects whether the target expression is used figuratively in a given context, based on whether the expression occurs in canonical form or not.

However, modeling token-based detection as a

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 297–300,
Los Angeles, California, June 2010.

combination of type-based extraction and token-based classification has some drawbacks. First, type-based approaches typically compute statistics from multiple occurrences of a target expression, hence they cannot be applied to novel usages. Second, these methods were developed to detect figuratively used multi-word expressions (MWEs) and do not work for figuratively used individual words, like *sparrow* in example (2). Ideally, one would like to have a generic model that can detect any type of figurative usage in a given context. The model we propose in this paper is one step in this direction.

(2) During the Iraq war, he was a **sparrow**; he didn't condone the bloodshed but wasn't bothered enough to go out and protest.

3 Using Gaussian Mixture Model to Detect Figurative Language

We address the problem by using Gaussian Mixture Models (GMMs). We assume that the literal (l) and non-literal (n) data are generated by two different Gaussians (*literal* and *nonliteral* Gaussian). The token-based detection task is done by comparing which Gaussian has the higher probability of generating a specific instance.

The Gaussian mixture model is defined as:

$$p(x) = \sum_{c \in \{l,n\}} w_c \times N(x|\mu_c, \Sigma_c)$$

Where, c is the category of the Gaussian, μ_c is the mean, Σ_c is the covariance matrix, and w_c is the Gaussian weight.

Our method is based on the insight that figurative language exhibits less semantic cohesive ties with the context than literal language (Sporleder and Li, 2009). We use Normalized Google Distance to model semantic relatedness (Cilibrasi and Vitanyi, 2007) and represent the data by five types of semantic relatedness features $x = (x1, x2, x3, x4, x5)$:

$x1$ is the average relatedness between the target expression and context words,

$$x1 = \frac{2}{|T| \times |C|} \sum_{(w_i, c_j) \in T \times C} relatedness(w_i, c_j)$$

where w_i is a component word of the target expression (T); c_j is one of the context words (C); $|T|$ is the total number of words in the target expression, and $|C|$ is the total number of words in the context. The term $\frac{2}{|T| \times |C|}$ is the normalization factor, which is the total number of relatedness pairs between target component words and context words.

$x2$ is the average semantic relatedness in the context of the target expression,

$$x2 = \frac{1}{\binom{|C|}{2}} \sum_{(c_i, c_j) \in C \times C, i \neq j} relatedness(c_i, c_j)$$

$x3$ is the difference between the average semantic relatedness between the target expression and the context words and the average semantic relatedness of the context (i.e., $x3 = x1 - x2$). It is an indicator of how strongly the target expression is semantically related to the discourse context.

$x4$ is the feature used by Sporleder and Li (2009) for predicting literal or idiomatic use in the cohesion graph based method,

$$x4 = \begin{cases} 1 & \text{if } x3 < 0 \\ 0 & \text{else} \end{cases}$$

$x5$ is a high dimensional vector which represents the top relatedness scores between the component words of the target expression and the context,

$$x5(k) = \max_{(w_i, c_j) \in T \times C} (k, \{relatedness(w_i, c_j)\})$$

where the function $max(k, A)$ is defined to choose the k^{th} highest element from the set A.[1]

The detection task is done by a Bayes decision rule, which chooses the category by maximizing the probability of fitting the data into the different Gaussian components:

$$c(x) = \arg\max_{i \in \{l,n\}} \{w_i \times N(x|\mu_i, \Sigma_i)\}$$

4 Evaluating the GMM Approach

4.1 Data

We evaluate our method on two data sets. The first set (*idiom set*) is taken from Sporleder and Li (2009) and consists of 3964 idiom occurrences (17 idiom types) which were manually labeled as 'literal' or 'figurative'. The second data set (*V+NP set*), consists of a randomly selected sample of 500 V+NP constructions from the Gigaword corpus, which were manually labeled.

To determine how well our model deals with different types of figurative usage, we distinguish four phenomena: *Phrase-level figurative* means that the

[1] We set k to be 100 in our experiment.

whole phrase is used figuratively. We further divide this class into expressions which are potentially ambiguous between literal and figurative usage (**nsa**), e.g., *spill the beans*, and those that are unambiguously figurative irrespective of the context (**nsu**), e.g., *trip the light fantastic*. The latter can, theoretically, be detected by dictionary look-up, the former cannot. The label *token-level figurative* (**nw**) is used when part of the phrase is used figuratively (e.g., *sparrow* in (2)). Often it is difficult to determine whether a word is still used in a 'literal' sense or whether it is already used figuratively. Since we are interested in improving the performance of NLP applications such as MT, we take a pragmatic approach and classify usages as 'figurative' if they are not lexicalized, i.e., if the specific sense is not listed in a dictionary.[2] For example, we would classify *summit* in the 'meeting' sense as 'literal' (**l**). In our data set, 7.3% of the instances were annotated as 'nsa', 1.9% as 'nsu', 9.2% as 'nw' and 81.5% as 'l'. A randomly selected sample (100 instances) was annotated independently by a second annotator. The kappa score (Cohen, 1960) is 0.84, which suggest that the annotations are reliable.

4.2 GMM Estimated by EM

We used the MatLab package provided by Calinon (2009) for estimating the GMM model. The GMM is trained by the EM algorithm. The priors of Gaussian components, means and covariance of each components, are initialized by the k-means clustering algorithm (Hartigan, 1975).

To determine whether the GMM is able to perform token-based idiom classification, we applied it to the idiom data set. The results (see Table 1) show that the GMM can distinguish usages quite well and gains equally good results as Sporleder and Li's cohesion graph method (*Co-Graph*). In addition, this method can deal with unobserved occurrences of non-literal language.

Table 2 shows the results on the second data set. The baseline predicts 'idiomatic' and 'literal' according to a biased probability which is based on the true distribution in the annotated set. *GMM* shows the performance on the whole V+NP set. We also split the test set into three different subsets to determine how the GMM performs on distinguishing literal usage from the different types of figurative usage: *GMM{nsu, l}*, *GMM{nsa, l}*, *GMM{nw, l}*.

Model	C	Pre.	Rec.	F-S.	Acc.
Co-Graph	n	90.55	80.66	85.32	78.38
	l	50.04	69.72	58.26	
GMM	n	90.69	80.66	85.38	78.39
	l	50.17	70.15	58.50	

Table 1: Results on the idiom data set, n(on-literal) is the union of the predefined three sub-classes (nsu, nsa, nw), l(iteral), Acc(uracy), Pre(cision), Rec(all), F-S(core)

Model	C	Pre.	Rec.	F-S.	Acc.
Baseline	n	21.79	22.67	22.22	71.87
	l	83.19	82.47	82.83	
Co-Graph	n	37.29	84.62	51.76	70.92
	l	95.12	67.83	79.19	
GMM	n	40.71	73.08	52.29	75.41
	l	92.58	75.94	83.44	
GMM{nsu,l}	n	8.79	1.00	16.16	76.49
	l	1.00	75.94	86.33	
GMM{nsa,l}	n	22.43	77.42	34.78	76.06
	l	97.40	75.94	85.34	
GMM{nw,l}	n	23.15	64.10	34.01	74.74
	l	94.93	75.94	84.38	

Table 2: Results on the V+NP data set, Gaussian component parameters estimated by EM

The unsupervised GMM model beats the baseline and achieves good results on the V+NP data set. It also outperforms the Co-Graph approach, which suggests that the statistical model, GMM, is more likely to boost the performance by capturing statistical properties of the data for more difficult cases (*idioms* vs. *general figurative usages*), compared with the Co-Graph approach.

In conclusion, the model is not only able to classify idiomatic expressions but also to detect new figurative expressions. However, the performance on the second data set is worse compared with running the same model on the idiom data set. This is because the V+NP data set contains more difficult examples, e.g., expressions which are only partially figurative (e.g., (2)). One would expect the literal part of the expression to exhibit cohesive ties with the context, hence the cohesion based features may fail to detect this type of figurative usage. Consequently the performance of the GMM is lower for figuratively used words ('nw') than for idioms ('nsa', 'nsu'). However, even for 'nw' cases the model still obtains a relatively high accuracy.

[2] We used `http://www.askoxford.com`.

4.3 GMM estimated from Annotated Data

In a second experiment, we tested how well the GMM performs when utilizing the annotated idiom data set to estimate the two Gaussian components instead of using EM. We give equal weights to the two Gaussian components and predict the label on the V+NP data set by fixing the mixture model which is estimated from the training set (GMM+f). This method further improves the performance compared to the unsupervised approach (Table 3).

We also experimented with setting a threshold and abstaining from making a prediction when the probability of an instance belonging to the Gaussian is below the threshold (GMM+f+s). Table 3 shows the performance when only evaluating on the subset for which a classification was made. It can be seen that the accuracy and the overall performance on the literal class improve, but the precision for the non-literal class remains relatively low, i.e., many literal instances are still misclassified as 'non-literal'. One reason for this may be that there are a few instances containing named entities, which exhibit weak cohesive ties with the context even if though they are used literally. Using a named-entity tagger before applying the GMM might solve the problem.

Model	C	Pre.	Rec.	F-S.	Acc.
GMM+f	n	42.22	73.08	53.52	76.60
	l	92.71	77.39	84.36	
GMM+f+s	n	41.38	54.55	47.06	83.44
	l	92.54	87.94	90.18	

Table 3: Results on the V+NP data set, Gaussian component parameters estimated by annotated data

Finally, Table 4 shows the result when using different idioms to generate the nonliteral Gaussian. The literal Gaussian can be generated from the automatically obtained nonliteral examples by Li and Sporleder (2009). We found the estimation of the GMM is not sensitive to idioms; our model is robust and can use any existing idiom data to discover new figurative expressions. Furthermore, Table 4 also shows that the GMM does not need a large amount of annotated data for parameter estimation. A few hundred instances are sufficient.

5 Conclusion

We described a GMM based approach for detecting figurative expressions. This method not only works for distinguishing literal and non-literal usages of a potential idiomatic expression in a discourse context, but also discovers new figurative expressions.

Train (size)	C	Pre.	Rec.	F-S.	Acc.
bite one's tongue (166)	n	40.79	79.49	53.91	74.94
	l	94.10	73.91	82.79	
break the ice (541)	n	39.05	52.56	44.81	76.12
	l	88.36	81.45	84.77	

Table 4: Results on the V+NP dataset, Gaussian component parameters estimated on different idioms

The components of the GMM can be effectively estimated using the EM algorithm. The performance can be further improved when employing an annotated data set for parameter estimation. Our results show that the estimation of Gaussian components are not idiom-dependent. Furthermore, a small annotated data set is enough to obtain good results.

Abstract

We investigate methods of generating additional bilingual phrase pairs for a phrase-based decoder by translating short sequences of source text. Because our translation task is more constrained, we can use a model that employs more linguistically rich features than a traditional decoder. We have implemented an example of this approach. Experimental results suggest that the phrase pairs produced by our method are useful to the decoder, and lead to improved sentence translations.

1 Introduction

Recently, there have been a number of successful attempts at improving phrase-based statistical machine translation by exploiting linguistic knowledge such as morphology, part-of-speech tags, and syntax. Many translation models use such knowledge before decoding (Xia and McCord, 2004) and during decoding (Birch et al., 2007; Gimpel and Smith, 2009; Koehn and Hoang, 2007; Chiang et al., 2009), but they are limited to simpler features for practical reasons, often restricted to conditioning left-to-right on the target sentence. Traditionally, n-best rerankers (Shen et al., 2004) have applied expensive analysis after the translation process, on both the source and target side, though they suffer from being limited to whatever is on the n-best list (Hasan et al., 2007).

We argue that it can be desirable to pre-translate parts of the source text before sentence-level decoding begins, using a richer model that would typically be out of reach during sentence-level decoding. In this paper, we describe a particular method of generating additional bilingual phrase pairs for a new source text, using what we call *phrase prototypes*, which are are learned from bilingual training data. Our goal is to generate improved translations of relatively short phrase pairs to provide the SMT decoder with better phrasal choices. We validate the idea through experiments on Arabic-English translation. Our method produces a 1.3 BLEU score increase (3.3% relative) on a test set.

2 Approach

Re-ranking tends to use expensive features of the entire source and target sentences, s and t, and alignments, a, to produce a score for the translation. We will call this scoring function $\phi(s, t, a)$. While $\phi(\cdot)$ might capture quite a bit of linguistic information, it can be problematic to use this function for decoding directly. This is due to both the expense of computing it, and the difficulty in using it to guide the decoder's search. For example, a choice of $\phi(\cdot)$ that relies on a top-down parser is difficult to integrate into a left-to-right decoder (Charniak et al., 2003).

Our idea is to use an expensive scoring function to guide the search for potential translations for *part* of a source sentence, S, even if translating all of it isn't feasible. We can then provide these translations to the decoder, along with their scores, to incorporate them as it builds the complete translation of S. This differs from approaches such as (Och and Ney, 2004) because we generate new phrase pairs in isolation, rather than incorporating everything into the sentence-level decoder. The baseline system is the Moses phrase-based translation system (Koehn

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 301–304,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

et al., 2007).

2.1 Description of Our Scoring Function

For this work, we consider a scoring function based on part-of-speech (POS) tags, $\phi_{POS}(\cdot)$. It operates in two steps: it converts the source and target phrases, plus alignments, into what we call a *phrase prototype*, then assigns a score to it based on how common that prototype was during training.

Each phrase pair prototype is a tuple containing the source prototype, target prototype, and alignment prototype, respectively. The source and target prototypes are a mix of surface word forms and POS tags, such as the Arabic string $\langle$`NN Al JJ`$\rangle$, or the English string $\langle$`NN NN`$\rangle$. For example, the source and target prototypes above might be used in the phrase prototype $\langle \texttt{NN}_0\ \texttt{Al}\ \texttt{JJ}_1\ ,\ \texttt{NN}_1\ \texttt{NN}_0 \rangle$, with the alignment prototype specified implicitly via subscripts for brevity. For simplicity, the alignment prototype is restricted to allow a source or target word/tag to be unaligned, plus 1:1 alignments between them. We do not consider 1:many, many:1, or many:many alignments in this work.

For any input $\langle s, t, a \rangle$, it is possible to construct potentially many phrase prototypes from it by choosing different subsets of the source and target words to represent as POS tags. In the above example, the Arabic determiner `Al` could be converted into an unaligned POS tag, making the source prototype $\langle$`NN DT JJ`$\rangle$. For this work, we convert all aligned words into POS tags. As a practical concern, we insist that unaligned words are always kept as their surface form.

$\phi_{POS}(s, t, a)$ assign a score based on the probability of the resulting prototypes; more likely prototypes should yield higher scores. We choose:

$$\phi_{POS}(s, t, a) = p(SP, AP|TP) \cdot p(TP, AP|SP)$$

where SP is the source prototype constructed from s, t, a. Similarly, TP and AP are the target and alignment prototypes, respectively.

To compute $\phi_{POS}(\cdot)$, we must build a model for each of $p(SP, AP|TP)$ and $p(TP, AP|SP)$. To do this, we start with a corpus of aligned, POS-tagged bilingual text. We then find phrases that are consistent with (Koehn et al., 2003). As we extract these phrase pairs, we convert each into a phrase prototype by replacing surface forms with POS tags for all aligned words in the prototype.

After we have processed the bilingual training text, we have collected a set of phrase prototypes and a count of how often each was observed.

2.2 Generating New Phrases

To generate phrases, we scan through the source text to be translated, finding any span of source words that matches the source prototype of at least one phrase prototype. For each such phrase, and for each phrase prototype which it matches, we generate all target phrases which also match the target and alignment prototypes.

To do this, we use a word-to-word dictionary to generate all target phrases which honor the alignments required by the alignment prototype. For each source word which is aligned to a POS tag in the target prototype, we substitute all single-word translations in our dictionary[1].

For each target phrase that we generate, we must ensure that it matches the target prototype. We give each phrase to a POS tagger, and check the resulting tags against any tags in the target prototype. If there are no mismatches, then the phrase pair is retained for the phrase table, else it is discarded. In the latter case, $\phi_{POS}(\cdot)$ would assign this pair a score of zero.

2.3 Computing Phrase Weights

In the Moses phrase table, each entry has four parameters: two lexical weights, and the two conditional phrase probabilities $p(s|t)$ and $p(t|s)$. While the lexical weights can be computed using the standard method (Koehn et al., 2003), estimating the conditional phrase probabilities is not straightforward for our approach because they are not observed in bilingual training data. Instead, we estimate the *maximum* conditional phrase probabilities that would be assigned by the sentence-level decoder for this phrase pair, as if it had generated the target string from the source string using the baseline phrase table[2]. To do this efficiently, we use some

[1] Since we required that all unaligned target words are kept as surface forms in the target prototype, this is sufficient. If we did not insist this, then we might be faced with the unenviable task of choosing a target languange noun, without further guidance from the source text.

[2] If we use these probabilities for our generated phrase pair's probability estimates, then the sentence-level decoder would see

simplifying assumptions: we do not restrict how often a source word is used during the translation, and we ignore distortion / reordering costs. These admit a simple dynamic programming solution.

We must also include the score from $\phi_{POS}(\cdot)$, to give the decoder some idea of our confidence in the generated phrase pair. We include the phrase pair's score as an additional weight in the phrase table.

3 Experimental Setup

The Linguistic Data Consortium Arabic-English corpus2[3] is used to train the baseline MT system (34K sentences, about one million words), and to learn phrase prototypes. The LDC multi-translation Arabic-English corpus (NIST2003)[4] is used for tuning and testing; the tuning set consists of the first 500 sentences, and the test set consists of the next 500 sentences. The language model is a 4-gram model built from the English side of the parallel corpus, plus the English side of the wmt07 German-English and French-English news commentary data. The baseline translation system is Moses (Koehn et al., 2007), with the `msd-bidirectional-fe` reordering model. Evaluation is done using the BLEU (Papineni et al., 2001) metric with four references. All text is lowercased before evaluation; recasing is not used. We use the Stanford Arabic POS Tagging system, based on (Toutanova et al., 2003)[5]. The word-to-word dictionary that is used in the phrase generation step of our method is extracted from the highest-scoring translations for each source word in the baseline phrase table. For some closed-class words, we use a small, manually constructed dictionary to reduce the noise in the phrase table that exists for very common words. We use this in place of a stand-alone dictionary to reduce the need for additional resources.

4 Experiments

To see the effect on the BLEU score of the resulting sentence-level translation, we vary the amount of bilingual data used to build the phrase prototypes.

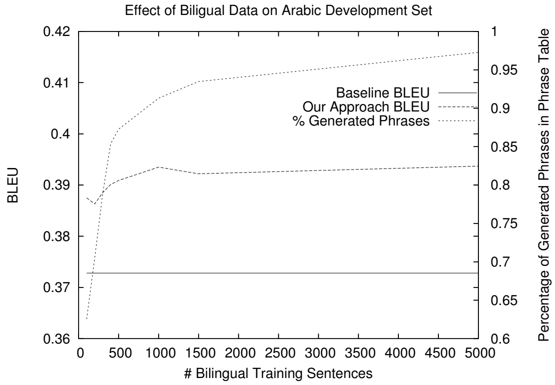

Figure 1: Bilingual training size vs. BLEU score (middle line, left axis) and phrase table composition (top line, right axis) on Arabic Development Set. The baseline BLEU score (bottom line) is included for comparison.

As we increase the amount of training data, we expect that the phrase prototype extraction algorithm will observe more phrase prototypes. This will cause it to generate more phrase pairs, introducing both more noise and more good phrases into the phrase table. Because quite a few phrase prototypes are built in any case, we require that each is seen at least three times before we use it to generate phrases. Phrase prototypes seen fewer times than this are discarded before phrase generation begins. Varying this minimum support parameter does not affect the results noticeably.

The results on the tuning set are seen in Figure 1. The BLEU score on the tuning set generally improves as the amount of bilingual training data is increased, even as the percentage of generated phrases approaches 100%. Manual inspection of the phrase pairs reveals that many are badly formed; this suggests that the language model is doing its job in filtering out disfluent phrases.

Using the first 5,000 bilingual training sentences to train our model, we compare our method to the baseline moses system. Each system was tuned via MERT (Och, 2003) before running it on the test set. The tuned baseline system scores 38.45. Including our generated phrases improves this by 1.3 points to 39.75. This is a slightly smaller gain than exists in the tuning set experiment, due in part that we did not

(approximately) no difference between building the generated phrase using the baseline phrase table, or using our generated phrase pair directly.

run MERT for experiment shown in Figure 1.

5 Discussion

As one might expect, generated phrases both help and hurt individual translations. A sentence that can be translated starting with the phrase “`korea added that the syrian prime minister`” is translated by the baseline system as “`korean | foreign minister | added | that | the syrian`”. While “`the syrian foreign minister`” is an unambiguous source phrase, the baseline phrase table does not include it; the language and reordering models must stitch the translation together. Ours method generates “`the syrian foreign minister`” directly.

Generated phrases are not always correct. For example, a generated phrase causes our system to choose “`europe role`”, while the baseline system picks “`the role of | europe`”. While the same prototype is used (correctly) for reordering Arabic “$\mathtt{NN}_0$ $\mathtt{JJ}_1$” constructs into English as “$\mathtt{NN}_1$ $\mathtt{NN}_0$” in many instances, it fails in this case. The language model shares the blame, since it does not prefer the correct phrase over the shorter one. In contrast, a 5-gram language model based on the LDC Web IT 5-gram counts[6] prefers the correct phrase.

6 Conclusion

We have shown that translating short spans of source text, and providing the results to a phrase-based SMT decoder can improve sentence-level machine translation. Further, it permits us to use linguistically informed features to guide the generation of new phrase pairs.

Putting the User in the Loop: Interactive Maximal Marginal Relevance for Query-Focused Summarization

Jimmy Lin, Nitin Madnani, and **Bonnie J. Dorr**
University of Maryland
College Park, MD 20742, USA
jimmylin@umd.edu, {nmadnani,bonnie}@umiacs.umd.edu

Abstract

This work represents an initial attempt to move beyond "single-shot" summarization to *interactive* summarization. We present an extension to the classic Maximal Marginal Relevance (MMR) algorithm that places a user "in the loop" to assist in candidate selection. Experiments in the complex interactive Question Answering (ciQA) task at TREC 2007 show that interactively-constructed responses are significantly higher in quality than automatically-generated ones. This novel algorithm provides a starting point for future work on interactive summarization.

1 Introduction

Document summarization, as captured in modern comparative evaluations such as TAC and DUC, is mostly conceived as a "one-shot" task. However, researchers have long known that information seeking is an iterative activity, which suggests that an interactive approach might be worth exploring.

This paper present a simple extension of a well-known algorithm, Maximal Marginal Relevance (MMR) (Goldstein et al., 2000), that places the user in the loop. MMR is an iterative algorithm, where at each step a candidate extract c (e.g., a sentence) is assigned the following score:

$$\lambda \mathrm{Rel}(q, c) - (1 - \lambda) \max_{s \in S} \mathrm{Sim}(s, c)$$

The score consists of two components: the relevance of the candidate c with respect to the query q (Rel) and the similarity of the candidate c to each extract s in the current summary S (Sim). The maximum score from these similarity comparisons is subtracted from the relevance score, subjected to a tuning parameter that controls the emphasis on relevance and anti-redundancy. Scores are recomputed after each step and the algorithm iterates until a stopping criterion has been met (e.g., length quota).

We propose a simple extension to MMR: at each step, we interactively ask the user to select the best sentence for inclusion in the summary. That is, instead of the system automatically selecting the candidate with the highest score, it presents the user with a ranked list of candidates for selection.

2 Complex, Interactive QA

One obstacle to assessing the effectiveness of interactive summarization algorithms is the lack of a suitable evaluation vehicle. Given the convergence of complex QA and summarization (particularly the query-focused variant) in recent years, we found an appropriate evaluation vehicle in the ciQA (complex, interactive Question Answering) task at TREC 2007 (Dang et al., 2007).

Information needs in the ciQA task, called topics, consist of two parts: the question template and the narrative. The question template is a stylized information need that has a fixed structure and free slots whose instantiation varies across different topics. The narrative is unstructured prose that elaborates on the information need. For the evaluation, NIST assessors developed 30 topics, grouped into five templates. See Figure 1 for an example.

Participants in the task were able to deploy fully-functional web-based QA systems, with which the

Topic Number: 58
Template: What evidence is there for transport of [opium] from [Afghanistan] to [Europe]?
Narrative: The analyst would like to know the extent to which export of opium from Afghanistan to Europe contributes to heroin addiction in Europe and what efforts are made to interrupt this trade as distinct from destruction of opium poppy crops.

Current Answer:

- As well as being a key route for the smuggling drugs out of Afghanistan to addicts in the Middle East and Europe, he said there was also evidence that precursor chemicals needed to refine opium into heroin were being smuggled through Pakistan into Afghanistan.

Please indicate the next sentence you would add to your answer:

1. The two men arrested were suspected of stacking the opium for transport to Afghanistan, where it was to be processed into heroin.

2. In Thursday's debate in Florida, Democratic candidate Sen. John F. Kerry cited the burgeoning opium crop as evidence of President Bush's ''colossal misjudgment`` in turning his attention from Afghanistan to wage war in Iraq.

3. Police in southern Afghanistan have arrested four men transporting 237 kilograms (521 pounds) of opium, the US military said Friday.

4. Afghanistan is the world's top producer of opium, used to make heroin, and is the source of 90 percent of the heroin on the streets of Europe.

Figure 2: Screenshot of the interface for interactive MMR, which shows the current topic (A), the current answer (B), and a ranked list of document extracts (C).

NIST assessors interacted (serving as surrogates for users). Upon receiving the topics, participants first submitted an initial run. During a pre-arranged period of time shortly thereafter, each assessor was given five minutes to interact with the participant's system, live over the web. After this interaction period, participants submitted a final run, which had presumably gained the benefit of user interaction. By comparing initial and final runs, it was possible to quantify the effect of the interaction.

The target corpus was AQUAINT-2, which consists of around 970k documents totaling 2.5 GB. System responses consisted of multi-line answers and were evaluated using the "nugget" methodology with the "nugget pyramid" extension (Lin and Demner-Fushman, 2006).

3 Experiment Design

This section describes our experiments for the TREC 2007 ciQA task. In summary: the initial run was generated automatically using standard MMR. The web-based interactions consisted of iterations of interactive MMR, where the user selected the best candidate extract at each step. The final run consisted of the output of interactive MMR padded with automatically-generated output.

Sentence extracts were used as the basic response unit. For each topic, the top 100 documents were retrieved from the AQUAINT-2 collection with Lucene, using the topic template verbatim as the query. Neither the template structure nor the narrative text were exploited. All documents were then broken into individual sentences, which served as the pool of candidates. The relevance of each sentence was computed as the sum of the inverse document frequencies of matching terms from the topic template. Redundancy was computed as the cosine similarity between the current answer (consisting of all previously-selected sentences) and the current candidate. The relevance and redundancy scores were then normalized and combined ($\lambda = 0.8$). For the initial run, the MMR algorithm iterated until 25 candidates had been selected.

For interactive MMR, a screenshot of the web-based system is shown in Figure 2. The interface consists of three elements: at the top (label A) is the current topic; in the middle (label B) is the current answer, containing user selections from previous iterations; the bottom area (label C) shows a ranked list of candidate sentences ordered by MMR score. At each iteration, the user is asked to select one candidate by clicking the "Add to answer" button next to that candidate. The selected candidate is then added to the current answer. Ten answer candidates are shown per page. Clicking on a button labeled "Show more candidates" at the bottom of the page (not shown in the screenshot) displays the next ten candidates. In the ciQA 2007 evaluation, NIST assessors engaged with this interface for the entire allotted five minute interaction period. Note that this simple interface was designed only to assess the effectiveness of interactive MMR, and not intended to represent an actual interactive system.

To prevent users from seeing the same sentences repeatedly once a candidate selection has been recorded, we divide the scores of all candidates ranked higher than the selected candidate by two (an

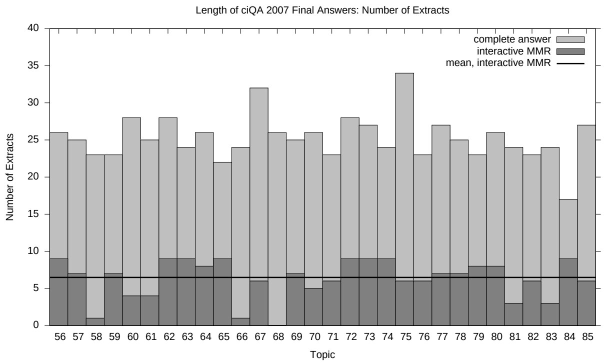

Figure 3: Per-topic lengths of final run in terms of number of extracts. Bars show contribution from interactive MMR (darker) and "padding" (lighter).

arbitrary constant). For example, if the user clicked on candidate five, scores for candidates one through four are cut in half. Previous studies have shown that users generally examine ranked lists in order, so the lack of a selection can be interpreted as negative feedback (Joachims et al., 2007).

The answers constructed interactively were submitted to NIST as the final (post-interaction) run. However, since these answers were significantly shorter than the initial run (given the short interaction period), the responses were "padded" by running additional iterations of automatic MMR until a length quota of 4000 characters had been achieved.

4 Results and Discussion

First, we present descriptive statistics of the final run submitted to NIST. Lengths of the answers on a per-topic basis are shown in Figure 3 in terms of number of extracts: darker bars show the number of manually-selected extracts for each topic during the five-minute interaction period (i.e., the number of interactive MMR iterations). The average across all topics was 6.5 iterations, shown by the horizontal line; the average length of answers (all user selections) was 1186 characters. The average rank of the user selection was 4.9, and the user selected the top ranking sentence 28% of the time. Note that the interaction period included system processing as well as delays caused by network traffic. The number of extracts contained in the padding is shown by the lighter gray portions of the bars. For topic 68, the system did not record any user interactions (possibly resulting from a network glitch).

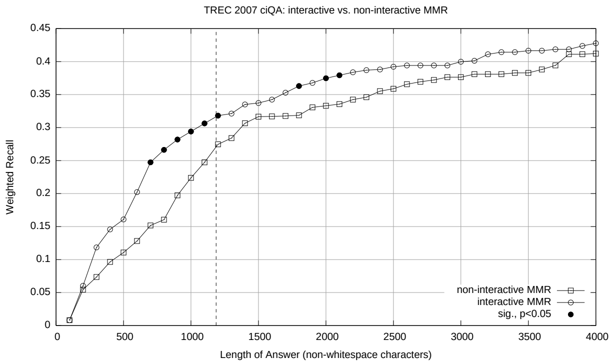

Figure 4: Weighted recall at different length increments, comparing interactive and non-interactive MMR.

The official metric for the ciQA task was F-measure, but a disadvantage of this single-point metric is that it doesn't account for answers of varying lengths. An alternative proposed by Lin (2007) and used as the secondary metric in the evaluation is recall-by-length plots, which characterize weighted nugget recall at varying length increments. Weighted recall captures how much relevant information is contained in the system response (weighted by each nugget's importance, with an upper bound of one). Responses that achieve higher nugget recall at shorter length increments are desirable in providing concise, informative answers.

Recall-by-length plots for both the initial run (non-interactive MMR) and final run (interactive MMR with padding) are shown in Figure 4, in length increments of 1000 characters. The vertical dotted line denotes the average length of interactive MMR answers (without padding). Taking length as a proxy for time, one natural interpretation of this plot is how quickly users are able to "learn" about the topic of interest under the two conditions.

We see that interactive MMR yields higher weighted recall at all length increments. The Wilcoxon signed-rank test was applied to assess the statistical significance of the differences in weighted recall at each length increment. Solid circles in the graph represent improvements that are statistically significant ($p < 0.05$). Furthermore, in the 700–1000 character range, weighted recall is significantly higher for interactive MMR at the 99% level.

Viewing weighted recall as a proxy for answer quality, interactive MMR yields responses that are significantly better than non-interactive MMR at a range of length increments. This is an important finding, since effective interaction techniques that require little training and work well in limited-duration settings are quite elusive. Often, user input actually makes answers worse. Results from both ciQA 2006 and ciQA 2007 show that, overall, F-measure improved little between initial and final runs. Although it is widely accepted that user feedback can enhance interactive IR, effective interaction techniques to exploit this feedback are by no means obvious.

To better understand the characteristics of interactive MMR, it is helpful to compare our experiments with the ciQA task-wide baseline. As a reference for all participants, the organizers of the task submitted a pair of runs to help calibrate effectiveness. According to Dang et al. (2007), the first run was prepared by submitting the question template verbatim as a query to Lucene to retrieve the top 20 documents. These documents were then tokenized into individual sentences. Sentences that contained at least one non-stopword from the question were retained and returned as the initial run (up to a quota of 5,000 characters). Sentence order within each document and across the ranked list was preserved. The interaction associated with this run asked the assessor for relevance judgments on each of the sentences. Three options were given: “relevant”, “not relevant”, and “no opinion”. The final run was prepared by removing sentences judged not relevant.

Other evidence suggests that the task-wide sentence retrieval algorithm represents a strong baseline. Similar algorithms performed well in other complex QA tasks—in TREC 2003, a sentence retrieval variant beat all but one run on definition questions (Voorhees, 2003). The sentence retrieval baseline also performed well in ciQA 2006.

The MMR runs are compared to the task-wide reference runs in Figure 5: diamonds denote the sentence retrieval baseline and triangles mark the manual sentence selection final run. The manual sentence selection run outperforms the sentence retrieval baseline (as expected), but its weighted recall is still below that of interactive MMR across almost all length increments. The weighted recall of interactive MMR is significantly better at 1000 characters (at the 95% level), but nowhere else. So, the bottom line is: for limited-duration interactions, interactive MMR is more effective than simply asking for relevance judgments, but not significantly so.

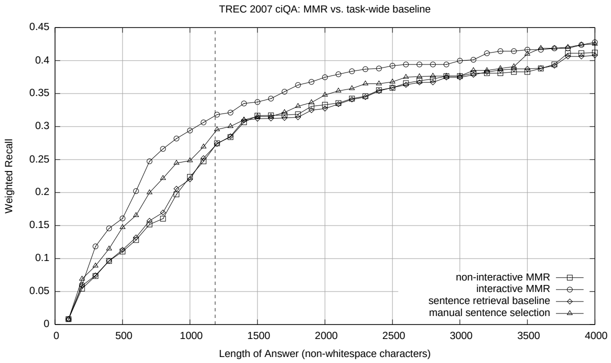

Figure 5: Weighted recall at different length increments, comparing MMR with the task-wide baseline.

5 Conclusion

We present an interactive extension of the Maximal Marginal Relevance algorithm for query-focused summarization. Results from the TREC 2007 ciQA task demonstrate it is a simple yet effective technique for involving users in interactively constructing responses to complex information needs. These results provide a starting point for future work in interactive summarization.

Abstract

In this paper we examine different linguistic features for sentimental polarity classification, and perform a comparative study on this task between blog and review data. We found that results on blog are much worse than reviews and investigated two methods to improve the performance on blogs. First we explored information retrieval based topic analysis to extract relevant sentences to the given topics for polarity classification. Second, we adopted an adaptive method where we train classifiers from review data and incorporate their hypothesis as features. Both methods yielded performance gain for polarity classification on blog data.

1 Introduction

Sentimental analysis is a task of text categorization that focuses on recognizing and classifying opinionated text towards a given subject. Different levels of sentimental analysis has been performed in prior work, from binary classes to more fine grained categories. Pang et al. (2002) defined this task as a binary classification task and applied it to movie reviews. More sentiment classes, such as document objectivity and subjectivity as well as different rating scales on the subjectivity, have also been taken into consideration (Pang and Lee, 2005; Boiy et al., 2007). In terms of granularity, this task has been investigated from building word level sentiment lexicon (Turney, 2002; Moilanen and Pulman, 2008) to detecting phrase-level (Wilson et al., 2005; Agarwal et al., 2009) and sentence-level (Riloff and Wiebe, 2003; Hu and Liu, 2004) sentiment orientation. However, most previous work has mainly focused on reviews (Pang et al., 2002; Hu and Liu, 2004), news resources (Wilson et al., 2005), and multi-domain adaptation (Blitzer et al., 2007; Mansour et al., 2008). Sentiment analysis on blogs (Chesley et al., 2005; Kim et al., 2009) is still at its early stage.

In this paper we investigate binary polarity classification (positive vs. negative). We evaluate the genre effect between blogs and review data and show the difference of feature effectiveness. We demonstrate improved polarity classification performance in blogs using two methods: (a) integrating topic relevance analysis to perform topic specific polarity classification; (b) adopting an adaptive method by incorporating multiple classifiers' hypotheses from different review domains as features. Our manual analysis also points out some challenges and directions for further study in blog domain.

2 Features for Polarity Classification

For the binary polarity classification task, we use a supervised learning framework to determine whether a document is positive or negative. We used a subjective lexicon, containing 2304 positive words and 4145 negative words respectively, based on (Wilson et al., 2005). The features we explored are listed below.

(i) Lexical features (LF)

We use the bag of words for the lexical features as they have been shown very useful in previous work.

(ii) Polarized lexical features (PL)

We tagged each sentiment word in our data set with its polarity tag based on the sentiment lexicon ("POS" for positive, and "NEG" for negative), along with its part-of-speech tag. For example, in the sentence "It is good, and I like it", "good" is tagged as "POS/ADJ", "like" is tagged as "POS/VRB". Then we encode the number of the polarized tags in a document as features.

(iii) Polarized bigram features (PB)

Contextual information around the polarized words can be useful for sentimental analysis. A word may flip the polarity of its neighboring sentiment words even though this word itself is not necessarily a negative word. For example, in "Given her sudden celebrity with those on the left..." (a sentence in a political blog), "sudden" preceding "celebrity" implies the author's negative attitude towards "her". We combine the sentiment word's polarized tag and its following and preceding word or its part-of-speech to comprise different bigram features to represent this kind of contextual information. For ex-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 309–312,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

ample, in “I recommend this.”, “recommend” is a positive verb, denoted as “POS/VRB”, and the bigram features including this tag and its previous word “I” are “I_POS/VRB” and “pron_POS/VRB”.

(iv) Transition word features (T)

Transition words, such as “although”, “even though”, serve as function words that may change the literal opinion polarity in the current sentence. This information has not been widely explored for sentiment analysis. In this study, we compiled a transition word list containing 31 words. We use the co-occurring feature between a transition word and its nearby content words (noun, verb, adjective and adverb) or polarized tags of sentiment words within the same sentence, but not spanning over other transition words. For example, in “Although it is good”, we use features like “although_is”,“although_good” and “although_POS/ADJ”, where “POS/ADJ” is the PL feature for word “good”.

3 Feature Effectiveness on Blogs and Reviews

The blog data we used is from the TREC Blog Track evaluation in 2006 and 2007. The annotation was conducted for the 100 topics used in the evaluation (blogs are relevant to a given topic and also opinionated). We use 6,896 positive and 5,300 negative blogs. For the review data, we combined multiple review data sets from (Pang et al., 2002; Blitzer et al., 2007) together. It contains reviews from movies and four product domains (kitchen, electronics, books, and dvd), each of which has 1000 negative and 1000 positive samples. For the data without sentence information (e.g., blog data, some review data), we generated sentences using the maximum entropy sentence boundary detection tool[1]. We used TnT tagger to obtain the part-of-speech tags for these data sets.

For classification, we use the maximum entropy classifier[2] with a Gaussian prior of 1 and 100 iterations in model training. For all the experiments below, we use a 10-fold cross validation setup and report the average classification accuracy. Table 1 shows classification results using various feature sets on blogs and review data. We keep the lexical feature (LF) as a base feature, and investigate the effectiveness of adding more different features. We used Wilcox signed test for statistical significance test. Symbols “†” and “§” in the table indicate the significant level of 0.05 and 0.1 respectively, compared to the baseline performance using LF feature setup.

For the review domain, most of the feature sets can significantly improve the classification performance over the baseline of using “LF” features. “PB” features yielded more significant improvement than “PL” or “T” feature categories. Combining “PL” and “T” features resulted in some slight further improvement, achieving the best accuracy of 83.94%. We notice that incorporating our proposed transition feature (T) always achieves some gain on different feature settings, suggesting that those transition features are useful for sentimental analysis on reviews.

Feature Set	Blogs	Reviews
LF	72.07	81.67
LF+PL	70.93	81.93
LF+PB	72.44	83.62†
LF+T	72.17	81.76
LF+PL+PB	70.81	83.61†
LF+PL+T	72.74	82.13§
LF+PB+T	72.29	83.73†
LF+PL+PB+T	71.85	83.94†

Table 1: Polarity classification results (accuracy in %) using different features for blogs and reviews.

From Table 1, we can see that overall the performance on blogs is worse than on the review data. We hypothesize this may be due to the large variation in terms of contents and styles in blogs. Regarding the feature effectiveness, we also observe some differences between blogs and reviews. Adding the polarized bigram feature and transition feature (PB and T) individually can yield some improvement; however, adding both of them did not result in any further improvement – performance degrades compared to LF+PB. Interestingly, although “PL” feature alone does not seem to help, by adding “PL” and “T” together, the performance achieved the best accuracy of 72.74%. We also found that adding all the features together hurts the performance, suggesting that different features interact with each other and some do not combine well (e.g., PB and T features). In addition, all the improvements here are not statistically significant.

Note that for the blog data, we randomly split them for the cross validation experiments regardless of the queries. In order to better understand whether the poor results on blog data is due to the effect of different queries, we performed another experiment where for each query, we randomly divided the corresponding blogs into training and test splits. Only 66 queries were kept for this experiments – we did not include those queries that have fewer than 10 relevant blogs. The results for the query balanced split on blogs are shown in Figure 1. We also include results for the five individual review data sets in order to see the topic effect. We present results using four representative feature sets chosen according to Table 1. For the review data, we notice some difference across different data sets, suggesting their inherent difference in terms of task difficulty. We observe slight performance increase for some feature sets using the query balanced setup for blog data, but overall it is still much worse than the review data. This shows that the query unbalanced training/test split does not explain the performance gap between blogs and reviews. This is consistent with (Zhang et al., 2007) that found that a query-independent classifier performs even better than query-dependent one. We expect that the

[1] http://stp.ling.uu.se/~gustav/java/classes/MXTERMINATOR.html

[2] http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html

query unbalanced setup is more realistic, therefore, in the following experiments, we continue with this setup.

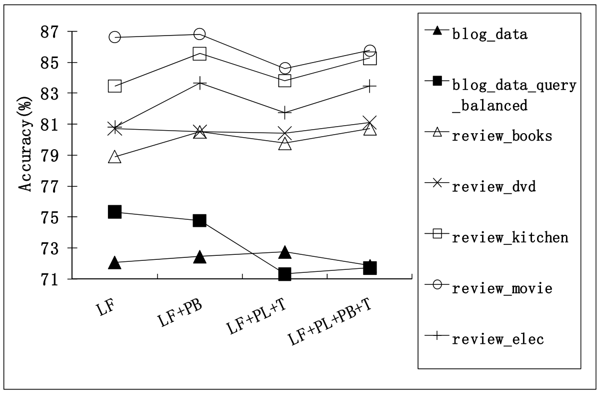

Figure 1: Polarity classification results on query balanced blog data and five individual review data sets.

4 Improving Blog Polarity Classification

To improve the performance of polarity classification on blogs, we propose two methods: (a) extract only topic-relevant segments from blogs for sentiment analysis; (b) apply adaptive methods to leverage review data.

4.1 Using topic-relevant blog context

Generally a review is written towards one product or one kind of service, but a blog may cover several topics with possibly different opinions towards each topic. The blog data we used is annotated based on some specific topics in the TREC Blog Track evaluation. Take topic 870 in the data as an example, "Find opinions on alleged use of steroids by baseball player Barry". There is one blog that talks about 5 different baseball players in issues of using steroids. Since the reference opinion tag of a blog is determined by polarity towards the given query topic, it might be confusing for the classifier if we use the whole blog to derive features. Recently topic analysis has been used for polarity classification (Zhang et al., 2007; Titov and McDonald, 2008; Wiegand and Klakow, 2009). We take a different approach in this study.

In order to obtain a topic-relevant context, we retrieved the top 10 relevant sentences corresponding to the given topic using the Lemur toolkit[3]. Then we used these sentences and their immediate previous and following sentences for feature extraction in the same way as what we did on the whole blog. In addition to using all the words in the relevant context, we also investigated using only content words since those are more topic indicative than function words. We extracted content words (nouns, verbs, adjectives and adverbs) from each blog in their original order and apply the same feature extraction process as for using all the words.

Table 2 shows the blog polarity classification results using the whole blog vs. relevant context composed of all the words or only content words. For the significance test, the comparison was done for using relevant context with all the words vs. using the whole blog; and using content words only vs. using all the words in relevant context. Each comparison was with respect to the same feature setup. We observe improved polarity classification performance when using sentence retrieval based topic analysis to extract relevant context. Using all the words in the topic relevant context, all the improvements compared to using the original entire blog are statistically significant at the level of 0.01. We also notice that unlike on the entire blog document, the "PL" features contribute positively when combined with "LF". All the feature settings with "PL" perform very well. The best accuracy of 75.32% is achieved using feature combination of "LF+PL" or "LF+PL+T". This suggests that polarized lexical features suffered from the off-topic content when using the entire blog and are more useful within contexts of certain topics.

When using content words only, we observe consistent gain across all the feature sets. Three feature settings, "LF+PB","LF+T" and "LF+PL+PB+T", achieve statistically significant further improvement (compared to using all the words of relevant contexts). The best accuracy (75.6%) is achieved by using the "LF+PB" features.

Feature Set	Whole Blog	Relevant Context	
		All Words	Content Words
LF	72.07	74.92†	75.14
LF+PL	70.93	75.32†	75.34
LF+PB	72.44	75.03†	75.6†
LF+T	72.17	75.01†	75.35§
LF+PL+PB	70.81	75.27†	75.35
LF+PL+T	72.74	75.32†	75.41
LF+PB+T	72.29	75.17†	75.42
LF+PL+PB+T	71.85	75.21†	75.45§

Table 2: Blog polarity classification results (accuracy in %) using topic relevant context composed of all the words or only content words.

4.2 Adaptive methods using review data

Domain adaptation has been studied in some previous work (e.g., (Blitzer et al., 2007; Mansour et al., 2008)). In this paper, we evaluate two adaptive approaches in order to leverage review data to improve blog polarity classification. In the first approach, in each of the 10-fold cross-validation training, we pool the blog training data (90% of the entire blog data) together with all the review data from 5 different domains. In the second method, we augment features with hypotheses obtained from classifiers trained using other domain data. Specifically, we first trained 5 classifiers from 5 review domain data sets respectively, and encoded the hypotheses from different classifiers as features for blog training (together with the original features of the blog data). Results of these two approaches are shown in Table 3. We use the topic rele-

[3] http://www.lemurproject.org/lemur/

vant context with content words only in this experiment, and present results for different feature combinations (except the baseline "LF" setting). The significance test is conducted in comparison to the results using only blog data for training, for the same feature setting.

We find that the first approach does not yield any gain, even though the added data is about the same size as the blog data. It indicates that due to the large difference between the two genres, simply combining blogs and reviews in training is not effective. However, we can see that using augmented features in training significantly improved the performance across different feature sets. The best result is achieved using "LF+T" features, 76.84% compared with the best accuracy of 75.6% when using the blog data only ("LF+PB" features).

Feature Set	Only Blog	Pool Data	Augment Features
LF+PL	75.34	75.05	76.12†
LF+PB	75.6	74.35	76.28†
LF+T	75.35	74.47	76.84†
LF+PL+PB	75.35	74.94	76.7†
LF+PL+T	75.41	74.85	76.32†
LF+PB+T	75.42	74.46	76.3†
LF+PL+PB+T	75.45	74.96	76.53†

Table 3: Results (accuracy in %) of blog polarity classification using two methods leveraging review data.

4.3 Error analysis

Notice that after achieving some improvements the performance on blogs is still much worse than on review data. Thus we performed a manual error analysis for a better understanding of the difficulties of sentiment analysis on blog data, and identified the following challenges.

(a) Idiomatic expressions. Compared to reviews, bloggers seem to use more idioms. For example, "Of course he has me over the barrel..." expresses negative opinion, however, there are no superficially indicative features.

(b) Ironic writing style. Some bloggers prefer ironic style especially when speaking against something or somebody, whereas opinions are often expressed using plain writing style in reviews. Simply using the surface word level features is not able to model these properly.

(c) Background knowledge. In some political blogs, the polarized expressions are implicit. Correctly recognizing them requires background knowledge and deeper language analysis techniques.

5 Conclusions and Future Work

In this paper, we have evaluated various features and the domain effect on sentimental polarity classification. Our experiments on blog and review data demonstrated different feature effectiveness and the overall poorer performance on blogs than reviews. We found that the polarized features and the transition word features we introduced are useful for polarity classification. We also show that by extracting topic-relevant context and considering only content words, the system can achieve significantly better performance on blogs. Furthermore, an adaptive method using augmented features can effectively leverage data from other domains, and yield improvement compared to using in-domain training or training on combined data from different domains. For our future work, we plan to investigate other adaption methods, and try to address some of the problems identified in our error analysis.

Creating Local Coherence: An Empirical Assessment

nenkova@seas.upenn.edu

Abstract

Two of the mechanisms for creating natural transitions between adjacent sentences in a text, resulting in local coherence, involve discourse relations and switches of focus of attention between discourse entities. These two aspects of local coherence have been traditionally discussed and studied separately. But some empirical studies have given strong evidence for the necessity of understanding how the two types of coherence-creating devices interact. Here we present a joint corpus study of discourse relations and entity coherence exhibited in news texts from the Wall Street Journal and test several hypotheses expressed in earlier work about their interaction.

1 Introduction

Coherent discourse is characterized by local properties that are crucial for comprehension. In fact, a long line of linguistics and computational linguistics tradition has proposed that several levels of structure contribute to the creation of coherent discourse. Among these, the attentional structure (Grosz et al., 1995) and the relational structure (Mann and Thompson, 1988) of text, are the most widely discussed in the literature.

Centering theory (Grosz et al., 1995) is the dominant approach for describing and analyzing attentional structure. It assumes that readers of the text focus (center) their attention on a small number of salient discourse entities at a time and that there are preferred patterns for switching attention between entities mentioned in adjacent sentences. Relational structure theories, on the other hand, describe how certain discourse (also called rhetorical or coherence) relations such as CONTRAST and CAUSE are inferred by the reader between adjacent units of text. The existence of richly annotated corpora and the development of automatic applications based on the theories have allowed empirical assessments of the validity and generality of these theories individually.

Such work has also provided increasingly strong evidence that attentional and relational structures need to be taken into account simultaneously. The motivation behind such proposals have been the empirical findings that "weak" discourse relations such as ELABORATION are the most common type of relations, and that a large percentage of adjacent sentences in fact do not have *any* entities in common.

In particular, a corpus based evaluation of Centering theory found that only 42% of pairs of adjacent sentences have at least one entity in common and hypothesized that discourse relations are responsible for creating local coherence in the remaining cases (Poesio et al., 2004). At the same time, the work of Knott et al. (2001) has discussed several theoretical complications arising from the existence of the very common and semantically weak ELABORATION relation. These researchers propose that replacing ELABORATION by an account of entity coherence such as Centering will be most beneficial. But work in information ordering (Karamanis, 2007) has not been able to confirm such claims that better results can be obtained by combining entity coherence with discourse relations.

Till recently, the absence of large corpora annotated for both discourse relations and coreference information has prohibited a detailed joint analysis of attentional and relational structure. We combine two

recently released corpora: discourse relations from the Penn Discourse Treebank and coreference annotations from the OntoNotes corpus, to assess the prevalence and interplay between factors that create local coherence in newspaper text.

Specifically, in our study we examine how three hypotheses formulated in prior work play out in the Wall Street Journal texts in our corpus:

Hypothesis 1 Adjacent sentences that do not share entities are related by non-elaboration discourse relations [Poesio et al. (2004) Sec. 5.2.2 Pg. 354].

Hypothesis 2 Adjacent sentences joined by non-elaboration discourse relation have lower entity coherence: such pairs are less likely to mention the same entities [Knott et al. (2001) Sec. 7 Pg. 10].

Hypothesis 3 Almost all pairs of sentences in a coherent text either share entities or participate in non-elaboration discourse relation (Knott et al., 2001; Poesio et al., 2004).

None of these hypotheses are validated. We find that only 38.65% of pairs that do not share entities participate in "core" relations such as temporal, contingency or comparison; the rate of coreference in these "core" relations is similar to that in weaker elaboration relations; about 30% of all sentence pairs neither share entities nor participate in a "core" discourse relation.

2 Data

In order to jointly analyze both discourse relations and noun phrase coreference between adjacent sentences, we combine annotations from two corpora, OntoNotes and the Penn Discourse Treebank. The two individual corpora are larger, but a smaller subset of 590 Wall Street Journal articles appear in both. All our analysis is for *adjacent sentences within paragraphs* in this subset of texts.

Penn Discourse Treebank The Penn Discourse Treebank (PDTB) (Prasad et al., 2008) is the largest available corpus of annotations for discourse relations, covering one million words of the Wall Street Journal (WSJ). In the PDTB, two kinds of discourse relations are annotated. In *explicit relations*, a discourse connective such as "because", "but" or "so" is present, as in the example below.

[Ex. 1] There is an incredible pressure on school systems and teachers to raise test scores. *So* efforts to beat the tests are also on the rise.

On the other hand, relations can also exist without an explicit signal. In *Ex. 2*, it is clear that the second sentence is the *result* of the event mentioned in the first.

[Ex. 2] In July, the Environmental Protection Agency imposed a gradual ban on virtually all uses of asbestos. By 1997, almost all remaining uses of cancer-causing asbestos will be outlawed.

Such relations are called *implicit relations*. In the PDTB, they are annotated between all adjacent sentences within a paragraph which do not already participate in an explicit discourse relation.

For both implicit and explicit relations, the semantic sense of the discourse relation is assigned from a hierarchy of senses. There are four classes of discourse relations at the topmost general level. The second level senses are shown within parantheses: Comparison (*Concession, Contrast, Pragmatic Concession/Contrast*), Contingency (*Cause, Condition, Pragmatic Cause/Condition*), Temporal (*Asynchronous, Synchronous*) and Expansion (*Alternative, Conjunction, Exception, Instantiation, List, Restatement*).

Some of the adjacent sentences in the texts, however, were found not to have a discourse relation between the events or propositions mentioned in them. Instead, they were related because both sentences mention the same entity, directly or indirectly, and the second sentence provides some further description of that entity. An *Entity Relation (EntRel)* was annotated for such sentence pairs as below.

[Ex. 3] Pierre Vinken, 61 years old, will join the board as a nonexecutive director Nov. 29. Mr. Vinken is chairman of Elsevier N.V., the Dutch publishing group.

OntoNotes For coreference information, we use the WSJ portion of the OntoNotes corpus version 2.9 (Hovy et al., 2006) which contains 590 documents. For these documents, we also have the PDTB annotations available. In OntoNotes, all noun phrases–pronouns, names and nominals are marked for coreference without any limitation to specific semantic categories.

3 Corpus study findings

For ease of presentation in the following analysis, we will call the Expansion and Entity relations "weak" and Temporal, Contingency and Compari-

0 to 100	0.41	500 to 1000	0.50
100 to 200	0.37	above 1000	0.51
200 to 500	0.48		

Table 1: Proportion of sentence pairs that *don't share* any entities for different document lengths (in words)

Type	**Relation**	**No shared entities**
Core	Temporal	122 (2.98)
	Contingency	752 (18.40)
	Comparison	706 (17.27)
Weak	Expansion	1870 (45.74)
	EntRel	638 (15.61)

Table 2: Distribution of the 4088 *non-entity sharing* sentence pairs. The proportions are shown in brackets.

son relations "core", following the intuition that the semantics of the latter class is much more clearly defined. Implicit and explicit relations were not distinguished in the analysis.[1]

Hypothesis 1 The first hypothesis is that adjacent sentences that do not share entities participate in core relations and so remain locally coherent.

Pairs of adjacent sentences that do not share any entities are common. In prior work, Poesio et al. (2004) found that 58% of adjacent sentence pairs in their corpus of museum object descriptions did not have overlapping mentions of any entity. The distribution in the WSJ texts is similar, as seen in Table 1. Depending on the length of the article, 37% to 51% of sentence pairs do not have any entity in common.[2]

Table 2 shows the distribution of discourse relations for the 4088 sentence pairs in the corpus that do not share any entities. Contrary to expectation, the majority of such pairs, 61%, are related by a weak discourse relation. Especially unexpected is the high percentage of *entity relations (EntRel)* that don't have actual entity overlap:

[Ex. 4] All four demonstrators were arrested. The law, which Bush allowed to take effect without his signature, went into force Friday.

[Ex. 5] Authorities in Hawaii said the wreckage of a missing commuter plane with 20 people aboard was spotted in a remote valley on the island of Molokai. There wasn't any evidence of survivors.

Type	**Relation**	**Total**	**Share entities**
Core	Temporal	365	243 (66.57)
	Contingency	1570	818 (52.10)
	Comparison	1477	771 (52.20)
Weak	Expansion	3569	1699 (47.60)
	EntRel	1424	786 (55.20)

Table 3: Rate of *entity sharing*

	Share entities	**No sharing**
core relations	1832 (21.80)	1580 (18.80)
weak relations	2485 (29.56)	2508 (29.84)

Table 4: Total number (proportion) of sentence pairs in the corpus in the given categories

Hypothesis 2 The second hypothesis states that adjacent sentences joined by a core discourse relation are less likely to mention the same entities in comparison to weak relations. But as Table 3 reveals, this is generally not the case.

Adjacent sentences in Temporal relation are very likely to share entities—almost 70% of them do. Over half of all Contingency and Comparison relations also share entities. But, the rates of sharing in Comparison and Contingency relations are significantly lower compared to Entity relations (under a two-sided binomial test). *Ex. 6* shows a Contingency relation without entity sharing.

[Ex. 6] Without machines, good farms can't get bigger. So the potato crop, once 47 million tons, is down to 35.

However, adjacent sentences with Expansion relation turn out least likely to share entities. The entity sharing rates of all the other relations were found to be significantly higher than Expansion.

Hypothesis 3 Finally, we test the hypothesis that the majority of adjacent sentences exhibit coherence because they either share entities or form the arguments of a core discourse relation.

This hypothesis is not supported in the WSJ data (see Table 4): 30% of all sentence pairs are in a weak discourse relation—Expansion or EntRel—and do not have any entities in common. In a sense, neither of the theories of entity or relational coherence can explain what mechanisms create the local coherence for these pairs. In order to glean some insights of how coherence is created there, we examine the behavior of different types of Elaboration relations (Table 5). There is a wide variation between the dif-

[1] For brevity we present combined results for both implicit and explicit relations. However, most of our conclusions remain the same when the two types are distinguished.

[2] There are around 100 documents in each length range.

Alternative	67 (0.63)	Instantiation	490 (0.34)
Restatement	960 (0.56)	List	165 (0.28)
Conjunction	1021 (0.48)	EntRel	1424 (0.55)

Table 5: Total number of different Expansion relations and their coreference probability (in brackets)

ferent types of Expansions.

When the function of an expansion sentence is to provide an *alternative explanation* or *restate* an utterance, the probability of entity overlap is very high and patterns similarily with entity relations (around 60%). Below is an example restatement sentence.

[Ex. 7] $\{$Researchers in Belgium$\}_r$ said $\{$they$\}_r$ have developed a genetic engineering technique for creating hybrid plants for a number of crops, such as cotton, soybeans and rice. $\{$The scientists at Plant Genetic Systems N.V.$\}_r$ isolated a gene that could lead to a generation of plants possessing a high-production trait.

However, the two classes–Instantiation and List largely appear with very little entity overlap, 37% and 29% respectively. An Instantiation relation is used to provide an example and hence has little overlap with the previous sentence (Ex. 8 and 9).

[Ex. 8] There may be a few cases where the law breaking is well pinpointed and so completely non-invasive of the rights of others that it is difficult to criticize it. The case of Rosa Parks, the black woman who refused to sit at the back of the bus, comes to mind as an illustration.

[Ex. 9] The economy is showing signs of weakness, particularly among manufacturers. Exports, which played a key role in fueling growth over the last two years, seem to have stalled.

List relations, on the other hand, connect sentences where each of them elaborates on a common proposition mentioned earlier in the discourse. Here is an example five sentence paragraph with list relations but no entity repetition at all.

> **[Ex. 10]** Designs call for a L-shaped structure with a playground in the center. *[Implicit List]* There will be recreation and movie rooms. *[Implicit List]* Teens will be able to listen to music with headsets. *[Implicit List]* Study halls, complete with reference materials will be available. *[Explicit List]* And there will be a nurse's station and rooms for children to meet with the social workers.

In *Ex. 10,* as well as some others, a broad notion of entity coherence–bridging anaphora can be applied. Poesio et al. (2004) also note this fact, but also say that such instances are very difficult to annotate reliably. Our work is based on coreference annotations which can be marked with considerably high inter-annotator agreement.

4 Conclusions

The recent release of corpora annotated for coreference and discourse relations for the same texts have made possible to empirically assess claims about the interaction between two types of local coherence: relational and entity. We find that about half of the pairs of adjacent sentences do not share any entities at all, and about 60% are related by weak discourse relations. We test the hypothesis from prior work that these two types of coherence are complementary to each other and taken together explain most local coherence. We find that the two types of coherence mechanisms are neither mutually exclusive nor do they explain all the data. Future work in discourse analysis will need to develop better understanding of how the two types of coherence interact.

Abstract

Sentence fusion enables summarization and question-answering systems to produce output by combining fully formed phrases from different sentences. Yet there is little data that can be used to develop and evaluate fusion techniques. In this paper, we present a methodology for collecting fusions of similar sentence pairs using Amazon's Mechanical Turk, selecting the input pairs in a semi-automated fashion. We evaluate the results using a novel technique for automatically selecting a representative sentence from multiple responses. Our approach allows for rapid construction of a high accuracy fusion corpus.

1 Introduction

Summarization and question-answering systems must transform input text to produce useful output text, condensing an input document or document set in the case of summarization and selecting text that meets the question constraints in the case of question answering. While many systems use sentence extraction to facilitate the task, this approach risks including additional, irrelevant or non-salient information in the output, and the original sentence wording may be inappropriate for the new context in which it appears. Instead, recent research has investigated methods for generating new sentences using a technique called *sentence fusion* (Barzilay and McKeown, 2005; Marsi and Krahmer, 2005; Filippova and Strube, 2008) where output sentences are generated by fusing together portions of related sentences.

While algorithms for automated fusion have been developed, there is no corpus of human-generated fused sentences available to train and evaluate such systems. The creation of such a dataset could provide insight into the kinds of fusions that people produce. Furthermore, since research in the related task of sentence compression has benefited from the availability of training data (Jing, 2000; Knight and Marcu, 2002; McDonald, 2006; Cohn and Lapata, 2008), we expect that the creation of this corpus might encourage the development of supervised learning techniques for automated sentence fusion.

In this work, we present a methodology for creating such a corpus using Amazon's Mechanical Turk[1], a widely used online marketplace for crowdsourced task completion. Our goal is the generation of accurate fusions between pairs of sentences that have some information in common. To ensure that the task is performed consistently, we abide by the distinction proposed by Marsi and Krahmer (2005) between *intersection* fusion and *union* fusion. Intersection fusion results in a sentence that contains only the information that the sentences had in common and is usually shorter than either of the original sentences. Union fusion, on the other hand, results in a sentence that contains all information content from the original two sentences. An example of intersection and union fusion is shown in Figure 1.

We solicit multiple annotations for both union and intersection tasks separately and leverage the different responses to automatically choose a representative response. Analysis of the responses shows that our approach yields 95% accuracy on the task of union fusion. This is a promising first step and indicates that our methodology can be applied towards efficiently building a highly accurate corpus for sentence fusion.

2 Related Work

The combination of fragments of sentences on a common topic has been studied in the domain of single document summarization (Jing, 2000; Daumé III and Marcu, 2002; Xie et al., 2008). In contrast to these approaches, sentence fusion was introduced to combine fragments of sentences with common information for multi-document summarization (Barzilay and McKeown, 2005). Automated fusion of sentence pairs has since received attention as an independent task (Marsi and Krahmer, 2005; Filippova and Strube, 2008). Although generic fusion of sentence pairs based on importance does not yield high agreement when performed by humans (Daumé III and Marcu, 2004), fusion in the context of a query has been shown to produce better agreement (Krahmer et al., 2008). We examine similar fusion annotation tasks in this paper, but we asked workers to provide two specific types of fusion, intersection and union, thus avoiding the less specific definition based on importance. Furthermore, as our goal is the generation of corpora, our target for evaluation is *accuracy* rather than agreement.

This work studies an approach to the automatic construction of large fusion corpora using workers through Amazon's Mechanical Turk service. Previous studies using this online task marketplace have shown that the collective judgments of many workers are comparable to those of trained annotators on labeling tasks (Snow et al., 2008) although these judgments can be obtained at a fraction of the cost and effort. However, our task presents an additional challenge: building a corpus for sentence fusion requires workers to enter free text rather than simply choose between predefined options; the results are prone to variation and this makes comparing and aggregating multiple responses problematic.

A. After a decade on the job, Gordon had become an experienced cop.
B. Gordon has a lot of experience in the police force.

Figure 2: An example of sentences that were judged to be too similar for inclusion in the dataset

3 Collection Methodology

Data collection involved the identification of the types of sentence pairs that would make suitable candidates for fusion, the development of a system to automatically identify good pairs and manual filtering of the sentence pairs to remove erroneous choices. The selected sentence pairs were then presented to workers on Mechanical Turk in an interface that required them to manually type in a fused sentence (intersection or union) for each case.

Not all pairs of related sentences are useful for the fusion task. When sentences are too similar, the result of fusion is simply one of the input sentences. For example (Fig. 2), if sentence A contains all the information in sentence B but not vice versa, then B is also their intersection while A is their union and no sentence generation is required. On the other hand, if the two sentences are too dissimilar, then no intersection is possible and the union is just the conjunction of the sentences.

We experimented with different similarity metrics aimed at identifying pairs of sentences that were inappropriate for fusion. The sentences in this study were drawn from clusters of news articles on the same event from the Newsblaster summarization system (McKeown et al., 2002). While these clusters are likely to contain similar sentences, they will contain many more dissimilar than similar pairs and thus a metric that emphasizes precision over recall is important. We computed pairwise similarity between sentences within each cluster using three standard metrics: word overlap, n-gram overlap and cosine similarity. Bigram overlap yielded the best precision in our experiments. We empirically arrived at a lower threshold of .35 to remove dissimilar sentences and an upper threshold of .65 to avoid near-identical sentences, yielding a false-positive rate of 44.4%. The remaining inappropriate pairs were then manually filtered. This semi-automated procedure enabled fast selection of suitable sentence pairs: one person was able to select 30 pairs an hour yielding the 300 pairs for the full experiment in ten hours.

Responses	Intersection	Union
All (1500)	0.49	0.88
Representatives (300)	0.54	0.95

Table 1: Union and intersection accuracy

3.1 Using Amazon's Mechanical Turk

Based on a pilot study with 20 sentence pairs, we designed an interface for the full study. For intersection tasks, the interface posed the question "*How would you combine the following two sentences into a single sentence conveying only the information they have in common?*". For union tasks, the question was "*How would you combine the following two sentences into a single sentence that contains ALL of the information in each?*".

We used all 300 pairs of similar sentences for both union and intersection and chose to collect five worker responses per pair, given the diversity of responses that we found in the pilot study. This yielded a total of 3000 fused sentences with 1500 intersections and 1500 unions.

3.2 Representative Responses

Using multiple workers provides little benefit unless we are able to harness the collective judgments of their responses. To this end, we experiment with a simple technique to select one representative response from all responses for a case, hypothesizing that such a response would have a lower error rate. We test the hypothesis by comparing the accuracy of representative responses with the average accuracy over all responses.

Our strategy for selecting representatives draws on the common assumption used in human computation that human agreement in independently-generated labels implies accuracy (von Ahn and Dabbish, 2004). We approximate agreement between responses using a simple and transparent measure for overlap: cosine similarity over stems weighted by *tf-idf* where *idf* values are learned over the Gigawords corpus[2]. After comparing all responses in a pairwise fashion, we need to choose a representative response. As using the centroid directly might not be robust to the presence of erroneous responses, we first select the pair of responses with the greatest overlap as *candidates* and then choose the candidate which has the greatest total overlap with all other responses.

Errors	Intersection	Union
Missing clause	2	7
Union/Intersection	46	6
S1/S2	21	8
Additional clause	10	1
Lexical	3	1

Table 2: Errors seen in 30 random cases (150 responses)

4 Results and Error Analysis

For evaluating accuracy, fused sentences were manually compared to the original sentence pairs. Due to the time-consuming nature of the evaluation, 50% of the 300 cases were randomly selected for analysis. 10% were initially analyzed by two of the authors; if a disagreement occurred, the authors discussed their differences and came to a unified decision. The remaining 40% were then analyzed by one author. In addition to this high-level analysis, we further analyzed 10% of the cases to identify the the types of errors made in fusion as well as the techniques used and the effect of task difficulty on performance.

The accuracy for intersection and union tasks is shown in Table 1. For both tasks, accuracy of the selected representatives significantly exceeded the average response accuracy. In our error analysis, we found that workers often answered the intersection task by providing a union, possibly due to a misinterpretation of the question. This caused intersection accuracy to be significantly worse than union. We analyzed the impact of this error by computing accuracy on the first 30 cases (10%) without this error and the accuracy for intersection increased 22%.

Error types were categorized as "missing clause", "using union for intersection and vice versa", "choosing an input sentence (S1/S2)", "additional clause" and "lexical error". Table 2 shows the number of occurrences of each in 10% of the cases.

We binned the sentence pairs according to the difficulty of the fusion task for each pair (easy/medium/hard) and found that performance was not dependent on difficulty level; accuracy was relatively similar across bins. We also observed that workers typically performed fusion by selecting one sentence as a base and removing clauses or merging in additional clauses from the other sentence.

[2] LDC Catalog No. LDC2003T05

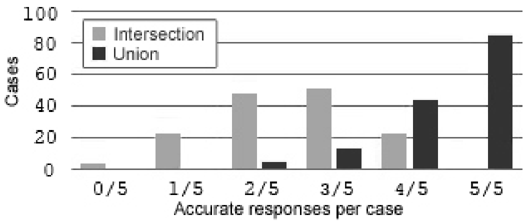

Figure 3: Number of cases in which $x/5$ workers provided accurate responses for fusion

In order to determine the benefit of using many workers, we studied the number of workers who answered correctly for each case. Figure 3 reveals that 2/5 or more workers (summing across columns) responded accurately in 99% of union cases and 82% of intersection cases. The intersection results are skewed due to the question misinterpretation issue which, though it was the most common error, was made by 3/5 workers only 17% of the time. Thus, in the majority of the cases, accurate fusions can still be found using the representative method.

5 Conclusion

We presented a methodology to build a fusion corpus which uses semi-automated techniques to select similar sentence pairs for annotation on Mechanical Turk[3]. Additionally, we showed how multiple responses for each fusion task can be leveraged by automatically selecting a representative response. Our approach yielded 95% accuracy for union tasks, and while intersection fusion accuracy was much lower, our analysis showed that workers sometimes provided unions instead of intersections and we suspect that an improved formulation of the question could lead to better results. Construction of the fusion dataset was relatively fast; it required only ten hours of labor on the part of a trained undergraduate and seven days of active time on Mechanical Turk.

Towards Cross-Lingual Textual Entailment

{mehdad,negri,federico}@fbk.eu

Abstract

This paper investigates *cross-lingual textual entailment* as a semantic relation between two text portions in different languages, and proposes a prospective research direction. We argue that cross-lingual textual entailment (CLTE) can be a core technology for several cross-lingual NLP applications and tasks. Through preliminary experiments, we aim at proving the feasibility of the task, and providing a reliable baseline. We also introduce new applications for CLTE that will be explored in future work.

1 Introduction

Textual Entailment (TE) (Dagan and Glickman, 2004) has been proposed as a generic framework for modeling language variability. Given two texts T and H, the task consists in deciding if the meaning of H can be inferred from the meaning of T. So far, TE has been only applied in a *monolingual* setting, where both texts are assumed to be written in the same language. In this work, we propose and investigate a *cross-lingual* extension of TE, where we assume that T and H are written in different languages.

The great potential of integrating (monolingual) TE recognition components into NLP architectures has been reported in several works, such as question answering (Harabagiu and Hickl, 2006), information retrieval (Clinchant et al., 2006), information extraction (Romano et al., 2006), and document summarization (Lloret et al., 2008).

To the best of our knowledge, mainly due to the absence of cross-lingual TE (CLTE) recognition components, similar improvements have not been achieved yet in any cross-lingual application. As a matter of fact, despite the great deal of attention that TE has received in recent years (also witnessed by five editions of the Recognizing Textual Entailment Challenge[1]), interest for cross-lingual extensions has not been in the mainstream of TE research, which until now has been mainly focused on the English language.

Nevertheless, the strong interest towards cross-lingual NLP applications (both from the market and research perspectives, as demonstrated by successful evaluation campaigns such as CLEF[2]) is, to our view, a good reason to start investigating CLTE, as well. Along such direction, research can now benefit from recent advances in other fields, especially machine translation (MT), and the availability of: *i)* large amounts of parallel and comparable corpora in many languages, *ii)* open source software to compute word-alignments from parallel corpora, and *iii)* open source software to set-up strong MT baseline systems. We strongly believe that all these resources can potentially help in developing inference mechanisms on multilingual data.

Building on these considerations, this paper aims to put the basis for future research on the cross-lingual Textual Entailment task, in order to allow for semantic inference across languages in different NLP tasks. Among these, as a long-term goal, we plan to adopt CLTE to support the alignment of text portions that express the same meaning in different languages. As a possible application scenario, CLTE

can be used to address *content merging* tasks in tidy multilingual environments, such as commercial Web sites, digital libraries, or user generated content collections. Within such framework, as it will be discussed in the last section of this paper, CLTE components can be used for automatic content synchronization in a concurrent, collaborative, and multilingual editing setting, *e.g.* Wikipedia.

2 Cross Lingual Textual Entailment

Adapting the definition of TE we define CLTE as a relation between two natural language portions in different languages, namely a text T (*e.g.* in English), and a hypothesis H (*e.g.* in French), that holds if a human after reading T would infer that H is most likely true, or otherwise stated, the meaning of H can be entailed (inferred) from T.

We can see two main orthogonal directions for approaching CLTE: *i)* simply bring CLTE back to the monolingual case by translating H into the language of T, or vice-versa; *ii)* try to embed cross-lingual processing techniques inside the TE recognition process. In the following, we briefly overview and motivate each approach.

Basic approaches. The simplest approach is to add a MT component to the front-end of an existing TE engine. For instance, let the French hypothesis H be translated into English and then run the TE engine on T and the translation of H. There are several good reasons to follow this divide-and-conquer approach, as well as some drawbacks. Decoupling the cross-lingual and the entailment components results in a simple and modular architecture that, according to well known software engineering principles, results easier to develop, debug, and maintain. Moreover, a decoupled CLTE architecture would allow for easy extensions to other languages as it just requires extra MT systems. Along the same idea of pivoting through English, in fact, the same TE system can be employed to perform CLTE between any language pair, once MT is available from each language into English. A drawback of the decoupled approach is that as MT is still far from being perfect, translation errors are propagated to the TE engine and might likely affect performance. To cope with this issue, we explored the alternative approach of applying TE on a list of *n*-best translations provided by the MT engine, and take a final decision based on some system combination criterion. This latter approach potentially reduces the impact of translation errors, but might significantly increase the computational requirements of CLTE.

Advanced approaches. The idea is to move towards a cross-lingual TE approach that takes advantage of a tighter integration of MT and TE algorithms and techniques. This could result in methods for recognizing TE across languages without translating the texts and, in principle, with a lower complexity. When dealing with phrase-based statistical MT (Koehn et al., 2007), a possible approach is to extract information from the phrase-table to enrich the inference and entailment rules which could be used in a distance based entailment system. As an example the entailment relations between the French phrase "*ordinateur portable*" and the English phrase "*laptop*", or between the German phrase "*europaeischen union*" and the English word "*Europe*" could be captured from parallel corpora through statistical phrase-based MT approaches.

There are several implications that make this approach interesting. First of all, we believe that research on CLTE can employ inference mechanisms and semantic knowledge sources to augment existing MT methods, leading to improvements in the translation quality (*e.g.* (Padó et al., 2009)). In addition, the acquired rules could as well enrich the available multilingual resources and dictionaries such as MultiWordNet[3].

3 Feasibility studies

The main purpose of our preliminary experiments is to verify the feasibility of CLTE, as well as setting baseline results to be further improved over time. To this aim, we started by adopting the basic approach previously discussed. In particular, starting from an English/French corpus of T-H pairs, we automatically translated each H fragment from French into English.

Our decisions build on several motivations. First of all, the reason for setting English and French as a first language pair for experiments is to rely on higher quality translation models, and larger amounts of parallel data for future improvements.

[3] http://multiwordnet.fbk.eu/

Second, the reason for translating the hypotheses is that, according to the notion of TE, they are usually shorter, less detailed, and barely complex in terms of syntax and concepts with respect to the texts. This makes them easier to translate preserving the original meaning. Finally, from an application-oriented perspective, working with English Ts seems more promising due the richness of English data available (*e.g.* in terms of language variability, and more detailed elaboration of concepts). This increases the probability to discover entailment relations with Hs in other languages.

In order to create a realistic and standard setting, we took advantage of the available RTE data, selecting the RTE3 development set and manually translating the hypotheses into French. Since the manual translation requires trained translators, and due to time and logistics constraints, we obtained 520 translated hypotheses (randomly selected from the entire RTE3 development set) which built our bilingual entailment corpus for evaluation.

In the initial step, following our basic approach, we translated the French hypotheses to English using Google[4] and Moses[5]. We trained a phrase-base translation model using Europarl[6] and News Commentary parallel corpora in Moses, applying a 6-gram language model trained on the New York Times portion of the English Gigaword corpus[7].

As a TE engine , we used the EDITS[8] package (Edit Distance Textual Entailment Suite). This system is an open source software package based on edit distance algorithms, which computes the T-H distance as the cost of the edit operations (*i.e.* insertion, deletion and substitution) that are necessary to transform T into H. By defining the edit distance algorithm and a cost scheme (*i.e.* which defines the costs of each edit operation), this package is able to learn a distance model over a set of training pairs, which is used to decide if an entailment relation holds over each test pair.

In order to obtain a monolingual TE model, we trained and tuned (Mehdad, 2009) our model on the RTE3 test set, to reduce the overfitting bias, since our original data was created over the RTE3 development set. Moreover, we used a set of lexical entailment rules extracted from Wikipedia and WordNet, as described in (Mehdad et al., 2009). To begin with, we used this model to classify the created cross-lingual entailment corpus in three different settings: 1) hypotheses translated by Google, 2) hypotheses translated by Moses (1^{st} best), and 3) the original RTE3 monolingual English pairs.

Results reported in Table 1 show that using Google as a translator, in comparison with the original manually-created data, does not cause any drop in performance. This confirms that merely translating the hypothesis using a very good translation model (Google) is a feasible and promising direction for CLTE. Knowing that Google has one of the best French-English translation models, the downtrend of results using Moses translator, in contrast with Google, is not out of our expectation. Trying to bridge this gap brings us to the next round of experiments, where we extracted the n-best translations produced by Moses, to have a richer lexical variability, beneficial for improving the TE recognition. The graph in Figure 1 shows an incremental improvement when the n-best translated hypotheses are used. Besides that, trying to reach a more monotonic distribution of the results, we normalized the ranking score (from 0 to 1) given by Moses, and in each step we chose the first n results over a normalized score. In this way, having the hypotheses with the score of above 0.4, we achieved the highest accuracy of 62.9%. This is exactly equal to adopting the 30-best hypotheses translated by Moses. Using this method, we could improve the performance up to 1.5% above the 1^{st} best results, achieving almost the same level of performance obtained with Google.

	Orig.	**Google**	**Moses** 1st best	**Moses** 30 best	**Moses** > 0.4
Acc.	63.48	63.48	61.37	62.90	62.90

Table 1: Results comparison over 520 test pairs.

4 A possible application scenario

Among the many possible applications, the task of managing textual information in multiple languages represents an ideal application scenario for CLTE. Along such direction, our long-term goal is to use

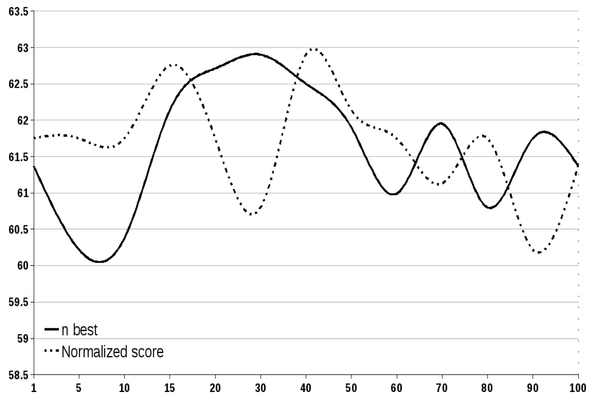

Figure 1: Accuracy gained by *n*-best Moses translations.

CLTE components in the task of *synchronizing* the content of documents about the same topic (*e.g.* Wikipedia articles), written in different languages. Currently, multilingual Wikis rely on users to manually translate different Wiki pages on the same subject. This is not only a time-consuming procedure but also the source of many inconsistencies, as users update the different language versions separately, and every update would require translators to compare the different language versions and synchronize the updates. Our goal is to automate this process by integrating MT and CLTE in a two-step process where: *i)* CLTE is used to identify text portions that should "migrate" from one page to the other, and *ii)* MT is used to actually translate these portions in the appropriate target language.

The adoption of entailment-based techniques to address the multilingual content synchronization task looks promising, as several issues inherent to such task can be formalized as TE-related problems. Given two pages (P1 and P2), these issues include identifying (and then properly managing):

1. Text portions in P1 and P2 that express exactly the same meaning (bi-directional entailment, or semantic equivalence) and which should not migrate across pages;

2. Text portions in P1 that are more specific than portions of P2 (unidirectional entailment between P2 and P1 or vice-versa) and should replace them;

3. Text portions in P1 describing facts that are not present in P2, and which should be added in P2 or vice-versa (the "unknown" cases in RTE parlance);

4. Meaning discrepancies between text portions in P1 and text portions in P2 ("contradictions" in RTE parlance).

5 Conclusion

This paper presented a preliminary investigation towards cross-lingual Textual Entailment, focusing on possible research directions and alternative methodologies. Baseline results have been provided to demonstrate the potentialities of a simple approach that integrates MT and monolingual TE components. Overall, our work sets a novel framework for further studies and experiments to improve cross-lingual NLP tasks. In particular, CLTE can be scaled to more complex problems, such as cross-lingual content merging and synchronization.

Abstract

Sentence retrieval is a very important part of question answering systems. Term clustering, in turn, is an effective approach for improving sentence retrieval performance: the more similar the terms in each cluster, the better the performance of the retrieval system. A key step in obtaining appropriate word clusters is accurate estimation of *pairwise* word similarities, based on their tendency to co-occur in similar contexts. In this paper, we compare four different methods for estimating word co-occurrence frequencies from two different corpora. The results show that different, commonly-used contexts for defining word co-occurrence differ significantly in retrieval performance. Using an appropriate co-occurrence criterion and corpus is shown to improve the mean average precision of sentence retrieval form 36.8% to 42.1%.

1 Corpus-Driven Clustering of Terms

Since the search in Question Answering (QA) is conducted over smaller segments of text than in document retrieval, the problems of data sparsity and exact matching become more critical. The idea of using class-based language model by applying term clustering, proposed by Momtazi and Klakow (2009), is found to be effective in overcoming these problems.

Term clustering has a very long history in natural language processing. The idea was introduced by Brown et al. (1992) and used in different applications, including speech recognition, named entity tagging, machine translation, query expansion, text categorization, and word sense disambiguation. In most of the studies in term clustering, one of several well-know *notions of co-occurrence*—appearing in the same document, in the same sentence or following the same word—has been used to estimate term similarity. However, to the best of our knowledge, none of them explored the relationship between different notions of co-occurrence and the effectiveness of their resulting clusters in an end task.

In this research, we present a comprehensive study of how different notions of co-occurrence impact retrieval performance. To this end, the Brown algorithm (Brown et al., 1992) is applied to pairwise word co-occurrence statistics based on different *definitions* of word co-occurrence. Then, the word clusters are used in a class-based language model for sentence retrieval. Additionally, impact of corpus size and domain on co-occurrence estimation is studied.

The paper is organized as follows. In Section 2, we give a brief description of class-based language model for sentence retrieval and the Brown word clustering algorithm. Section 3 presents different methods for estimating the word co-occurrence. In Section 4, experimental results are presented. Finally, Section 5 summarizes the paper.

2 Term Clustering Method and Application

In language model-based sentence retrieval, the probability $P(Q|S)$ of generating query Q conditioned on a candidate sentence S is first calculated. Thereafter sentences in the search collection are ranked in descending order of this probability. For word-based unigram, $P(Q|S)$ is estimated as

$$P(Q|S) = \prod_{i=1 \ldots M} P(q_i|S), \tag{1}$$

where M is the number of query terms, q_i denotes the i^{th} query term in Q, and S is the sentence model.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 325–328,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

For class-based unigrams, $P(Q|S)$ is computed using only the *cluster labels* of the query terms as

$$P(Q|S) = \prod_{i=1...M} P(q_i|C_{q_i}, S)P(C_{q_i}|S), \qquad (2)$$

where C_{q_i} is the cluster that contains q_i and $P(q_i|C_{q_i}, S)$ is the emission probability of the i^{th} query term given its cluster and the sentence. $P(C_{q_i}|S)$ is analogous to the sentence model $P(q_i|S)$ in (1), but is based on clusters instead of terms. To calculate $P(C_{q_i}|S)$, each cluster is considered an atomic entity, with Q and S interpreted as sequences of such entities.

In order to cluster lexical items, we use the algorithm proposed by Brown et al (1992), as implemented in the SRILM toolkit (Stolcke, 2002). The algorithm requires an input corpus statistics in the form $\langle w, w', f_{ww'}\rangle$, where $f_{ww'}$ is the number of times the word w' is seen in the context w. Both w and w' are assumed to come from a common vocabulary. Beginning with each vocabulary item in a separate cluster, a bottom-up approach is used to merge the pair of clusters that minimizes the loss in *Average Mutual Information* (AMI) between the word cluster $C_{w'}$ and its context cluster C_w. Different words seen in the same contexts are good candidates for merger, as are different contexts in which the same words are seen.

While originally proposed with bigram statistics, the algorithm is *agnostic* to the definition of co-occurrence. E.g. if $\langle w, w'\rangle$ are verb-object pairs, the algorithm clusters verbs based on their selectional preferences, if $f_{ww'}$ is the number of times w and w' appear in the same document, it will produce semantically (or topically) related word-clusters, etc.

Several notions of co-occurrence have been used in the literature to cluster words, as described next.

3 Notions of Word Co-occurrence

Co-occurrence in a Document

If two content words w and w' are seen in the same document, they are usually topically related. In this notion of co-occurrence, how near or far away from each other they are in the document is irrelevant, as is their order of appearance in the document. *Document-wise* co-occurrence has been successfully used in many NLP applications such as automatic thesaurus generation (Manning et al., 2008)

Statistics of document-wise co-occurrence may be collected in two different ways. In the first case, $f_{ww'} = f_{w'w}$ is simply the number of documents that contain both w and w'. This is usually the notion used in ad hoc retrieval. Alternatively, we may want to treat each *instance* of w' in a document that contains an instance of w to be a co-occurrence event. Therefore if w' appears three times in a document that contains two instances of w, the former method counts it as one co-occurrence, while the latter as six co-occurrences. We use the latter statistic, since we are concerned with retrieving sentence sized "documents," wherein a repeated word is more significant.

Co-occurrence in a Sentence

Since topic changes sometimes happen within a single document, and our end task is sentence retrieval, we also investigate the notion of word co-occurrence in a smaller segment of text such as a sentence. In contrast to the document-wise model, *sentence-wise* co-occurrence does not consider whole documents, and only concerns itself with the number of times that two words occur in the same sentence.

Co-occurrence in a Window of Text

The *window-wise* co-occurrence statistic is an even narrower notion of context, considering only terms in a window surrounding w'. Specifically, a window of a fixed size is moved along the text, and $f_{ww'}$ is set as the number of times both w and w' appear in the window. Since the window size is a free parameter, different sizes may be applied. In our experiments we use two window sizes, 2 and 5, that have been studied in related research (Church and Hanks, 1990).

Co-occurrence in a Syntactic Relationship

Another notion of word similarity derives from having the same syntactic relationship with the context w. This *syntax-wise* co-occurrence statistic is similar to the sentence-wise co-occurrence, in that co-occurrence is defined at the sentence level. However, in contrast to the sentence-wise model, w and w' are said to co-occur only if there is a syntactic relation between them in that sentence. E.g., this type of co-occurrence can help cluster nouns that are used as objects of same verb, such as 'tea', 'water', and 'cola,' which all are used with the verb 'drink'.

To gather such statistics, all sentences in the corpus must be syntactically parsed. We found that a dependency parser is an appropriate tool for our goal: it directly captures dependencies between words without the mediation of any virtual (nonterminal) nodes. Having all sentences in the parsed format, $f_{ww'}$ is defined as the number of times that the words w and w' have a parent-child relationship of *any syntactic type* in the dependency parse tree. For our experiments we use MINIPAR (Lin, 1998) to parse the whole corpus due to its robustness and speed.

4 Sentence Retrieval Experiments

4.1 Derivatives of the TREC QA Data Sets

The set of questions from the TREC 2006 QA track[1] was used as the test data to evaluate our models, while the TREC 2005 set was used for development.

The TREC 2006 QA task contains 75 question-series, each on one topic, for a total of 403 factoid questions which is used as queries for sentence retrieval. For sentence-level relevance judgments, the *Question Answer Sentence Pair* corpus of Kaisser and Lowe (2008) was used. All the documents that contain relevant sentences are from the NIST AQUAINT1 corpus.

QA systems typically employ sentence retrieval after initial, high quality document retrieval. To simulate this, we created a separate *search collection* for each question using all sentences from all documents relevant to the topic (question-series) from which the question was derived. On average, there are 17 relevant documents per topic, many *not* relevant to the question itself: they may be relevant to another question. So the sentence search collection is realistic, even if somewhat optimistic.

4.2 Corpora for Term Clustering

We investigated two different corpora[2], *AQUAINT1* and *Google n-grams*, to obtain word co-occurrence statistics for term clustering. Based on this we can also evaluate the impact of corpus size and corpus domain on the result of term clustering.

AQUAINT1 consists of English newswire text extracted from the Xinhua, the New York Times and the Associated Press Worldstream News Services.

The Google *n*-gram counts were generated from publicly accessible English web pages. Since there is no possibility of extracting document-wise, sentence-wise or syntax-wise co-occurrence statistics from the Google *n*-gram corpus, we only collect window-wise statistics to the extent available in the corpus.

Corpus	Co-occurrence	# Word Pairs
AQUAINT1	document	368,109,133
AQUAINT1	sentence	104,084,473
AQUAINT1	syntax	12,343,947
AQUAINT1	window-5	46,307,650
AQUAINT1	window-2	14,093,661
Google *n*-grams	window-5	12,005,479
Google *n*-grams	window-2	328,431,792

Table 1: Statistics for different notions of co-occurrence.

Table 1 shows the number of word pairs extracted from the two corpora with different definitions of co-occurrence. The statistics only include word pairs for which both constituent words are present in the 35,000 word vocabulary of our search collection.

4.3 Sentence Retrieval Results and Discussion

Sentence retrieval performance for term clustering using different definitions of word co-occurrence is shown in Figure 1. Since the Brown algorithm requires specifying the number of clusters, tests were conducted for 50, 100, 200, 500, and 1000 clusters of the term vocabulary. The baseline system is the word-based sentence retrieval model of Equation (1).

Figure 1(a) shows the *Mean Average Precision* (MAP) for class-based sentence retrieval of Equation (2) using clusters based on different co-occurrence statistics from AQUAINT1. Note that

(i) the best result achieved by sentence-wise co-occurence is better the best result of document-wise, perhaps due to more local and relevant information that it captures;

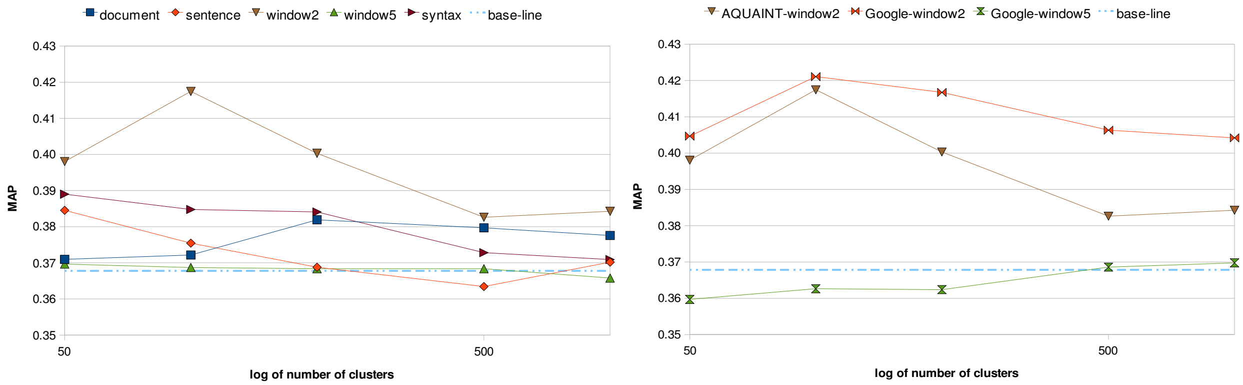
(ii) all the results achieved by syntax-wise co-occurrence are better than sentence-wise, indicating that merely co-occurring in a sentence is not very indicative of word similarity, while relations extracted from syntactic structure improve system performance significantly;

(iii) window-2 significantly outperforms all other notions of co-occurrence; i.e., the bigram statistics achieve the best clustering results. In comparison, window-5 has the worst results, with performance very close to baseline.

Although window-5 co-occurrence has been reported

[1] See http://trec.nist.gov.

[2] See catalog numbers LDC2002T31 and LDC2006T13 respectively at http://www.ldc.upenn.edu/Catalog.



(a)

(b)

Figure 1: MAP of sentence retrieval for different word co-occurrence statistics from AQUAINT1 and Google *n*-grams.

to be effective in other applications, it is not helpful in sentence retrieval.

Figure 1(b) shows the MAP for class-based sentence retrieval of Equation (2) when window-wise co-occurrence statistics from the Google *n*-grams are used. For better visualization, we repeated the MAP results using AQUAINT1 window-2 co-occurrence statistics from Figure 1(a) in 1(b). Note that

(iv) window-2 co-occurrence statistics significantly outperform window-5 for the Google *n*-grams, consistent with results from AQUAINT1;

(v) Google *n*-gram window-2 co-occurrence statistics consistently result in better MAP than AQUAINT window-2.

The last result indicates that even though the Google *n*-grams are from a different (and much broader) domain than the test data, they significantly improve the system performance due to sheer size. Finally

(vi) Google *n*-gram window-2 MAP curve is flatter than AQUAINT window-2; i.e., performance is not very sensitive to the number of clusters.

The best overall result is from Google window-2 co-occurrence statistics with 100 clusters, achieving 42.1% MAP while the best result derived from AQUAINT1 is 41.7% MAP for window-2 co-occurrence with 100 clusters, and the MAP of the word-based model (baseline) is 36.8%.

5 Concluding Remarks

We compared different notions of word co-occurrence for clustering terms, using document-wise, sentence-wise, window-wise, and syntax-wise co-occurrence statistics derived from AQUAINT1. We found that different notions of co-occurrence significantly change the behavior of a sentence retrieval system, in which window-wise model with size 2 achieves the best result. In addition, Google *n*-grams were used for window-wise model to study the impact of corpus size and domain on the clustering result. The result showed that although the domain of the Google *n*-grams is dissimilar to the test set, it outperforms models derived from AQUAINT1 due to sheer size.

Information Content Measures of Semantic Similarity Perform Better Without Sense-Tagged Text

Ted Pedersen
Department of Computer Science
University of Minnesota, Duluth
Duluth, MN 55812
tpederse@d.umn.edu
http://wn-similarity.sourceforge.net

Abstract

This paper presents an empirical comparison of similarity measures for pairs of concepts based on Information Content. It shows that using modest amounts of untagged text to derive Information Content results in higher correlation with human similarity judgments than using the largest available corpus of manually annotated sense–tagged text.

1 Introduction

Measures of semantic similarity based on WordNet have been widely used in Natural Language Processing. These measures rely on the structure of WordNet to produce a numeric score that quantifies the degree to which two concepts (represented by a sense or synset) are similar (or not). In their simplest form these measures use path length to identify concepts that are physically close to each other and therefore considered to be more similar than concepts that are further apart.

While this is a reasonable first approximation to semantic similarity, there are some well known limitations. Most significant is that path lengths between very specific concepts imply much smaller distinctions in semantic similarity than do comparable path lengths between very general concepts. One proposed improvement is to augment concepts in WordNet with *Information Content* values derived from sense–tagged corpora or from raw unannotated corpora (Resnik, 1995).

This paper shows that Information Content measures based on modest amounts of unannotated corpora have greater correlation with human similarity judgements than do those based on the largest corpus of sense-tagged text currently available.[1] The key to this success is not in the specific type of corpora used, but rather in increasing the number of concepts in WordNet that have counts associated with them. These results show that Information Content measures of semantic similarity can be significantly improved without requiring the creation of sense–tagged corpora (which is very expensive).

1.1 Information Content

Information Content (IC) is a measure of specificity for a concept. Higher values are associated with more specific concepts (e.g., *pitch_fork*), while those with lower values are more general (e.g., *idea*). Information Content is computed based on frequency counts of concepts as found in a corpus of text. The frequency associated with a concept is incremented in WordNet each time that concept is observed, as are the counts of the ancestor concepts in the WordNet hierarchy (for nouns and verbs). This is necessary because each occurrence of a more specific concept also implies the occurrence of the more general ancestor concepts.

When a corpus is sense–tagged, mapping occurrences of a word to a concept is straightforward (since each sense of a word corresponds with a concept or synset in WordNet). However, if the text has not been sense–tagged then all of the possible senses of a given word are incremented (as are their ancestors). For example, if *tree* (as a plant) occurs in a sense–tagged text, then only the concept associated

[1] These experiments were done with version 2.05 of WordNet::Similarity (Pedersen et al., 2004).

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 329–332,
Los Angeles, California, June 2010.

with tree as a kind of plant would be incremented. If the text is untagged, then all of the possible senses of *tree* would be incremented (such as the mathematical sense of tree, a shoe tree, a plant, etc.) In this case the frequency of all the occurrences of a word are divided equally among the different possible senses. Thus, if a word occurs 42 times in a corpus and there are six possible senses (concepts), each sense and all of their ancestors would have their frequency incremented by seven.[2]

For each concept (synset) c in WordNet, Information Content is defined as the negative log of the probability of that concept (based on the observed frequency counts):

$$IC(c) = -logP(c)$$

Information Content can only be computed for nouns and verbs in WordNet, since these are the only parts of speech where concepts are organized in hierarchies. Since these hierarchies are separate, Information Content measures of similarity can only be applied to pairs of nouns or pairs of verbs.

2 Semantic Similarity Measures

There are three Information Content measures implemented in WordNet::Similarity: (res) (Resnik, 1995), (jcn) (Jiang and Conrath, 1997), and (lin) (Lin, 1998).

These measures take as input two concepts c_1 and c_2 (i.e., senses or synsets in WordNet) and output a numeric measure of similarity. These measures all rely to varying degrees on the idea of a least common subsumer (LCS); this is the most specific concept that is a shared ancestor of the two concepts. For example, the LCS of *automobile* and *scooter* is *vehicle*.

The Resnik (res) measure simply uses the Information Content of the LCS as the similarity value:

$$res(c_1, c_2) = IC(LCS(c_1, c_2))$$

The Resnik measure is considered somewhat coarse, since many different pairs of concepts may share the same LCS. However, it is less likely to suffer from zero counts (and resulting undefined values) since in general the LCS of two concepts will not be a very specific concept (i.e., a leaf node in WordNet), but will instead be a somewhat more general concept that is more likely to have observed counts associated with it.

Both the Lin and Jiang & Conrath measures attempt to refine the Resnik measure by augmenting it with the Information Content of the individual concepts being measured in two different ways:

$$lin(c_1, c_2) = \frac{2*res(c_1,c_2)}{IC(c_1)+IC(c_2)}$$

$$jcn(c_1, c_2) = \frac{1}{IC(c_1)+IC(c_2)-2*res(c_1,c_2)}$$

All three of these measures have been widely used in the NLP literature, and have tended to perform well in a wide range of applications such as word sense disambiguation, paraphrase detection, and Question Answering (c.f., (Resnik, 1999)).

3 Experimental Data

Information Content in WordNet::Similarity is (by default) derived from SemCor (Miller et al., 1993), a manually sense–tagged subset of the Brown Corpus. It is made up of approximately 676,000 words, of which 226,000 are sense–tagged. SemCor was originally created using sense–tags from version 1.6 of WordNet, and has been mapped to subsequent versions to stay current.[3] This paper uses version 3.0 of WordNet and SemCor.

WordNet::Similarity also includes a utility (rawtextFreq.pl) that allows a user to derive Information Content values from any corpus of plain text. This utility is used with the untagged version of SemCor and with various portions of the English GigaWord corpus (1st edition) to derive alternative Information Content values.

English GigaWord contains more than 1.7 billion words of newspaper text from the 1990's and early 21st century, divided among four different sources: Agence France Press English Service (afe), Associated Press Worldstream English Service (apw), The New York Times Newswire Service (nyt), and The Xinhua News Agency English Service (xie).

This paper compares the ranking of pairs of concepts according to Information Content measures in WordNet::Similarity with a number of manually created gold standards. These include the (RG) (Rubenstein and Goodenough, 1965) collection of 65 noun

[2] This is the –resnik counting option in WordNet::Similarity.

[3] http://www.cse.unt.edu/˜rada/downloads.html

Table 1: Rank Correlation of Existing Measures

measure	WS	MC	RG
vector	**.46**	**.89**	**.73**
lesk	.42	.83	.68
wup	.34	.74	.69
lch	.28	.71	.70
path	.26	.68	.69
random	-.20	-.16	.15

pairs, the (MC) (Miller and Charles, 1991) collection of 30 noun pairs (a subset of RG), and the (WS) WordSimilarity-353 collection of 353 pairs (Finkelstein et al., 2002). RG and MC have been scored for similarity, while WS is scored for relatedness, which is a more general and less well–defined notion than similarity. For example *aspirin* and *headache* are clearly related, but they aren't really similar.

4 Experimental Results

Table 1 shows the Spearman's rank correlation of several other measures of similarity and relatedness in WordNet::Similarity with the gold standards discussed above. The WordNet::Similarity vector relatedness measure achieves the highest correlation, followed closely by the adapted lesk measure. These results are consistent with previous findings (Patwardhan and Pedersen, 2006). This table also shows results for several path–based measures.[4]

Table 2 shows the correlation of jcn, res, and lin when Information Content is derived from 1) the sense-tagged version of SemCor (semcor), 2) SemCor without sense tags (semcor-raw), and 3) steadily increasing subsets of the 133 million word xie portion of the English GigaWord corpus. These subsets start with the entire first month of xie (199501, from January 1995) and then two months (199501-02), three months (199501-03), up through all of 1995 (199501-12). Thereafter the increments are annual, with two years of data (1995-1996), then three (1995-1997), and so on until the entire xie corpus is used (1995-2001). The afe, apw, and nyt portions of GigaWord are also used individually and then combined all together along with xie *(all)*.

The size (in tokens) of each corpus is shown in the second column of Table 2 *(size)*, which is expressed in thousands (k), millions (m), and billions (b).

The third column (*cover*) shows what percentage of the 96,000 noun and verb synsets in WordNet receive a non-zero frequency count when Information Content is derived from the specified corpus. These values show that the 226,000 sense–tagged instances in SemCor cover about 24%, and the untagged version of SemCor covers 37%. As it happens the correlation results for semcor-raw are somewhat better than semcor, suggesting that coverage is at least as important (if not more so) to the performance of Information Content measures than accurate mapping of words to concepts.

A similar pattern can be seen with the xie results in Table 2. This again shows that an increase in WordNet coverage is associated with increased performance of the Information Content measures. As coverage increases the correlation improves, and in fact the results are better than the path–based measures and approach those of lesk and vector (see Table 1). The one exception is with respect to the WS gold standard, where vector and lesk perform much better than the Information Content measures. However, this seems reasonable since they are relatedness measures, and the WS corpus is annotated for relatedness rather than similarity.

As a final test of the hypothesis that coverage matters as much or more than accurate mapping of words to concepts, a simple baseline method was created that assigns each synset a count of 1, and then propagates that count up to the ancestor concepts. This is equivalent to doing add-1 smoothing without any text (add1only). This results in correlation nearly as high as the best results with xie and semcor-raw, and is significantly better than semcor.

5 Conclusions

This paper shows that semantic similarity measures based on Information Content can be significantly improved by increasing the coverage of the frequency counts used to derive Information Content. Increased coverage can come from unannotated text or simply assigning counts to every concept in WordNet and does not require sense–tagged text.

[4] *wup* is the Wu & Palmer measure, *lch* is the Leacock & Chodorow measure, *path* relies on edge counting, and *random* provides a simple sanity check.

Abstract

Generating expository dialogue from monologue is a task that poses an interesting and rewarding challenge for Natural Language Processing. This short paper has three aims: firstly, to motivate the importance of this task, both in terms of the benefits of expository dialogue as a way to present information and in terms of potential applications; secondly, to introduce a parallel corpus of monologues and dialogues which enables a data-driven approach to this challenge; and, finally, to describe work-in-progress on semi-automatic construction of Monologue-to-Dialogue (M2D) generation rules.

1 Introduction

The tasks of text generation – e.g., Reiter et al. (2005) and Demir et al. (2008) – and generation in dialogue – e.g., Stent (2002) and DeVault et al. (2008) – are central topics in Natural Language Generation (NLG). What sets the two tasks apart is the interactive nature of dialogue, where participants need to adapt their contributions to each other.

This paper introduces an NLG task, the generation of expository dialogue, to the Computational Linguistics community which occupies the middle ground between these two tasks. An expository dialogue is an authored conversation between two fictive characters. It can be presented as text, audio or film. Although there is no real-time interactivity, in expository dialogue the contributions of the characters do need to mesh with each other. The main purpose of expository dialogue is to present information (a description, explanation or definition) to the reader, hearer or viewer, in contrast with dramatic dialogue, which tells a story.

The use of expository dialogue goes back as far as Plato (c. 470-399 BC), who expressed his ideas as dialogues between Socrates and his contemporaries. Recently, a number of empirical studies show that for some purposes expository dialogue has advantages over monologue: for learners, dialogue can be more memorable, stimulate them to formulate their own questions (Craig et al., 2000), and get them to talk with each other (Lee et al., 1998). Expository dialogue has also been found to be more effective for persuasion (Suzuki and Yamada, 2004).

Additionally, dialogue lends itself very well for multimedia presentations by computer-animated agents (André et al., 2000; van Deemter et al., 2008). Potential application domains include education, (serious) games and E-Health. In education, information from textbooks could be presented in dialogue form, possibly using virtual reality platforms such as Second Life. Automatically generating dialogue from text for non-player characters could have a tremendous impact on the gaming industry; e.g., (IGDA Game Writers SIG, 2003) state that the amount of dialogue script for a character-driven computer game is usually many times that for the average film. In connection with E-health, consider patient information leaflets, which are often left unread; presenting them as movies between a virtual pharmacist and client may help address this. Thus instead of being presented with

(1) a. You can take aspirin,
b. if you have a headache.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 333–336,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

c. Though aspirin does have side effects:
d. it can harm circulation.

the patient could watch a movie on their mobile device of an exchange between a virtual client (*layman*, L) and pharmacist (*expert*, E):

(2) *L*: What if I have a headache?
E: You can take aspirin
L: But does it have side effects?
E: Yes, it can harm circulation.

So far, research on generating expository dialogue has been firmly rooted in classical AI approaches. Work in this area starts from knowledge representations or databases (André et al., 2000), and even research that does take text as input – e.g., Piwek et al. (2007) describe a system for generating dialogues such as Example 2 – relies on handcrafted rules. Two challenges present themselves for NLP research: 1) generation of expository dialogue from text, and 2) use of data-driven, rather than manually authored, generation rules.

Apart from the cost of manually authoring generation rules, previous research has found that human-authored rules can result in 'too much information [being] given too quickly' (Williams et al., 2007), which can be addressed by conversational padding. We argue that rather than trying to invent padding rules, the best strategy is to learn rules automatically from professionally authored dialogues.

2 The CODA Corpus

To make inroads into data-driven dialogue generation, we first need to have the necessary resources. We propose to view Monologue-to-Dialogue (M2D) generation as analogous to machine translation; consequently we need a parallel corpus for learning mappings from the source (monologue) to the target (dialogue) texts. In the ongoing CODA[1] project we have created such a corpus. It consists of professionally authored dialogues[2] that have been aligned with monologues (written by ourselves) expressing the same information. Since our ultimate aim is to generate dialogues that resemble those written by acclaimed authors, we started with professionally authored dialogues and created the corresponding monologues. From a practical point of view, it was more feasible to use existing dialogue by acclaimed authors than to hire professional authors to write dialogue based on monologues.

Sp	Dialog act	Dialogue Turn	Monologue
E:	Complex Question	When you have a pain in your foot, how do you know it?	When you have a pain in your foot (i) you know it because you
L:	Explain	I feel it.	can feel it. (ii)
E:	Explain-Contradict	But you do not feel it until a nerve reports the hurt to the brain.	But you do not feel it until a nerve reports the hurt to the brain. (iii)
E:	YN-Question	Yet the brain is the seat of the mind , is it not?	Yet the brain is the seat of the mind. (iv)

Table 1: Parallel Monologue and Dialogue Example from Mark Twain's "What is Man?"

We have annotated both dialogues and monologues: dialogue with dialogue acts and monologue with discourse relations.[3] We achieved 91% agreement on segmentation and *kappa*=.82 for dialogue act annotation on 11 dialogue act tags. We developed a *D2MTranslation* tool for monologue authoring, segmentation and dialogue annotation.

In January 2010, the corpus included 500 turns from "What is man?", a dialogue by Mark Twain, and 88 turns from "Evolving Algebras", an academic paper in the form of dialogue by Yuri Gurevich.[4] Both of these expository dialogues present conversation between an *expert* (Old Man in Twain and Author in Gurevich) and a *layman* (Young Man in Twain and Quisani in Gurevich). Table 1 shows an example of a dialogue fragment, aligned monologue and dialogue act annotations. The discourse structure of the monologue is depicted in Figure 1.

Table 2 shows the distribution of the dialogue acts between expert and layman. In both dialogues, the

[1] COherent Dialogue Automatically generated from text

[2] Most dialogues are from the Gutenberg library to facilitate our planned release of the corpus to the research community.

[3] See (Stoyanchev and Piwek, 2010) for details.

[4] In addition to these dialogues we are working on a dialogue by Berkeley (Three Dialogues between Hylas and Philonous) and a selection of shorter fragments (for copyrights reasons) by authors such as Douglas Hofstadter and Paul Feyerabend.

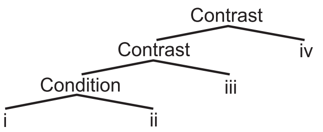

Figure 1: Discourse structure of the monologue in Table 1

most frequent dialogue act is *Explain*, where a character presents information (as a new idea or as a response to another utterance). Also, in both dialogues the *layman* asks more often for clarification than the *expert*. The distribution over information requests (yes/no, factoid, and complex questions) and responses (yes, no, factoid) differs between the two dialogues: in Twain's dialogue, the expert mostly requests information and the layman responds to requests, whereas in Gurevich's dialogue it is the other way around.

The differences in style suggests that the M2D mapping rules will be author or style-specific. By applying M2D rules obtained from two different authors (e.g., Twain and Gurevich) to the same text (e.g., the aspirin example) we can generate two different dialogues. This will enable us to vary the presentation style of automatically generated dialogues.

	Twain		Gurevich	
Tag	Expert	Layman	Expert	Layman
Explain	69	55	49	24
Clarify	1	15	0	6
Request	60	26	2	29
Response	14	43	9	0

Table 2: Dialogue act tag frequencies for *expert* and *layman* in a sample of 250 turns from Twain and 88 turns from Gurevich dialogues.

3 Rules

We automatically derive M2D rules from the aligned discourse relations and dialogue acts in our parallel corpus of monologues and dialogues. Table 3 shows three rules generated from the parallel dialogue–monologue fragment in Table 1. The first rule, R1, is based on the complete discourse structure of the monologue (i–iv), whereas R2 and R3 are based on only a part of it: R2 is based on i–iii, whereas R3 is based on i and ii. By generating rules from subtrees of a discourse structure, we obtain several rules from a single dialogue fragment in the corpus.

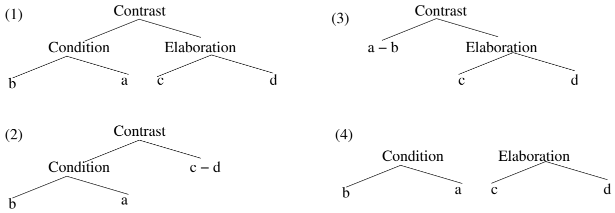

Figure 2: Discourse structures of the monologue in Example 1. a-b and c-d indicate a concatenation of two clauses.

Let us illustrate the use of such rules by applying them to Example 1 about aspirin. The relations between the clauses of the example are depicted in Figure 2 (1). To generate a dialogue, we apply a matching M2D rule. Alternatively, we can first simplify the discourse structure of the monologue by removing relation nodes as illustrated in Figure 2 (2–4).

The simplified structure in Figure 2 (2) matches rule R2 from Table 3. By applying R2 we generate the dialogue in Table 4: the expert asks a complex question composed of clauses a and b, which the layman answers with an explanation generated from the same set of clauses. Then the expert offers a contradicting explanation generated from c and d. To generate dialogue sentences for a corresponding discourse structure we are adapting the approach to paraphrasing of Barzilay and McKeown (2001).

4 Conclusion

This short paper presented three angles on the Monologue-to-Dialogue (M2D) task. First, as an opinion piece, it motivates the task of generating expository dialogue from monologue. We described empirical research that provides evidence for the effectiveness of expository dialogue and discussed applications from education, gaming and E-health. Second, we introduced the CODA corpus for addressing the task. Finally, we reported on work-in-progress on semi-automatic construction of M2D rules. Our implemented algorithm extracts several M2D rules from the corpus that are applicable even to a relatively simple input. Additionally, frequency analysis of dialogue tags suggests that there is scope for generating different dialogue styles.

The timeliness of this research is evidenced by the emergence of a Question Generation (QG) commu-

ID	Dialogue Structure	Monologue Structure
R1	E: Complex Question (i-ii) L: Explain (i-ii) E: Explain-Contradict (iii) E: YNQuestion (iv)	Contrast (Contrast (Condition(i,ii), iii, iv))
R2	E: Complex Question (i-ii) L: Explain(i-ii) E: Explain-Contradict (iii)	Contrast (Condition(i,ii), iii)
R3	E: Complex Question (i-ii) L: Explain (i-ii)	Condition (i,ii)

Table 3: Monologue-to-Dialogue rules extracted from the parallel example in Table 1

Sp	Dialogue act	Dialogue Turn
E:	Complex Question a-b	If you have a headache, what do you do?

The Simple Truth about Dependency and Phrase Structure Representations

An Opinion Piece

Owen Rambow
CCLS, Columbia University
New York, NY, USA
rambow@ccls.columbia.edu

Abstract

There are many misconceptions about dependency representations and phrase structure representations for syntax. They are partly due to terminological confusion, partly due to a lack of meta-scientific clarity about the roles of representations and linguistic theories. This opinion piece argues for a simple but clear view of syntactic representation.

1 Introduction

To the machine learning community, treebanks are just collections of data, like pixels with captions, structural and behavioral facts about genes, or observations about wild boar populations. In contrast, to us computational linguists, treebanks are not naturally occurring data at all: they are the result of a very complex annotation process. While the text that is annotated (usually) is naturally occurring, the annotation itself is already the result of a scientific activity. This opinion piece argues that the level of discourse about treebanks often found in our community does not reflect this fact (presumably due to the influence of the brute machine learning perspective). We, as a community of computational linguists, need to be very precise when talking about treebanks and syntactic representations in general.

So let's start with three very important concepts which we must always distinguish. The **representation type**: what type of mathematical object is used to represent syntactic facts? In this opinion piece, I only consider dependency trees (DTs) and phrase structure trees (PSTs) (Section 2). The represented **syntactic content**: the morphological and syntactic facts of the analyzed sentence (Section 3). The **syntactic theory**: it explains how syntactic content is represented in the chosen representation type (Section 4).

A crucial confusing factor is the fact that the terms *dependency* and *phrase structure* both have both a mathematical and a linguistic meaning. The mathematical meaning refers **representation types**. The linguistic meaning refers to **syntactic content**. I discuss this issue in Section 3. I discuss the issue of converting between DTs and PSTs in Section 5, as an example of how my proposed conceptualization of syntactic representation throws light on a computational problem.

This opinion piece will be a success if after reading it, the reader concludes that actually he or she knew this all along. In fact, this opinion piece does not advocate for a controversial position; its mission is to make its readers be more precise when talking about syntactic representations. This opinion piece is intentionally polemical for rhetorical reasons.

2 DTs and PSTs as Representation Types

Assume we have two disjoint symbol sets: a set of terminal symbols which contains the words of the language we are describing; and a set of nonterminal symbols. A **Dependency Tree** (DT) is a tree in which all nodes are labeled with words (elements of the set of terminal symbols) or empty strings. A **Phrase Structure Tree** (PST) is a tree in which all and only the leaf nodes are labeled with words or empty strings, and internal nodes are labeled with nonterminal symbols. There is nothing more to the

definitions. Trees of both types can have many other properties which are not part of the two definitions, and which do not follow from the definitions. I mention some such properties.

Unordered trees. DTs and PSTs can be ordered or unordered. For example, the Prague Theory (Sgall et al., 1986) uses unordered DTs at the deeper level of representation and ordered DTs at a more surfacy level. GPSG (Gazdar et al., 1985) uses unordered trees (or at any rate context-free rules whose right-hand side is ordered by a separate component of the grammar), as does current Chomskyan theory (the PST at spell-out may be unordered).

Empty categories. Empty categories can be empty pronouns, or traces, which are co-indexed with a word elsewhere in the tree. Empty pronouns are widely used in both DT- and PST-based representations. While most DT-based approaches do not use traces, Lombardo and Lesmo (1998) do; and while traces are commonly found in PST-based approaches, there are many that do not use them, such as the c-structure of LFG.

Discontinuous Constituents or **Non-Projectivity**. Both types of trees can be used with or without discontinuous constituents; PSTs are more likely to use traces to avoid discontinuous constituents, but linguistic proposals for PSTs with discontinuous constituents have been made (work by McCawley, or (Becker et al., 1991)).

Labeled Arcs. In DTs, arcs often have labels; arcs in PSTs usually do not, but we can of course label PST arcs as well, as is done in the German TIGER corpus.I note that in both DTs and PSTs we can represent the arc label as a feature on the daughter node, or as a separate node.

3 Syntactic Content

While there is lots of disagreement about the proper **representation type** for syntax, there is actually a broad consensus among theoretical and descriptive syntacticians of all persuasions about the range of syntactic phenomena that *exist*. What exactly is this content, then? It is not a theory-neutral representation of syntax (Section 4). Rather, it is the *empirical matter* which linguistic theory attempts to represent or explain. We cannot represent it without a theory, but we can refer to it without a theory, using names such as *control constructions* or *transitive verb*. In the same manner, we use the word *light* and physicists will agree on what the phenomenon is, but we cannot represent light within a theory without choosing a representation as either particles or wave.

Note that in linguistics, the terms *dependency* and *phrase structure* refer to **syntactic content**, i.e., syntactic facts we can represent. **Syntactic dependency** is direct relation between words. Usually, this relation is labeled (or typed), and is identical to (or subsumes) the notion of **grammatical function**, which covers relations such as SUBJECT, OBJECT, TEMPORAL-ADJUNCT and so forth. **Syntactic phrase structure**, also known as **syntactic constituency structure** is recursive representation using sets of one or more linguistic units (words and empty strings), such that at each level, each set (constituent) acts as a unit syntactically. Linguistic phrase structure is most conveniently expressed in a phrase structure tree, while linguistic dependency is most conveniently expressed in a dependency tree. However, we can express the same content in either type of tree! For example, the English Penn Treebank (PTB) encodes the predicate-argument structure of English using structural conventions and special nonterminal labels ("dashtags"), such as NP-SBJ. And a dependency tree represents constituency: each node can be interpreted both as a preterminal node (X^0) and as a node heading a constituent containing all terminals included in the subtree it heads (the XP). Of course, what is more complex to encode in a DT are intermediate projections, such as VP. I leave a fuller discussion aside for lack of space, but I claim that the syntactic content which is expressed in intermediate projections can also be expressed in a DT, through the use of features and arc labels.

4 Syntactic Theory

The choice of representation type does not determine the representation for a given sentence. This is obvious, but it needs to be repeated; I have heard "What is the DT for this sentence?" one too many times. There are many possible DTs and PSTs, proposed by serious syntacticians, for even simple sentences, even when the syntacticians agree on what the syntactic content (a transitive verb with SVO order, for example) of the analysis should be! What is going on?

In order to make sense of this, we need a third player in addition to the **representation type** and the **content**. This is the **syntactic theory**. A linguistic theory chooses a representation type and then defines a coherent mapping for a well-defined set of content to the chosen representation type. Here, "coherent representation" means that the different choices made for conceptually independent content are also representationally independent, so that we can compose representational choices. Note that a theory can decide to omit some content; for example, we can have a theory which does not distinguish raising from control (the English PTB does not).

There are different types of syntactic theories. A **descriptive theory** is an account of the syntax of one language. Examples of descriptive grammars include works such as Quirk for English, or the annotation manuals of monolingual treebanks, such as (Marcus et al., 1994; Maamouri et al., 2003). The annotation manual serves two purposes: it tells the annotators how to represent a syntactic phenomenon, and it tells the users of the treebank (us!) how to interpret the annotation. A treebank without manual is meaningless. And an arborescent structure does not mean the same thing in all treebanks (for example, a "flat NP" indicates an unannotated constituent in the English ATB but a fully annotated construction in the Arabic Treebank is).

An **explanatory theory** is a theory which attempts to account for the syntax of all languages, for example by reducing their diversity to a set of principles and finite-valued parameters. Linguistic theories (and explanatory theories in particular) often take the form of a one-to-many mapping from a simple representation of syntactic dependency (predicate-argument structure) to a structural representation that determines surface word order. The linguistic theory itself is formulated as a (computational) device that relates the deeper level to the more surfacy level. LFG has a very pure expression of this approach, with the deeper level expressed using a DT (actually, dependency directed acyclic graphs, but the distinction is not relevant here), and the surfacy level expressed using a PST. But the Chomskyan approaches fit the same paradigm, as do many other theories of syntax.

Therefore, there is no theory-neutral representation of a sentence or a set of sentences, because *every* representation needs a theory for us to extract its meaning! Often what is meant by "theory-neutral tree" is a tree which is interpreted using some notion of consensus theory, perhaps a stripped-down representation which omits much content for which there is no consensus on how to represent it.

5 Converting Between DTs and PSTs

Converting a set of DS annotations to PS or *vice versa* means that we want to obtain a representation which expresses exactly the same **content**. This is frequently done these days as interest in dependency parsing grows but many languages only have PS treebanks. However, this process is often not understood.

To start, I observe that uninterpreted structures (i.e., structures without a syntactic theory, or trees from a treebank without a manual) cannot be converted from or into, as we do not know what they mean and we cannot know if we are preserving the same content or not.

Now, my central claim about the possibility of automatically converting between PSTs and DTs is the following. If we have an interpretation for the source representation and the goal representation (as we must in order for this task to be meaningful), then we can convert any facts that are represented in the source structure, and we cannot convert any facts that are not represented in the source structure. It is that simple. If we are converting from a source which contains less information than the target, then we cannot succeed. For example, if we are converting from a PS treebank that does not distinguish particles from prepositions to a DS treebank that does, then we will fail. General claims about the possibility of conversion ("it is easier to convert PS to DS than DS to PS") are therefore *meaningless*. It only matters **what** is represented, not **how** it is represented.

There is, however, no guarantee that there is a *simple* algorithm for conversion, such as a parametrized head percolation algorithm passed down from researcher to researcher like a sorcerer's incantation. In general, if the two representations are independently devised and both are linguistically motivated, then we have no reason to believe that the conversion can be done using a specific simple approach, or using conversion rules which have some fixed property (say, the depth of the trees in the rules templates). In the general case, the only way to write an automatic converter between two representations is to study the two annotation manuals and to create a case-by-case converter, covering all linguistic phenomena represented in the target representation.

Machine learning-based conversion (for example, (Xia and Palmer, 2001)) is an interesting exercise, but it does not give us any general insights into dependency or phrase structure. Suppose the source contains all the information that the target should contain. Then if machine learning-based conversion fails or does not perform completely correctly, the exercise merely shows that the machine learning is not adequate. Now suppose that the source does not contain all the information that the target should contain. Then no fancy machine learning can ever provide a completely correct conversion. Also, note that unlike, for example, parsers which are based on machine learning and which learn about a natural phenomenon (language use), machine learning of conversion merely learns an artificial phenomenon: the relation between the two syntactic theories in question, which are created by researchers. (Of course, in practice, machine learning of automatic conversion between DT to PSTs is useful.)

6 Conclusion

I have argued that when talking about dependency and phrase structure representations, one should always distinguish the type of representation (dependency or phrase structure) from the content of the representation, and one needs to understand (and make explicit if it is implicit) the linguistic theory that relates content to representation. Machine learning researchers have the luxury of treating syntactic representations as mere fodder for their mills; we as computational linguists do not, since this is our area of expertise.

Acknowledgments

I would like to thank my colleagues on the Hindi-Urdu treebank project (Bhatt et al., 2009) (NSF grant CNS-0751089) for spirited discussions about the issues discussed here. I would like to thank Sylvain Kahane, Yoav Goldberg, and Joakim Nivre for comments that have helped me improve this paper. The expressed opinions have been influenced by far too many people to thank individually here.

Abstract

The class of Linear Inversion Transduction Grammars (LITGs) is introduced, and used to induce a word alignment over a parallel corpus. We show that alignment via Stochastic Bracketing LITGs is considerably faster than Stochastic Bracketing ITGs, while still yielding alignments superior to the widely-used heuristic of intersecting bidirectional IBM alignments. Performance is measured as the translation quality of a phrase-based machine translation system built upon the word alignments, and an improvement of 2.85 BLEU points over baseline is noted for French–English.

1 Introduction

Machine translation relies heavily on word alignments, which are usually produced by training IBM-models (Brown et al., 1993) in both directions and combining the resulting alignments via some heuristic. Automatically training an Inversion Transduction Grammar (ITG) has been suggested as a viable way of producing superior alignments (Saers and Wu, 2009). The main problem of using Bracketing ITGs for alignment is that exhaustive biparsing runs in $\mathcal{O}(n^6)$ time. Several ways to lower the complexity of ITGs has been suggested, but in this paper, a different approach is taken. Instead of using full ITGs, we explore the possibility of subjecting the grammar to a linear constraint, making exhaustive biparsing of a sentence pair in $\mathcal{O}(n^4)$ time possible. This can be further improved by applying pruning.

2 Background

A transduction is the bilingual version of a language. A language (L_l) can be formally viewed as a set of sentences, sequences of tokens taken from a specified vocabulary (V_l). A transduction ($T_{e,f}$) between two languages (L_e and L_f) is then a set of sentence pairs, sequences of bitokens from the cross production of the vocabularies of the two languages being transduced ($V_{e,f} = V_e \times V_f$). This adds an extra layer of complexity to finding transductions from raw bitexts, as an alignment has to be imposed.

Simple (STG) and Syntax Directed (SDTG) Transduction Grammars (Aho and Ullman, 1972) can be used to parse transductions between context-free languages. Both work fine as long as a grammar is given and parsing is done as transduction, that is: a sentence in one language is rewritten into the other language. In NLP, interest has shifted away from hand-crafted grammars, towards stochastic grammars induced from corpora. To induce a stochastic grammar from a parallel corpus, expectations of all possible parses over a sentence pair are typically needed. STGs can biparse sentence pairs in polynomial time, but are unable to account for the complexities typically found in natural languages. SDTGs do account for the complexities in natural languages, but are intractable for biparsing.

Inversion transductions (Wu, 1995; Wu, 1997) are a special case of transductions that are not monotone, but where permutations are severely limited. By limiting the possible permutations, biparsing becomes tractable. This in turn means that ITGs can be induced from parallel corpora in polynomial time,

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 341–344,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

as well as account for most of the reorderings found between natural languages.

An Inversion transduction is limited so that it must be expressible as non-overlapping groups, internally permuted either by the identity permutation or the inversion permutation (hence the name). This requirement also means that the grammar is binarizable, yielding a two-normal form. A production with the identity permutation is written inside square brackets, while productions with the inversion permutation is written inside angled brackets. This gives us a two-normal form that looks like this (where e/f is a biterminal):

$$\begin{aligned}A &\rightarrow [B\ C]\\ A &\rightarrow \langle B\ C\rangle\\ A &\rightarrow e/f\end{aligned}$$

The time complexity for exhaustive ITG biparsing is $\mathcal{O}(Gn^6)$, which is typically too large to be applicable to large grammars and long sentence. The grammar constant G can be eliminated by limiting the grammar to a bracketing ITG (BITG), which only has one nonterminal symbol. Saers & Wu (2009) show that it is possible to apply exhaustive biparsing to a large parallel corpus ($\sim 100,000$ sentence pairs) of short sentences (≤ 10 tokens in both language). The word alignments read off the Viterbi parse also increased translation quality when used instead of the alignments from bidirectional IBM alignments.

The $\mathcal{O}(n^6)$ time complexity is somewhat prohibitive for large corpora, so pruning in some form is needed. Saers, Nivre & Wu (2009) introduce a beam pruning scheme, which reduces time complexity to $\mathcal{O}(bn^3)$. They also show that severe pruning is possible without significant deterioration in alignment quality. Haghighi et. al (2009) use a simpler aligner as guidance for pruning, which reduce the time complexity by two orders of magnitude, and also introduce block ITG, which gives many-to-one instead of one-to-one alignments. Zhang et. al (2008) present a method for evaluating spans in the sentence pair to determine whether they should be excluded or not. The algorithm has a best case time complexity of $\mathcal{O}(n^3)$.

In this paper we introduce Linear ITG (LITG), and apply it to a word-alignment task which is evaluated by the phrase-based statistical machine translation (PBSMT) system that can be built from that.

3 Stochastic Bracketing Linear Inversion Transduction Grammar

A Bracketing Linear Inversion Transduction Grammar (BLITG) is a BITG where rules may have at most one nonterminal symbol in their production. This gives us a normal form that is somewhat different from the usual ITG:

$$\begin{aligned}X &\rightarrow [Xe/f]\\ X &\rightarrow [e/fX]\\ X &\rightarrow \langle Xe/f\rangle\\ X &\rightarrow \langle e/fX\rangle\\ X &\rightarrow \epsilon/\epsilon\end{aligned}$$

where one but not both of the tokens in the biterminal may be the empty string ϵ, if a nonterminal is produced. By associating each rule with a probability, we get a Stochastic BLITG (SBLITG).

3.1 Biparsing Algorithm

The sentence pair to be biparsed consists of two vectors of tokens ($\mathbf{e}$ and $\mathbf{f}$). An item is represented as a nonterminal (X), and one span in each of the languages ($e_{s..t}$ and $f_{u..v}$). For notational convenience, an item will be written as the nonterminal with the spans as subscripts ($X_{s,t,u,v}$). The length of an item is defined as the sum of the length of the two spans: $|X_{s,t,u,v}| = t - s + v - u$. Items are gathered in buckets, B_n, according to their length so that $X_{s,t,u,v} \in B_{|X_{s,t,u,v}|}$. The algorithm is initialized with the item spanning the entire sentence pair:

$$X_{0,|\mathbf{e}|,0,|\mathbf{f}|} \in B_{|X_{0,|\mathbf{e}|,0,|\mathbf{f}|}|}$$

Starting from this top bucket, buckets are processed in larger to smaller order: $B_n, B_{n-1}, \ldots, B_1$. While processing a bucket, only smaller items are added, meaning that B_0 is fully constructed by the time B_1 has been processed. Each item in B_0 can have the rule $X \rightarrow \epsilon/\epsilon$ applied to it, eliminating the nonterminal and halting processing. If there are no items in B_0, parsing has failed.

To process a bucket, each item is extended by all applicable rules, and the nonterminals in the productions are added to their respective buckets.

System	**BLEU**	**NIST**	**Phrases**
GIZA++ (`intersect`)	0.2629	6.7968	146,581,109
GIZA++ (`grow-diag-final`)	0.2632	6.7410	1,298,566
GIZA++ (`grow-diag-final-and`)	0.2742	6.9228	7,340,369
SBLITG ($b = 25$)	**0.3027**	**7.3664**	13,551,915
SBLITG ($b = \infty$)	0.3008	7.3303	12,673,361

Table 1: Results for French–English.

$$\begin{array}{ll} X_{s,t,u,v} \rightarrow & \\ & [e_{s,s+1}/f_{u,u+1}\ X_{s+1,t,u+1,v}] \\ | & [X_{s,t-1,u,v-1}\ e_{t-1,t}/f_{v-1,v}] \\ | & \langle e_{s,s+1}/f_{v-1,v}\ X_{s+1,t,u,v-1}\rangle \\ | & \langle X_{s,t-1,u+1,v}\ e_{t-1,t}/f_{u,u+1}\rangle \\ | & [e_{s,s+1}/\epsilon\ X_{s+1,t,u,v}] \mid \langle e_{s,s+1}/\epsilon\ X_{s+1,t,u,v}\rangle \\ | & [\epsilon/f_{u,u+1}\ X_{s,t,u+1,v}] \mid \langle X_{s,t,u+1,v}\ \epsilon/f_{u,u+1}\rangle \\ | & [X_{s,t-1,u,v}\ e_{t-1,t}/\epsilon] \mid \langle X_{s,t-1,u,v}\ e_{t-1,t}/\epsilon\rangle \\ | & [X_{s,t,u,v-1}\ \epsilon/f_{v-1,v}] \mid \langle \epsilon/f_{v-1,v}\ X_{s,t,u,v-1}\rangle \end{array}$$

Note that there are two productions on each of the four last rows. These are distinct rules, but the symbols in the productions are identical. This phenomenon is due to the fact that the empty symbols can be "read" off either end of the span. In our experiments, such rules were merged into their non-inverting form, effectively eliminating the last four inverted rules (productions enclosed in angled brackets) above.

3.2 Analysis

Let n be the length of the longer sentence in the pair. The number of buckets will be $\mathcal{O}(n)$, since the longest item will be at most $2n$ long. Within a bucket, there can be $\mathcal{O}(n^2)$ starting points for items, but once the length of one of the spans is fixed, the length of the other follows, adding a factor $\mathcal{O}(n)$, making the total number of items in a bucket $\mathcal{O}(n^3)$. Each item in a bucket can be analyzed in 8 possible ways, requiring $\mathcal{O}(1)$ time. In summary, we have: $\mathcal{O}(n) \times \mathcal{O}(n^3) \times \mathcal{O}(1) = \mathcal{O}(n^4)$

The pruning scheme works by limiting the number of items that are processed from each bucket, reducing the cost of processing a bucket from $\mathcal{O}(n^3)$ to $\mathcal{O}(b)$, where b is the beam width. This gives time complexity $\mathcal{O}(n) \times \mathcal{O}(b) \times \mathcal{O}(1) = \mathcal{O}(bn)$.

4 Experiments

We used the guidelines of the shared task of WMT'08[1] to train our baseline system as well as our experimental system. This includes induction of word alignments with GIZA++ (Och and Ney, 2003), induction of a Phrase-based SMT system (Koehn et al., 2007), and tuning with minimum error rate training (Och, 2003), as well as applying some utility scripts provided for the workshop. The translation model is combined with a 5-gram language model (Stolcke, 2002).

Our experimental system uses alignments from the Viterbi parses, extracted during EM training of an SBLITG on the training corpus, instead of GIZA++. Since EM will converge fairly slowly, it was limited to 10 iterations, after which it was halted.

We used the French–English part of the WMT'08 shared task, but limited the training set to sentence pairs where both sentences were of length 20 or less. This was necessary in order to carry out exhaustive search in the SBLITG algorithm. In total, we had 381,780 sentence pairs for training, and 2,000 sentence pairs each for tuning and testing. The language model was trained with the entire training set.

To evaluate the systems we used BLEU (Papineni et al., 2002) and NIST (Doddington, 2002)

Results are presented in Table 1. It is interesting to note that there is no correlation between the number of phrases extracted and translation quality. The only explanation for the results we are seeing is that the SBLITGs find *better* phrases. Since the only difference is the word alignment strategy, this suggests that the word alignments from SBLITGs are better suited for phrase extraction than those from bidirectional IBM-models. The fact that SBLITGs extract more phrases than bidirectional IBM-models under

[1] `http://www.statmt.org/wmt08/`

the grow-diag-x heuristics is significant, since more phrases means that more translation possibilities are extracted. The fact that SBLITGs extract fewer phrases than bidirectional IBM-models under the intersect heuristic is also significant, since it implies that simply adding more phrases is a bad strategy. Combined, the two observations leads us to believe that there are some alignments missed by the bidirectional IBM-models that are found by the SBLITG-models. It is also interesting to see that the pruned version outperforms the exhaustive version. We believe this to be because the pruned version approaches the correct grammar faster than the exhaustive. That would mean that the exhaustive SBLITG would be better in the limit, but the experiment was limited to 10 iterations.

5 Conclusion

In this paper we have focused on the benefits of applying SBLITGs to the task of inducing word alignments, which leads to a 2.85 BLEU points improvement compared to the standard model (heuristically combined bidirectional IBM-models). In the future, we hope that LITGs will be a spring board towards full ITGs, with more interesting nonterminals than the BITGs seen in the literature so far. With the possibility of inducing full ITG from parallel corpora it becomes viable to use ITG decoders directly as machine translation systems.

Abstract

Named entity recognition systems sometimes have difficulty when applied to data from domains that do not closely match the training data. We first use a simple rule-based technique for domain adaptation. Data for robust validation of the technique is then generated, and we use crowdsourcing techniques to show that this strategy produces reliable results even on data not seen by the rule designers. We show that it is possible to extract large improvements on the target data rapidly at low cost using these techniques.

1 Introduction

1.1 Named entities and errors

In this work, we use crowdsourcing to generate evaluation data to validate simple techniques designed to adapt a widely-used high-performing named entity recognition system to new domains. Specifically, we achieve a roughly 10% improvement in precision on text from the information technology (IT) business press via *post hoc* rule-based error reduction. We first tested the system on a small set of data that we annotated ourselves. Then we collected data from Amazon Mechanical Turk in order to demonstrate that the gain is stable. To our knowledge, there is no previous work on crowdsourcing as a rapid means of evaluating error mitigation in named entity recognizer development.

Named entity recognition (NER) is a well-known problem in NLP which feeds into many other related tasks such as information retrieval (IR) and machine translation (MT) and more recently social network discovery and opinion mining. Generally, errors in the underlying NER technology correlate with a steep price in performance in the NLP systems further along a processing pipeline, as incorrect entities propagate into incorrect translations or erroneous graphs of social networks.

Not all errors carry the same price. In some applications, omitting a named entity has the consequence of reducing the availability of training data, but including an incorrectly identified piece of text *as* as a named entity has the consequence of producing misleading results. Our application would be opinion mining; an omitted entity may prevent the system from attributing an opinion to a source, but an incorrect entity reveals non-existent opinion sources.

Machine learning is currently used extensively in building NER systems. One such system is BBN's Identifinder (Bikel et al., 1999). The IdentiFinder algorithm, based on Hidden Markov Models, has been shown to achieve F-measure scores above 90% when the training and testing data happen to be derived from Wall Street Journal text produced in the 1990s. We use IdentiFinder 3.3 as a starting point for performance improvement in this paper.

The use of machine learning in existing systems requires us to produce new and costly training data if we want to adapt these systems directly to other domains. Our *post hoc* error reduction strategy is therefore profoundly different: it relieves us of the burden of generating complete training examples. The data we generate are strictly corrections of the existing system's output. Our thus cheaper evaluation is therefore primarily on improvements to pre-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 345–348,

cision, while minimizing damage to recall, unlike an evaluation based on retraining with new, fully-annotated text.

1.2 Crowdsourcing

Crowdsourcing is the use of the mass collaboration of Internet passers-by for large enterprises on the World Wide Web such as Wikipedia and survey companies. However, a generalized way to monetize the many small tasks that make up a larger task is relatively new. Crowdsourcing platforms like Amazon Mechanical Turk have allowed some NLP researchers to acquire data for small amounts of money from large, unspecified groups of Internet users (Snow et al., 2008; Callison-Burch, 2009).

The use of crowdsourcing for an NLP annotation task required careful definition of the specifics of the task. The individuals who perform these tasks have no specific training, and they are trying to get through as many tasks as they can, so each task must be specified very simply and clearly.

Part of our work was to define a named entity error detection task simply enough that the results would be consistent across anonymous annotators.

2 Methodology

2.1 Process overview

The overall process for running this experiment was as follows (figure 1).

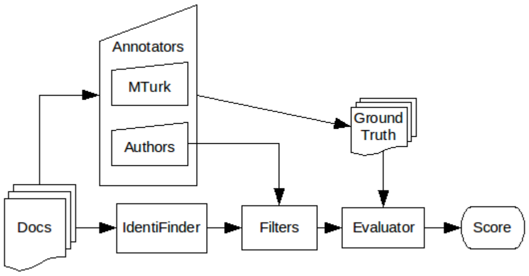

Figure 1: Diagram of data pipeline.

First, we performed an initial performance assessment of IdentiFinder on our domain. We selected 200 articles from an IT trade journal. IdentiFinder was used to tag persons and organizations in these documents. Domain experts (in this case, the authors of this paper) analyzed the entity tags produced by the NER system and annotated the erroneous tags. We built an error reduction system based on our error analysis. We then ran the IdentiFinder output through the error reduction system and evaluated its performance against our annotations.

Next, we constructed an Amazon Mechanical Turk-based interface for naïve web users or "Turkers" to annotate the IdentiFinder entities for errors. We measured the interannotator agreement between the Turkers and the domain experts, and we evaluated the IdentiFinder output and the repaired output against the expert-generated and Turker gold standards.

We selected a new batch of 800 articles and ran IdentiFinder and the filters on them, and we again ran our Mechanical Turk application on the IdentiFinder output. We measured the performance of IdentiFinder and filtered output against the Turker annotations.

2.2 Performance evaluation

Performance is evaluated in terms of standard precision and recall of entities. If the system output contains a person or organization labelled correctly as such, it considers this to be a hit. If it contains a person or organization that is mislabelled or otherwise incorrect in the gold standard annotation, it is a miss. We compute the F-measure as the harmonic mean of precision and recall.

As the IdentiFinder output is the baseline, and we ignore missed entities, by definition the baseline recall is 100%.

3 Experiments and results

Here we delve into further detail about the techniques we used and the results that they yielded. The results are summarized in table 1.

3.1 Baseline performance assessment

We randomly selected 200 documents from InformationWeek, a major weekly magazine in the IT business press. Running them through IdentiFinder produces NIST ACE-standard XML entity markup. We focused on the ENAMEX tags of person and organization type that IdentiFinder produces.

After we annotated the ENAMEX tags for errors, we found that closer inspection of the errors in the IdentiFinder output allowed us to classify the majority of them into three major categories:

Annotator	Collection	System	Precision	Recall	F-measure
Authors	200 document	IdentiFinder only	0.74	1	0.85
Authors	200 document	Filtered	0.86	0.98	0.92
MTurk	200 document	IdentiFinder only	0.69	1	0.82
MTurk	200 document	Filtered	0.79	0.97	0.87
MTurk	800 document	IdentiFinder only	0.67	1	0.80
MTurk	800 document	Filtered	0.77	0.95	0.85

Table 1: Results of evaluation of different document sets against ground truth source by annotation technique.

- IdentiFinder tags words that are simply not named entities.
- IdentiFinder assigns the wrong category (person or organization) to an entity.
- IdentiFinder includes extraneous words in an otherwise correct entity.

The second and third types of error are particularly challenging. An example of the second type is the following:

> **Yahoo** is a reasonably strong competitor to *Google*. It gets about half as much online revenue and search traffic as *Google*, . . .

Google is marked twice incorrectly as being a person rather than an organization.

Finally, here is an example of the third error type:

> A San Diego bartender reported that *Bill Gates danced* the night away in his bar on Nov. 11.

IdentiFinder incorrectly marks "danced" as part of a person tag.

We were able to find the precision of IdentiFinder against our annotations: 0.74. This is poorer than the reported performance of IdentiFinder on Wall Street Journal text (Bikel et al., 1999).

3.2 Domain-specific error reduction

We wrote a series of rule-based filters to remove instances of the error types—of which there were many subtypes—described in the previous section. For instance, the third example above was eliminated via the use of a part-of-speech tagger; "danced" was labelled as a verb, and entities with tagged verbs were removed. In the second case, the mislabelling of Google as a person rather than an organization is identified by looking at IdentiFinder's majority labelling of Google throughout the corpus—as an organization. Simple rules about capitalization allow instances like the first example to be identified as errors.

This step increases the precision of the system output to 86%, while only sacrificing a tiny amount of recall. We see that this 10% increase is maintained even on the Mechanical Turk-generated annotations.

3.3 Mechanical Turk tasks

The basic unit of Mechanical Turk is the Human Intelligence Task (HIT). Turkers select HITs presented as web pages and perform the described task. Datacollectors create HITs and pay Amazon to disburse small amounts of money to Turkers who complete them.

We designed our Mechanical Turk process so that every HIT we create corresponds to an IdentiFinder-marked document. Within its corresponding HIT, each document is broken up into paragraphs. Following every paragraph is a table whose rows consist of every person/organization ENAMEX discovered by IdentiFinder and whose columns consist of one of the four categories: "Person," "Organization," "Neither," and "Don't Know." Then for each entity, the user selects exactly one of the four options.

Each HIT is assigned to three different Turkers. Every entity in that HIT is assigned a person or organization ENAMEX tag if two of the three Turkers agreed it was one of those (majority vote); otherwise, it is marked as an invalid entity.

We calculated the agreement between our annotations and those developed from the Turker majority vote scheme. This yields a Cohen's κ of 0.68. We considered this to be substantial agreement.

After processing the same 200 document set from our own annotation, we found that the precision of IdentiFinder was 69%, but after error reduction, it increased to 79% with only a miniscule loss of known valid entities (recall).

We then took another 800 documents from InformationWeek and ran them through IdentiFinder. We did not annotate these documents ourselves, but instead turned them over to Turkers. IdentiFinder output alone has a 67% precision, but after error reduction, it rises to 77%, and recall is still minimally affected.

4 Discussion

4.1 Benefits

It appears that high-performing NER systems exhibit rather severe domain adaption problems. The performance of IdentiFinder is quite low on the IT business press. However, a simple rule-based system was able to gain 10% improvement in precision with little recall sacrificed. This is a particularly important improvement in applications with low tolerance for erroneous entities.

However, rule-based systems built by experts are known to be vulnerable to new data unseen by the experts. In order to apply this domain-specific error reduction reliably, it has to be tested on data gathered elsewhere. We used crowdsourced data to show that the rule-based system was robust when confronted with data that the designers did not see.

One danger in crowdsourcing is a potential lack of commitment on the part of the annotators, as they attempt to get through tasks as quickly as possible. It turns out that in an NER context, we can design a crowdsourced task that yields relatively reliable results across data sets by ensuring that for every data point, there were multiple annotators making only simple decisions about entity classification.

This method also provides us with a source of easily acquired supervised training data for testing more advanced techniques, if required.

4.2 Costs

It took not more than an estimated two person weeks to complete this work. This includes doing the expert annotations, designing the Mechanical Turk tasks, and building the domain-specific error reduction rules.

For each HIT, each annotator was paid 0.05 USD. For three annotators for 1000 documents, that is 150.00 USD (plus additional small Amazon surcharges and any taxes that apply).

5 Conclusions and Future Work

This work was done on a single publication in a single domain. One future experiment would be to see whether these results are reliable across other publications in the domain. Another set of experiments would be to determine the optimum number of annotators; we assumed three, but cross-domain results may be more stable with more annotators.

Retraining an NER system for a particular domain can be expensive if new annotations must be generated from scratch. While there is work on using advanced machine learning techniques for domain transfer (Guo et al., 2009), simply repairing the the errors *post hoc* via a rule-based system can have a low cost for high gains. This work shows a case where the results are reliable and the verification simple, in a context where reducing false positives is a high priority.

Generalizing Hierarchical Phrase-based Translation using Rules with Adjacent Nonterminals

Hendra Setiawan and Philip Resnik

hendra, resnik @umd.edu

Abstract

Hierarchical phrase-based translation (Hiero, (Chiang, 2005)) provides an attractive framework within which both short- and long-distance reorderings can be addressed consistently and efficiently. However, Hiero is generally implemented with a constraint preventing the creation of rules with adjacent nonterminals, because such rules introduce computational and modeling challenges. We introduce methods to address these challenges, and demonstrate that rules with adjacent nonterminals can improve Hiero's generalization power and lead to significant performance gains in Chinese-English translation.

1 Introduction

Hierarchical phrase-based translation (Hiero, (Chiang, 2005)) has proven to be a very useful compromise between syntactically informed and purely corpus-driven translation. By automatically learning synchronous grammar rules from parallel text, Hiero captures short- and long-distance reorderings consistently and efficiently. However, implementations of Hiero generally forbid adjacent nonterminal symbols on the source side of hierarchical rules, a practice we will refer to as the *non-adjacent nonterminals constraint*. The main argument against such rules is that they cause the system to produce multiple derivations that all lead to the same translation – a form of redundancy known as *spurious ambiguity*. Spurious ambiguity can lead to drastic reductions in decoding efficiency, and the obvious solutions, such as reducing beam width, erode translation quality.

In Section 2, we argue that the non-adjacent nonterminals constraints severely limits Hiero's generalization power, limiting its coverage of important reordering phenomena. In Section 3, we discuss the challenges that arise in relaxing this constraint. In Section 4 we introduce new methods to address those challenges, and Section 5 validates the approach empirically.

Improving Hiero via variations on rule pruning and filtering is well explored, e.g., (Chiang, 2005; Chiang et al., 2008; Zollmann and Venugopal, 2006), to name just a few. These proposals differ from each other mainly in the specific linguistic knowledge being used, and on which side the constraints are applied. In contrast, we complement previous work by showing that *adding* rules to Hiero can provide benefits if done judiciously.

2 Judicious Use of Adjacent Nonterminals

Our motivations largely follow Menezes and Quirk's (2007) discussion of reorderings and generalization. As a specific example, we will use a Chinese to English verb phrase (VP) translation (Fig. 1), which represents one of the most prominent phrase constructions in Chinese. Here the construction of the Chinese VP involves joining a prepositional phrase (PP) and a smaller verbal phrase (VP-A), with the preposition at the beginning as a PP marker. In the translation, the VP-A precedes the PP, a shift from pre-verbal PP in Chinese to post-verbal in English.

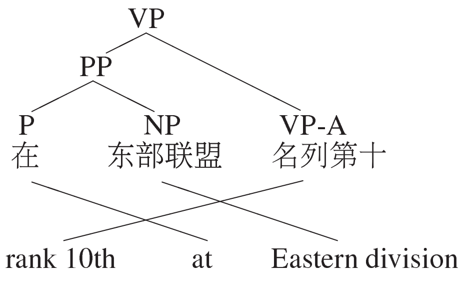

Figure 1: A Chinese-English verb phrase translation

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 349–352,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

Hiero can correctly translate the example if it learns any of the following rules from training data:

$$X \rightarrow \langle \text{在 } X_1 \text{ 名列第十, rank 10th at } X_1 \rangle \tag{1}$$

$$X \rightarrow \langle \text{ 在东部联盟 } X_1, X_1 \text{ at Eastern div.} \rangle \tag{2}$$

$$X \rightarrow \langle X_1 \text{ 东部联盟 } X_2, X_2\ X_1 \text{ Eastern div.} \rangle \tag{3}$$

However, in practice, data sparsity makes the chance of learning these rules rather slim. For instance, learning Rule 1 depends on training data containing instances of the shift with identical wording for the VP-A, which belongs to an open word class.

If Hiero fails to learn any of the above rules, it will apply the "glue rules" $S \rightarrow \langle S\ X_1,\ S\ X_1 \rangle$ and $S \rightarrow \langle X,\ X \rangle$. But these glue rules clearly cannot model the VP-A's movement. In failing to learn Rules 1-3, Hiero has no choice but to translate VP-A in a monotone order.

On the other hand, consider the following rules with adjacent nonterminals on the source side (or *XX rules*, for brevity):

$$X \rightarrow \langle \text{在 } X_1 X_2, X_2 \text{ at } X_1 \rangle \tag{4}$$

$$X \rightarrow \langle X_1 X_2 \text{ 名列第十, rank 10th } X_1 X_2 \rangle \tag{5}$$

$$X \rightarrow \langle X_1 X_2, X_2 X_1 \rangle \tag{6}$$

Note that although XX rules 4-6 can potentially increase the chance of modeling the pre-verbal to post-verbal shift, not all of them are beneficial to learn. For instance, Rule 5 models the word order shift but introduces spurious ambiguity, since the nonterminals are translated in monotone order. Rule 6, which resembles the inverted rule of the Inversion Transduction Grammar (Wu, 1997), is highly ambiguous because its application has no lexical grounding. Rule 4 avoids both problems, and is also easier to learn, since it is lexically anchored by a preposition, 在(at), which we can expect to appear frequently in training. These observations will motivate us to focus on rules that model non-monotone reordering of phrases surrounding a lexical item on the target side.

3 Addressing XX Rule Challenges

The first challenge created by introducing XX rules is computational: relaxing the constraint significantly increases the grammar size. Motivated by our earlier discussion, we address this by permitting only rules that model non-monotone reordering, i.e. those rules whose nonterminals are projected into the target language in a different word order, leaving monotone mappings to be handled by the glue rules as previously. This choice helps keep the search space more manageable, and also avoids spurious ambiguity. In addition, we disallow rules in which nonterminals are adjacent on both the source and target sides, by imposing the non adjacent nonterminal constraint on the target side whenever the constraint is relaxed on the source side. This forces any non-monotone reorderings to always be grounded in lexical evidence. We refer to the permitted subset of XX rules as *XX-nonmono* rules.

The second challenge involves modeling: introducing XX rules places them in competition with the existing glue rules. In particular, these two kinds of rules try to model the same phenomena, namely the translations of phrases that appear next to each other. However, they differ in terms of the features associated with the rules. XX rules will be associated with the same features as any other hierarchical rules, since they are all learned via an identical training method. In contrast, glue rules are introduced into the grammar in an *ad hoc* manner, and the only feature associated with them is a "glue penalty". These distinct feature sets makes direct comparison of scores unreliable. As a result the decoder may simply prefer to always select glue rules because they are associated with fewer features resulting in adjacent phrases always being translated in a monotone order. To address this issue, we introduce a new model, which we call the *target-side function words orientation-based model*, or simply P_{ori_t}, which evaluates the application of the two kinds of rules on the same context, i.e. for our example, it is the function word 在(at).

4 Target-side Function Words Orientation-based Model

The P_{ori_t} model is motivated by the *function words reordering hypothesis* (Setiawan et al., 2007), which suggests that function words encode essential information about the (re)ordering of their neighboring phrases. In contrast to Setiawan et al. (2007), who looked at neighboring contexts for function words on the source side, we focus here on modeling the influence of function words on neighboring phrases on the *target* side. We argue that this focus better fits our purpose, since the phrases that we want to model are the function words' neighbors on the target side, as illustrated in Fig. 1.

To develop this idea, we first define an ori_t function that takes a source function word as a reference point, along with its neighboring phrase on the target side. The ori_t function outputs one of the following orientation values (Nagata et al., 2006): Monotone-Adjacent (MA); Reverse-Adjacent (RA); Monotone-Gap (MG); and Reverse-Gap (RG). The Monotone/Reverse distinction indicates whether the source order follows the target order. The Adjacent/Gap distinction indicates whether the two phrases are adjacent or separated by an intervening phrase on the source side. For example, in Fig. 1, the value of ori_t for right neighbor *Eastern division* with respect to function word 在 (at) is MA, since its corresponding source phrase 东部联盟 is adjacent to 在 (at) and their order is preserved on the English side. The value for left neighbor *rank 10th* with respect to 在 (at) is RG, since 名列第十 is separated from 在 (at) and their order is reversed on the English side.

More formally, we define $P_{ori_t}(ori_t(Y, X)|Y)$, where $ori_t(Y, X) \in \{\mathrm{MA}, \mathrm{RA}, \mathrm{MG}, \mathrm{RG}\}$ is the orientation of a target phrase X with a source function word Y as the reference point.[1]

We estimate the orientation model using maximum likelihood, which involves counting and normalizing events of interest: $(Y, o = ori_t(Y, X))$. Specifically, we estimate $P_{ori_t}(o|Y) = C(Y, o)/C(Y, \cdot)$. Collecting training counts $C(Y, o)$ involves several steps. First, we run GIZA++ on the training bitext and apply the "grow-diag-final" heuristic over the training data to produce a bi-directional word alignment. Then, we enumerate all occurrences of Y and determine $ori_t(Y, X)$. To ensure uniqueness, we enforce that neighbor X be the longest possible phrase that satisfies the consistency constraint (Och and Ney, 2004). Determining $ori_t(Y, X)$ can then be done in a straightforward manner by looking at the monotonicity (monotone or reverse) and adjacency (adjacent or gap) between Y's and X.

	MT06	MT08

$+ori_t$	30.19	*23.69*
+XX-nonmono+ori_t	***31.49***	***24.73***

Table 1: Experimental results where better than baseline results are *italicized*, and statistically significant better ($p < 0.01$) are in **bold**.

5 Experiments

We evaluated the generalization of Hiero to include XX rules on a Chinese-to-English translation task. We treat the $N = 128$ most frequent words in the corpus as function words, an approximation that has worked well in the past and minimized dependence on language-specific resources (Setiawan et al., 2007). We report BLEU r4n4 and assess significance using the standard bootstrapping approach.

We trained on the NIST MT06 Eval corpus excluding the UN data (approximately 900K sentence pairs), segmenting Chinese using the Harbin segmenter (Zhao et al., 2001). Our 5-gram language model with modified Kneser-Ney smoothing was trained on the English side of our training data plus portions of the Gigaword v2 English corpus. We optimized the feature weights using minimum error rate training, using the NIST MT03 test set as the development set. We report the results on the NIST 2006 evaluation test (MT06) and the NIST 2008 evaluation test (MT08).

Table 1 reports experiments in an incremental fashion, starting from the baseline model (the original Hiero), then adding different sets of rules, and finally adding the orientation-based model. In our first experiments, we investigated the introduction of three different sets of XX rules. First (+itg), we simply add the ITG's inverted rule (Rule 6) to the baseline system in an ad-hoc manner, similar to the glue rules. This hurts performance consistently across MT06 and MT08 sets, which we suspect is a result of ITG rule applications often aggravating search error. Second (+XX), we permitted general XX rules. This results in a grammar size increase of 25-26%, filtering out rules irrelevant for the test set,

[1] In fact, separate models are developed for left and right neighbors, although for clarity we suppress this distinction throughout.

and leads to a significant performance drop, again perhaps attributable to search error. When we inspected the rules, we observe that the majority of these rules involve spurious word insertions. Third (+XX-nonmono), we introduced only XX-nonmono rules; this produced only a 5% additional rules, and yielded a marginal but consistent gain.

In a second experiment ($+ori_t$), we introduced the target-side function words orientation-based model. Note that this experiment is orthogonal to the first set, since we introduce no additional rules. Results are mixed, worse for MT06 but better (with significance) for MT08. Here, we suspect the model's potential has not been fully realized, since Hiero only considers monotone reordering in unseen cases.

Finally, we combine both the XX-nonmono rules and the P_{ori_t} model (+XX-nonmono+ori_t). The combination produces a significant, consistent gain across all test sets. This result suggests that the orientation model contributes more strongly in unseen cases when Hiero also considers non-monotone reordering. We interpret this result as a validation of our hypothesis that carefully relaxing the non-adjacent constraint improves translation.

6 Discussion and Future Work

To our knowledge, the work reported here is the first to relax the non-adjacent nonterminals constraint in hierarchical phrase-based models. The results confirm that judiciously *adding* rules to a Hiero grammar, adjusting the modeling accordingly, can achieve significant gains.

Although we found that XX-nonmono rules performed better than general XX rules, we believe the latter may nonetheless prove useful. Manually inspecting our system's output, we find that the output is often shorter than the references, and the missing words often correspond to function words that are modeled by those rules. Using XX rules to model legitimate word insertions is a topic for future work.

The Effect of Ambiguity on the Automated Acquisition of WSD Examples

Mark Stevenson and Yikun Guo

m.stevenson@dcs.shef.ac.uk and g.yikun@dcs.shef.ac.uk

Abstract

Several methods for automatically generating labeled examples that can be used as training data for WSD systems have been proposed, including a semi-supervised approach based on relevance feedback (Stevenson et al., 2008a). This approach was shown to generate examples that improved the performance of a WSD system for a set of ambiguous terms from the biomedical domain. However, we find that this approach does not perform as well on other data sets. The levels of ambiguity in these data sets are analysed and we suggest this is the reason for this negative result.

1 Introduction

Several studies, for example (Mihalcea et al., 2004; Pradhan et al., 2007), have shown that supervised approaches to Word Sense Disambiguation (WSD) outperform unsupervised ones. But these rely on labeled training data which is difficult to create and not always available (e.g. (Weeber et al., 2001)). Various techniques for creating labeled training data automatically have been suggested in the literature. Stevenson et al. (2008a) describe a semi-supervised approach that used relevance feedback (Rocchio, 1971) to analyse existing labeled examples and use the information produced to generate further ones. The approach was tested on the biomedical domain and the additional examples found to improve performance of a WSD system. However, biomedical documents represent a restricted domain. In this paper the same approach is tested against two data sets that are not limited to a single domain.

2 Application to a Range of Data Sets

In this paper the relevance feedback approach described by Stevenson et al. (2008a) is evaluated using three data sets: the **NLM-WSD** corpus (Weeber et al., 2001) which Stevenson et al. (2008a) used for their experiments, the **Senseval-3** lexical sample task (Mihalcea et al., 2004) and the coarse-grained version of the **SemEval** English lexical sample task (Pradhan et al., 2007).

2.1 Generating Examples

To generate examples for a particular sense of an ambiguous term all of the examples where the term is used in that sense are considered to be "relevant documents" while the examples in which any other sense of the term is used are considered to be "irrelevant documents". Relevance feedback (Rocchio, 1971) is used to generate a set of query terms designed to identify relevant documents, and therefore instances of the sense. The top five query terms are used to retrieve documents and these are used as labeled examples of the sense. Further details of this process are described by Stevenson et al. (2008a).

This process requires a collection of documents that can be queried to generate the additional examples. For the NLM-WSD data set we used PubMed, a database of biomedical journal abstracts queried using the Entrez retrieval system (http://www.ncbi.nlm.nih.gov/sites/gquery). The British National Corpus (BNC) was used for Senseval-3 and SemEval.[1] Lucene (http://lucene.apache.org) was used to index the BNC and retrieve examples.

[1] We also experimented with the English WaCky corpus (Baroni et al., 2009) which contains nearly 2 billion words automatically retrieved from the web. However, results were not as good as when the BNC was used.

2.2 WSD System

We use a WSD system that has been shown to perform well when evaluated against ambiguities found in both general text and the biomedical domain (Stevenson et al., 2008b). Medical Subject Headings (MeSH), a controlled vocabulary used for document indexing, are obtained from PubMed and used as additional features for the NLM-WSD data set since they have been shown to improve performance. The features are combined using the Vector Space Model, a simple memory-based learning algorithm.

2.3 Experiment

Experiments were carried out comparing performance when the WSD system was trained using either the examples in the original data set (**original**), the examples generated from these using the relevance feedback approach (**additional**) or a combination of these (**combined**). The Senseval-3 and SemEval corpora are split into training and test portions so the training portion is used as the original data set and the WSD system evaluated against the held-back data. As there is no such recognised standard split for the NLM-WSD corpus, 10-fold cross-validation was used. For each fold the training portion is used as the original data set and automatically generated examples created by examining just that part of the data. Evaluation is carried out against the fold's test data and the average result across the 10 folds reported.

Table 1 shows the results of this experiment.[2] Examples generated using the relevance feedback approach only improve results for one data set, the NLM-WSD corpus. In this case there is a significant improvement (Mann-Whitney, $p < 0.01$) when the original and automatically generated examples are combined. There is no such improvement for the other two data sets: WSD results using the additional data are noticeably worse than when the original data is used alone and, although performance improves when these examples are combined with the original data, results are still lower than using the original data. When examples are combined there is a drop in performance of 1.2% and 2.9% for SemEval and Senseval-3 respectively.

Corpus	Original	Additional	Combined
NLM-WSD	87.9	87.6	89.2
SemEval	83.7	74.6	82.5
Senseval-3	68.8	56.3	65.9

Table 1: Results of relevance feedback approach applied to three data sets

These results indicate that the relevance feedback approach described by Stevenson et al. (2008a) is not able to generate useful examples for the Senseval-3 and SemEval data sets, although it can for the NLM-WSD data set. We hypothesise that these corpora contain different levels of ambiguity which effect suitability of the approach.

3 Analysis of Ambiguities

The three data sets are compared using measures designed to determine the level of ambiguity they contain. Section 3.1 reports results using various widely used measures based on the distribution of senses. Section 3.2 introduces a measure based on the semantic similarity between the possible senses of ambiguous terms.

3.1 Sense Distributions

Three measures for characterising the difficulty of WSD data sets based on their sense distribution were used. The first is the widely applied most frequent sense (MFS) baseline (McCarthy et al., 2004), i.e. the proportion of examples for an ambiguous term that are labeled with the commonest sense. The second is number of senses per ambiguous term. The final measure, the entropy of the sense distribution, has been shown to be a good indication of disambiguation difficulty (Kilgarriff and Rosenzweig, 2000). For two of these measures (number of senses and entropy) a higher figure indicates greater ambiguity while for the MFS measure a lower figure indicates a more difficult data set.

Table 2 shows the results of computing these measures averaged across all terms in the corpus. For two measures (number of senses and entropy) the NLM-WSD corpus is least ambiguous, Senseval-3 the most ambiguous with SemEval between them. The MFS scores are very similar for two data sets (NLM-WSD and SemEval), both of which are much higher than for Senseval-3.

[2] Results reported here for the NLM-WSD corpus are slightly different from those reported by (Stevenson et al., 2008a). We used an additional feature (MeSH headings), which improved the baseline performance, and more query terms which improved the quality of the additional examples for all three data sets.

These measures suggest that the NLM-WSD corpus is less ambiguous than the other two and also that the Senseval-3 corpus is the most ambiguous of the three.

Corpus	MFS	Senses	Entropy
NLM-WSD	78.0	2.63	0.73
SemEval	78.4	3.60	0.91
Senseval-3	53.8	6.43	1.75

Table 2: Properties of Data Sets using sense distribution measures

3.2 Semantic Similarity

We also developed a measure that takes into account the similarity in meaning between the possible senses for an ambiguous term. This measure is similar to the one used by Passoneau et al. (2009) to analyse levels of inter-annotator agreement in word sense annotation. Our measure is shown in equation 1 where $Senses$ is the set of possible senses for an ambiguous term, $|Senses| = n$ and $\binom{Senses}{2}$ is the set of all subsets of $Senses$ containing two of its members (i.e the set of unordered pairs). The similarity between a pair of senses, $sim(x, y)$, can be computed using any lexical similarity measure, see Pedersen et al. (2004). Essentially this measure computes the mean of the similarities between each pair of senses for the term.

$$sim\_measure = \frac{\sum_{\{x,y\}\epsilon\binom{Senses}{2}} sim(x,y)}{\binom{n}{2}} \quad (1)$$

One problem with comparing the data sets used here is that they use a range of sense inventories. Although lexical similarity measures have been applied to WordNet (Pedersen et al., 2004) and UMLS (Pedersen et al., 2007), it is not clear that the scores they produce can be meaningfully compared. To avoid this problem we mapped the sense inventories onto a single resource: WordNet version 3.0.

The mapping was most straightforward for Senseval-3 which uses WordNet 1.7.1 and could be automatically mapped onto WordNet 3.0 senses using publicly available mappings (Daudé et al., 2000). The SemEval data contains a mapping from the OntoNotes senses to groups of WordNet 2.1 senses. The first sense from this group was mapped to WordNet 3.0 using the same mappings.

Mapping the NLM-WSD corpus was more problematic and had to be carried out manually by comparing sense definitions in UMLS and WordNet 3.0. We had expected this process to be difficult but found clear mappings for the majority of senses. There were even found cases in which the sense definitions were identical in both resources. (The most likely reason for this is that some of the resources that are included in the UMLS were used to compile WordNet.) Another, more serious, problem is related to the annotation scheme used in the NLM-WSD corpus. If none of the possible senses in UMLS were judged to be appropriate the annotators could label the sense as “None”. We did not map these senses since it would require examining each instance to determine the most appropriate sense or senses in WordNet and we expected this to be error prone. In addition, there is no guarantee that all of the instances of a particular term labeled with “None” refer to the same meaning. All of the “None” senses were removed from the NLM-WSD data set and any terms where there were more than ten instances marked as “None” were also rejected from the similarity analysis. This allowed us to compute the similarity score for just 20 examples (40% of the total) although we felt that this was a large enough sample to provide insight into the data set.

The `WordNet::Similarity` package (Pedersen et al., 2004) was used to compute similarity scores. Results are reported for three of the measures in this package. (Other measures produced similar results.) The simple **path** measure computes the similarity between a pair of nodes in WordNet as the reciprocal of the number of edges in the shortest path between them, the **LCh** measure (Leacock et al., 1998) also uses information about the length of the shortest path between a pair of nodes and combines this with information about the maximum depth in WordNet and the **JCn** measure (Jaing and Conrath, 1997) makes use of information theory to assign probabilities to each of the nodes in the WordNet hierarchy and computes similarity based on these scores.

Table 3 shows the values of equation 1 for the three similarity measures with scores averaged across terms. These results indicate that for all measures the Senseval-3 data set contains the most ambiguity and NLM-WSD the least. This analysis is consistent with the one carried out using measures based on sense distributions (Section 3.1)

Corpus	Measure		
	Path	JCn	LCh
NLM-WSD	0.074	0.032	1.027
SemEval	0.136	0.061	1.292
Senseval-3	0.159	0.063	1.500

Table 3: Semantic similarity for each data set using a variety of measures

and suggest that the senses in the NLM-WSD data set are more clearly distinguished than the other two.

4 Conclusion

This paper has explored a semi-supervised approach to the generation of labeled training data for WSD that is based on relevance feedback (Stevenson et al., 2008a). It was tested on three data sets but was only found to generate examples that were accurate enough to improve WSD performance for one of these. The data set in which a performance improvement was observed represented a limited domain (biomedicine) while the other two were not restricted in this way. Measures designed to quantify the level of ambiguity were applied to these data sets including ones based on the distribution of senses and another designed to quantify similarities between senses. These measures provided evidence that the corpus for which the relevance feedback approach was successful contained less ambiguity than the other two and this suggests that the relevance feedback approach is most appropriate when the level of ambiguity is low.

The experiments described in this paper highlight the importance of the level of ambiguity on the relevance feedback approach's ability to generate useful labeled examples. Since it is semi-supervised the ambiguity level can be checked using the measures used in this paper (Section 3) and the performance of any automatically generated examples can be compared with the manually labeled ones (see Section 2.3) before deciding whether or not they should be applied.

Word Sense Subjectivity for Cross-lingual Lexical Substitution

Abstract

We explore the relation between word sense subjectivity and cross-lingual lexical substitution, following the intuition that good substitutions will transfer a word's (contextual) sentiment from the source language into the target language. Experiments on English-Chinese lexical substitution show that taking a word's subjectivity into account can indeed improve performance. We also show that just using word sense subjectivity can perform as well as integrating fully-fledged fine-grained word sense disambiguation for words which have both subjective and objective senses.

1 Introduction

Cross-lingual lexical substitution has been proposed as a Task at SemEval-2010.[1] Given a target word and its context in a source language (like English), the goal is to provide correct translations for that word in a target language (like Chinese). The translations must fit the given context.

In this paper, we explore the relation between the sentiment of the used word in the source language and translation choice in the target language, focusing on English as the source and Chinese as the target language. Our work is motivated by the intuition that most good word translations will be *sentiment-invariant*, i.e. if a source word is used in a subjective (opinion-carrying) sense it will be often translated with a subjective sense in the target language whereas if it used in an objective sense, it will be translated with an objective sense. As an example, consider the two words *positive* and *collaborate* with example senses from WordNet 2.0 below.

(1) positive—greater than zero; "positive numbers" (*objective*)

(2) plus, positive—involving advantage or good; "a plus (or positive) factor" (*subjective*)

(3) collaborate, join forces, cooperate—work together on a common enterprise of project; "We joined forces with another research group"(*objective*)

(4) collaborate—cooperate as a traitor; (*subjective*)

In most cases, if the word *positive* is used in the sense *"greater than zero"* (**objective**) in an English context, the corresponding Chinese translation is "正的"; if *"involving advantage or good"*(**subjective**) is used, its Chinese translations are "积极的, 好的". Similarly, for the word *collaborate*, the sense *"work together on a common enterprise of project"* (**objective**) corresponds to "合作, 协作" in Chinese translation, and *"cooperate as a traitor"* (**subjective**) corresponds to "勾结, 狼狈为奸". Therefore, subjectivity information should be effective for improving lexical translation for what we previously (Su and Markert, 2008) termed *subjectivity-ambiguous* words, i.e. words with both subjective and objective senses such as *positive* and *collaborate* above.

We therefore incorporate subjectivity word sense disambiguation (SWSD) as defined in Akkaya et al. (2009) into lexical substitution. SWSD is a binary classification task that decides in context whether a word occurs with one of its subjective or one of its objective senses. In contrast to standard

multi-class Word Sense Disambiguation (WSD), it uses a coarse-grained sense inventory that allows to achieve higher accuracy than WSD and therefore introduces less noise when embedded in another task such as word translation. For example, the accuracy reported in Akkaya et al. (2009) for SWSD is over 20% higher than for standard WSD. Coarse-grained senses are also easier to annotate, so getting training data for learning is less arduous. On the minus side, SWSD can only be useful for subjectivity-ambiguous words. However, we showed (Su and Markert, 2008) that subjectivity-ambiguity is frequent (around 30% of common words).

2 Related Work

McCarthy and Navigli (2007) organized a monolingual English lexical substitution task in Semeval-2007, i.e finding English substitutions for an English target word. Mihalcea et al. organize an English-Spanish lexical substitution task in SemEval-2010. Approaches to lexical substitution in the past competitions did not use sentiment features.

Independent of these lexical substitution tasks, the connection between word senses and word translation has been explored in Chan et al. (2007) and Carpuat and Wu (2007), who predict the probabilities of a target word being translated as an item in a "sense inventory", where the sense inventory is a list of possible translations. They then incorporate these probabilities into machine translation. However, they do not consider sentiment explicitly.

Subjectivity at the word sense level has been discussed by (Wiebe and Mihalcea, 2006; Su and Markert, 2008; Akkaya et al., 2009). Wiebe and Mihalcea (2006) and Su and Markert (2008) both show that this is a well-defined concept via human annotation as well as automatic recognition. Akkaya et al. (2009) show that subjectivity word sense disambiguation (SWSD) can boost the performance of a sentiment analysis system. None of these paper considers the impact of word sense subjectivity on cross-lingual lexical substitution.

3 Methodology

3.1 Task and Dataset

We constructed an English-Chinese lexical substitution gold standard by translating the English target words in the SENSEVAL 2 and SENSEVAL 3 lexical sample training and test sets into Chinese. We choose the SENSEVAL datasets as they are relatively domain-independent and also because we can use them for our SWSD/WSD subtasks as well. The translation is carried out by two native Chinese speakers with a good command of English. First, candidate Chinese translations (denoted by **T**) of the English target words are provided from the on-line English-Chinese dictionary *iciba*[2], which is composed of more than 150 different English-Chinese dictionaries. To reduce annotation bias, the order of the Senseval sentences is randomized. The annotators then independently assign the most fitting Chinese translation(s) (from **T**) for the English target words in the given Senseval sentences. For the agreement study, different Chinese translations (for example, "权威" and "泰斗" of the word *authority*) that are actually synonyms are merged. The observed agreement between the two annotators is 86.7%. Finally, the two annotators discuss the disagreed examples together, leading to a gold standard.

Since we evaluate how word sense subjectivity affects cross-lingual lexical substitution, we limited our study to the SENSEVAL words that are subjectivity-ambiguous. Therefore, following the annotation schemes in (Su and Markert, 2008; Wiebe and Mihalcea, 2006), all senses of all target words in SENSEVAL 2&3 are annotated by a near-native English speaker as *subjective* or*objective*. This annotator was not involved in the English to Chinese translation. We also discard subjectivity-ambiguous words if its *subjective* or *objective* senses do not appear in both training and test set. In total we collect 28 subjectivity-ambiguous words. Their English example sentences and translations yield 2890 training sentence pairs and 1444 test sentence pairs.

3.2 Algorithms

For the English-Chinese lexical substitution task, we first develop a basic system (called **B**) to assign Chinese translations to the target English words in context. This system uses only standard contextual features from the English sentences (see Section 3.3). We then add word sense subjectivity information to

[2] http://www.iciba.com

the basic system (see Section 3.4). We also compare including word sense subjectivity to the inclusion of full fine-grained sense information (Section 3.5).

All systems are supervised classifiers trained on the SENSEVAL training data and evaluated on the SENSEVAL test data for each of the 28 words. We employ an SVM classifier from the `libsvm` package[3] with a linear kernel.

3.3 Common Features

In the basic system **B**, we adopt features which are commonly used in WSD or lexical translation.

Surrounding Words: Lemmatized bag of words with stop word filtering.

Part-of-Speech (POS): The POS of the neighbouring words of the target word. We extract POS tag of the 3 words to the right and left together with position information.

Collocation: The neighbouring words of the target word. We extract 4 lemmatized words to the right and left, together with position information.

Syntactic Relations: We employ the MaltParser[4] for dependency parsing and extract 4 features: the head word of the target word, POS of the head word, the dependency relation between head word and target word, and the relative position (left or right) of the head word to the target word.

3.4 Subjectivity Features

We add a feature that incorporates whether the original English word is used subjectively or objectively. For an upper bound, we use the SENSEVAL gold standard sense annotation (**gold-subj**), mapped onto binary subjective/objective labels. For a more realistic assessment, we use SWSD to derive the subjectivity sense label automatically (**auto-subj**) using standard supervised binary SVMs and the features in Section 3.3 on the SENSEVAL data.

3.5 Sense Features

We compare using subjectivity information to using full fine-grained word sense information, incorporating a feature that specifies the exact word sense of the target word to be translated. This setting also compares the SENSEVAL gold standard (**gold-senses**) and automatically predicted sense information (**auto-senses**), the latter via supervised multi-class learning on the SENSEVAL dataset.

4 Experiments and Evaluation

For the English-Chinese lexical substitution task, we evaluate 6 different methods: **Baseline** (assign the most frequent translation to all examples), **B** (use common features), **B+gold subj** (incorporate gold standard word sense subjectivity), **B+gold sense** (incorporate gold standard sense), **B+auto subj** (incorporate automatically predicted word sense subjectivity), and **B+auto sense** (incorporate automatically predicted fine-grained senses). We measure lexical substitution accuracy on the SENSEVAL test data by comparing to the human gold standard annotation (see Section 3.1). Results are listed in Table 1.

Results. Table 1 shows that our standard lexical substitution system **B** improves strongly (near 11% average accuracy gain) over the most frequent translation baseline. Incorporating sense subjectivity as in **B+gold subj** leads to a further strong improvement, confirming our hypothesis that word sense subjectivity can improve lexical substitution. Incorporating fine-grained senses **B+gold senses** yields only a slightly higher gain, showing that a coarse-grained subjective/objective classification might be sufficient for subjectivity-ambiguous words for aiding translation. In addition, the small gain using fine-grained senses might disappear in practice as automatic WSD is a more challenging task than SWSD: in our experiment, **B+auto sense** performs worse than **B+auto subj**. The current improvement of **B+auto subj** over **B** is significant (McNemar test at the 5% level). The difference between the actual performance of word sense subjectivity and its potential as exemplified in **B+gold subj** is, obviously, caused by imperfect performance of the SWSD component, mostly due to a distributional bias in the SENSEVAL training data, with few examples for rarer senses of the target words.

For some words (such as *authority* and *stress*), the additional sense subjectivity feature does not improve lexical substitution, even when gold standard labels are used. There are two main reasons for this. First, one candidate Chinese translation might cover

AVERAGE		**57.4%**	**68.5%**	**77.9%**	**80.2%**	**70.7%**	**70.1%**

both subjective and objective uses of the word. For example, both the objective sense (*"physics force that produces strain on a physical body"*) and subjective senses (*"difficulty that causes worry or emotional emotional tension"* and *" a state of mental or emotional strain or suspense"*) of *stress* are often translated as "压力" in Chinese. Second, in some cases, subjectivity word sense disambiguation is too coarse-grained and finer-grained WSD is actually necessary. For example, the subjective usages of *authority* in SENSEVAL examples are often translated as "专家, 权威", "自信" or "可信" (called **List-S**), and objective usages are often translated as "局, 部","当局","权力, 职权" or "授权, 批准" (called **List-O**). In this case, word sense subjectivity might help to distinguish **List-S** from **List-O**, but not among the candidate translations within a single list.

5 Discussion

We tackle cross-lingual lexical substitution as a supervised task, using sets of manual translations for a target word as training data even for baseline system **B**. However, we do not necessarily need dedicated human translated data as we could also use existing parallel texts in which the target word occurs. Therefore, we think that a supervised approach to lexical substitution is feasible. However, we do need additional monolingual sense-tagged data in the source language for incorporating our word sense subjectivity features.[5] Although a disadvantage, more and more sense-tagged data does become available (such as OntoNotes). We also only need tagging at a coarse-grained sense level, which is much easier to create than fine-grained data.

6 Conclusion and Future Work

We investigate the relation between word sense subjectivity and cross-lingual lexical substitution. The experimental results show that incorporating word sense subjectivity into a standard supervised classification model yields a significantly better performance for an English-Chinese lexical substitution task. We also compare the effect of sense subjectivity to the effect of fine-grained sense information on lexical substitution. The differences between the two methods turn out to be small, making a case for the "easier", coarse-grained SWSD over WSD for subjectivity-ambiguous words. Future work will widen the study by (i) looking at a wider range of words and languages, (ii) improving automatic SWSD results for better application and (iii) integrating unsupervised subjectivity features into cross-lingual lexical substitution.

Query Ambiguity Revisited: Clickthrough Measures for Distinguishing Informational and Ambiguous Queries

Abstract

Understanding query ambiguity in web search remains an important open problem. In this paper we reexamine query ambiguity by analyzing the result clickthrough data. Previously proposed clickthrough-based metrics of query ambiguity tend to conflate informational and ambiguous queries. To distinguish between these query classes, we introduce novel metrics based on the entropy of the click distributions of individual searchers. Our experiments over a clickthrough log of commercial search engine demonstrate the benefits of our approach for distinguishing informational from truly ambiguous queries.

1 Introduction

Since query interpretation is the first crucial step in the operation of the web search engines, more reliable query intent classification, such as detecting whether a query is ambiguous, could allow a search engine to provide more diverse results, better query suggestions, or otherwise improve user experience.

In this paper we re-examine query ambiguity in connection with searcher clickthrough behavior. That is, we posit that clickthrough information could provide important evidence for classifying query ambiguity. However, we find that previously proposed clickthrough-based measures tend to conflate informational and ambiguous queries. We propose a novel clickthrough measure for query classification, *user click entropy*, and show that it helps distinguish between informational and truly ambiguous queries.

Previous research on this topic focused on binary classification of query ambiguity. Notably, (Teevan et al., 2008) used click entropy as a proxy for query ambiguity to estimate the potential for search personalization. (Mei and Church, 2008) considered click entropy as measure of search difficulty. More broadly, clickthrough information has been used for many other tasks such as improving search ranking (Zhu and Mishne, 2009), learning semantic categories (Komachi et al., 2009), and for topical query classification (Li et al., 2008). However, our work sheds new light on distinguishing between informational and ambiguous queries, by using clickthrough data. Our contributions include:

- More precise definition of query ambiguity in terms of clickthrough behavior (Section 2).
- Entropy-based formalization of resulting click behaviors (Section 3).
- Empirical validation of our methods on a large real query and clickthrough log (Section 4).

2 Defining Query Ambiguity

In this study we focus on two orthogonal query intent dimensions, adapted from the top level of user goal taxonomies such as (Rose and Levinson, 2004). Specifically, a query could be *ambiguous* or *unambiguous*; as well as *informational* or *navigational*. Consider the example queries of each type below:

	Ambiguous	Unambiguous
Informational	“al pacino”	“lyrics”
Navigational	“people”	“google”

The query “al pacino”, the name of a famous actor, is a typical ambiguous and informational query. In the clickthrough logs that we examined, the most popular searcher destinations include sites with pictures of Al Pacino, movie sites, and biography sites – corresponding to different informational intents. In contrast, the query “lyrics” has an unambiguous informational intent, which is to explore websites with song lyrics. For the ambiguous navigational query “people”, popular destinations include people.com, Yahoo People or People’s United Bank. Finally, the

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 361–364,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

query “google” is unambiguous and navigational, with over 94% of the clicks on the Google’s homepage.

Definitions of query classes: we now more formally define the query classes we consider:

- **Clear**: Unambiguous navigational query, such as “google”.
- **Informational**: Unambiguous informational query, such as “lyrics”
- **Ambiguous**: Ambiguous informational or navigational query, such as “people” or “al pacino”.

The key challenge in distinguishing the last two classes, Informational and Ambiguous, is that the overall clickthrough patterns for these classes are similar: in both cases, there are clicks on many results, without a single dominant result for the query.

3 Clickthrough Measures for Distinguishing Ambiguous and Informational Queries

In this section we describe the features used to represent a query for intent classification, listed in Table 1. In addition to popular features such as clickthrough frequency and query length, we introduce novel features related to user click entropy, to capture the distinction between informational and ambiguous queries.

Overall Entropy: Previous methods for query classification utilize entropy of all result clicks for a query, or overall entropy (the uncertainty associated with obtaining a click on any specific result), defined as:

$$H(R_q) = -\sum_{r \in R_q} p(r) \log p(r)$$

R_q is the set of results r, clicked by all users after submitting the query q. For example, a clear query “target” has the overall entropy of 0.36, and most results corresponding to this query point to Target’s company website. The click log data shows that 85% of the users click the Target website for this query. In contrast, an unclear query “lyrics” has the overall entropy of 2.26. However, overall entropy is insufficient for distinguishing between informational and ambiguous queries. To fill this gap, we introduce new clickthrough metrics to detect such ambiguous queries.

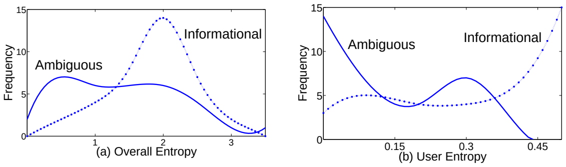

Figure 1: Frequency of ambiguous and informational queries by Overall Entropy (a) and User Entropy (b).

User Entropy: Recall, that both informational queries and ambiguous queries could have high overall entropy, making it difficult to distinguish them. Thus, we introduce a new metric, *user entropy of a query* q $H(U_q)$, as the average entropy of a distribution of clicks for each *searcher*:

$$H(U_q) = \frac{-\sum_{u \in U_q} \sum_{r \in R_u} p(r) \log p(r)}{|U_q|}$$

where U_q is the set of users who have submitted the query q, and R_u is the set of results r, clicked by the user u. For the example informational query “lyrics”, a single user may click many different URLs, thereby increasing user entropy of this query to 0.317. While for an ambiguous query, which has multiple meanings, a user typically searches for only one meaning of this query at a time, so the results clicked by each user will concentrate on one topic. For example, the query “people” is ambiguous, and has the overall entropy of 1.73 due to the variety of URLs clicked. However, a particular user usually clicks only one of the websites, resulting in low *user entropy* of 0.007. Figure 1 illustrates the difference in the distributions of informational and ambiguous queries according to their overall and user entropy values: more informational queries tend to have medium to high User Entropy values, compared to the truly ambiguous queries.

Domain Entropy: One problem with the above measures is that clickthrough data for individual URLs is sparse. A common approach is to *backoff* to the URLs domain, with the assumption that URLs within the same domain usually relate to the same topic or concept. Therefore, domain entropy $H(D_q)$ of a query may be more robust, and is defined as:

$$H(D_q) = -\sum_{d \in D_q} p(d) \log p(d)$$

where D_q are the domains of all URL clicked for q. For example, the query “excite” is a navigational and clear query, as all the different clicked URLs for this query are within the same domain, *excite.com*.

Query Feature	**Description**
QueryLength	Number of tokens (words) in the query
ClickFrequency	Number of total clicks for this query
OverallEntropy	Entropy of all URLs for this query
UserEntropy*	Average entropy of the URLs clicked by one user for this query
OverallDomainEntropy	Entropy of all URL domains for this query
UserDomainEntropy*	Average entropy of URL domains clicked by one user for this query
RelativeUserEntropy*	Fraction of UserEntropy divided by OverallEntropy
RelativeOverallEntropy*	Fraction of OverallEntropy divided by UserEntropy
RelativeUserDomainEntropy*	Fraction of UserDomainEntropy divided by OverallDomainEntropy
RelativeOverallDomainEntropy*	Fraction of OverallDomainEntropy divided by UserDomainEntropy

Table 1: Features used to represent a query (* indicates features derived from User Entropy).

While this query has high Overall and User Entropy values, the Domain Entropy is low, as all the clicked URLs for this query are within the same domain.

The features described here can then be used as input to many available classifiers. In particular, we use the Weka toolkit[1], as described below.

4 Experimental Results

We describe the dataset and annotation process, and then present and analyze the experimental results.

Dataset: We use an MSN Search query log (from 2006 Microsoft data release) with 15 million queries, from US users, sampled over one month. Queries with click frequency under 10 are discarded. As a result, 84,703 unique queries remained, which form our universe of queries. To separately analyze queries with different frequencies, we divide the queries into three groups: low frequency group (10-100 clicks), medium frequency group (100-1000 clicks) and high frequency group (over 1000 clicks). From each group, we draw a random sample of 50 queries for manual labeling, for the total of 150 queries. Each query was labeled by three members of our lab. The inter-annotator agreeement was 85%, and Cohen's Kappa value was 0.77.

Table 2 reports the distribution of query classes in our dataset. Note that low frequency queries dominate, but are equally represented in the data samples used for classification training and prediction (we will separately analyze performance on different query frequency groups).

Results: Table 3 shows that best classification required User Entropy features. The Weka classifiers were Naive Bayes (NB), Logistic Regression (Logistic), and Support Vector Machines (SVM).

	Clear	Informational	Ambiguous	Frequency (%)
High	76%	8%	16%	255 (0.3%)
Medium	52%	20%	28%	3802 (4.5%)
Low	32%	46%	22%	80646 (95.2%)

Table 6: Binary classification performance for queries manually labeled as unclear.

clear category). For classification between clear and unclear queries, the accuracy was 90%, precision was 91%, and recall was 90%. The results for subsequently classifying ambiguous vs. information queries are reported in Table 6. For this task, User Entropy features are beneficial, while the χ^2 value or Overall Entropy is 0, supporting our claim that User Entropy is more useful for distinguishing informational from ambiguous queries.

Discussion: Interestingly, User Entropy does not show a large effect on classification of High and Medium frequency queries. However, as Table 2 indicates, High and Medium frequency queries are largely *clear* (76% and 52%, respectively). As discussed above, User Entropy helps classify unclear queries, but there are fewer such queries among the High frequency group, which also tend to have larger click entropy in general.

An *ambiguous* query is difficult to detect when most users interpret it only one way. For instance, query "ako" was annotated as *ambiguous*, as it could refer to different popular websites, such as the site for Army Knowledge Online and the company site for A.K.O., Inc. However, most users select the result for the Army Knowledge Online site, making the overall entropy low, resulting in prediction as a *clear* query. On the positive side, we find that User Entropy helps detect ambiguous queries, such as "laguna beach", which was labeled *ambiguous* as it could refer to both a geographical location and a popular MTV show. As a result, while the Overall Entropy value of the clickthrough is high, the low User Entropy value identifies the query as truly ambiguous and not informational.

In summary, our techniques are of most help for Low frequency queries and moderately helpful for Medium frequency queries. These results are promising, as Low frequency queries make up the majority of queries processed by search engines, and also contain the highest proportion of informational queries, which our techniques can identify.

5 Conclusions

We explored clickthrough-based metrics for distinguishing between ambiguous and informational queries - which, while exhibiting similar *overall* clickthrough distributions, can be more accurately identified by using our User Entropy-based features. We demonstrated substantial improvements for *low-frequency* queries, which are the most frequent in query logs. Hence, our results are likely to have noticeable impact in a real search setting.

For the sake of simplicity: Unsupervised extraction of lexical simplifications from Wikipedia

Mark Yatskar, Bo Pang, Cristian Danescu-Niculescu-Mizil and Lillian Lee
my89@cornell.edu, bopang@yahoo-inc.com, cristian@cs.cornell.edu, llee@cs.cornell.edu

Abstract

We report on work in progress on extracting lexical simplifications (e.g., "*collaborate*" → "*work together*"), focusing on utilizing edit histories in Simple English Wikipedia for this task. We consider two main approaches: (1) deriving simplification probabilities via an edit model that accounts for a mixture of different operations, and (2) using metadata to focus on edits that are more likely to be simplification operations. We find our methods to outperform a reasonable baseline and yield many high-quality lexical simplifications not included in an independently-created manually prepared list.

1 Introduction

Nothing is more simple than greatness; indeed, to be simple is to be great. —Emerson, *Literary Ethics*

Style is an important aspect of information presentation; indeed, different contexts call for different styles. Here, we consider an important dimension of style, namely, *simplicity*. Systems that can rewrite text into simpler versions promise to make information available to a broader audience, such as non-native speakers, children, laypeople, and so on.

One major effort to produce such text is the Simple English Wikipedia (henceforth SimpleEW)[1], a sort of spin-off of the well-known English Wikipedia (henceforth ComplexEW) where human editors enforce simplicity of language through rewriting. The crux of our proposal is to learn lexical simplifications from SimpleEW edit histories, thus leveraging the efforts of the 18K pseudonymous individuals who work on SimpleEW. Importantly, not all the changes on SimpleEW are simplifications; we thus also make use of ComplexEW edits to filter out non-simplifications.

Related work and related problems Previous work usually involves general syntactic-level transformation rules [1, 9, 10].[2] In contrast, we explore data-driven methods to learn *lexical simplifications* (e.g., "*collaborate*" → "*work together*"), which are highly specific to the lexical items involved and thus cannot be captured by a few general rules.

Simplification is strongly related to but distinct from paraphrasing and machine translation (MT). While it can be considered a directional form of the former, it differs in spirit because simplification must trade off meaning preservation (central to paraphrasing) against complexity reduction (not a consideration in paraphrasing). Simplification can also be considered to be a form of MT in which the two "languages" in question are highly related. However, note that ComplexEW and SimpleEW do not together constitute a clean parallel corpus, but rather an extremely noisy comparable corpus. For example, Complex/Simple same-topic document pairs are often written completely independently of each other, and even when it is possible to get good sentence alignments between them, the sentence pairs may reflect operations other than simplification, such as corrections, additions, or edit spam.

Our work joins others in using Wikipedia revisions to learn interesting types of directional lexical relations, e.g, "eggcorns"[3] [7] and entailments [8].

2 Method

As mentioned above, a key idea in our work is to utilize SimpleEW edits. The primary difficulty in working with these modifications is that they include not only simplifications but also edits that serve other functions, such as spam removal or correction of grammar or factual content ("fixes"). We describe two main approaches to this problem: a probabilistic model that captures this mixture of different edit operations (§2.1), and the use of *metadata* to filter out undesirable revisions (§2.2).

[1] http://simple.wikipedia.org

[2] One exception [5] changes verb tense and replaces pronouns. Other lexical-level work focuses on medical text [4, 2], or uses frequency-filtered WordNet synonyms [3].

[3] A type of lexical corruption, e.g., "acorn"→"eggcorn".

2.1 Edit model

We say that the k^{th} article in a Wikipedia corresponds to (among other things) a title or *topic* (e.g., “Cat”) and a sequence $\vec{d_k}$ of article versions caused by successive edits. For a given lexical item or phrase A, we write $A \in \vec{d_k}$ if there is any version in $\vec{d_k}$ that contains A. From each $\vec{d_k}$ we extract a collection $e_k = (e_{k,1}, e_{k,2}, \ldots, e_{k,n_k})$ of *lexical edit instances*, *repeats allowed*, where $e_{k,i} = A \rightarrow a$ means that phrase A in one version was changed to a in the next, $A \neq a$; e.g., “*stands for*” → “*is the same as*”. (We defer detailed description of how we extract lexical edit instances from data to §3.1.) We denote the collection of $\vec{d_k}$ in ComplexEW and SimpleEW as C and S, respectively.

There are at least four possible edit operations: *fix* (o_1), *simplify* (o_2), *no-op* (o_3), or *spam* (o_4). However, for this initial work we assume $P(o_4) = 0$.[4]

Let $P(o_i \mid A)$ be the probability that o_i is applied to A, and $P(a \mid A, o_i)$ be the probability of $A \rightarrow a$ given that the operation is o_i. The key quantities of interest are $P(o_2 \mid A)$ in S, which is the probability that A should be simplified, and $P(a \mid A, o_2)$, which yields proper simplifications of A. We start with an equation that models the probability that a phrase A is edited into a:

$$P(a \mid A) = \sum_{o_i \in \Omega} P(o_i \mid A) P(a \mid A, o_i), \quad (1)$$

where Ω is the set of edit operations. This involves the desired parameters, which we solve for by estimating the others from data, as described next.

Estimation Note that $P(a \mid A, o_3) = 0$ if $A \neq a$. Thus, if we have estimates for o_1-related probabilities, we can derive o_2-related probabilities via Equation 1. To begin with, we make the working assumption that occurrences of simplification in ComplexEW are negligible in comparison to fixes. Since we are also currently ignoring edit spam, we thus assume that only o_1 edits occur in ComplexEW.[5]

Let $f_C(A)$ be the fraction of $\vec{d_k}$ in C containing A in which A is modified: $f_C(A) = \frac{|\{\vec{d_k} \in C \mid \exists a,i \text{ such that } e_{k,i} = A \rightarrow a\}|}{|\{\vec{d_k} \in C \mid A \in \vec{d_k}\}|}$.

We similarly define $f_S(A)$ on $\vec{d_k}$ in S. Note that we count topics (version sequences), not individual versions: if A appears at some point and is not edited until 50 revisions later, we should *not* conclude that A is unlikely to be rewritten; for example, the intervening revisions could all be minor additions, or part of an edit war.

If we assume that the probability of any particular fix operation being applied in SimpleEW is proportional to that in ComplexEW— e.g., the SimpleEW fix rate might be dampened because already-edited ComplexEW articles are copied over — we have[6]

$$\widehat{P}(o_1 \mid A) = \alpha f_C(A)$$

where $0 \leq \alpha \leq 1$. Note that in SimpleEW,

$$P(o_1 \vee o_2 \mid A) = P(o_1 \mid A) + P(o_2 \mid A),$$

where $P(o_1 \vee o_2 \mid A)$ is the probability that A is changed to a different word in SimpleEW, which we estimate as $\widehat{P}(o_1 \vee o_2 \mid A) = f_S(A)$. We then set

$$\boxed{\widehat{\mathbf{P}}(\mathbf{o_2} \mid \mathbf{A}) = \max(\mathbf{0}, \mathbf{f_S}(\mathbf{A}) - \alpha \mathbf{f_C}(\mathbf{A})).}$$

Next, under our working assumption, we estimate the probability of A being changed to a as a fix by the proportion of ComplexEW edit instances that rewrite A to a:

$$\widehat{P}(a \mid A, o_1) = \frac{|\{(k,i) \text{ pairs} \mid e_{k,i} = A \rightarrow a \wedge \vec{d_k} \in C\}|}{\sum_{a'} |\{(k,i) \text{ pairs} \mid e_{k,i} = A \rightarrow a' \wedge \vec{d_k} \in C\}|}.$$

A natural estimate for the conditional probability of A being rewritten to a under any operation type is based on observations of $A \rightarrow a$ in SimpleEW, since that is the corpus wherein both operations are assumed to occur:

$$\widehat{P}(a \mid A) = \frac{|\{(k,i) \text{ pairs} \mid e_{k,i} = A \rightarrow a \wedge \vec{d_k} \in S\}|}{\sum_{a'} |\{(k,i) \text{ pairs} \mid e_{k,i} = A \rightarrow a' \wedge \vec{d_k} \in S\}|}.$$

Thus, from (1) we get that for $A \neq a$:

$$\boxed{\widehat{\mathbf{P}}(\mathbf{a} \mid \mathbf{A}, \mathbf{o_2}) = \frac{\widehat{\mathbf{P}}(\mathbf{a} \mid \mathbf{A}) - \widehat{\mathbf{P}}(\mathbf{o_1} \mid \mathbf{A}) \widehat{\mathbf{P}}(\mathbf{a} \mid \mathbf{A}, \mathbf{o_1})}{\widehat{\mathbf{P}}(\mathbf{o_2} \mid \mathbf{A})}.}$$

2.2 Metadata-based methods

Wiki editors have the option of associating a comment with each revision, and such comments sometimes indicate the intent of the revision. We therefore sought to use comments to identify “trusted”

[4] Spam/vandalism detection is a direction for future work.

[5] This assumption also provides useful constraints to EM, which we plan to apply in the future, by reducing the number of parameter settings yielding the same likelihood.

[6] Throughout, “hats” denote estimates.

revisions wherein the extracted lexical edit instances (see §3.1) would be likely to be simplifications.

Let $\vec{r}_k = (r_k^1, \ldots, r_k^i, \ldots)$ be the sequence of revisions for the k^{th} article in SimpleEW, where r_k^i is the set of lexical edit instances ($A \rightarrow a$) extracted from the i^{th} modification of the document. Let c_k^i be the comment that accompanies r_k^i, and conversely, let $R(Set) = \{r_k^i | c_k^i \in Set\}$.

We start with a seed set of trusted comments, $Seed$. To initialize it, we manually inspected a small sample of the 700K+ SimpleEW revisions that bear comments, and found that comments containing a word matching the regular expression *simpl* (e.g, "simplify") seem promising. We thus set $Seed := \{ * \mathsf{simpl} * \}$ (abusing notation).

The SIMPL **method** Given a set of trusted revisions $TRev$ (in our case $TRev = R(Seed)$), we score each $A \rightarrow a \in TRev$ by the point-wise mutual information (PMI) between A and a.[7] We write RANK($TRev$) to denote the PMI-based ranking of $A \rightarrow a \in TRev$, and use SIMPL to denote our most basic ranking method, RANK($R(Seed)$).

Two ideas for bootstrapping We also considered bootstrapping as a way to be able to utilize revisions whose comments are not in the initial $Seed$ set.

Our first idea was to iteratively expand the set of trusted comments to include those that most often accompany already highly ranked simplifications. Unfortunately, our initial implementations involved many parameters (upper and lower comment-frequency thresholds, number of highly ranked simplifications to consider, number of comments to add per iteration), making it relatively difficult to tune; we thus omit its results.

Our second idea was to iteratively expand the set of trusted revisions, adding those that contain already highly ranked simplifications. While our initial implementation had fewer parameters than the method sketched above, it tended to terminate quickly, so that not many new simplifications were found; so, again, we do not report results here.

An important direction for future work is to differentially weight the edit instances within a revision, as opposed to placing equal trust in all of them; this could prevent our bootstrapping methods from giving common fixes (e.g., "*a*" → "*the*") high scores.

3 Evaluation[8]

3.1 Data

We obtained the revision histories of both SimpleEW (November 2009 snapshot) and ComplexEW (January 2008 snapshot). In total, ∼1.5M revisions for 81733 SimpleEW articles were processed (only 30% involved textual changes). For ComplexEW, we processed ∼16M revisions for 19407 articles.

Extracting lexical edit instances. For each article, we aligned sentences in each pair of adjacent versions using tf-idf scores in a way similar to Nelken and Shieber [6] (this produced satisfying results because revisions tended to represent small changes). From the aligned sentence pairs, we obtained the aforementioned lexical edit instances $A \rightarrow a$. Since the focus of our study was not word alignment, we used a simple method that identified the longest differing segments (based on word boundaries) between each sentence, except that to prevent the extraction of entire (highly non-matching) sentences, we filtered out $A \rightarrow a$ pairs if either A or a contained more than five words.

3.2 Comparison points

Baselines RANDOM returns lexical edit instances drawn uniformly at random from among those extracted from SimpleEW. FREQUENT returns the most frequent lexical edit instances extracted from SimpleEW.

Dictionary of simplifications The SimpleEW editor "Spencerk" (Spencer Kelly) has assembled a list of simple words and simplifications using a combination of dictionaries and manual effort[9]. He provides a list of 17,900 simple words — words that do not need further simplification — and a list of 2000 transformation pairs. We did not use Spencerk's set as the gold standard because many transformations we found to be reasonable were not on his list. Instead, we measured our agreement with the list of transformations he assembled (SPLIST).

[7] PMI seemed to outperform raw frequency and conditional probability.

[8] Results at http://www.cs.cornell.edu/home/llee/data/simple

[9] http://www.spencerwaterbed.com/soft/simple/about.html

3.3 Preliminary results

The top 100 pairs from each system (edit model[10] and SIMPL and the two baselines) plus 100 randomly selected pairs from SPLIST were mixed and all presented in random order to three native English speakers and three non-native English speakers (all non-authors). Each pair was presented in random orientation (i.e., either as $A \rightarrow a$ or as $a \rightarrow A$), and the labels included "simpler", "more complex", "equal", "unrelated", and "?" ("hard to judge"). The first two labels correspond to simplifications for the orientations $A \rightarrow a$ and $a \rightarrow A$, respectively. Collapsing the 5 labels into "simplification", "not a simplification", and "?" yields reasonable agreement among the 3 native speakers ($\kappa = 0.69$; 75.3% of the time all three agreed on the same label). While we postulated that non-native speakers[11] might be more sensitive to what was simpler, we note that they disagreed more than the native speakers ($\kappa = 0.49$) and reported having to consult a dictionary. The native-speaker majority label was used in our evaluations.

Here are the results; "-x-y" means that x and y are the number of instances discarded from the precision calculation for having no majority label or majority label "?", respectively:

Method	Prec@100	# of pairs
SPLIST	86% (-0-0)	2000
Edit model	77% (-0-1)	1079
SIMPL	66% (-0-0)	2970
FREQUENT	17% (-1-7)	-
RANDOM	17% (-1-4)	-

Both baselines yielded very low precisions — clearly not all (frequent) edits in SimpleEW were simplifications. Furthermore, the edit model yielded higher precision than SIMPL for the top 100 pairs. (Note that we only examined one simplification per A for those A where $\widehat{P}(o_2 \mid A)$ was well-defined; thus "# of pairs" does not directly reflect the full potential recall that either method can achieve.) Both, however, produced many high-quality pairs (62% and 71% of the *correct* pairs) *not* included in SPLIST. We also found the pairs produced by these two systems to be complementary to each other. We believe that these two approaches provide a good starting point for further explorations.

Finally, some examples of simplifications found by our methods: "*stands for*" → "*is the same as*", "*indigenous*" → "*native*", "*permitted*" → "*allowed*", "*concealed*" → "*hidden*", "*collapsed*" → "*fell down*", "*annually*" → "*every year*".

3.4 Future work

Further evaluation could include comparison with machine-translation and paraphrasing algorithms. It would be interesting to use our proposed estimates as initialization for EM-style iterative re-estimation. Another idea would be to estimate *simplification priors* based on a model of inherent lexical complexity; some possible starting points are number of syllables (which is used in various readability formulae) or word length.

Predicting Human-Targeted Translation Edit Rate via Untrained Human Annotators

Omar F. Zaidan and **Chris Callison-Burch**

{ozaidan,ccb}@cs.jhu.edu

Abstract

In the field of machine translation, automatic metrics have proven quite valuable in system development for tracking progress and measuring the impact of incremental changes. However, human judgment still plays a large role in the context of *evaluating* MT systems. For example, the GALE project uses human-targeted translation edit rate (HTER), wherein the MT output is scored against a post-edited version of itself (as opposed to being scored against an existing human reference). This poses a problem for MT researchers, since HTER is not an easy metric to calculate, and would require hiring and training human annotators to perform the editing task. In this work, we explore soliciting those edits from *untrained* human annotators, via the online service Amazon Mechanical Turk. We show that the collected data allows us to predict HTER-ranking of documents at a significantly higher level than the ranking obtained using automatic metrics.

1 Introduction

In the early days of machine translation (MT), it was typical to evaluate MT output by soliciting judgments from human subjects, such as evaluating the fluency and adequacy of MT output (LDC, 2005). While this approach was appropriate (indeed desired) for evaluating a system, it was not a practical means of tracking the progress of a system during its development, since collecting human judgments is both costly and time-consuming. The introduction of automatic metrics like BLEU contributed greatly to MT research, for instance allowing researchers to measure and evaluate the impact of small modifications to an MT system.

However, manual evaluation remains a core component of system evaluation. Teams on the GALE project, a DARPA-sponsored MT research program, are evaluated using the HTER metric, which is a version of TER whereby the output is scored against a post-edited version of itself, instead of a preexisting reference. Moreover, emphasis is placed on performing well across all documents and across all genres. Therefore, it is important for a research team to be able to evaluate their system using HTER, or at least determine the ranking of the documents according to HTER, for purposes of error analysis. Instead of hiring a human translator and training them, we propose moving the task to the virtual world of Amazon's Mechanical Turk (AMT), hiring workers to edit the MT output and predict HTER from those edits. We show that edits collected this way are better at predicting document ranking than automatic metrics, and furthermore that it can be done at a low cost, both in terms of time and money.

The paper is organized as follows. We first discuss options available to predict HTER, such as automatic metrics. We then discuss the possibility of relying on human annotators, and the inherent difficulty in training them, before discussing the concept of soliciting edits over AMT. We detail the task given to the workers and summarize the data that we collected, then show how we can combine their data to obtain significanly better rank predictions of documents.

2 Human-Targeted TER

Translation edit rate (TER) measures the number of edits required to transform a hypothesis into an appropriate sentence in terms of grammaticality and meaning (Snover et al., 2006). While TER usually scores a hypothesis against an existing reference sentence, *human-targeted* TER scores a hypothesis against a post-edited version of itself.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 369–372,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

While HTER has been shown to correlate quite well with human judgment of MT quality, it is quite challenging to obtain HTER scores for MT output, since this would require hiring and training human subjects to perform the editing task. Therefore, other metrics such as BLEU or TER are used as proxies for HTER.

2.1 Amazon's Mechanical Turk

The high cost associated with hiring and training a human editor makes it difficult to imagine an alternative to automatic metrics. However, we propose soliciting edits from workers on Amazon's Mechanical Turk (AMT). AMT is a virtual marketplace where "requesters" can post tasks to be completed by "workers" (aka *Turkers*) around the world. Two main advantages of AMT are the pre-existing infrastructure, and the low cost of completing tasks, both in terms of time and money. Data collected over AMT has already been used in several papers such as Snow et al. (2008) and Callison-Burch (2009).

When a requester creates a task to be completed over AMT, it is typical to have completed by more than one worker. The reason is that the use of AMT for data collection has an inherent problem with data quality. A requester has fewer tools at their disposal to ensure workers are doing the task properly (via training, feedback, etc) when compared to hiring annotators in the 'real' world. Those redundant annotations are therefore collected to increase the likelihood of at least one submission from a faithful (and competent) worker.

2.2 AMT for HTER

The main idea it to mimic the real-world HTER setup by supplying workers with the original MT output that needs to be edited. The worker is also given a human reference, produced independently from the MT output. The instructions ask the worker to modify the MT output, using as few edits as possible, to match the human reference in meaning and grammaticality.

The submitted edited hypothesis can then be used as the reference for calculating HTER. The idea is that, with this setup, a competent worker would be able to closely match the editing behavior of the professionally trained editor.

3 The Datasets

We solicited edits of the output from one of GALE's teams on the Arabic-to-English task. This MT output was submitted by this team and HTER-scored by LDC-hired human translators. Therefore, we already had the edits produced by a professional translator. These edits were used as the "gold-standard" to evaluate the edits solicited from AMT and to evaluate our methods of combining Turkers' submissions.

The MT output is a translation of more than 2,153 Arabic segments spread across 195 documents in 4 different genres: broadcast conversations (BC), broadcast news (BN), newswire (NW), and blogs (WB). Table 1 gives a summary of each genre's dataset.

Genre	# docs	Segs/doc	Words/seg
BC	40	15.8	28.3
BN	48	9.6	36.1
NW	54	8.7	39.5
WB	53	11.1	31.6

Table 1: The 4 genres of the dataset.

For each of the 2,153 MT output segments, we collected edits from 5 distinct workers on AMT, for a total of 10,765 post-edited segments by a total of about 500 distinct workers.[1] The segments were presented in 1,210 groups of up to 15 segments each, with a reward of $0.25 per group. Hence the total rewards to workers was around $300, at a rate of 36 post-edited segments per dollar (or 2.8 pennies per segment).

4 What are we measuring?

We are interested in predicting the ranking the documents according to HTER, not necessarily predicting the HTER itself (though of course attempting to predict the latter accurately is the cornerstone of our approach to predict the former). To measure the quality of a predicted ranking, we use Spearman's rank correlation coefficient, ρ, where we first convert the raw scores into ranks and then use the following formula to measure correlation:

$$\rho(X,Y) = 1 - \frac{6\sum_{i=1}^{n}(rank(x_i) - rank(y_i))^2}{n(n^2 - 1)}$$

[1] Data available at `http://cs.jhu.edu/~ozaidan/hter`.

where *n* is the number of documents, and each of *X* and *Y* is a vector of *n* HTER scores.

Notice that values for ρ range from –1 to 1, with +1 indicating perfect rank correlation, –1 perfect inverse correlation, and 0 no correlation. That is, for a fixed *X*, the best-correlated *Y* is that for which $\rho(X,Y)$ is highest.

5 Combining Tukers' Edits

Once we have collected edits from the human workers, how should we attempt to predict HTER from them? If we could assume that all Turkers are doing the task faithfully (and doing it adequately), we should use the annotations of the worker performing the least amount of editing, since that would mirror the real-life scenario.

However, data collected from AMT should be treated with caution, since a non-trivial portion of the collected data is of poor quality. Note that this does not necessarily indicate a 'cheating' worker, for even if a worker is acting in good faith, they might not be able to perform the task adequately, due to misunderstanding the task, or neglecting to attempt to use a small number of edits.

And so we need to combine the redundant edits in an intelligent manner. Recall that, given a segment, we collected edits from multiple workers. Some baseline methods include taking the minimum over the edits, taking the median, and taking the average.

Once we start thinking of averages, we should consider taking a *weighted* average of the edits for a segment. The weight associated with a worker should reflect our confidence in the quality of that worker's edits. But how can we evaluate a worker in the first place?

5.1 Self Verification of Turkers

We have available "gold-standard" editing behavior for the segments, and we treat a small portion of the segments edited by a Turker as a verification dataset. On that portion, we evaluate how closely the Turker matches the LDC editor, and weight them accordingly when predicting the number of edits of the rest of that group's segments. Specifically, the Turker's weight is the absolute difference between the Turker's edit count and the professional editor's edit count.

Notice that we are not simply interested in a worker whose edited submission closely matches the edited submission of the professional translator. Rather, we are interested in mirroring the professional translator's edit *rate*. That is, the closer a Turker's edit *rate* is to the LDC editor's, the more we should prefer the worker. This is a subtle point, but it is indeed possible for a Turker to have similar edit rate as the LDC editor but still require a large number of edits to get the LDC editor's submission itself.

6 Experiments

We examine the effectiveness of any of the above methods by comparing the resulting document ranking versus the desired ranking by HTER. In addition to the above methods, we use a baseline a ranking predicted by TER to a human reference. (For clarity, we omit discussion with other metrics such as BLEU and (TER–BLEU)/2, since those baselines are not as strong as the TER baseline.

6.1 Experimental Setup

We examine each genre individually, since genres vary quite a bit in difficulty, and, more importantly, we care about the internal ranking within each genre, to mirror the GALE evaluation procedure.

We examine the effect of varying the amount of data by which we judge a Turker's data quality. The amount of this "verification" data is varied as a percentage of the total available segments. Those segments are chosen at random, and we perform 100 trials for each point.

6.2 Experimental Results

Figure 1 shows the rank correlations for various methods across different sizes of verification subsets. Notice that some methods, such as the TER baseline, have horizontal lines, since these do not rate a Turker based on a verification subset.

It is worth noting that the oracle performs very well. This is an indication that predicting HTER accurately is mostly a matter of identifying the best worker. While oracle scenarios usually represent unachievable upper bounds, keep in mind that there are only a very small number of editors per segment (five, as opposed to oracle scenarios dealing with 100-best lists, etc).

Other than that, in general, it is possible to achieve very high rank correlation using Turkers' data, significantly outperforming the TER ranking, even with a small verification subset. The genres do vary quite a bit in difficulty for Turkers, with BC and especially NW being quite difficult, though in the case of NW for instance, this is due to the human reference doing quite well to begin with, rather than Turkers performing poorly.

7 Conclusions and Future Work

We proposed soliciting edits of MT output via Amazon's Mechanical Turk and showed we can predict ranking significantly better than an automatic metric. The next step is to explicitly identify undesired worker behavior, such as not editing the MT output at all, or using the human reference as is instead of editing the MT output. This can be detected by not limiting our verification to comparing behavior to the professional editor's, but also by comparing submitted edits to the MT output itself and to the human reference. In other words, a worker's submission could be characterized in terms of its distance to the MT output and to the human reference, thus building a complete 'profile' of the worker, and adding another component to guard against poor data quality and to reward the desired behavior.

Abstract

This work incorporates Selectional Preferences (SP) into a Semantic Role (SR) Classification system. We learn separate selectional preferences for noun phrases and prepositional phrases and we integrate them in a state-of-the-art SR classification system both in the form of features and individual class predictors. We show that the inclusion of the refined SPs yields statistically significant improvements on both in domain and out of domain data (14.07% and 11.67% error reduction, respectively). The key factor for success is the combination of several SP methods with the original classification model using meta-classification.

1 Introduction

Semantic Role Labeling (SRL) is the process of extracting simple event structures, i.e., "who" did "what" to "whom", "when" and "where". Current systems usually perform SRL in two pipelined steps: argument *identification* and argument *classification*. While identification is mostly syntactic, classification requires semantic knowledge to be taken into account. Semantic information is usually captured through lexicalized features on the predicate and the head–word of the argument to be classified. Since lexical features tend to be sparse, SRL systems are prone to overfit the training data and generalize poorly to new corpora.

Indeed, the SRL evaluation exercises at CoNLL-2004 and 2005 (Carreras and Màrquez, 2005) observed that all systems showed a significant performance degradation ($\sim$10 F_1 points) when applied to test data from a different genre of that of the training set. Pradhan et al. (2008) showed that this performance degradation is essentially caused by the argument classification subtask, and suggested the lexical data sparseness as one of the main reasons. The same authors studied the contribution of the different feature types in SRL and concluded that the lexical features were the most salient features in argument classification (Pradhan et al., 2007).

In recent work, we showed (Zapirain et al., 2009) how automatically generated selectional preferences (SP) for verbs were able to perform better than pure lexical features in a role classification experiment, disconnected from a full-fledged SRL system. SPs introduce semantic generalizations on the type of arguments preferred by the predicates and, thus, they are expected to improve results on infrequent and unknown words. The positive effect was especially relevant for out-of-domain data. In this paper we advance (Zapirain et al., 2009) in two directions:
(1) We learn separate SPs for prepositions and verbs, showing improvement over using SPs for verbs alone.
(2) We integrate the information of several SP models in a state-of-the-art SRL system (SwiRL[1]) and show significant improvements in SR classification. The key for the improvement lies in a meta-classifier, trained to select among the predictions provided by several role classification models.

2 SPs for SR Classification

SPs have been widely believed to be an important knowledge source when parsing and performing SRL, especially role classification. Still, present parsers and SRL systems use just lexical features, which can be seen as the most simple form of SP,

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 373–376,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

where the headword needs to be seen in the training data, and otherwise the SP is not satisfied. Gildea and Jurafsky (2002) showed barely significant improvements in semantic role classification of NPs for FrameNet roles using distributional clusters. In (Erk, 2007) a number of SP models are tested in a pseudo-task related to SRL. More recently, we showed (Zapirain et al., 2009) that several methods to automatically generate SPs generalize well and outperform lexical match in a large dataset for semantic role classification, but the impact on a full system was not explored.

In this work we apply a subset of the SP methods proposed in (Zapirain et al., 2009). These methods can be split in two main families, depending on the resource used to compute similarity: WordNet-based methods and distributional methods. Both families define a similarity score between a word (the headword of the argument to be classified) and a set of words (the headwords of arguments of a given role).

WordNet-based similarity: One of the models that we used is based on Resnik's similarity measure (1993), referring to it as res. The other model is an in-house method (Zapirain et al., 2009), referred as wn, which only takes into account the depth of the most common ancestor, and returns SPs that are as specific as possible.

Distributional similarity: Following (Zapirain et al., 2009) we considered both first order and second order similarity. In first order similarity, the similarity of two words was computed using the cosine (or Jaccard measure) of the co-occurrence vectors of the two words. Co-occurrence vectors where constructed using freely available software (Padó and Lapata, 2007) run over the British National Corpus. We used the optimal parameters (Padó and Lapata, 2007, p. 179). We will refer to these similarities as sim_{cos} and sim_{Jac}, respectively. In contrast, second order similarity uses vectors of similar words, i.e., the similarity of two words was computed using the cosine (or Jaccard measure) between the thesaurus entries of those words in Lin's thesaurus (Lin, 1998). We refer to these as sim^2_{cos} and sim^2_{Jac}.

Given a target sentence with a verb and its arguments, the task of SR classification is to assign the correct role to each of the arguments. When using SPs alone, we only use the headwords of the arguments, and each argument is classified independently of the rest. For each headword, we select the role (r) of the verb (c) which fits best the head word (w), where the goodness of fit ($SP_{sim}(v, r, w)$) is modeled using one of the similarity models above, between the headword w and the headwords seen in training data for role r of verb v. This selection rule is formalized as follows:

$$R_{sim}(v, w) = \arg \max_{r \in Roles(v)} SP_{sim}(v, r, w) \quad (1)$$

In our previous work (Zapirain et al., 2009), we modelled SPs for pairs of predicates (verbs) and arguments, independently of the fact that the argument is a core argument (typically a noun) or an adjunct argument (typically a prepositional phrase). In contrast, (Litkowski and Hargraves, 2005) show that prepositions have SPs of their own, especially when functioning as adjuncts. We therefore decided to split SPs according to whether the potential argument is a Prepositional Phrase (PP) or a Noun Phrase (NP). For NPs, which tend to be core arguments[2], we use the SPs of the verb (as formalized above). For PPs, which have an even distribution between core and adjunct arguments, we use the SPs of the prepositions alone, ignoring the verbs. Implementation wise, this means that in Eq. (1), we change v for p, where p is the preposition heading the PP.

3 Experiments with SPs in isolation

In this section we evaluate the use of SPs for classification in isolation, i.e., we use formula 1, and no other information. In addition we contrast the use of both verb-role and preposition-role SPs, as compared to the use of verb-role SPs alone.

The dataset used in these experiments (and in Section 4) is the same as provided by the CoNLL-2005 shared task on SRL (Carreras and Màrquez, 2005). This dataset comprises several sections of the PropBank corpus (news from the WSJ) as well as an extract of the Brown Corpus. Sections 02-21 are used for generating the SPs and training, Section 00 for development, and Section 23 for testing, as customary. The Brown Corpus is used for out-of-domain testing, but due to the limited size of the provided section, we extended it with instances from SemLink[3]. Since the focus of this work is on argument

[2] In our training data, NPs are adjuncts only 5% of the times

classification, we use the gold PropBank data to identify argument boundaries. Considering that SPs can handle only nominal arguments, in these experiments we used only arguments mapped to NPs and PPs containing a nominal head. From the training sections, we extracted over 140K such arguments for the supervised generation of SPs. The development and test sections contain over 5K and 8K examples, respectively, and the portion of the Brown Corpus comprises an amount of 8.1K examples.

Table 1 lists the results of the different SPs in isolation. The results reported in the left part of Table 1 are comparable to those we reported in (Zapirain et al., 2009). The differences are due to the fact that we do not discard roles like MOD, DIS, NEG and that our previous work used only the subset of the data that could be mapped to VerbNet (around 50%). All in all, the table shows that splitting SPs into verb and preposition SPs yields better results, both in precision and recall, improving F_1 up to 10 points in some cases.

4 Integrating SPs in a SRL system

For these experiments we modified SwiRL (Surdeanu et al., 2007): (a) we matched the gold boundaries against syntactic constituents predicted internally using the Charniak parser (Charniak, 2000); and (b) we classified these constituents with their semantic role using a modified version of SwiRL's feature set.

We explored two different strategies for integrating SPs in SwiRL. The first, obvious method is to extend SwiRL's feature set with features that model the preferences of the SPs, i.e., for each SP model SP_i we add a feature whose value is R_i. The second method combines SwiRL's classification model and our SP models using meta-classification. We opted for a binary classification approach: first, for each constituent we generate n datums, one for each distinct role label proposed by the pool of base models; then we use a binary meta-classifier to label each candidate role as correct or incorrect. Table 2 lists the features of the meta-classifier. We trained the meta-classifier on the usual PropBank training partition, using cross-validation to generate outputs for the base models that require the same training material. At prediction time, for each candidate constituent we selected the role label that was classified as correct with the highest confidence.

Table 3 compares the performance of both combination approaches against the standalone SwiRL classifier. We show results for both core arguments (Core), adjunct arguments (Arg) and all arguments combined (All). In the table, the SwiRL+SP_* models stand for SwiRL classifiers enhanced with one feature from the corresponding SP. Adding more than one SP-based feature to SwiRL did not improve results. Our conjecture is that the SwiRL classifier enhanced with SP-based features does not learn relevant weights for these features because their signal is "drowned" by SwiRL's large initial feature set and the correlation between the different SPs. This observation motivated the development of the meta-classifier. The meta-classifier shown in the table combines the output of the SwiRL+SP_* models with the predictions of SP models used in isolation. We implemented the meta-classifier using Support Vector Machines (SVM)[4] with a quadratic polynomial kernel, and

Table 3: Classification accuracy for the combination approaches. +SP_x stands for SwiRL plus each SP model.

$C = 0.01$ (tuned in development).

Table 3 indicates that four out of the six SwiRL+SP_* models perform better than SwiRL in domain (WSJ-test), and all of them outperform SwiRL out of domain (Brown). However, the improvements are small and, generally, not statistically significant. On the other hand, the meta-classifier outperforms SwiRL both in domain (14.07% error reduction) and out of domain (11.67% error reduction), and the differences are statistically significant (measured using two-tailed paired t-test at 99% confidence interval on 100 samples generated using bootstrap resampling). We also implemented two unsupervised voting baselines, one unweighted (each base model has the same weight) and one weighted (each base model is weighted by its accuracy in development). However, none of these baselines outperformed the standalone SwiRL classifier. This is further proof that, for SR classification, meta-classification is crucial because it can learn the distinct specializations of the various base models.

Finally, Table 3 shows that our approach yields consistent improvements for both core and adjunct arguments. Out of domain, we see a bigger accuracy improvement for adjunct arguments (5.64 absolute points) vs. core arguments (1.78 points). This is to be expected, as most core arguments fall under the Arg0 and Arg1 classes, which can typically be disambiguated based on syntactic information, i.e., subject vs. object. On the other hand, there are no syntactic hints for adjunct arguments, so the system learns to rely more on SP information in this case.

5 Conclusions

This paper is the first work to show that SPs improve a state-of-the-art SR classification system. Several decisions were crucial for success: (a) we deployed separate SP models for verbs and prepositions, which in conjunction outperform SP models for verbs alone; (b) we incorporated SPs into SR classification using a meta-classification approach that combines eight base models, developed from variants of a state-of-the-art SRL system and the above SP models. We show that the resulting system outperforms the original SR classification system for arguments mapped to nominal or prepositional constituents. The improvements are statistically significant both on in-domain and out-of-domain data sets.

Generalizing Syntactic Structures for Product Attribute Candidate Extraction

Yanyan Zhao, Bing Qin, Shen Hu, Ting Liu

Abstract

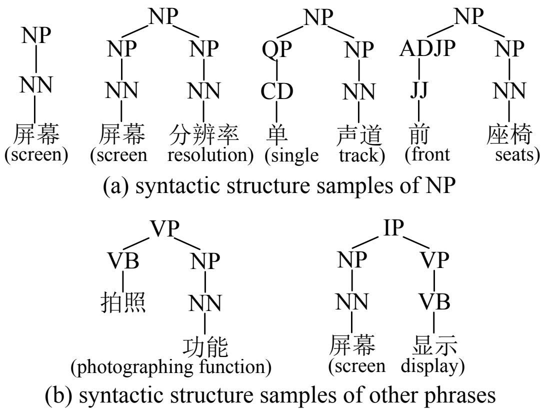
Noun phrases (NP) in a product review are always considered as the product attribute candidates in previous work. However, this method limits the recall of the product attribute extraction. We therefore propose a novel approach by generalizing syntactic structures of the product attributes with two strategies: intuitive heuristics and syntactic structure similarity. Experiments show that the proposed approach is effective.

1 Introduction

Product attribute extraction is a fundamental task of sentiment analysis. It aims to extract the product attributes from a product review, such as "picture quality" in the sentence "The picture quality of Canon is perfect." This task is usually performed in two steps: product attribute candidate extraction and candidate classification.

Almost all the previous work pays more attention to the second step, fewer researchers make in-depth research on the first step. They simply choose the NPs in a product review as the product attribute candidates (Hu and Liu, 2004; Popescu and Etzioni, 2005; Yi et al., 2003). However, this method limits the recall of the product attribute extraction for two reasons. First, there exist other structures of the product attributes except NPs. Second, the syntactic parsing is not perfect, especially for the Non-English languages, such as Chinese. Experiments on three Chinese datasets[1] show that nearly 15% product attributes are lost, when only using NPs as the candidates. Obviously, if using the candidate classification techniques on these NP candidates, it would lead to poor performance (especially for recall) for the final product attribute extraction.

Based on the above discussion, it can be observed that product attribute candidate extraction is well worth studying. In this paper, we propose an approach by generalizing the *syntactic structures* of the product attributes to solve this problem. Figure 1 lists some syntactic structure samples from an annotated corpus, including the special forms of NPs in Figure 1(a) and other syntactic structures, such as VP or IP in Figure 1(b). We can find that the syntactic structures can not only cover more phrase types besides NP, but also describe the detailed forms of the product attributes.



(a) syntactic structure samples of NP

(b) syntactic structure samples of other phrases

Figure 1: Syntactic structure samples of the product attributes (acquired by an automatic phrase parser).

In order to exploit more and useful syntactic structures, two generalization strategies: intuitive heuristics and syntactic structure similarity are used. Experiments on three Chinese domain-specific datasets show that our approach can significantly improve the recall of the product attribute candidate extraction, and furthermore, improve the performance of the final product attribute extraction.

[1] It refers to the training data in Section 3.1.

2 Approach

The standard syntactic structures of the product attributes can be collected from a training set[2]. Then a simple method of *exact matching* can be used to select the product attribute candidates from the test set. In particular, for a syntactic structure[3] T in the test set, if T exactly matches with one of the standard syntactic structures, then its corresponding string can be treated as a product attribute candidate.

However, this method fails to handle similar syntactic structures, such as the two structures in Figure 2. Besides, this method treats the syntactic structure as a whole during exact matching, without considering any structural information. Therefore, it is difficult to describe the syntactic structure information explicitly. All of these prevent this method from generalizing unseen data well.

To overcome the above problems, two generalization strategies are proposed in this paper. One is to generalize the syntactic structures with two intuitive heuristics. The other is to deeply mine the syntactic structure by decomposing it into several substructures. Both strategies will be introduced in the following subsections.

2.1 Intuitive Heuristics

Two intuitive heuristics are adopted to generalize the syntactic structures.

Heu1: For the near-synonymic grammar tags in syntactic structures, we can generalize them by a normalized one. Such as the red boxes in Figure 2, the POSs "NNS" and "NN" show the same syntactic meaning, we can generalize "NNS" with "NN". The near-synonymic grammar tags are listed in Table 1.

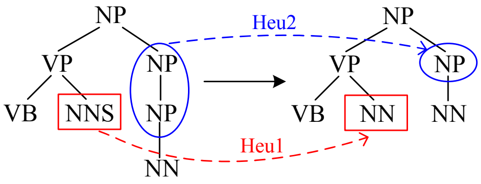

Figure 2: Generalizing a syntactic structure with two intuitive heuristics.

Heu2: For the sequence of identical grammar tags in syntactic structures, we can replace them with one. The reason is that the sequential grammar tags always describe the same syntactic function as one grammar tag. Such as the blue circles in Figure 2.

Replaced by	Near-synonymic grammar tags
JJ	JJR, JJS
NN	NNS, NNP, NNPS, CD, NR
RB	RBR, RBS
VB	VBD, VBG, VBN, VBP, VBZ, VV
S	SBAR, SBARQ, SINU, SQ

Table 1: The near-synonymic grammar tags.

2.2 Syntactic Structure Similarity

The heuristic generalization strategy is too restrictive to give a good coverage. Moreover, after this kind of generalization, the syntactic structure is used as a whole in exact matching all the same. Thus, as an alternative to the exact matching, tree kernel based methods can be used to implicitly explore the substructures of the syntactic structure in a high-dimensional space. This kind of methods can directly calculate the similarity between two substructure vectors using a kernel function. Tree kernel based methods are effective in modeling structured features, which are widely used in many natural language processing tasks, such as syntactic parsing (Collins and Duffy, 2001) and semantic role labeling (Che et al., 2008) and so on.

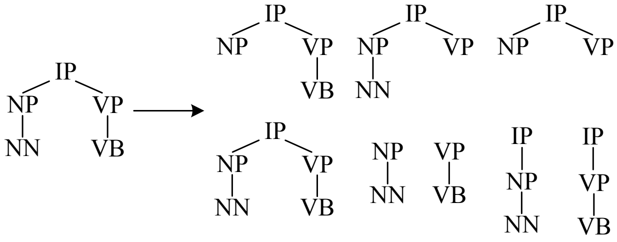

Figure 3: Substructures from a syntactic structure.

In this paper, the syntactic structure for a product attribute can be decomposed into several substructures, such as in Figure 3. Correspondingly, the syntactic structure T can be represented by a vector of integer counts of each substructure type:

$$\begin{aligned}\Phi(T) &= (\phi_1(T), \phi_2(T), ..., \phi_n(T)) \\ &= (\text{\# of substructures of type } 1, \\ &= \text{ \# of substructures of type } 2, \\ &\quad ..., \\ &= \text{ \# of substructures of type } n)\end{aligned}$$

[2] We use Dan Bikel's phrase parser for syntactic parsing.

[3] We simply select the syntactic structures of the strings under three words or four words with "的"("of" in English).

After syntactic structure decomposition, we can count the number of the common substructures as the similarity between two syntactic structures. The commonly used convolution tree kernel is applied in this paper. Its kernel function is defined as follows:

$$K(T_1, T_2) = \langle \Phi(T_1), \Phi(T_2) \rangle$$
$$= \sum_i (\phi_i(T_1) \cdot \phi_i(T_2))$$

Based on these, for a syntactic structure *T* in the test set, we can compute the similarity between *T* and all the standard syntactic structures by the above kernel function. A similarity threshold th_{sim}[4] is set to determine whether the string from *T* is a correct product attribute candidate.

3 Experiments

3.1 Datasets and Evaluation Metrics

Three domain-specific datasets are used in the experiments, which is from an official Chinese Opinion Analysis Evaluation 2008 (COAE2008) (Zhao et al., 2008). Table 2 shows the statistics of the three datasets, each of which is divided into training, development and test data in a proportion of 2:1:1.

Domain	# of sentences	# of standard product attributes
Camera	1,780	1,894
Car	2,166	2,504
Phone	2,196	2,293

Table 2: The datasets for three product domains.

Two evaluation metrics, recall and noise ratio, are designed to evaluate the performance of the product attribute candidate extraction. Recall refers to the proportion of correctly identified attribute candidates in all standard product attributes. Noise ratio refers to the proportion of incorrectly identified attribute candidates in all candidates.

3.2 Comparative methods

We choose the method, which considers NPs as the product attribute candidates, as the baseline (shown as **NPs_based**).

Besides, in order to assess the two generalization strategies' effectiveness, four experiments are designed as follows:

SynStru_based: It refers to the syntactic structure exact matching method, which is implemented without the two proposed generation strategies.

SynStru_*h*: It refers to the strategy only using the first generalization.

SynStru_*kernel*: It refers to the strategy only using the second generalization.

SynStru_*h+kernel*: It refers to the strategy using both two generalizations, i.e., it refers to our approach in this paper.

3.3 Results

Table 3 lists the comparative performances on the test data between our approach and the comparative methods for product attribute candidate extraction.

Domain	Method	Recall	Noise ratio
Camera	NPs_based	81.20%	63.64%
	SynStru_based	84.80%	67.67%
	SynStru_*h*	92.08%	74.74%
	SynStru_*kernel*	92.51%	75.92%
	SynStru_*h*+*kernel*	92.72%	76.25%
Car	NPs_based	85.25%	69.35%
	SynStru_based	86.31%	72.66%
	SynStru_*h*	93.78%	78.01%
	SynStru_*kernel*	94.56%	79.50%
	SynStru_*h*+*kernel*	94.71%	80.44%
Phone	NPs_based	84.11%	63.76%
	SynStru_based	86.26%	67.09%
	SynStru_*h*	93.13%	73.62%
	SynStru_*kernel*	93.47%	75.11%
	SynStru_*h*+*kernel*	93.63%	75.35%

Table 3: Comparisons between our approach and the comparative methods for product attribute candidate extraction.

Analyzing the recalls in Table 3, we can find that:

1. The performance of SynStru_based method is better than NPs_based method for each domain. This can illustrate that syntactic structures can cover more forms of the product attributes. However, the recall of SynStru_based method is not high, either.

2. The two generalization strategies, SynStru_*h* and SynStru_*kernel* can both significantly improve the performance for each domain, comparing to the SynStru_based method. This can illustrate that our two generalization strategies are helpful.

3. Our approach SynStru_*h*+*kernel* achieves the best performance. This can illustrate that the two generalization strategies are complementary to each

[4] In the experiments, th_{sim} is set to 0.7, which is tuned on the development set.

other. And further, mining and generalizing the syntactic structures is effective for candidate extraction.

However, the noise ratio for each domain is increasing when employing our approach. That's because, more kinds of syntactic structures are considered, more noise is added. However, we can easily remove the noise in the candidate classification step. Thus in the next section, we will assess our candidate extraction approach by applying it to the product attribute extraction task.

4 Application in Product Attribute Extraction

For the extracted product attribute candidates, we train a maximum entropy (ME) based binary classifier to find the correct product attributes. Several commonly used features are listed in Table 4.

Feature	Description
lexical	the words of the product attribute(PA)
	the POS for each word of the PA
	three words before the PA
	three words after the PA
	the words' number of the PA
syntactic	the syntactic structure of the PA
binary (Y/N)	Is there a stop word in the PA?
	Is there a polarity word in the PA?
	Is there an English word or number in the PA?

Table 4: The feature set for product attribute extraction.

Table 5 shows the product attribute extraction performances on the test data. We can find that the performance (F1) of our approach is better than NPs_based method for each domain. We discuss the results as follows:

1. Comparing to the NPs_based method, the recall of our approach increases a lot for each domain. This demonstrates that generalized syntactic structures can cover more forms of product attributes.

2. Comparing to the NPs_based method, the precision of our approach also increases for each domain. That's because syntactic structures are more specialized than the phrase forms (such as NP, VP) in the previous work, which can filter some noises from the phrase(NP) candidates.

5 Conclusion

This paper describes a simple but effective way to extract the product attribute candidates from product reviews. The proposed approach is based on deep analysis into syntactic structures of the product attributes, via intuitive heuristics and syntactic structure decomposition. Experimental results indicate that our approach is promising. In future, we will try more syntactic structure generalization strategies.

Domain	Method	R (%)	P (%)	F1 (%)
Camera	NPs_based	59.62	68.38	63.70
	Our approach	62.96	73.32	67.74
Car	NPs_based	59.94	64.87	62.31
	Our approach	67.34	65.90	66.61
Phone	NPs_based	58.53	71.14	64.22
	Our approach	67.84	76.13	71.74

Table 5: Comparisons between our approach and the NPs_based method for product attribute extraction.

Investigating Parser Performance on Discussion Forum Posts

Jennifer Foster
National Centre for Language Technology
School of Computing
Dublin City University
jfoster@computing.dcu.ie

Abstract

We evaluate the Berkeley parser on text from an online discussion forum. We evaluate the parser output with and without gold tokens and spellings (using Sparseval and Parseval), and we compile a list of problematic phenomena for this domain. The Parseval f-score for a small development set is 77.56. This increases to 80.27 when we apply a set of simple transformations to the input sentences and to the Wall Street Journal (WSJ) training sections.

1 Introduction

Parsing techniques have recently become efficient enough for parsers to be used as part of a pipeline in a variety of tasks. Another recent development is the rise of user-generated content in the form of blogs, wikis and discussion forums. Thus, it is both interesting and necessary to investigate the performance of NLP tools trained on edited text when applied to unedited Web 2.0 text. McClosky et al. (2006) report a Parseval f-score decrease of 5% when a WSJ-trained parser is applied to Brown corpus sentences. In this paper, we move even further from the WSJ by investigating the performance of the Berkeley parser (Petrov et al., 2006) on user-generated content.

We create gold standard phrase structure trees for the posts on two threads of the same online discussion forum. We then parse the sentences in one thread, our development set, with the Berkeley parser under three conditions: 1) when it performs its own tokenisation, 2) when it is provided with gold tokens and 3) when misspellings in the input have been corrected. A qualitative evaluation is then carried out on parser output under the third condition. Based on this evaluation, we identify some “low-hanging fruit” which we attempt to handle either by transforming the input sentence or by transforming the WSJ training material. The success of these transformations is evaluated on our development and test sets, with encouraging results.

2 Parser Evaluation Experiments

Data Our data consists of sentences that occur on the BBC Sport 606 Football discussion forum. The posts on this forum are quite varied, ranging from throwaway comments to more considered essay-like contributions. The development set consists of 42 posts (185 sentences) on a thread discussing a controversial refereeing decision in a soccer match.[1] The test set is made up of 40 posts (170 sentences) on a thread discussing a player’s behaviour in the same match.[2] The average sentence length in the development set is 18 words and the test set 15 words. Tokenisation and spelling correction were carried out by hand on the sentences in both sets.[3] They were then parsed using Bikel’s parser (Bikel, 2004) and corrected by hand using the Penn Treebank Bracketing Guidelines (Bies et al., 1995).

Parser The Berkeley parser is an unlexicalised phrase structure parser which learns a latent variable PCFG by iteratively splitting the treebank non-

[1] http://www.bbc.co.uk/dna/606/F15264075?thread=7065503&show=50

[2] http://www.bbc.co.uk/dna/606/F15265997?thread=7066196&show=50

[3] Note that abbreviated forms such as *cos* which are typical of computer-mediated communication are not corrected.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 381–384,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

terminals, estimating rule probabilities for the new grammar using EM and merging the less useful splits. We train a PCFG from WSJ2-21 by carrying out five cycles of the split-merge process (SM5).

Tokenisation and Spelling Effects In the first experiment, the parser is given the original development set sentences which contain spelling mistakes and which have not been tokenised. We ask the parser to perform its own tokenisation. In the second experiment, the parser is given the hand-tokenised sentences which still contain spelling mistakes. These are corrected for the third experiment.

Since the yields of the parser output and gold trees are not guaranteed to match exactly, we cannot use the `evalb` implementation of the Parseval evaluation metrics. Instead we use Sparseval (Roark et al., 2006), which was designed to be used to evaluate the parsing of *spoken* data and can handle this situation. An unaligned dependency evaluation is carried out: head-finding rules are used to convert a phrase structure tree into a dependency graph. Precision and recall are calculated over the dependencies

The Sparseval results are shown in Table 1. For the purposes of comparison, the WSJ23 performance is displayed in the top row. We can see that performance suffers when the parser performs its own tokenisation. A reason for this is the under-use of apostrophes in the forum data, with the result that words such as *didnt* and *im* remain untokenised and are tagged by the parser as common nouns:

*(NP (NP (DT the) (NNS refs)) (SBAR (S (NP (NN **didnt**)) (VP want to make it to obvious))))*

To properly see the effect of the 39 spelling errors on parsing accuracy, we factor out the mismatches between the correctly spelled words in the reference set and their incorrectly spelled equivalents. We do this by evaluating against a version of the gold standard which contains the original misspellings (third row). We can see that the effect of spelling errors is quite small. The Berkeley parser's mechanism for handling unknown words makes use of suffix information and it is able to ignore many of the content word spelling errors. It is the errors in function words that appear to cause a greater problem:

*(NP (DT the) (JJ zealous) (NNS fans) **(NN whpo)** (NN care) (JJR more))*

Test Set	R	P	F
WSJ 23	88.66	88.66	88.66
Football	68.49	70.74	69.60
Football Gold Tokens	71.54	73.25	72.39
Ft Gold Tok (misspelled gold)	73.49	75.25	74.36
Football Gold Tokens+Spell	73.94	75.59	74.76

Table 1: **Sparseval** scores for Berkeley SM5

Test Set	R	P	F
WSJ 23	88.88	89.46	89.17
Football Gold Tokens+Spell	78.15	76.97	77.56

Table 2: **Parseval** scores for Berkeley SM5

Gold Tokens and Spelling Leaving aside the problems of automatic tokenisation and spelling correction, we focus on the results of the third experiment. The Parseval results are given in Table 2. Note that the performance degradation is quite large, more than has been reported for the Charniak parser on the Brown corpus. We examine the parser output for each sentence in the development set. The phenomena which lead the parser astray are listed in Table 3. One problem is coordination which is difficult for parsers on in-domain data but which is exacerbated here by the omission of conjunctions, the use of a comma as a conjunction and the tendency towards unlike constituent coordination.

Parser Comparison We test the lexicalised Charniak parser plus reranker (Charniak and Johnson, 2005) on the development set sentences. We also test the Berkeley parser with an SM6 grammar. The f-scores are shown in Table 4. The parser achieving the highest score on WSJ23, namely, the C&J reranking parser, also achieves the highest score on our development set. The difference between the two Berkeley grammars supports the claim that an SM6 grammar overfits to the WSJ (Petrov and Klein, 2007). However, the differences between the four parser/grammar configurations are small.

Parser	WSJ23	Football
Berkeley SM5	89.17	77.56
Berkeley SM6	89.56	77.01
Charniak First-Stage	89.13	77.13
C & J Reranking	91.33	78.33

cos instead of *because*	*or it was cos you lost* (VP (VBD was) (ADJP (NN cos) (SBAR (S (NP (PRP you)) (VP (VBD lost))))))

Table 3: Phenomena which lead the parser astray. The output of the parser is given for each example.

3 Initial Improvements

Parsing performance on noisy data can be improved by transforming the input data so that it resembles the parser's training data (Aw et al., 2006), transforming the training data so that it resembles the input data (van der Plas et al., 2009), applying semi-supervised techniques such as the self-training protocol used by McClosky et al. (2006), and changing the parser internals, e.g. adapting the parser's unknown word model to take into account variation in capitalisation and function word misspelling.[4]

We focus on the first two approaches and attempt to transform both the input data and the WSJ training material. The transformations that we experiment with are shown in Table 5. The treebank transformations are performed in such a way that their frequency distribution mirrors their distribution in the development data. We remove discourse-marking acronyms such as *lol*[5] from the input sentence, but do not attempt to handle acronyms which are integrated into the sentence.[6]

We examine the effect of each transformation on development set parsing performance and discard those which do not improve performance. We keep all the input sentence transformations and those treebank transformations which affect lexical rules, i.e. changing the endings on adverbs and changing the first character of proper nouns. The treebank transformations which delete subject pronouns and coordinating conjunctions are not as effective. They work in individual cases, e.g. the original analysis of the sentence *Will be here all day* is
(S (NP (NNP Will)) (VP be here all day) (. .))
After applying the treebank transformation, it is
(S (VP (MD Will) (VP be here all day)) (. .))
Their overall effect is, however, negative. It is likely that, for complex phenomena such as coordination and subject ellipsis, the development set is still too small to inform how much of and in what way the original treebank should be transformed. The results of applying the effective transformations to the development set and the test set are shown in Table 6.

[4] Even when spelling errors have been corrected, unknown words are still an issue: 8.5% of the words in the football development set do not occur in WSJ2-21, compared to 3.6% of the words in WSJ23.

[5] In a study of teenage instant messaging, Tagliamonte and Dennis (2008) found that forms such as *lol* are not as ubiquitous as is commonly perceived. Although only occurring a couple of times in our data, they are problematic for the parser.

[6] An example is: *your loss to Wigan would be more scrutunized (**cba** to check spelling) than it has been this year*

Input Sentence
cos → because
Sentences consisting of all uppercase characters converted to standard capitalisation *DEAL WITH IT → Deal with it*
Remove certain acronyms *lol → ϵ*
Treebank
Delete subject noun phrases when the subject is a pronoun *(S (NP (PRP It)) (VP (VBD arrived)... ⟶ (S (VP (VBD arrived)...*
Delete or replace conjunctions with a comma (for sentence coordination) *(S ...) (CC and) (S ...) ⟶ (S ...) (, ,) (S ...)* OR *(S ...) (CC and) (S ...) ⟶ (S ...) (S ...)*
Delete *ly* from adverbs *(VP (VBD arrived) (ADVP (RB quickly))) ⟶ (VP (VBD arrived) (ADVP (RB quick)))*
Replace uppercase first character in proper nouns *(NP (NP (NNP Warner) (POS 's)) (NN price)) ⟶ (NP (NP (NNP warner) (POS 's)) (NN price))*

Table 5: Input Sentence and Treebank Transformations

Configuration	Recall	Precision	F-Score
Baseline Dev	78.15	76.97	77.56
Transformed Dev	80.83	79.73	80.27
Baseline Test	77.61	79.14	78.37
Transformed Test	80.10	79.77	79.93

Table 6: Effect of transformations on dev and test set

The recall and precision improvements on the development set are statistically significant ($p < 0.02$), as is the recall improvement on the test set ($p < 0.05$).

4 Conclusion

Ongoing research on the problem of parsing unedited informal text has been presented. At the moment, because of the small size of the data sets and the variety of writing styles in the development set, only tentative conclusions can be drawn. However, even this small data set reveals clear problems for WSJ-trained parsers: the handling of long coordinated sentences (particularly in the presence of erratic punctuation usage), domain-specific fixed expressions and unknown words. We have presented some preliminary experimental results using simple transformations to both the input sentence and the parser's training material. Treebank transformations need to be more thoroughly explored with use made of the Switchboard corpus as well as the WSJ.

Coreference Resolution in a Modular, Entity-Centered Model

Abstract

Coreference resolution is governed by syntactic, semantic, and discourse constraints. We present a generative, model-based approach in which each of these factors is modularly encapsulated and learned in a primarily unsupervised manner. Our semantic representation first hypothesizes an underlying set of latent *entity types*, which generate specific entities that in turn render individual mentions. By sharing lexical statistics at the level of abstract entity types, our model is able to substantially reduce semantic compatibility errors, resulting in the best results to date on the complete end-to-end coreference task.

1 Introduction

Coreference systems exploit a variety of information sources, ranging from syntactic and discourse constraints, which are highly configurational, to semantic constraints, which are highly contingent on lexical meaning and world knowledge. Perhaps because configurational features are inherently easier to learn from small data sets, past work has often emphasized them over semantic knowledge.

Of course, all state-of-the-art coreference systems have needed to capture semantic compatibility to some degree. As an example of nominal headword compatibility, a "president" can be a "leader" but cannot be not an "increase." Past systems have often computed the compatibility of specific headword pairs, extracted either from lexical resources (Ng, 2007; Bengston and Roth, 2008; Rahman and Ng, 2009), web statistics (Yang et al., 2005), or surface syntactic patterns (Haghighi and Klein, 2009). While the pairwise approach has high precision, it is neither realistic nor scalable to explicitly enumerate all pairs of compatible word pairs. A more compact approach has been to rely on named-entity recognition (NER) systems to give coarse-grained entity types for each mention (Soon et al., 1999; Ng and Cardie, 2002). Unfortunately, current systems use small inventories of types and so provide little constraint. In general, coreference errors in state-of-the-art systems are frequently due to poor models of semantic compatibility (Haghighi and Klein, 2009).

In this work, we take a primarily unsupervised approach to coreference resolution, broadly similar to Haghighi and Klein (2007), which addresses this issue. Our generative model exploits a large inventory of distributional entity types, including standard NER types like PERSON and ORG, as well as more refined types like WEAPON and VEHICLE. For each type, distributions over typical heads, modifiers, and governors are learned from large amounts of unlabeled data, capturing type-level semantic information (e.g. "spokesman" is a likely head for a PERSON). Each entity inherits from a type but captures entity-level semantic information (e.g. "giant" may be a likely head for the Microsoft entity but not all ORGs). Separately from the type-entity semantic module, a log-linear discourse model captures configurational effects. Finally, a mention model assembles each textual mention by selecting semantically appropriate words from the entities and types.

Despite being almost entirely unsupervised, our model yields the best reported end-to-end results on a range of standard coreference data sets.

2 Key Abstractions

The key abstractions of our model are illustrated in Figure 1 and described here.

Mentions: A mention is an observed textual reference to a latent real-world entity. Mentions are as-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 385–393,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

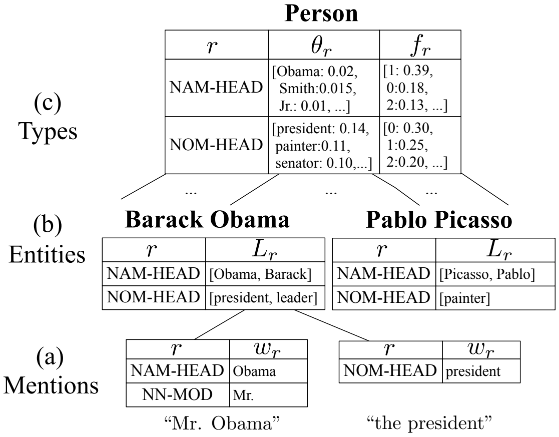

Figure 1: The key abstractions of our model (Section 2). (a) Mentions map properties (r) to words (w_r). (b) Entities map properties (r) to word lists (L_r). (c) Types map properties (r) to distributions over property words (θ_r) and the fertilities of those distributions (f_r). For (b) and (c), we only illustrate a subset of the properties.

sociated with nodes in a parse tree and are typically realized as NPs. There are three basic forms of mentions: proper (denoted NAM), nominal (NOM), and pronominal (PRO). We will often describe proper and nominal mentions together as *referring* mentions.

We represent each mention M as a collection of key-value pairs. The keys are called *properties* and the values are words. For example, the left mention in Figure 1(a) has a proper head property, denoted NAM-HEAD, with value "Obama." The set of properties we consider, denoted $\mathcal{R}$, includes several varieties of heads, modifiers, and governors (see Section 5.2 for details). Not every mention has a value for every property.

Entities: An entity is a specific individual or object in the world. Entities are always latent in text. Where a mention has a single word for each property, an entity has a *list* of signature words. Formally, entities are mappings from properties $r \in \mathcal{R}$ to lists L_r of "canonical" words which that entity uses for that property. For instance in Figure 1(b), the list of nominal heads for the Barack Obama entity includes "president."

Types: Coreference systems often make a mention / entity distinction. We extend this hierarchy to include *types*, which represent classes of entities (PERSON, ORGANIZATION, and so on). Types allow the sharing of properties across entities and mediate the generation of entities in our model (Section 3.1). See Figure 1(c) for a concrete example.

We represent each type τ as a mapping between properties r and pairs of multinomials (θ_r, f_r). Together, these distributions control the lists L_r for entities of that type. θ_r is a unigram distribution of words that are semantically licensed for property r. f_r is a "fertility" distribution over the integers that characterizes entity list lengths. For example, for the type PERSON, θ_r for proper heads is quite flat (there are many last names) but f_r is peaked at 1 (people have a single last name).

3 Generative Model

We now describe our generative model. At the parameter level, we have one parameter group for the types $\boldsymbol{\tau} = (\phi, \tau_1, \ldots, \tau_t)$, where ϕ is a multinomial prior over a fixed number t of types and the $\{\tau_i\}$ are the parameters for each individual type, described in greater detail below. A second group comprises log-linear parameters $\boldsymbol{\pi}$ over discourse choices, also described below. Together, these two groups are drawn according to $P(\boldsymbol{\tau}|\boldsymbol{\lambda})P(\boldsymbol{\pi}|\sigma^2)$, where $\boldsymbol{\lambda}$ and σ^2 are a small number of scalar hyper-parameters described in Section 4.

Conditioned on the parameters $(\boldsymbol{\tau}, \boldsymbol{\pi})$, a document is generated as follows: A *semantic module* generates a sequence $\mathbf{E}$ of entities. $\mathbf{E}$ is in principle infinite, though during inference only a finite number are ever instantiated. A *discourse module* generates a vector $\mathbf{Z}$ which assigns an entity index Z_i to each mention position i. Finally, a *mention generation module* independently renders the sequence of mentions ($\mathbf{M}$) from their underlying entities. The syntactic position and structure of mentions are treated as observed, including the mention forms (pronominal, etc.). We use $\mathbf{X}$ to refer to this ungenenerated information. Our model decomposes as follows:

$$
\begin{aligned}
&P(\mathbf{E}, \mathbf{Z}, \mathbf{M}|\boldsymbol{\tau}, \boldsymbol{\pi}, \mathbf{X}) = \\
&\quad P(\mathbf{E}|\boldsymbol{\tau}) \text{ [Semantic, Section 3.1]} \\
&\quad P(\mathbf{Z}|\boldsymbol{\pi}, \mathbf{X}) \text{ [Discourse, Section 3.2]} \\
&\quad P(\mathbf{M}|\mathbf{Z}, \mathbf{E}, \boldsymbol{\tau}) \text{ [Mention, Section 3.3]}
\end{aligned}
$$

We detail each of these components in subsequent sections.

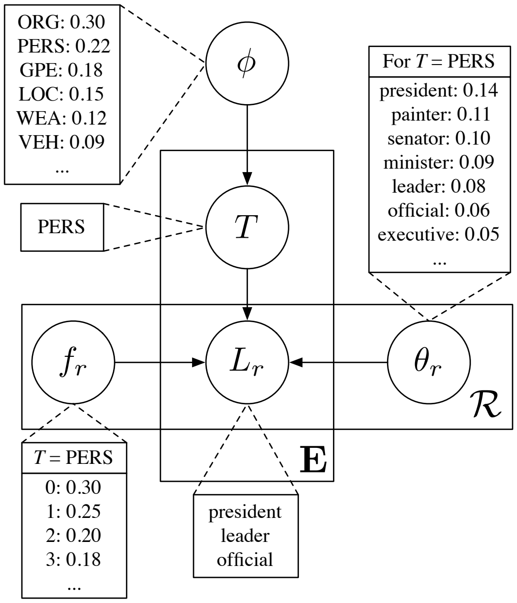

Figure 2: Depiction of the entity generation process (Section 3.1). Each entity draws a type (T) from ϕ, and, for each property $r \in \mathcal{R}$, forms a word list (L_r) by choosing a length from T's f_r distribution and then independently drawing that many words from T's θ_r distribution. Example values are shown for the person type and the nominal head property (NOM-HEAD).

3.1 Semantic Module

The semantic module is responsible for generating a sequence of entities. Each entity E is generated independently and consists of a type indicator T, as well as a collection $\{L_r\}_{r \in \mathcal{R}}$ of word lists for each property. These elements are generated as follows:

```
Entity Generation
Draw entity type $T \sim \phi$
For each mention property $r \in \mathcal{R}$,
    Fetch $\{(f_r, \theta_r)\}$ for $\tau_T$
    Draw word list length $|L_r| \sim f_r$
    Draw $|L_r|$ words from $w \sim \theta_r$
```

See Figure 2 for an illustration of this process. Each word list L_r is generated by first drawing a list length from f_r and then independently populating that list from the property's word distribution θ_r.[1] Past work has employed broadly similar distributional models for unsupervised NER of proper mentions (Collins and Singer, 1999; Elsner et al., 2009). However, to our knowledge, this is the first work to incorporate such a model into an entity reference process.

3.2 Discourse Module

The discourse module is responsible for choosing an entity to evoke at each of the n mention positions. Formally, this module generates an entity assignment vector $\mathbf{Z} = (Z_1, \ldots, Z_n)$, where Z_i indicates the entity index for the ith mention position. Most linguistic inquiry characterizes NP anaphora by the pairwise relations that hold between a mention and its antecedent (Hobbs, 1979; Kehler et al., 2008). Our discourse module utilizes this pairwise perspective to define each Z_i in terms of an intermediate "antecedent" variable A_i. A_i either points to a previous antecedent mention position ($A_i < i$) and "steals" its entity assignment or begins a new entity ($A_i = i$). The choice of A_i is parametrized by affinities $s_{\boldsymbol{\pi}}(i, j; \mathbf{X})$ between mention positions i and j. Formally, this process is described as:

```
Entity Assignment
For each mention position, $i = 1, \ldots, n$,
  Draw antecedent position $A_i \in \{1, \ldots, i\}$:
      $P(A_i = j | X) \propto s_{\boldsymbol{\pi}}(i, j; X)$
  $Z_i = \begin{cases} Z_{A_i}, \text{ if } A_i < i \\ K + 1, \text{ otherwise} \end{cases}$
```

Here, K denotes the number of entities allocated in the first i-1 mention positions. This process is an instance of the sequential distance-dependent Chinese Restaurant Process (DD-CRP) of Blei and Frazier (2009). During inference, we variously exploit both the A and Z representations (Section 4).

For nominal and pronoun mentions, there are several well-studied anaphora cues, including centering (Grosz et al., 1995), nearness (Hobbs, 1978), and deterministic constraints, which have all been utilized in prior coreference work (Soon et al., 1999; Ng and Cardie, 2002). In order to combine these cues, we take a log-linear, feature-based approach and parametrize $s_{\boldsymbol{\pi}}(i, j; X) = \exp\{\boldsymbol{\pi}^\top \mathbf{f}_{\mathbf{X}}(i, j)\}$, where $\mathbf{f}_{\mathbf{X}}(i, j)$ is a feature vector over mention positions i and j, and $\boldsymbol{\pi}$ is a parameter vector; the features may freely condition on $\mathbf{X}$. We utilize the following features between a mention and an an-

[1] There is one exception: the sizes of the proper and nominal head property lists are jointly generated, but their word lists are still independently populated.

tecedent: tree distance, sentence distance, and the syntactic positions (subject, object, and oblique) of the mention and antecedent. Features for starting a new entity include: a definiteness feature (extracted from the mention's determiner), the top CFG rule of the mention parse node, its syntactic role, and a bias feature. These features are conjoined with the mention form (nominal or pronoun). Additionally, we restrict pronoun antecedents to the current and last two sentences, and the current and last three sentences for nominals. Additionally, we disallow nominals from having direct pronoun antecedents.

In addition to the above, if a mention is in a deterministic coreference configuration, as defined in Haghighi and Klein (2009), we force it to take the required antecedent. In general, antecedent affinities learn to prefer close antecedents in prominent syntactic positions. We also learn that new entity nominals are typically indefinite or have SBAR complements (captured by the CFG feature).

In contrast to nominals and pronouns, the choice of entity for a proper mention is governed more by entity frequency than antecedent distance. We capture this by setting $s_{\boldsymbol{\pi}}(i, j; \mathbf{X})$ in the proper case to 1 for past positions and to a fixed α otherwise. [2]

3.3 Mention Module

Once the semantic module has generated entities and the discourse model selects entity assignments, each mention M_i generates word values for a set of observed properties R_i:

```
Mention Generation
For each mention $M_i$, $i = 1, \ldots, n$
  Fetch $(T, \{L_r\}_{r \in \mathcal{R}})$ from $E_{Z_i}$
  Fetch $\{(f_r, \theta_r)\}_{r \in \mathcal{R}}$ from $\mathcal{T}_T$
  For $r \in R_i$ :
      $w \sim (1 - \alpha_r)\textsc{Uniform}(L_r) + (\alpha_r)\theta_r$
```

For each property r, there is a hyper-parameter α_r which interpolates between selecting a word from the entity list L_r and drawing from the underlying type property distribution θ_r. Intuitively, a small value of α_r indicates that an entity prefers to re-use a small number of words for property r. This is typically the case for proper and nominal heads as well as modifiers. At the other extreme, setting α_r to 1 indicates the property isn't particular to the entity itself, but rather only on its type. We set α_r to 1 for pronoun heads as well as for the governor of the head properties.

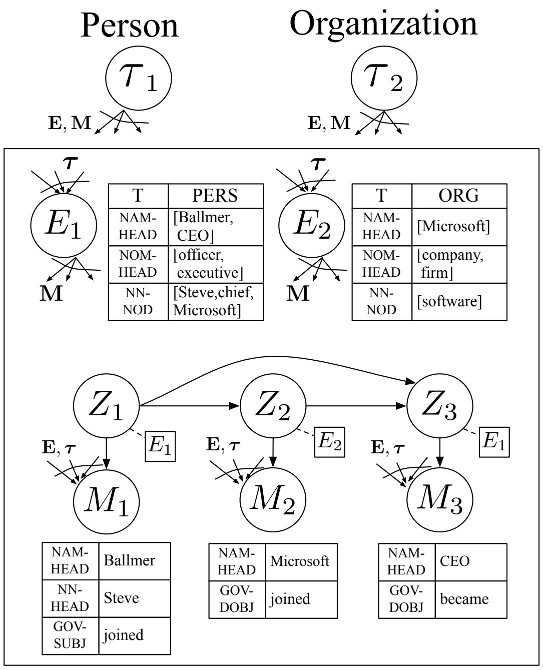

Figure 3: Depiction of the discourse module (Section 3.2); each random variable is annotated with an example value. For each mention position, an entity assignment (Z_i) is made. Conditioned on entities (E_{Z_i}), mentions (M_i) are rendered (Section 3.3). The $\overset{\mathbf{Y}}{\nearrow\!\!\!\!\nwarrow}$ symbol denotes that a random variable is the parent of all $\mathbf{Y}$ random variables.

4 Learning and Inference

Our learning procedure involves finding parameters and assignments which are likely under our model's posterior distribution $P(\mathbf{E}, \mathbf{Z}, \boldsymbol{\tau}, \boldsymbol{\pi} | \mathbf{M}, \mathbf{X})$. The model is modularized in such a way that running EM on all variables simultaneously would be very difficult. Therefore, we adopt a variational approach which optimizes various subgroups of the variables in a round-robin fashion, holding approximations to the others fixed. We first describe the variable groups, then the updates which optimize them in turn.

Decomposition: We decompose the entity vari-

[2] As Blei and Frazier (2009) notes, when marginalizing out the A_i in this trivial case, the DD-CRP reduces to the traditional CRP (Pitman, 2002), so our discourse model roughly matches Haghighi and Klein (2007) for proper mentions.

ables $\mathbf{E}$ into types, $\mathbf{T}$, one for each entity, and word lists, $\mathbf{L}$, one for each entity and property. We decompose the mentions $\mathbf{M}$ into *referring* mentions (propers and nominals), $\mathbf{M}^r$, and pronominal mentions, $\mathbf{M}^p$ (with sizes n_r and n_p respectively). The entity assignments $\mathbf{Z}$ are similarly divided into $\mathbf{Z}^r$ and $\mathbf{Z}^p$ components. For pronouns, rather than use $\mathbf{Z}^p$, we instead work with the corresponding antecedent variables, denoted $\mathbf{A}^p$, and marginalize over antecedents to obtain $\mathbf{Z}^p$.

With these variable groups, we would like to approximation our model posterior $P(\mathbf{T}, \mathbf{L}, \mathbf{Z}^r, \mathbf{A}^p, \boldsymbol{\tau}, \boldsymbol{\pi} | \mathbf{M}, \mathbf{X})$ using a simple factored representation. Our variational approximation takes the following form:

$$Q(\mathbf{T}, \mathbf{L}, \mathbf{Z}^r, \mathbf{A}^p, \boldsymbol{\tau}, \boldsymbol{\pi}) = \delta_r(\mathbf{Z}^r, \mathbf{L}) \left(\prod_{k=1}^{n} q_k(T_k) \right) \left(\prod_{i=1}^{n_p} r_i(A_i^p) \right) \delta_s(\boldsymbol{\tau}) \delta_d(\boldsymbol{\pi})$$

We use a mean field approach to update each of the RHS factors in turn to minimize the KL-divergence between the current variational posterior and the true model posterior. The δ_r, δ_s, and δ_d factors place point estimates on a single value, just as in hard EM. Updating these factors involves finding the value which maximizes the model (expected) log-likelihood under the other factors. For instance, the δ_s factor is a point estimate of the type parameters, and is updated with:[3]

$$\delta_s(\boldsymbol{\tau}) \leftarrow \operatorname*{argmax}_{\boldsymbol{\tau}} \mathbb{E}_{Q_{-\delta_s}} \ln P(\mathbf{E}, \mathbf{Z}, \mathbf{M}, \boldsymbol{\tau}, \boldsymbol{\pi}) \quad (1)$$

where $Q_{-\delta_s}$ denotes all factors of the variational approximation except for the factor being updated. The r_i (pronoun antecedents) and q_k (type indicator) factors maintain a soft approximation and so are slightly more complex. For example, the r_i factor update takes the standard mean field form:

$$r_i(A_i^p) \propto \exp\{\mathbb{E}_{Q_{-r_i}} \ln P(\mathbf{E}, \mathbf{Z}, \mathbf{M}, \boldsymbol{\tau}, \boldsymbol{\pi})\} \quad (2)$$

We briefly describe the update for each additional factor, omitting details for space.

Updating type parameters $\delta_s(\boldsymbol{\tau})$: The type parameters $\boldsymbol{\tau}$ consist of several multinomial distributions which can be updated by normalizing expected counts as in the EM algorithm. The prior $P(\boldsymbol{\tau}|\boldsymbol{\lambda})$ consists of several finite Dirichlet draws for each multinomial, which are incorporated as pseudocounts.[4] Given the entity type variational posteriors $\{q_k(\cdot)\}$, as well as the point estimates of the $\mathbf{L}$ and $\mathbf{Z}^r$ elements, we obtain expected counts from each entity's attribute word lists and referring mention usages.

Updating discourse parameters $\delta_d(\boldsymbol{\pi})$: The learned parameters for the discourse module rely on pairwise antecedent counts for assignments to nominal and pronominal mentions.[5] Given these expected counts, which can be easily obtained from other factors, the update reduces to a weighted maximum entropy problem, which we optimize using LBFGS. The prior $P(\boldsymbol{\pi}|\sigma^2)$ is a zero-centered normal distribution with shared diagonal variance σ^2, which is incorporated via L2 regularization during optimization.

Updating referring assignments and word lists $\delta_r(\mathbf{Z}^r, \mathbf{L})$: The word lists are usually concatenations of the words used in nominal and proper mentions and so are updated together with the assignments for those mentions. Updating the $\delta_r(\mathbf{Z}^r, \mathbf{L})$ factor involves finding the referring mention entity assignments, $\mathbf{Z}^r$, and property word lists $\mathbf{L}$ for instantiated entities which maximize $\mathbb{E}_{Q_{-\delta_r}} \ln P(\mathbf{T}, \mathbf{L}, \mathbf{Z}^r, \mathbf{A}^p, \mathbf{M}, \boldsymbol{\tau}, \boldsymbol{\pi})$. We actually only need to optimize over $\mathbf{Z}^r$, since for any $\mathbf{Z}^r$, we can compute the optimal set of property word lists $\mathbf{L}$. Essentially, for each entity we can compute the L_r which optimizes the probability of the referring mentions assigned to the entity (indicated by $\mathbf{Z}^r$). In practice, the optimal L_r is just the set of property words in the assigned mentions. Of course enumerating and scoring all $\mathbf{Z}^r$ hypotheses is intractable, so we instead utilize a left-to-right sequential beam search. Each partial hypothesis is an assignment to a prefix of mention positions and is scored as though it were a complete hypothesis. Hypotheses are extended via adding a new mention to an existing entity or creating a new one. For our experiments, we limited the number of hypotheses on the beam to the top fifty and did not notice an improvement in model score from increasing beam size.

[3] Of course during learning, the argmax is performed over the entire document collection, rather than a single document.

[4] See software release for full hyper-parameter details.

[5] Propers have no learned discourse parameters.

Updating pronominal antecedents $r_i(A_i^p)$ and entity types $q_k(T_k)$: These updates are straightforward instantiations of the mean-field update (2).

To produce our final coreference partitions, we assign each referring mention to the entity given by the δ_r factor and each pronoun to the most likely entity given by the r_i.

4.1 Factor Staging

In order to facilitate learning, some factors are initially set to fixed heuristic values and only learned in later iterations. Initially, the assignment factors δ_r and $\{r_i\}$ are fixed. For δ_r, we use a deterministic entity assignment $\mathbf{Z}^r$, similar to the Haghighi and Klein (2009)'s SYN-CONSTR setting: each referring mention is coreferent with any past mention with the same head or in a deterministic syntactic configuration (appositives or predicative nominatives constructions).[6] The $\{r_i\}$ factors are heuristically set to place most of their mass on the closest antecedent by tree distance. During training, we proceed in stages, each consisting of 5 iterations:

Stage	Learned	Fixed	$B^3 All$
1	$\delta_s, \delta_d, \{q_k\}$	$\{r_i\}$,δ_r	74.6
2	$\delta_s, \delta_d, \{q_k\}, \delta_r$	$\{r_i\}$	76.3
3	$\delta_s, \delta_d, \{q_k\}, \delta_r, \{r_i\}$	–	78.0

We evaluate our system at the end of stage using the $B^3 All$ metric on the A05CU development set (see Section 5 for details).

5 Experiments

We considered the challenging end-to-end system mention setting, where in addition to predicting mention partitions, a system must identify the mentions themselves and their boundaries automatically. Our system deterministically extracts mention boundaries from parse trees (Section 5.2). We utilized no coreference annotation during training, but did use minimal prototype information to prime the learning of entity types (Section 5.3).

5.1 Datasets

For evaluation, we used standard coreference data sets derived from the ACE corpora:

- **A04CU**: Train/dev/test split of the newswire portion of the ACE 2004 training set[7] utilized in Culotta et al. (2007), Bengston and Roth (2008) and Stoyanov et al. (2009). Consists of 90/68/38 documents respectively.
- **A05ST**: Train/test split of the newswire portion of the ACE 2005 training set utilized in Stoyanov et al. (2009). Consists of 57/24 documents respectively.
- **A05RA**: Train/test split of the ACE 2005 training set utilized in Rahman and Ng (2009). Consists of 482/117 documents respectively.

For all experiments, we evaluated on the dev and test sets above. To train, we included the text of all documents above, though of course not looking at either their mention boundaries or reference annotations in any way. We also trained on the following much larger unlabeled datasets utilized in Haghighi and Klein (2009):

- **BLLIP**: 5k articles of newswire parsed with the Charniak (2000) parser.
- **WIKI**: 8k abstracts of English Wikipedia articles parsed by the Berkeley parser (Petrov et al., 2006). Articles were selected to have subjects amongst the frequent proper nouns in the evaluation datasets.

5.2 Mention Detection and Properties

Mention boundaries were automatically detected as follows: For each noun or pronoun (determined by parser POS tag), we associated a mention with the maximal NP projection of that head or that word itself if no NP can be found. This procedure recovers over 90% of annotated mentions on the A05CU dev set, but also extracts many unannotated "spurious" mentions (for instance events, times, dates, or abstract nouns) which are not deemed to be of interest by the ACE annotation conventions.

Mention properties were obtained from parse trees using the the Stanford typed dependency extractor (de Marneffe et al., 2006). The mention properties we considered are the mention head (annotated with mention type), the typed modifiers of the head, and the governor of the head (conjoined with

[6] Forcing appositive coreference is essential for tying proper and nominal entity type vocabulary.

[7] Due to licensing restriction, the formal ACE test sets are not available to non-participants.

Table 1: Experimental results with system mentions. All systems except Haghighi and Klein (2009) and current work are fully supervised. The current work outperforms all other systems, supervised or unsupervised. For comparison purposes, the B^3None variant used on A05RA is calculated slightly differently than other B^3None results; see Rahman and Ng (2009).

the mention's syntactic position). We discard determiners, but make use of them in the discourse component (Section 3.2) for NP definiteness.

5.3 Prototyping Entity Types

While it is possible to learn type distributions in a completely unsupervised fashion, we found it useful to prime the system with a handful of important types. Rather than relying on fully supervised data, we took the approach of Haghighi and Klein (2006). For each type of interest, we provided a (possibly-empty) prototype list of proper and nominal head words, as well as a list of allowed pronouns. For instance, for the PERSON type we might provide:

NAM	Bush, Gore, Hussein
NOM	president, minister, official
PRO	he, his, she, him, her, you, ...

The prototypes were used as follows: Any entity with a prototype on any proper or nominal head word attribute list (Section 3.1) was constrained to have the specified type; i.e. the q_k factor (Section 4) places probability one on that single type. Similarly to Haghighi and Klein (2007) and Elsner et al. (2009), we biased these types' pronoun distributions to the allowed set of pronouns.

In general, the choice of entity types to prime with prototypes is a domain-specific question. For experiments here, we utilized the types which are annotated in the ACE coreference data: person (PERS), organization (ORG), geo-political entity (GPE), weapon (WEA), vehicle (VEH), location (LOC), and facility (FAC). Since the person type in ACE conflates individual persons with groups of people (e.g., *soldier* vs. *soldiers*), we added the group (GROUP) type and generated a prototype specification.

We obtained our prototype list by extracting at most four common proper and nominal head words from the newswire portions of the 2004 and 2005 ACE training sets (A04CU and A05ST); we chose prototype words to be minimally ambiguous with respect to type.[8] When there are not at least three proper heads for a type (WEA for instance), we did not provide any proper prototypes and instead strongly biased the type fertility parameters to generate empty NAM-HEAD lists.

Because only certain semantic types were annotated under the arbitrary ACE guidelines, there are many mentions which do not fall into those limited categories. We therefore prototype (refinements of) the ACE types and then add an equal number of unconstrained "other" types which are automatically induced. A nice consequence of this approach is that we can simply run our model on *all* mentions, discarding at evaluation time any which are of non-prototyped types.

5.4 Evaluation

We evaluated on multiple coreference resolution metrics, as no single one is clearly superior, partic-

[8] Meaning those headwords were assigned to the target type for more than 75% of their usages.

ularly in dealing with the system mention setting. We utilized MUC (Vilain et al., 1995), $B^3 All$ (Stoyanov et al., 2009), $B^3 None$ (Stoyanov et al., 2009), and Pairwise F1. The $B^3 All$ and $B^3 None$ are B^3 variants (Bagga and Baldwin, 1998) that differ in their treatment of spurious mentions. For Pairwise F1, precision measures how often pairs of predicted coreferent mentions are in the same annotated entity. We eliminated any mention pair from this calculation where both mentions were spurious.[9]

5.5 Results

Table 1 shows our results. We compared to two state-of-the-art supervised coreference systems. The Stoyanov et al. (2009) numbers represent their THRESHOLD_ESTIMATION setting and the Rahman and Ng (2009) numbers represent their highest-performing cluster ranking model. We also compared to the strong deterministic system of Haghighi and Klein (2009).[10] Across all data sets, our model, despite being largely unsupervised, consistently outperforms these systems, which are the best previously reported results on end-to-end coreference resolution (i.e. including mention detection). Performance on the A05RA dataset is generally lower because it includes articles from blogs and web forums where parser quality is significantly degraded.

While Bengston and Roth (2008) do not report on the full system mention task, they do report on the more optimistic setting where mention detection is performed but non-gold mentions are removed for evaluation using an oracle. On this more lenient setting, they report 78.4 B^3 on the A04CU test set. Our model yields 80.3.

6 Analysis

We now discuss errors and improvements made by our system. One frequent source of error is the merging of mentions with explicitly contrasting modifiers, such as *new president* and *old president*. While it is not unusual for a single entity to admit multiple modifiers, the particular modifiers *new* and *old* are incompatible in a way that *new* and *popular* are not. Our model does not represent the negative covariance between these modifiers.

We compared our output to the deterministic system of Haghighi and Klein (2009). Many improvements arise from correctly identifying mentions which are semantically compatible but which do not explicitly appear in an appositive or predicate-nominative configuration in the data. For example, *analyst* and *it* cannot corefer in our system because *it* is not a likely pronoun for the type PERSON.

While the focus of our model is coreference resolution, we can also isolate and evaluate the type component of our model as an NER system. We test this component by presenting our learned model with boundary-annotated non-pronominal entities from the A05ST dev set and querying their predicted type variable T. Doing so yields 83.2 entity classification accuracy under the mapping between our prototyped types and the coarse ACE types. Note that this task is substantially more difficult than the unsupervised NER in Elsner et al. (2009) because the inventory of named entities is larger (7 vs. 3) and because we predict types over nominal mentions that are more difficult to judge from surface forms. In this task, the plurality of errors are confusions between the GPE (geo-political entity) and ORG entity types, which have very similar distributions.

7 Conclusion

Our model is able to acquire and exploit knowledge at either the level of individual entities ("Obama" is a "president") and entity types ("company" can refer to a corporation). As a result, it leverages semantic constraints more effectively than systems operating at either level alone. In conjunction with reasonable, but simple, factors capturing discourse and syntactic configurational preferences, our entity-centric semantic model lowers coreference error rate substantially, particularly on semantically disambiguated references, giving a sizable improvement over the state-of-the-art.[11]

Abstract

Typical statistical machine translation systems are trained with static parallel corpora. Here we account for scenarios with a continuous incoming stream of parallel training data. Such scenarios include daily governmental proceedings, sustained output from translation agencies, or crowd-sourced translations. We show incorporating recent sentence pairs from the stream improves performance compared with a static baseline. Since frequent batch retraining is computationally demanding we introduce a fast incremental alternative using an online version of the EM algorithm. To bound our memory requirements we use a novel data-structure and associated training regime. When compared to frequent batch retraining, our online time and space-bounded model achieves the same performance with significantly less computational overhead.

1 Introduction

There is more parallel training data available today than there has ever been and it keeps increasing. For example, the European Parliament[1] releases new parallel data in 22 languages on a regular basis. Project Syndicate[2] translates editorials into seven languages (including Arabic, Chinese and Russian) every day. Existing translation systems often get ‘crowd-sourced’ improvements such as the option to contribute a better translation to GoogleTranslate[3]. In these and many other instances, the data can be viewed as an incoming *unbounded stream* since the corpus grows continually with time. Dealing with such unbounded streams of parallel sentences presents two challenges: making retraining efficient and operating within a bounded amount of space.

Statistical Machine Translation (SMT) systems are typically batch trained, often taking many CPU-days of computation when using large volumes of training material. Incorporating new data into these models forces us to retrain from scratch. Clearly, this makes rapidly adding newly translated sentences into our models a daunting engineering challenge. We introduce an adaptive training regime using an online variant of EM that is capable of incrementally adding new parallel sentences without incurring the burdens of full retraining.

For situations with large volumes of incoming parallel sentences we are also forced to consider placing space-bounds on our SMT system. We introduce a dynamic suffix array which allows us to add and delete parallel sentences, thereby maintaining bounded space despite processing a potentially high-rate input stream of unbounded length.

Taken as a whole we show that online translation models operating within bounded space can perform as well as systems which are batch-based and have no space constraints thereby making our approach suitable for stream-based translation.

2 Stepwise Online EM

The EM algorithm is a common way of inducing latent structure from unlabeled data in an unsupervised manner (Dempster et al., 1977). Given a set of unlabeled examples and an initial, often uniform guess at a probability distribution over the latent variables, the EM algorithm maximizes the marginal

log-likelihood of the examples by repeatedly computing the expectation of the conditional probability of the latent data with respect to the current distribution, and then maximizing the expectations over the observations into a new distribution used in the next iteration. EM (and related variants such as variational or sampling approaches) form the basis of how SMT systems learn their translation models.

2.1 Batch vs. Online EM

Computing an expectation for the conditional probabilities requires collecting the *sufficient statistics* $\mathbf{S}$ over the set of n unlabeled examples. In the case of a multinomial distribution, $\mathbf{S}$ is comprised of the counts over each conditional observation occurring in the n examples. In traditional *batch* EM, we collect the counts over the entire dataset of n unlabeled training examples via the current 'best-guess' probability model $\hat{\theta}_t$ at iteration t (E-step) before normalizing the counts into probabilities $\bar{\theta}(\mathbf{S})$ (M-step)[4]. After each iteration all the counts in the sufficient statistics vector $\mathbf{S}$ are cleared and the count collection begins anew using the new distribution $\hat{\theta}_{t+1}$.

When we move to processing an incoming data stream, however, the batch EM algorithm's requirement that all data be available for each iteration becomes impractical since we do not have access to all n examples at once. Instead we receive examples from the input stream incrementally. For this reason online EM algorithms have been developed to update the probability model $\hat{\theta}$ incrementally without needing to store and iterate through all the unlabeled training data repeatedly.

Various online EM algorithms have been investigated (see Liang and Klein (2009) for an overview) but our focus is on the *stepwise online* EM (sOEM) algorithm (Cappe and Moulines, 2009). Instead of iterating over the full set of training examples, sOEM stochastically approximates the batch E-step and incorporates the information from the newly available streaming observations in steps. Each step is called a *mini-batch* and is comprised of one or more new examples encountered in the stream.

Unlike in batch EM, in sOEM the expected counts are retained between EM iterations and not cleared. That is, for each new example we interpolate its expected count with the existing set of sufficient statistics. For each step we use a *stepsize* parameter γ which mixes the information from the current example with information gathered from all previous examples. Over time the sOEM model probabilities begin to stabilize and are guaranteed to converge to a local maximum (Cappe and Moulines, 2009).

Algorithm 1: Batch EM for Word Alignments

```
Input: $\{F$(source),$E$ (target)$\}$ sentence-pairs
Output: MLE $\hat{\theta}_T$ over alignments $\mathbf{a}$
$\hat{\theta}_0$ ←MLE initialization;
for iteration $k = 0, \dots, T$ do
    $S \leftarrow 0$;                          // reset counts
    foreach $(f, e) \in \{F, E\}$ do           // E-step
        $S \leftarrow S + \sum_{a' \in \mathbf{a}} \Pr(f, a'|e; \hat{\theta}_t)$;
    end
    $\hat{\theta}_{t+1} \leftarrow \bar{\theta}_t(S)$ ;                // M-step
end
```

Note that the stepsize γ has a dependence on the current mini-batch. As we observe more incoming data the model's current probability distribution is closer to the true distribution so the new observations receive less weight. From Liang and Klein (2009), if we set the stepsize as $\gamma_t = (t+2)^{-\alpha}$, with $0.5 < \alpha \leq 1$, we can guarantee convergence in the limit as $n \to \infty$. If we set α low, γ weighs the newly observed statistics heavily whereas if γ is low new observations are down-weighted.

2.2 Batch EM for Word Alignments

Batch EM is used in statistical machine translation to estimate word alignment probabilities between parallel sentences. From these alignments, bilingual rules or phrase pairs can be extracted. Given a set of parallel sentence examples, $\{\mathbf{F}, \mathbf{E}\}$, with $\mathbf{F}$ the set of source sentences and $\mathbf{E}$ the corresponding target sentences, we want to find the latent alignments $\mathbf{a}$ for a sentence pair $(\mathbf{f}, \mathbf{e}) \in \{\mathbf{F}, \mathbf{E}\}$ that defines the most probable correspondence between words f_j and e_i such that $a_j = i$. We can induce these alignments using an *HMM-based* alignment model where the probability of alignment a_j is dependent only on the previous alignment at a_{j-1} (Vogel et al., 1996).

[4] As the M-step can be computed in closed form we designate it in this work as $\bar{\theta}(\mathbf{S})$.

We can write

$$\Pr(\mathbf{f}, \mathbf{a} \mid \mathbf{e}) = \sum_{a' \in \mathbf{a}} \prod_{j=1}^{|\mathbf{f}|} p(a_j \mid a_{j-1}, |\mathbf{e}|) \cdot p(f_j \mid e_{a_j})$$

where we assume a first-order dependence on previously aligned positions.

To find the most likely parameter weights for the translation and alignment probabilities for the HMM-based alignments, we employ the EM algorithm via dynamic programming. Since HMMs have multiple local minima, we seed the HMM-based model probabilities with a better than random guess using IBM Model 1 (Brown et al., 1993) as is standard. IBM Model 1 is of the same form as the HMM-based model except it uses a uniform distribution instead of a first-order dependency. Although a series of more complex models are defined, IBM Models 2 to Model 6 (Brown et al., 1993; Och and Ney, 2003), researchers typically find that extracting phrase pairs or translation grammar rules using Model 1 and the HMM-based alignments results in equivalently high translation quality. Nevertheless, there is nothing in our approach which limits us to using just Model 1 and the HMM model.

A high-level overview of the standard, batch EM algorithm applied to HMM-based word alignment model is shown in Algorithm 1.

2.3 Stepwise EM for Word Alignments

Application of sOEM to HMM and Model 1 based word aligning is straightforward. The process of collecting the counts over the expected conditional probabilities inside each iteration loop remains the same as in the batch case. However, instead of clearing the sufficient statistics between the iterations we retain them and interpolate them with the batch of counts gathered in the next iteration.

Algorithm 2 shows high level pseudocode of our sOEM framework as applied to HMM-based word alignments. Here we have an unbounded input stream of source and target sentences $\{\mathbf{F}, \mathbf{E}\}$ which we do not have access to in its entirety at once. Instead we observe mini-batches $\{\mathbf{M}\}$ comprised of chronologically ordered strict subsets of the full stream. To word align the sentences for each mini-batch $\mathbf{m} \in \mathbf{M}$, we use the probability assigned by the current model parameters and then interpolate the newest sufficient statistics $\bar{s}$ with our full count vector $\mathbf{S}$ using an interpolation parameter γ. The interpolation parameter γ has a dependency on how far along the input stream we are processing.

Algorithm 2: sOEM Algorithm for Word Alignments

```
Input: mini-batches of sentence pairs
        $\{M : M \subset \{F(source), E(target)\}\}$
Input: stepsize weight $\alpha$
Output: MLE $\hat{\theta}_T$ over alignments $\mathbf{a}$
$\hat{\theta}_0$ ←MLE initialization;
$S \leftarrow 0$; $k = 0$;
foreach mini-batch $\{m : m \in M\}$ do
    for iteration $t = 0, \ldots, T$ do
        foreach $(f, e) \in \{m\}$ do          // E-step
            $\bar{s} \leftarrow \sum_{a' \in \mathbf{a}} \Pr(f, a'|e; \hat{\theta}_t)$;
        end
        $\gamma = (k+2)^{-\alpha}; k = k+1;$ // stepsize
        $S \leftarrow \gamma\bar{s} + (1-\gamma)S;$   // interpolate
        $\hat{\theta}_{t+1} \leftarrow \bar{\theta}_t(S)$ ;            // M-step
    end
end
```

3 Dynamic Suffix Arrays

So far we have shown how to incrementally retrain translation models. We now consider how we might bound the space we use for them when processing (potentially) unbounded streams of parallel data.

Suffix arrays are space-efficient data structures for fast searching over large text strings (Manber and Myers, 1990). Treating the entire corpus as a single string, a suffix array holds in lexicographical order (only) the starting index of each suffix of the string. After construction, since the corpus is now ordered, we can query the suffix array quickly using binary search to efficiently find all occurrences of a particular token or sequence of tokens. Then we can easily compute, on-the-fly, the statistics required such as translation probabilities for a given source phrase. Suffix arrays can also be compressed, which make them highly attractive structures for representing massive translation models (Callison-Burch et al., 2005; Lopez, 2008).

We need to delete items if we wish to maintain

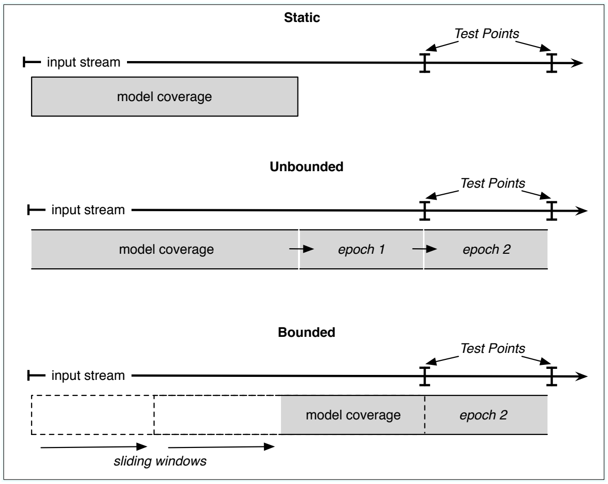

Figure 1: Streaming coverage conditions. In traditional batch based modeling the coverage of a trained model never changes. Unbounded coverage operates without any memory constraints so the model is able to continually add data from the input stream. Bounded coverage uses just a fixed window.

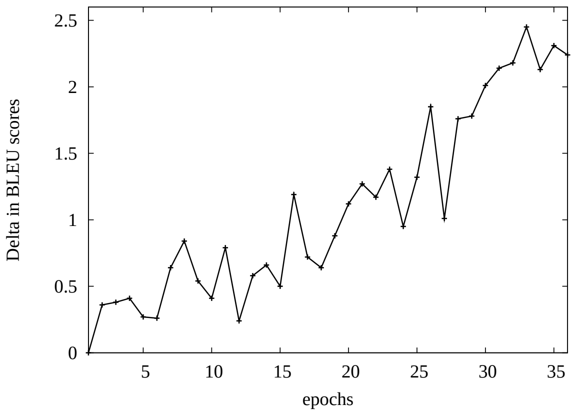

Figure 2: Recency effects to SMT performance. Depicted are the differences in BLEU scores for multiple test points decoded by a static baseline system and a system batched retrained on a fixed sized window prior to the test point in question. The results are accentuated at the end of the timeline when more time has passed confirming that recent data impacts translation performance.

constant space when processing unbounded streams. Standard suffix arrays are static, store a fixed corpus and do not support deletions. Nevertheless, a dynamic variant of the suffix array does support deletions as well as insertions and therefore can be used in our stream-based approach (Salson et al., 2009). Using a dynamic suffix array, we can compactly represent the set of parallel sentences from which we eventually extract grammar rules. Furthermore, when incorporating new parallel sentences, we simply insert them into the array and, to maintain constant space usage, we delete an equivalent number.

4 Experiments

In this section we describe the experiments conducted comparing various batch trained translation models (TMs) versus online incrementally retrained TMs in a full SMT setting with different conditions set on model coverage. We used publicly available resources for all our tests. We start by showing that recency motivates incremental retraining.

4.1 Effects of Recency on SMT

For language modeling, it is known that performance can be improved using the criterion of *recency* where training data is drawn from times chronologically closer to the test data (Rosenfeld, 1995). Given an incoming stream of parallel text, we gauged the extent to which incorporating recent data into a TM affects translation quality.

We used the Europarl corpus[5] with the Fr-En language pair using French as source and English as target. Europarl is released in the format of a daily parliamentary session per time-stamped file. The actual dates of the full corpus are interspersed unevenly (they do not convene daily) over a continuous timeline corresponding to the parliament sessions from April,1996 through October, 2006, but for conceptual simplicity we treated the corpus as a continual input stream over consecutive days.

As a baseline we aligned the first 500k sentence pairs from the beginning of the corpus timeline. We extracted a grammar for and translated 36 held out test documents that were evenly spaced along the remainder of the Europarl timeline. These test documents effectively divided the remaining training data into *epochs* and we used a *sliding window* over the timeline to build 36 distinct, overlapping training sets of 500k sentences each.

We then translated all 36 test points again using a new grammar for each document extracted from only the sentences contained in the epoch that was before it. To explicitly test the effect of recency

[5] Available at `http://www.statmt.org/europarl`

on the TM all other factors of the SMT pipeline remained constant including the language model and the feature weights. Hence, the only change from the static baseline to the epochs performance was the TM data which was based on recency. Note that at this stage we did not use any incremental retraining.

Results are shown in Figure 2 as the differences in BLEU score (Papineni et al., 2001) between the baseline TM versus the translation models trained on material chronologically closer to the given test point. The consistently positive deltas in BLEU scores between the model that is never retrained and the models that are retrained show that we achieve a higher translation performance when using more up-to-date TMs that incorporate recent sentence pairs. As the chronological distance between the initial, static model and the retrained models increases, we see ever-increasing differences in translation performance. This underlines the need to retrain translation models with timely material.

4.2 Unbounded and Bounded Translation Model Retraining

Here we consider how to process a stream along two main axes: by bounding time (batch versus incremental retraining) and by bounding space (either using all the stream seen so far, or only using a fixed sized sample of it).

To ensure the recency results reported above were not limited to French-English, this time our parallel input stream was generated from the German-English language pair of Europarl with German as source and English again as target. For testing we held out a total of 22k sentences from 10 evenly spaced intervals in the input stream which divided the input stream into 10 epochs. Stream statistics for three example epochs are shown in Table 1. We held out 4.5k sentence pairs as development data to optimize the feature function weights using minimum error rate training (Och, 2003) and these weights were used by all models. We used *Joshua* (Li et al., 2009), a syntax-based decoder with a suffix array implementation, and rule induction via the standard *Hiero* grammar extraction heuristics (Chiang, 2007) for the TMs. Note that nothing hinges on whether we used a syntax or a phrase-based system.

We used a 5-gram, Kneser-Ney smoothed language model (LM) trained on the initial segment of the target side parallel data used in the first baseline as described further in the next subsection. As our initial experiments aim to isolate the effect of changes to the TM on overall translation system performance, our in-domain LM remains static for every decoding run reported below until indicated.

Ep	From–To	Sent Pairs	Source/Target

03	02/2002–09/2002	70k	1.9M/2.0M
06	10/2003–03/2004	60k	1.6M/1.7M
10	03/2006–09/2006	73k	1.9M/2.0M

Table 1: Date ranges, total sentence pairs, and source and target word counts encountered in the input stream for example epochs. Epoch 00 is baseline data that is also used as a seed corpus for the online models.

We used the open-source toolkit GIZA++ (Och and Ney, 2003) for all word alignments. For the online adaptation experiments we modified Model 1 and the HMM model in GIZA++ to use the sOEM algorithm. Batch baselines were aligned using the standard version of GIZA++. We ran the batch and incremental versions of Model 1 and HMM for the same number of iterations each in both directions.

4.3 Time and Space Bounds

For both batch and sOEM we ran a number of experiments listed below corresponding to the different training scenarios diagrammed in Figure 1.

1. **Static**: We used the first half of the input stream, approximately 600k sentences and 15/16 million source/target words, as parallel training data. We then translated each of the 10 test sets using the static model. This is the traditional approach and the coverage of the model never changes.

2. **Unbounded Space**: Batch or incremental retraining with no memory constraint. For each epoch in the stream, we retrained the TM using *all* the data from the beginning of the input stream until just before the present with respect to a given test point. As more time passes our training data set grows so each *batch* run of GIZA++ takes more time. Overall this is the most computationally expensive approach.

			Baseline		Unbounded		Bounded	
Epoch	Test Date	Test Sent.	Train Sent.	Rules	Train Sent.	Rules	Train Sent.	Rules
03	09/23/2002	1.0k	580k	4.0M	800k	5.0M	580k	4.2M
06	03/29/2004	1.5k	580k	5.0M	1.0M	7.0M	580k	5.5M
10	09/26/2006	3.5k	580k	8.5M	1.3M	14.0M	580k	10.0M

Table 2: Translation model statistics for example epochs and the next test dates grouped by experimental condition. *Test* and *Train Sent.* is the number of sentence pairs in test and training data respectively. *Rules* is the count of unique Hiero grammar rules extracted for the corresponding test set.

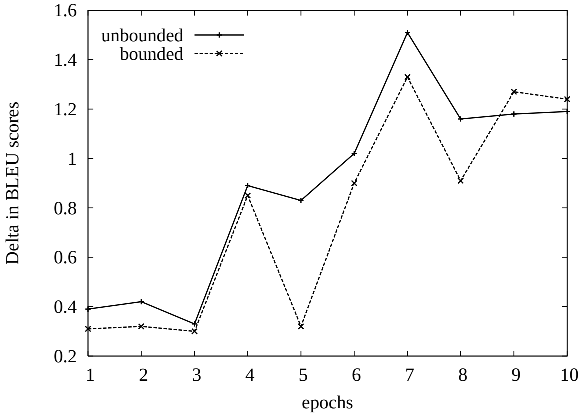

Figure 3: Static vs. online TM performance. Gains in translation performance measured by BLEU are achieved when recent German-English sentence pairs are automatically incorporated into the TM. Shown are relative BLEU improvements for the online models against the static baseline.

3. **Bounded Space**: Batch and incremental retraining with an enforced memory constraint. Here we batch or incrementally retrain using a *sliding window* approach where the training set size (the number of sentence pairs) remains constant. In particular, we ensured that we used the same number of sentences as the baseline. Each batch run of GIZA++ takes approximately the same time.

The *time* for aligning in the sOEM model is unaffected by the bounded/unbounded conditions since we always only align the mini-batch of sentences encountered in the last epoch. In contrast, for batch EM we must realign all the sentences in our training set from scratch to incorporate the new training data.

Similarly *space* usage for the batch training grows with the training set size. For sOEM, in theory memory used is with respect to vocabulary size (which grows slowly with the stream size) since we retain count history for the entire stream. To make space usage truly constant, we filter for just the needed word pairs in the current epoch being aligned. This effectively means that online EM is more memory efficient than the batch version. As our experiments will show, the sufficient statistics kept between epochs by sOEM benefits performance compared to the batch models which can only use information present within the batch itself.

4.4 Incremental Retraining Procedure

Our incremental adaptation procedure was as follows: after the latest mini-batch of sentences had been aligned using sOEM we added all newly aligned sentence pairs to the dynamic suffix arrays. For the experiments where our memory was bounded, we also *deleted* an equal number of sentences from the suffix arrays before extracting the Hiero grammar for the next test point. For the unbounded coverage experiments we deleted nothing prior to grammar extraction. Table 2 presents statistics for the number of training sentence pairs and grammar rules extracted for each coverage condition for various test points.

4.5 Results

Figure 3 shows the results of the static baseline against both the unbounded and bounded online EM models. We can see that both the online models outperform the static baseline. On average the unconstrained model that contains more sentence pairs for rule extraction slightly outperforms the bounded condition which uses less data per epoch. However, the static baseline and the bounded models both use the same number of sentence-pairs for TM training. We see there is a clear gain by incorporating recent sentence-pairs made available by the stream.

	Static Baseline	Retrained (Unbounded)		Retrained (Bounded)	
Test Date	Batch	Batch	Online	Batch	Online
09/23/2002	26.10	**26.60**	26.43	26.19	*26.40*
03/29/2004	27.40	28.33	**28.42**	28.06	*28.38*
09/26/2006	28.56	29.74	**29.75**	29.73	*29.80*

Table 3: Sample BLEU results for all baseline and online EM model conditions. The *static baseline* is a traditional model that is never retrained. The *batch unbounded* and *batch bounded* models incorporate new data from the stream but retraining is slow and computationally expensive (best results are bolded). In contrast both unbounded and bounded online models incrementally retrain only the mini-batch of new sentences collected from the incoming stream so quickly adopt the new data (best results are italicized).

Table 3 gives results of the online models compared to the batch retrained models. For presentation clarity we show only a sample of the full set of ten test points though all results follow the pattern that using more aligned sentences to derive our grammar set resulted in slightly better performance versus a restricted training set. However, for the same coverage constraints not only do we achieve comparable performance to batch retrained models using the sOEM method of incremental adaptation, we are able to align and adopt new data from the input stream orders of magnitude quicker since we only align the mini-batch of sentences collected from the last epoch. In the bounded condition, not only do we benefit from quicker adaptation, we also see that sOEM models slightly outperform the batch based models due to the online algorithm employing a longer history of count-based evidence to draw on when aligning new sentence pairs.

Figure 4 shows two example test sentences that benefited from the online TM adaptation. Translations from the online model produce more and longer matching phrases for both sentences (e.g., "creation of such a", "of the occupying forces") leading to more fluent output as well as the improvements achieved in BLEU scores.

We experimented with a variety of interpolation parameters (see Algorithm 2) but found no significant difference between them (the biggest improvement gained over all test points for all parameter settings was less than 0.1% BLEU).

4.6 Increasing LM Coverage

A natural and interesting extension to the experiments above is to use the target side of the incoming stream to extend the LM coverage alongside the TM. It is well known that more LM coverage (via larger training data sets) is beneficial to SMT performance (Brants et al., 2007) so we investigated whether recency gains for the TM were additive with recency gains afforded by a LM.

Test Date	Static	Unbounded	Bounded
09/23/2002	26.46	27.11	26.96
03/29/2004	28.11	29.53	29.20
09/26/2006	29.53	30.94	30.88

Table 4: Unbounded LM coverage improvements. Shown are the BLEU scores for each experimental conditional when we allow the LM coverage to increase.

To test this we added all the target side data from the beginning of the stream to the most recent epoch into the LM training set before each test point. We then batch retrained[6] and used the new LM with greater coverage for the next decoding run. Experiments were for the static baseline and online models.

Results are reported in Table 4. We can see that increasing LM coverage is complimentary to adapting the TM with recent data. Comparing Tables 3 and 4, for the bounded condition, adapting only the TM achieved an absolute improvement of +1.24 BLEU over the static baseline for the final test point. We get another absolute gain of +1.08 BLEU by allowing the LM coverage to adapt as well. Using an online, adaptive model gives a total gain of +2.32 BLEU over a static baseline that does not adapt.

[6] Although we batch retrain the LMs we could use an online LM that incorporates new vocabulary from the input stream as in Levenberg and Osborne (2009).

5 Related Work

5.1 Translation Model Domain Adaptation

Our work is related to domain adaptation for translation models. See, for example, Koehn and Schroeder (2007) or Bertoldi and Federico (2009). Most techniques center around using mixtures of translation models. Once trained, these models generally never change. They therefore fall under the *batch* training regime. The focus of this work instead is on incremental retraining and also on supporting bounded memory consumption. Our experiments examine updating model parameters in a single domain over different periods in time. Naturally, we could also use domain adaptation techniques to further improve how we incorporate new samples.

5.2 Online EM for SMT

For stepwise online EM for SMT models, the only prior work we are aware of is Liang and Klein (2009), where variations of online EM were experimented with on various NLP tasks including word alignments. They showed application of sOEM can produce quicker convergence compared to the batch EM algorithm. However, the model presented does not incorporate any unseen data, instead iterating over a static data set multiple times using sOEM. For Liang and Klein (2009) incremental retraining is simply an alternative way to use a fixed training set.

5.3 Streaming Language Models

Recent work in Levenberg and Osborne (2009) presented a streaming LM that was capable of adapting to an unbounded monolingual input stream in constant space and time. The LM has the ability to add or delete n-grams (and their counts) based on feedback from the decoder after translation points. The model was tested in an SMT setting and results showed recent data benefited performance. However, adaptation was only to the LM and no tests were conducted on the TM.

6 Conclusion and Future Work

We have presented an online EM approach for word alignments. We have shown that, for a SMT system, incorporating recent parallel data into a TM from an input stream is beneficial to translation performance compared to a traditional, static baseline.

Our strategy for populating the suffix array was simply to use a first-in, first-out stack. For future work we will investigate whether information provided by the incoming stream coupled with the feedback from the decoder allows for more sophisticated adaptation strategies that reinforce useful word alignments and delete bad or unused ones.

In the near future we also hope to test the online EM setup in an application setting such as a computer aided translation or crowdsourced generated streams via Amazon's Mechanical Turk.

Abstract

The quality of a statistical machine translation (SMT) system is heavily dependent upon the amount of parallel sentences used in training. In recent years, there have been several approaches developed for obtaining parallel sentences from non-parallel, or comparable data, such as news articles published within the same time period (Munteanu and Marcu, 2005), or web pages with a similar structure (Resnik and Smith, 2003). One resource not yet thoroughly explored is Wikipedia, an online encyclopedia containing linked articles in many languages. We advance the state of the art in parallel sentence extraction by modeling the document level alignment, motivated by the observation that parallel sentence pairs are often found in close proximity. We also include features which make use of the additional annotation given by Wikipedia, and features using an automatically induced lexicon model. Results for both accuracy in sentence extraction and downstream improvement in an SMT system are presented.

1 Introduction

For any statistical machine translation system, the size of the parallel corpus used for training is a major factor in its performance. For some language pairs, such as Chinese-English and Arabic-English, large amounts of parallel data are readily available, but for most language pairs this is not the case. The domain of the parallel corpus also strongly influences the quality of translations produced. Many parallel corpora are taken from the news domain, or from parliamentary proceedings. Translation quality suffers when a system is not trained on any data from the domain it is tested on.

While parallel corpora may be scarce, comparable, or semi-parallel corpora are readily available in several domains and language pairs. These corpora consist of a set of documents in two languages containing similar information. (See Section 2.1 for a more detailed description of the types of non-parallel corpora.) In most previous work on extraction of parallel sentences from comparable corpora, some coarse document-level similarity is used to determine which document pairs contain parallel sentences. For identifying similar web pages, Resnik and Smith (2003) compare the HTML structure. Munteanu and Marcu (2005) use publication date and vector-based similarity (after projecting words through a bilingual dictionary) to identify similar news articles.

Once promising document pairs are identified, the next step is to extract parallel sentences. Usually, some seed parallel data is assumed to be available. This data is used to train a word alignment model, such as IBM Model 1 (Brown et al., 1993) or HMM-based word alignment (Vogel et al., 1996). Statistics from this word alignment model are used to train a classifier which identifies bilingual sentence pairs as parallel or not parallel. This classifier is applied to all sentence pairs in documents which were found to be similar. Typically, some pruning is done to reduce the number of sen-

tence pairs that need to be classified.

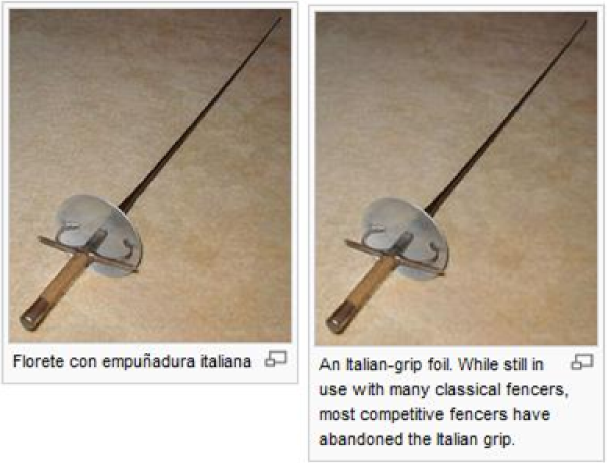
While these methods have been applied to news corpora and web pages, very little attention has been given to Wikipedia as a source of parallel sentences. This is surprising, given that Wikipedia contains annotated article alignments, and much work has been done on extracting bilingual lexicons on this dataset. Adafre and de Rijke (2006) extracted similar sentences from Wikipedia article pairs, but only evaluated precision on a small number of extracted sentences.

In this paper, we more thoroughly investigate Wikipedia's viability as a comparable corpus, and describe novel methods for parallel sentence extraction. Section 2 describes the multilingual resources available in Wikipedia. Section 3 gives further background on previous methods for parallel sentence extraction on comparable corpora, and describes our approach, which finds a global sentence alignment between two documents. In Section 4, we compare our approach with previous methods on datasets derived from Wikipedia for three language pairs (Spanish-English, German-English, and Bulgarian-English), and show improvements in downstream SMT performance by adding the parallel data we extracted.

2 Wikipedia as a Comparable Corpus

Wikipedia (Wikipedia, 2004) is an online collaborative encyclopedia available in a wide variety of languages. While the English Wikipedia is the largest, with over 3 million articles, there are 24 language editions with at least 100,000 articles.

Articles on the same topic in different languages are also connected via "interwiki" links, which are annotated by users. This is an extremely valuable resource when extracting parallel sentences, as the document alignment is already provided. Table 1 shows how many of these "interwiki" links are present between the English Wikipedia and the 16 largest non-English Wikipedias.



Florete con empuñadura italiana

An Italian-grip foil. While still in use with many classical fencers, most competitive fencers have abandoned the Italian grip.

Figure 1: Captions for an image of a foil in English and Spanish

Wikipedia's markup contains other useful indicators for parallel sentence extraction. The many hyperlinks found in articles have previously been used as a valuable source of information. (Adafre and de Rijke, 2006) use matching hyperlinks to identify similar sentences. Two links match if the articles they refer to are connected by an "interwiki" link. Also, images in Wikipedia are often stored in a central source across different languages; this allows identification of captions which may be parallel (see Figure 1). Finally, there are other minor forms of markup which may be useful for finding similar content across languages, such as lists and section headings. In Section 3.3, we will explain how features are derived from this markup.

2.1 Types of Non-Parallel Corpora

Fung and Cheung (2004) give a more fine-grained description of the types of non-parallel corpora, which we will briefly summarize. A *noisy parallel corpus* has documents which contain many parallel sentences in roughly the same order. *Comparable corpora* contain topic aligned documents which are not translations of each other. The corpora Fung and Cheung (2004) examine are *quasi-comparable*: they contain bilingual documents which are not necessarily on the same topic.

Wikipedia is a special case, since the aligned article pairs may range from being almost completely parallel (e.g., the Spanish and English entries for "Antiparticle") to containing almost no parallel sentences (the Spanish and English entries for "John Calvin"), despite being topic-aligned. It is best characterized as a mix of noisy parallel and comparable article pairs. Some Wikipedia authors will translate articles from another language; others

write the content themselves. Furthermore, even articles created through translations may later diverge due to independent edits in either language.

3 Models for Parallel Sentence Extraction

In this section, we will focus on methods for extracting parallel sentences from aligned, comparable documents. The related problem of automatic document alignment in news and web corpora has been explored by a number of researchers, including Resnik and Smith (2003), Munteanu and Marcu (2005), Tillmann and Xu (2009), and Tillmann (2009). Since our corpus already contains document alignments, we sidestep this problem, and will not discuss further details of this issue. That said, we believe that our methods will be effective in corpora without document alignments when combined with one of the aforementioned algorithms.

3.1 Binary Classifiers and Rankers

Much of the previous work involves building a binary classifier for sentence pairs to determine whether or not they are parallel (Munteanu and Marcu, 2005; Tillmann, 2009). The training data usually comes from a standard parallel corpus. There is a substantial class imbalance ($O(n)$ positive examples, and $O(n^2)$ negative examples), and various heuristics are used to mitigate this problem. Munteanu and Marcu (2005) filter out negative examples with high length difference or low word overlap (based on a bilingual dictionary).

We propose an alternative approach: we learn a ranking model, which, for each sentence in the *source* document, selects either a sentence in the *target* document that it is parallel to, or “null”. This formulation of the problem avoids the class imbalance issue of the binary classifier.

In both the binary classifier approach and the ranking approach, we use a Maximum Entropy classifier, following Munteanu and Marcu (2005).

3.2 Sequence Models

In Wikipedia article pairs, it is common for parallel sentences to occur in clusters. A global sentence alignment model is able to capture this phenomenon. For both parallel and comparable corpora, global sentence alignments have been used, though the alignments were monotonic (Gale and Church, 1991; Moore, 2002; Zhao and Vogel, 2002). Our model is a first order linear chain Conditional Random Field (CRF) (Lafferty et al., 2001). The set of source and target sentences are observed. For each *source* sentence, we have a hidden variable indicating the corresponding *target* sentence to which it is aligned (or null). The model is similar to the discriminative CRF-based word alignment model of (Blunsom and Cohn, 2006).

3.3 Features

Our features can be grouped into four categories.

Features derived from word alignments

We use a feature set inspired by (Munteanu and Marcu, 2005), who defined features primarily based on IBM Model 1 alignments (Brown et al., 1993). We also use HMM word alignments (Vogel et al., 1996) in both directions (*source* to *target* and *target* to *source*), and extract the following features based on these four alignments:[1]

1. Log probability of the alignment
2. Number of aligned/unaligned words
3. Longest aligned/unaligned sequence of words
4. Number of words with fertility 1, 2, and 3+

We also define two more features which are independent of word alignment models. One is a sentence length feature taken from (Moore, 2002),

[1] These are all derived from the one best alignment, and normalized by sentence length.

which models the length ratio between the *source* and *target* sentences with a Poisson distribution. The other feature is the difference in relative document position of the two sentences, capturing the idea that the aligned articles have a similar topic progression.

The above features are all defined on sentence pairs, and are included in the binary classifier and ranking model.

Distortion features

In the sequence model, we use additional distortion features, which only look at the difference between the position of the previous and current aligned sentences. One set of features bins these distances; another looks at the absolute difference between the expected position (one after the previous aligned sentence) and the actual position.

Features derived from Wikipedia markup

Three features are derived from Wikipedia's markup. The first is the number of matching links in the sentence pair. The links are weighted by their inverse frequency in the document, so a link that appears often does not contribute much to this feature's value. The image feature fires whenever two sentences are captions of the same image, and the list feature fires when two sentences are both items in a list. These last two indicator features fire with a negative value when the feature matches on one sentence and not the other.

None of the above features fire on a null alignment, in either the ranker or CRF. There is also a bias feature for these two models, which fires on all non-null alignments.

Word-level induced lexicon features

A common problem with approaches for parallel sentence classification, which rely heavily on alignment models trained from unrelated corpora, is low recall due to unknown words in the candidate sentence-pairs. One approach that begins to address this problem is the use of self-training, as in (Munteanu and Marcu, 2005). However, a self-trained sentence pair extraction system is only able to acquire new lexical items that occur in parallel sentences. Within Wikipedia, many linked article pairs do not contain any parallel sentences, yet contain many words and phrases that are good translations of each other.

In this paper we explore an alternative approach to lexicon acquisition for use in parallel sentence extraction. We build a lexicon model using an approach similar to ones developed for unsupervised lexicon induction from monolingual or comparable corpora (Rapp, 1999; Koehn and Knight, 2002; Haghighi et al., 2008). We briefly describe the lexicon model and its use in sentence-extraction.

The lexicon model is based on a probabilistic model $P(w_t|w_s, T, S)$ where w_t is a word in the target language, w_s is a word in the source language, and T and S are linked articles in the target and source languages, respectively.

We train this model similarly to the sentence-extraction ranking model, with the difference that we are aligning word pairs and not sentence pairs. The model is trained from a small set of annotated Wikipedia article pairs, where for some words in the source language we have marked one or more words as corresponding to the source word (in the context of the article pair), or have indicated that the source word does not have a corresponding translation in the target article. The word-level annotated articles are disjoint from the sentence-aligned articles described in Section 4. The following features are used in the lexicon model:

Translation probability. This is the translation probability $p(w_t|w_s)$ from the HMM word alignment model trained on the seed parallel data. We also use the probability in the other direction, as well as the log-probabilities in the two directions.

Position difference. This is the absolute value of the difference in relative position of words w_s and w_t in the articles S and T.

Orthographic similarity. This is a function of the edit distance between source and target words. The edit distance between words written in different alphabets is computed by first performing a deterministic phonetic translation of the words to a common alphabet. The translation is inexact and this is a promising area for improvement. A similar source of information has been used to create seed lexicons in (Koehn and Knight, 2002) and as part of the feature space in (Haghighi et al., 2008).

Context translation probability. This feature looks at all words occurring next to word w_s in the article S and next to w_t in the article T in a local context window (we used one word to the left and one word to the right), and computes several scoring functions measuring the translation correspondence between the contexts (using the IBM Model 1 trained from seed parallel data). This feature is similar to distributional similarity measures used in previous work, with the difference that it is limited to contexts of words within a linked article pair.

Distributional similarity. This feature corresponds more closely to context similarity measures used in previous work on lexicon induction. For each source headword w_s, we collect a distribution over context positions $o \in \{-2, -1, +1, +2\}$ and context words v_s in those positions based on a count of times a context word occurred at that offset from a headword: $P(o, v_s|w_s) \propto weight(o) \cdot C(w_s, o, v_s)$. Adjacent positions -1 and $+1$ have a weight of 2; other positions have a weight of 1. Likewise we gather a distribution over target words and contexts for each target headword $P(o, v_t|w_t)$. Using an IBM Model 1 word translation table $P(v_t|v_s)$ estimated on the seed parallel corpus, we estimate a cross-lingual context distribution as $P(o, v_t|w_s) = \sum_{v_s} P(v_t|v_s) \cdot P(o, v_s|w_s)$. We define the similarity of a words w_s and w_t as one minus the Jensen-Shannon divergence of the distributions over positions and target words.[2]

Given this small set of feature functions, we train the weights of a log-linear ranking model for $P(w_t|w_s, T, S)$, based on the word-level annotated Wikipedia article pairs. After a model is trained, we generate a new translation table $P_{lex}(t|s)$ which is defined as $P_{lex}(t|s) \propto \sum_{t \in T, s \in S} P(t|s, T, S)$. The summation is over occurrences of the source and target word in linked Wikipedia articles. This new translation table is used to define another HMM word-alignment model (together with distortion probabilities trained from parallel data) for use in the sentence extraction models. Two copies of each feature using the HMM word alignment model are generated: one using the seed data HMM model, and another using this new HMM model.

The training data for Bulgarian consisted of two partially annotated Wikipedia article pairs. For German and Spanish we used the feature weights of the model trained on Bulgarian, because we did not have word-level annotated Wikipedia articles.

4 Experiments

4.1 Data

We annotated twenty Wikipedia article pairs for three language pairs: Spanish-English, Bulgarian-English, and German-English. Each sentence in the *source* language was annotated with possible parallel sentences in the *target* language (the target language was English in all experiments). The pairs were annotated with a quality level: **1** if the sentences contained some parallel fragments, **2** if the sentences were mostly parallel with some missing words, and **3** if the sentences appeared to be direct translations. In all experiments, sentence pairs with quality **2** or **3** were taken as positive examples. The resulting datasets are available at http://research.microsoft.com/en-us/people/chrisq/wikidownload.aspx.

For our seed parallel data, we used the Europarl corpus (Koehn, 2005) for Spanish and German and the JRC-Aquis corpus for Bulgarian, plus the article titles for parallel Wikipedia documents, and translations available from Wiktionary entries.[3]

4.2 Intrinsic Evaluation

Using 5-fold cross-validation on the 20 document pairs for each language condition, we compared the binary classifier, ranker, and CRF models for parallel sentence extraction. To tune for precision/recall, we used minimum Bayes risk decoding. We define the loss $L(\tau, \mu)$ of picking target sentence τ when the correct target sentence is μ as 0 if $\tau = \mu$, λ if $\tau = \text{NULL}$ and $\mu \neq \text{NULL}$, and 1 otherwise. By modifying the null loss λ, the precision/recall trade-off can be adjusted. For the CRF model, we used posterior decoding to make the minimum risk decision rule tractable. As a summary measure of the performance of the models at different levels of recall we use average precision as defined in (Ido

[2] We restrict our attention to words with ten or more occurrences, since rare words have poorly estimated distributions. Also we discard the contribution from any context position and word pair that relates to more than 1,000 distinct source or target words, since it explodes the computational overhead and has little impact on the final similarity score.

[3] Wiktionary is an online collaborative dictionary, similar to Wikipedia.

Language Pair	Binary Classifier			Ranker			CRF		
	Avg Prec	R@90	R@80	Avg Prec	R@90	R@80	Avg Prec	R@90	R@80

Table 3: Average precision, recall at 90% precision, and recall at 80% precision for the Ranker and CRF in all three language pairs. "+Wiki" indicates that Wikipedia features were used, and "+Lex" means the lexicon features were used.

et al., 2006). We also report recall at precision of 90 and 80 percent. Table 2 compares the different models in all three language pairs.

In our next set of experiments, we looked at the effects of the Wikipedia specific features. Since the ranker and CRF are asymmetric models, we also experimented with running the models in both directions and combining their outputs by intersection. These results are shown in Table 3.

Identifying the agreement between two asymmetric models is a commonly exploited trick elsewhere in machine translation. It is mostly effective here as well, improving all cases except for the Bulgarian-English CRF where the regression is slight. More successful are the Wikipedia features, which provide an auxiliary signal of potential parallelism.

The gains from adding the lexicon-based features can be dramatic as in the case of Bulgarian (the CRF model average precision increased by nearly 9 points). The lower gains on Spanish and German may be due in part to the lack of language-specific training data. These results are very promising and motivate further exploration. We also note that this is perhaps the first successful practical application of an automatically induced word translation lexicon.

4.3 SMT Evaluation

We also present results in the context of a full machine translation system to evaluate the potential utility of this data. A standard phrasal SMT system (Koehn et al., 2003) serves as our testbed, using a conventional set of models: phrasal models of source given target and target given source; lexical weighting models in both directions, language model, word count, phrase count, distortion penalty, and a lexicalized reordering model. Given that the extracted Wikipedia data takes the standard form of parallel sentences, it would be easy to exploit this same data in a number of systems.

For each language pair we explored two training conditions. The "Medium" data condition used easily downloadable corpora: Europarl for German-English and Spanish-English, and JRC/Acquis for Bulgarian-English. Additionally we included titles of all linked Wikipedia articles as parallel sentences in the medium data condition. The "Large" data condition includes all the medium data, and also includes using a broad range of available sources such as data scraped from the web (Resnik and Smith, 2003), data from the United Nations, phrase books, software documentation, and more.

In each condition, we explored the impact of including additional parallel sentences automatically extracted from Wikipedia in the system training data. For German-English and Spanish-English, we extracted data with the null loss adjusted to achieve an estimated precision of 95 percent, and for English-Bulgarian a precision of 90 percent. Table 4 summarizes the characteristics of these data sets. We were pleasantly surprised at the amount of parallel sentences extracted from such a varied comparable corpus. Apparently the average Wikipedia article contains at least a handful of parallel sentences, suggesting this is a very fertile ground for training MT systems.

The extracted Wikipedia data is likely to make the greatest impact on broad domain test sets – indeed, initial experimentation showed little BLEU gain on in-domain test sets such as Europarl, where out-of-domain training data is unlikely to provide appropriate phrasal translations. Therefore, we experimented with two broad domain test sets.

First, Bing Translator provided a sample of translation requests along with translations in German-English and Spanish-English, which acted our standard development and test set. Unfortunately no such tagged set was available in Bulgarian-English, so we held out a portion of the large system's training data to use for development and test. In each language pair, the test set was split into a development portion ("Dev A") used for minimum error rate training (Och, 2003) and a test set ("Test A") used for final evaluation.

Second, we created new test sets in each of the three language pairs by sampling parallel sentences from held out Wikipedia articles. To ensure that this test data was clean, we manually filtered the sentence pairs that were not truly parallel and edited them as necessary to improve adequacy. We called this "Wikitest". This test set is available at http://research.microsoft.com/en-us/people/chrisq/wikidownload.aspx. Characteristics of these test sets are summarized in Table 5.

We evaluated the resulting systems using BLEU-4 (Papineni et al., 2002); the results are presented in Table 6. First we note that the extracted Wikipedia data are very helpful in medium data conditions, significantly improving translation performance in all conditions. Furthermore we found that the extracted Wikipedia sentences substantially improved translation quality on held-out Wikipedia articles. In every case, training on medium data plus Wikipedia extracts led to equal or better translation quality than the large system alone. Furthermore, adding the Wikipedia data to the large data condition still made substantial improvements.

5 Conclusions

Our first substantial contribution is to demonstrate that Wikipedia is a useful resource for mining parallel data. The sheer volume of extracted parallel sentences within Wikipedia is a somewhat surprising result in the light of Wikipedia's construction. We are also releasing several valuable resources to the community to facilitate further research: manually aligned document pairs, and an edited test set. Hopefully this will encourage research into Wikipedia as a resource for machine translation.

Secondly, we improve on prior pairwise models by introducing a ranking approach for sentence pair extraction. This ranking approach sidesteps the problematic class imbalance issue, resulting in improved average precision while retaining simplicity and clarity in the models.

Also by modeling the sentence alignment of the articles globally, we were able to show a substantial improvement in task accuracy. Furthermore a

Table 6: BLEU scores under various training and test conditions. The first column is from minimum error rate training; the next two columns are on held-out test sets. For training data conditions including extracted Wikipedia sentences, parenthesized values indicate absolute BLEU difference against the corresponding system without Wikipedia extracts.

small sample of annotated articles is sufficient to train these global level features, and the learned classifiers appear very portable across languages. It is difficult to say whether such improvement will carry over to other comparable corpora with less document structure and meta-data. We plan to address this question in future work.

Finally, initial investigations have shown that substantial gains can be achieved by using an induced word-level lexicon in combination with sentence extraction. This helps address modeling word pairs that are out-of-vocabulary with respect to the seed parallel lexicon, while avoiding some of the issues in bootstrapping.

Abstract

This paper investigates the impact of misspelled words in statistical machine translation and proposes an extension of the translation engine for handling misspellings. The enhanced system decodes a word-based confusion network representing spelling variations of the input text.

We present extensive experimental results on two translation tasks of increasing complexity which show how misspellings of different types do affect performance of a statistical machine translation decoder and to what extent our enhanced system is able to recover from such errors.

1 Introduction

With the widespread adoption of the Internet, of modern communication, multimedia and mobile device technologies, the amount of multilingual information distributed and available to anyone, anywhere, has exploded. So called social media have rapidly reshaped information exchange among Internet users, providing new means of communication (blogs, tweets, etc.), collaboration (e.g. wikis), and sharing of multimedia content, and entertainment. In particular, social media have today become also an important market for advertisement as well as a global forum for consumer opinions (Kushal et al., 2003).

The growing spread of user-generated content is scaling-up the potential demand for on-line machine translation (MT) but also setting new challenges to the field of natural language processing (NLP) in general. The language written and spoken in the social media presents an impressive variety of content and styles (Schler et al., 2006), and writing conventions that rapidly evolve over time. Moreover, much of the content is expressed in informal style, that more or less violates the standard grammar, contains many abbreviations and acronyms, and finally many misspelled words. From the point of view of MT, language of social media is hence very different from the one represented in the text corpora nowadays available to train statistical MT systems.

Facing all these challenges, we pragmatically scaled down our ambition and decided to investigate a basic, somehow preliminary, well defined problem: the impact of misspelled words in statistical MT. Unintentional typing errors are indeed remarkably frequent in online chats, blogs, wikis, reviews, and hence constitute a major source of noise (Subramaniam et al., 2009).

In this paper we aim at studying performance degradation of statistical MT under different levels and kinds of noise, and at analyzing to what extent statistical MT is able to recover from errors by enriching its input with spelling variations.

After a brief overview of NLP literature related to noisy texts, in Section 3 we consider different types of misspellings and derive simple but realistic models that are able to reproduce them. Such models are then used to generate errors in texts passed to a phrase-based statistical MT system. Next, in Section 4 we introduce an extension of a statistical MT system able to handle misspellings by exploiting confusion network decoding (Bertoldi et al., 2008).

Experiments are reported in Section 5 that in-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 412–419,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

vestigate the trade-off between complexity of the extended MT decoder versus translation accuracy. Moreover, as the proposed model for handling misspellings embeds specific assumptions on how errors are generated, we also measure the robustness of the enhanced MT decoder with respect to different noise sources. Experiments are reported on two tasks of different complexity, the translation of Europarl texts and weather bulletins, involving English and Italian languages.

2 Previous Work

Most contributions addressing NLP of noisy user-generated content are from the text mining community. A survey about the different types of noise that might affect text mining is in (Subramaniam et al., 2009), while an analysis of how noise phenomena, commonly occurring in blogs, affect an opinion mining application is in (Dey and Haque, 2009).

Concerning spelling correction literature, many works apply the noisy channel model which consists of two components: a source model (prior of word probabilities) and a channel (error) model, that accounts for spelling transformations on letter sequences. Several approaches have been proposed under this framework, that mainly differ in the employed error model; see for example: (Church and Gale, 1991), (Brill and Moore, 2000) and (Toutanova and Moore, 2002).

Comprehensive surveys on methods to model and recover spelling errors can be found in (Kukich, 1992) and (Pedler, 2007); in particular, the latter work is specifically centered on methods for correcting so-called real-word errors (cf. Section 3). The detection of errors and the suggestion of corrections typically rely on the availability of text corpora or human-made lexical resources. Search for correct alternatives can be based on word similarity measures, such as the edit distance (Mitton, 1995), anagram hashing (Reynaert, 2006), and semantic distance based on WordNet (Hirst and Budanitsky, 2005). More sophisticated approaches have been proposed by (Fossati and Di Eugenio, 2008), that mixes surface and Part-Of-Speech Information, and (Schaback and Li, 2007), which combines similarity measures at the character, phonetic, word, syntax, and semantic levels into one global feature-based framework.

*a) *W *w had just come in from Australia [Australia]*
*b) good service we *staid one week. [Tahiti]*
*c) The room was *exellent but the hallway was *filty . [NJ]*
*d) is a good place to stay, if you are looking for a hotel *arround LAX airport. [Tahiti]*
*e) The staff was *freindly ... I was *conerned about the noise [CT]*

Table 1: Examples of misspellings found in on-line reviews of an hotel close to Los Angeles Int'l Airport. Corresponding corrections are: a) *We*, ϵ, b) *stayed*, c) *excellent*, *filthy*, d) *around*, e) *friendly*, *concerned*.

Concerning the literature of statistical MT, interest in noisy data has been so far considering issues different from misspelled words. For instance, (Davis et al., 1995) and (Vogel, 2003) address training methods coping with noisy parallel data, in the sense that translations do not perfectly match. Work on speech translation (Casacuberta et al., 2008) focused instead on efficient methods to couple speech recognition and MT in order to avoid error propagation. Very recently, (Carrera et al., 2009) conducted a qualitative study on the impact of noisy social media content on statistical and rule-based MT. Unfortunately, this work does not report any quantitative result, it is only based on a small selection of examples that are manually evaluated, and finally it does not address the problem of integrating error correction with MT.

3 Types of Misspellings

In general, a misspelled word is a sequence of letters that corresponds to no correctly spelled word of the same language (*non-word error*), or to a correct spelling of another word (*real-word error*). In the examples shown in Table 1, all marked errors are non-word errors, but the one in sentence b), which indeed is likely a misspelling of the word *stayed*.

Causes of a misspelling may be an unintentional typing error (e.g. **freindly* for *friendly*), or lack of knowledge about the proper spelling. Typing errors can originate from six different typing operations (Kukich, 1992): substitution, insertion, deletion, transposition, run-on, and split.[1] Lack of knowledge could be the cause of the misspelled **exellent* in sentence c).

[1] Run-on and split are the special cases of deleting and inserting blank spaces, respectively.

1.	*your - you're*
2.	*then - than*
3.	*its - it's*
4.	*to - too - two*
5.	*were - where - we're*
6.	*there - their - they're*
7.	*a - an - and*
8.	*off - of*
9.	*here - hear*
10.	*lose - loose*

Table 2: List of frequent real-word errors found in blogs. Source: http://www.theprobabilist.com.

An interesting combination of cause and effect is when lack of linguistic competence results in confusing the spelling of a word with the spelling of another word that sounds similarly (Hirst and Budanitsky, 2005). This could be likely the case of the Polynesian tourist that authored sentence b).

A short list of words frequently confused in blogs is reported in Table 2 while a longer list can be found in the Wikipedia.[2] Real-word errors typically fool spell checkers because their identification requires analyzing the context in which they occur.

In this paper, we automatically corrupt clean text with three types of noise described below. This procedure permits us to analyze the MT performance against different sources and levels of noise and to systematically evaluate our error-recovering strategy.

Non-word Noise We randomly replace words in the text according to a list of 4,100 frequently non-word errors provided in the Wikipedia. A qualitative analysis of these errors reveals that all of them originate by one or two keyboard typing errors of the kind described beforehand. Practically, non-word noise is introduced by defining a desired level of corruption of the source text.

Real-word Noise Similarly to the previous case, real-word errors are automatically introduced by another list of frequently misused words in the Wikipedia. This list contains about 300 pairs of confusable words to which we also added the 10 frequent real-word errors occurring in blogs reported in Table 2.

Random Noise Finally, we may corrupt the original text by randomly replacing, inserting, and deleting characters in it up to a desired percentage.

4 Error-recovering Statistical MT

An enhancement of a statistical MT system is proposed with the goal of improving robustness to misspellings in the input. Rrror recovery is realized by performing a sequence of actions before the actual translation, which create reliable spelling alternatives of the input and store them into a compact word-based Confusion Network (CN).

Starting from the possibly noisy input text, spelling variations are generated by assuming that each character is a potential typing error, independent from other characters.

The variants are represented as a character-based CN that models possible substitutions, insertion, deletions of each character, with an empirically determined weight assigned to each alternative. The network is then searched by a non-monotonic search process that scores possible character sequences through a character n-gram language model, and outputs a set of multiple spelling variants that is finally converted into a word-based CN. The resulting word-based network is finally passed to the MT engine. In the following, more details are provided on the augmented MT system with the help of Figure 1, which shows how the system acts on the corrupted example "all off ame", supposed to be "hall of fame".

Step 1 The input text (**a**) is split into a sequence of characters (**b**) including punctuation marks and blank spaces (␣), which are here considered as standard characters. Moreover, single characters interleaved with the conventional empty character ϵ.

Step 2 A CN (**c**) is built by adding all alternative characters of the keyboard to each input character, including the space character ␣ and the empty character. When the string character is ␣, the only admitted alternative is ϵ. Possible alternative spellings of the original string correspond to paths in the CN. Notice that each CN column beginning with a standard character permits to manage insertion, substitution and split errors, while each column beginning with the empty character permits to handle deletion and run-on errors.

[2] See Wikipedia's "list of frequently misused English words".

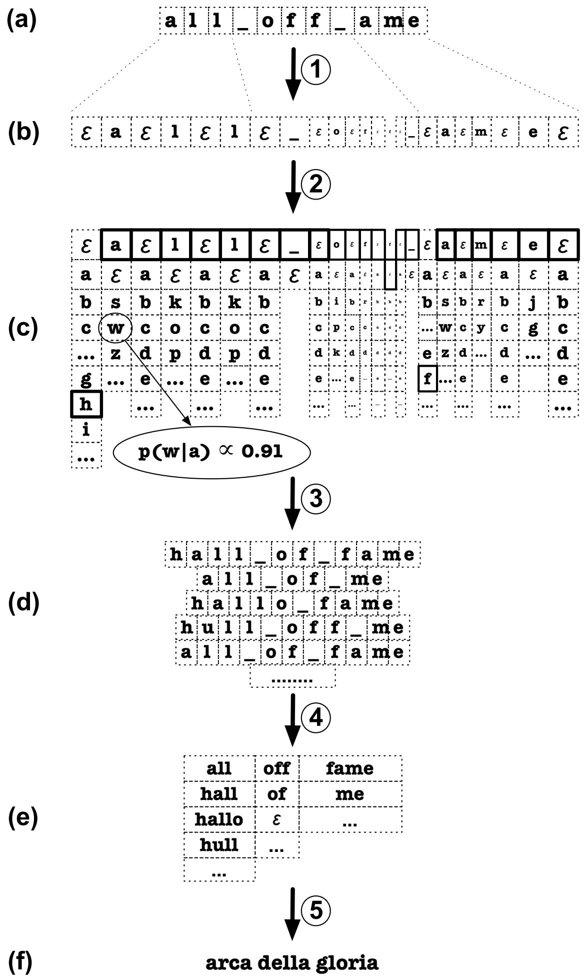

Figure 1: The whole process to translate the mistaken input "*all off ame* [*hall of fame*]" into "*arca della gloria*".

A probability distribution of confusable keystrokes is generated based on the distance between the keys on a standard QWERTY keyboard. This distribution is intended to model how a spelling error is actually produced. Hence, character alternatives in the CN are associated to a probability given by:

$$p\,(x|y) \propto \cdot \frac{1}{k \cdot d(x,y)+1} \qquad (1)$$

where $d(x,y)$ is the physical distance between the key of x and the key of y on the keyboard layout; for example, the character *a* has a distance of 3 from the character *c* on the considered keyboard layout. The free parameter k tunes the discriminative power of the model between correct and wrong typing. In this paper, k was empirically set to 0.1. The ϵ and ␣ characters are assigned a default distance of 9 and 999 from any other character, respectively.

For the sake of clarity, the probability $p(w|a)$ of just one entry is reported in Figure 1.

Step 3 The generation of spelling variations (**d**) is operated by means of the same decoder employed for translation (see below), but in a much simplified configuration which does not exploit any translation model. It is designed to search the input character-based CN for the n-best character sequences which better "correct" the mistaken input. In Figure 1 the best sequence is marked by bold boxes (**c**), and the empty character ϵ is removed for the sake of clarity (**d**). This process relies only on the character-based 6-gram language model trained on monolingual data in the source language. It is worth noticing that the generated spelling alternatives may in principle still contain non-words, just because they are selected by a character-based language model, which does not explicitly embed the notion of word.

Transposition errors are modeled both (i) indirectly through consecutive substitutions with appropriate characters and (ii) directly by permitting some re-orderings of adjacent characters. Moreover, preliminary experiments revealed that the explicit handling of deletion and run-on errors by interleaving input characters with the empty character ϵ (Step 1) is crucial to achieve good performance. Although the size of the character-based CN doubles, its decoding time increases only by a small factor.

Step 4 The n-best character sequences (**d**) are transformed into a word-based CN (**e**) (Mangu et al., 2000). First, each character-based sequence is transformed into a unifilar word-based lattice, whose edges correspond to words and timestamps to the character positions. Then, the unifilar lattices are put in parallel to create one lattice with all spelling variations of the input text (**a**). Finally, a word-based CN is generated by means of the *lattice-tool* available in the SRILM Toolkit (Stolcke, 2002).

Step 5 Translation of the CN (**e**) is performed with the Moses decoder (Koehn et al., 2007), that has been successfully applied mainly to text translation, but also to process multiple input hypotheses (Bertoldi et al., 2008), representing, for example, speech transcriptions, word segmentations, texts with possible punctuation marks, etc. In general,

set		#sent.	English		Italian	
			#wrd	dict.	#wrd	dict.
EP	train	1.2M	36M	106K	35M	146K
	test	2K	60K	6.5K	60K	8.3K
WF	train	42K	996K	2641	994K	2843
	test	328	8789	606	8704	697

Table 3: Statistics of train/test data of the Europarl (EP) and the Weather Forecast (WF) tasks.

Moses looks for the best translation exploring the search space defined by a set of feature functions (models), which are log-linearly interpolated with weights estimated during a tuning stage.

The rationale of storing the spelling alternatives into a word-based CN instead of n-best list is twofold: (i) the CN contains a significantly larger number of variations, and (ii) the translation system is much more efficient to translate CNs instead of n-best lists.

5 Experiments

Extensive experiments have been conducted on the Europarl shared task, from English to Italian, as specified by the Workshop on Statistical Machine Translation of the ACL 2008.[3] Additional experiments were conducted on a smaller task, namely the translation of weather forecast bulletins between the same language pair. Statistics on texts employed in experiments are reported in Table 3.

For both tasks, we created evaluation data by artificially corrupting input text with the noise sources described in Section 3. The module for generating spelling variations (Step 3) was trained on additional 4M and 16M running words in English and Italian, respectively.

We empirically investigated the following issues: (a) performance of the standard MT engine versus nature and level of the input noise; (b) performance of the error-recovering MT engine versus number of provided spelling variations; (c) portability of the approach to another task and translation direction; (d) computational requirements of the approach.

5.1 Impact of Noise

The first set of experiments involved the translation of corrupted versions of the Europarl test set. Figure 2 plots three curves of BLEU(%) scores, corresponding to different noise sources and noise ratios, given in terms of percentage of word error rate. It also shows the BLEU score on the original clean text. Notice that this baseline performance (25.16) represents the state-of-the-art[4] for this task.

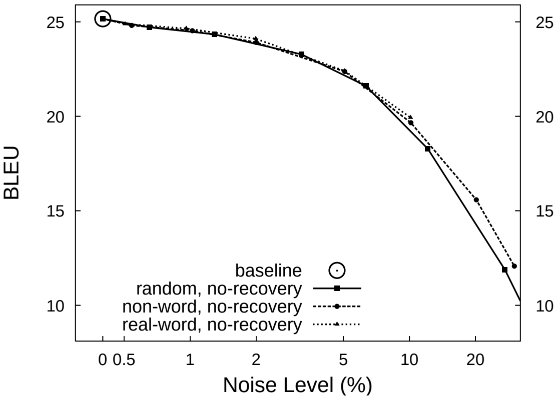

Figure 2: Translation performance as function of the noise level (in log-scale) for different types of noise.

The major outcome of these experiments is that the different types of errors seem to affect MT performance in a very similar manner. Quantitatively, performance degradation begins even for low noise levels – about 0.5 absolute BLEU loss at 1% of noise level – and reaches 50% when text corruption reaches the level of 30%. The similar impact of non-word and random errors is somehow expected. The plain reason is that both types of errors very likely[5] generate Out-Of-Vocabulary (OOV) words.

We find instead less predictable that the impact of real-word errors is indistinguishable from that of the other two noise sources. Notice also that most of the real-word errors produce indeed words known to the MT system. Hence, the question regards the behavior of the MT system when the sentence includes on OOV word or an out-of-context known word. Empirically it seems that in both cases the decoder produces translations with the same amount of errors. In some sense, the good news is that real-word errors do not induce more translation errors than OOV words do.

[5] Modulo noise in the parallel data and the chance that a random error generates a true word.

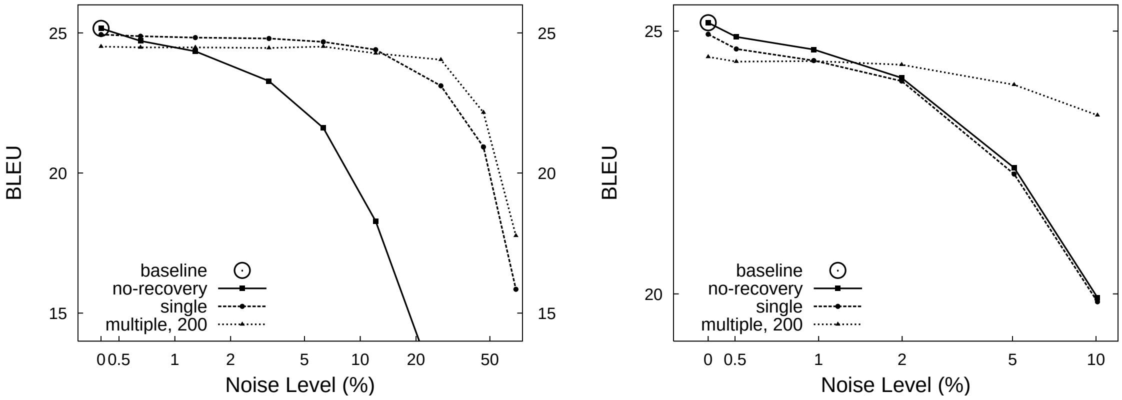

Figure 3: Performance of error-recovering method with random (left) and real-word (right) noise.

5.2 Impact of Multiple Corrections

Experiments presented here address evaluation of our enhanced MT system. In addition to nature and level of noise, translation performance is also analyzed with respect to the number (1 and 200) of spelling alternatives generated at Step 3. Figure 3 plots BLEU scores for random (left plot) and real-word (right plot) noises. For comparison purposes, the curves with no error recovery are also shown. Results with non-word noise are not provided since they are pretty similar to those with random noise. It is worth noticing that real-word errors are recovered in a different way than random errors; in fact, for the latter a single spelling alternative seems sufficient to guarantee a substantial error recovery, whereas for real-word errors this is not the case.

Concerning the use of spelling variations, it is worth remarking that our system is able to fully recover from both random and non-word errors up to noise levels of 10%, which remains high even for noise levels up to 20%, where the BLEU degradation is limited to around 5% relative.

Real-word errors are optimally recovered in the case of multiple spelling variations until they do not exceed 2% of the words in the input text; after that, the decrement of the MT quality becomes significant but still limited to about 5% BLEU relative for a noise level of 10%. So the question arises about what could be a realistic real-word noise level. Clearly this question is not easy to address. However, to get a rough idea we can look at the examples reported in Table 1. These five sentences were extracted from a text of about 100 words (of which Table 1 only shows the sentences containing errors) that contain in total 8 errors: 7 of which are non-words and 1 is a real-word. Although from these figures reliable statistics cannot be estimated, a reasonable assumption could be that a global noise level of 10%[6] might contain a 1/10 ratio for real-word vs. non-word errors. Thus, looking at the real-word error curve of Figure 3, the inability to recover errors for noise levels greater than 2-5% should actually be acceptable given this empirical observation.

Another relevant remark from Figure 3 is that for low noise levels (less than 1%) the use of the error-recovering module is counterproductive, since it introduces more errors than those actually affecting the original input text, causing a slight degradation of the translation performance. If the computational cost to generate variants, which will be analyzed in the next paragraph, is also taken into account, it results evident the importance of designing a good strategy for enabling or disabling on demand the error-recovering stage. A starting point for defining an effective activation strategy is the estimation of the noise rate. For doing this, non-words can be counted by exploiting proper dictionaries or spell checkers; concerning real-word noise, its rate can be inferred either from the non-word rate, or by means of the perplexity, which is expected to become higher as the real-word error rate increases (Subramaniam et al., 2009). Once the noise level of the input text is known, the decision of activating the correction module can be easily taken on a

[6] By the way, at this noise rate, an error-recovering strategy would be highly recommended.

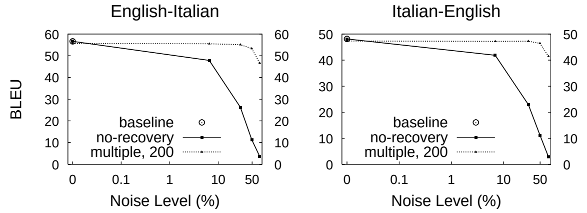

Figure 4: Effects of random noise and noise correction on translation performance for the WF task.

threshold basis. Alternatively, the proper working point, in terms of precision and recall, of the correction model could be dynamically chosen as a function of the actual noise level.

5.3 Computational Costs

Although our investigation does not address explicitly computational aspects of translating noisy input, nevertheless some general considerations can be drawn.

The effectiveness of our recovering approach relies on the compact representation of many spelling alternatives in a word-based CN. The CN decoding has been shown to be efficient, just minimally larger than the single string decoding (Bertoldi et al., 2008). On the contrary, in the current enhanced MT setting, the sequence of Steps 1 to 4 for building the CN from the noisy input text is quite costly. Rather than to an intrinsic complexity, this is due to our choice of creating a rich character-based CN in Step 3 for the sake of flexibility and to a naive implementation of Step 4.

5.4 Portability

So far we have analyzed in detail our approach on the medium-large sized Europarl task, for the English-to-Italian translation direction. For assessing portability, we also considered a simpler task –the translation of weather forecast bulletins– where the translation quality is definitely higher, for the same language pair but in both translation directions. The choice of the weather forecast task is not by chance. In fact, as the automatically translated bulletins are published on the Web, a very high translation quality is required, and then the presence of any typing error in the original text could be a concern. (By the way, for this task the presence of real-word errors is very marginal.)

Figure 4 plots curves of MT performance under random noise conditions against multiple spelling variations, for two translation directions. It can be noticed that the error-recovering system behaves qualitatively as for the Europarl task but even better from a quantitative viewpoint. Again, the recovering model introduces spurious errors which affect translation quality for low levels of noisy input, but in this case the break-even point is less than 0.1% noise level. On the other side, errors corrupting the input text are fully recovered up to 30-40% of noise levels, for which the BLEU score would be more than halved for non-corrected texts.

6 Future Work

There are a number of important issues that this work has still left open. First of all, we focused on a specific way of generating spelling variations, based on single characters, but other possible choices should be investigated and compared to our approach, like the use of n-grams of words.

An important open question regards efficiency of the proposed recovering strategy, since the problem has been only sketched in Section 5.3. It is our intention to analyze the intrinsic complexity of our model, possibly discover its bottlenecks and implement a more efficient solution.

Another topic, mentioned in Section 5.2, is the activation strategy of the misspelling recovery. Some further investigation is required on how its working point can be effectively selected; in fact, since the enhanced system necessarily introduces spurious errors, it would be desirable to increase its precision for low-corrupted input texts.

7 Conclusions

This paper addressed the issue of automatically translating written texts that are corrupted by misspelling errors. An enhancement of a state-of-the-art statistical MT system is proposed which efficiently performs the translation of multiple spelling variants of noisy input. These alternatives are generated by a character-based error recovery system under the assumption that misspellings are due to typing errors.

The enhanced MT system has been tested on texts corrupted with increasing noise levels of three different sources: random, non-word, and real-word errors.

Analysis of experimental results has led us to draw the following conclusions:

- The impact of misspelling errors on MT performance depends on the noise rate, but not on the noise source.
- The capability of the enhanced MT system to recover from errors differs according to the noise source: real-word noise is significantly harder to remove than random and non-word noise, which behave substantially the same.
- The exploitation of several spelling alternatives permits to almost fully recover from errors if the noise rate does not exceed 10% for non-word noise and 2% for real-word noise, which are likely above the corruption level observed in many social media.
- Finally, performance slightly decreases when input text is correct or just mistaken at a negligible level, because the error recovery module rewards recall rather than precision and hence tends to overgenerate correction alternatives, even if not needed.

Abstract

Most state of the art approaches for machine transliteration are data driven and require significant parallel names corpora between languages. As a result, developing transliteration functionality among n languages could be a resource intensive task requiring parallel names corpora in the order of ${}^{n}C_2$. In this paper, we explore ways of reducing this high resource requirement by leveraging the available parallel data between subsets of the n languages, transitively. We propose, and show empirically, that reasonable quality transliteration engines may be developed between two languages, X and Y, even when no direct parallel names data exists between them, but only transitively through language Z. Such systems alleviate the need for $O({}^{n}C_2)$ corpora, significantly. In addition we show that the performance of such transitive transliteration systems is in par with direct transliteration systems, in practical applications, such as CLIR systems.

1 Introduction

Names and Out Of Vocabulary (OOV) terms appear very frequently in written and spoken text and hence play a very important role in several Natural Language Processing applications. Several studies have shown that handling names correctly across languages can significantly improve the performance of CLIR Systems (Mandl and Womser-Hacker, 2004) and the utility of machine translation systems. The fact that translation lexicons or even statistical dictionaries derived from parallel data do not provide a good coverage of name and OOV translations, underscores the need for good transliteration engines to transform them between the language.

The importance of machine transliteration, in the above context, is well realized by the research community and several approaches have been proposed to solve the problem. However, most state of the art approaches are data driven and require significant parallel names corpora between languages. Such data may not always be available between every pair of languages, thereby limiting our ability to support transliteration functionality between many language pairs, and subsequently information access between languages. For example, let us consider a practical scenario where we have six languages from four different language families as shown in Figure 1. The nodes in the graph represent languages and the edges indicate the availability of data between that language pair and thus the availability of a Machine Transliteration system for that pair. It is easy to see the underlying characteristics of the graph. Data is available between a language pair due to one of the following three reasons:

Politically related languages: Due to the political dominance of English it is easy to obtain parallel names data between English and most languages.

Genealogically related languages: Arabic and Hebrew share a common origin and there is a significant overlap between their phoneme and grapheme inventory. It is easy to obtain parallel names data between these two languages.

Demographically related languages: Hindi and Kannada are languages spoken in the Indian subcontinent, though they are from different language families. However, due to the shared culture and demographics, it is easy to create parallel names data between these two languages.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 420–428,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

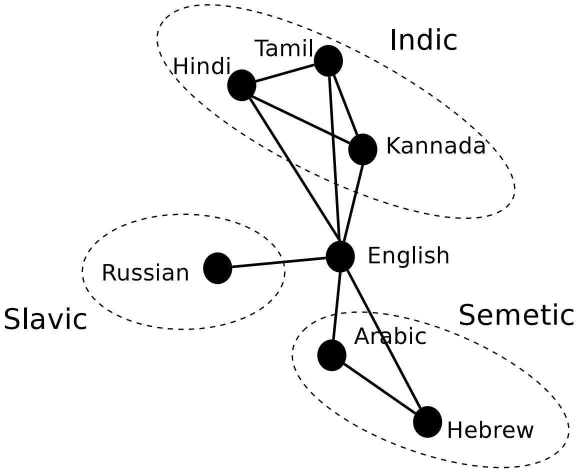

Figure 1: A connected graph of languages

On the other hand, for politically, demographically and genealogically unrelated languages such as, say, Hindi and Hebrew, parallel data is not readily available, either due to the unavailability of skilled bilingual speakers. Even the argument of using Wikipedia resources for such creation of such parallel data does not hold good, as the amount of interlinking may be very small to yield data. For example, only 800 name pairs between Hindi and Hebrew were mined using a state of the art mining algorithm (Udupa et al., 2009), from Wikipedia interwiki links.

We propose a methodology to develop a practical Machine Transliteration system between any two nodes of the above graph, provided a two-step path exists between them. That is, even when no parallel data exists between X & Y but sufficient data exists between X & Z and Z & Y it is still possible to develop transliteration functionality between X & Y by combining a $X \rightarrow Z$ system with a $Z \rightarrow Y$ system. For example, given the graph of Figure 1, we explore the possibility of developing transliteration functionality between Hindi and Russian even though no direct data is available between these two languages. Further, we show that in many cases the bridge language can be suitably selected to ensure optimal MT accuracy.

To establish the practicality and utility of our approach we integrated such a bridge transliteration system with a standard CLIR system and compared its performance with that of a direct transliteration system. We observed that such a bridge system performs well in practice and in specific instances results in improvement in CLIR performance over a baseline system further strengthening our claims that such bridge systems are good practical solutions for alleviating the resource scarcity problem.

To summarize, our main contributions in this paper are:

1. Constructing bridge transliteration systems and establishing empirically their quality.

2. Demonstrating their utility in providing practical transliteration functionality between two languages X & Y with no direct parallel data between them.

3. Demonstrating that in specific cases it is possible to select the bridge language so that optimal Machine Transliteration accuracy is ensured while stepping through the bridge language.

1.1 Organization of the Paper

This paper is organized in the following manner. In section 2 we present the related work and highlight the lack of work on transliteration in resource scarce scenarios. In section 3 we discuss the methodology of bridge transliteration. Section 4 discusses the experiments and datasets used. Section 4.3 discusses the results and error analysis. Section 5 discusses orthographic characteristics to be considered while selecting the bridge language. Section 6 demonstrates the effectiveness of such bridge systems in a practical scenario, *viz.*, Cross Language Information Retrieval. Section 7 concludes the paper, highlighting future research issues.

2 Related Work

Current models for transliteration can be classified as grapheme-based, phoneme-based and hybrid models. Grapheme-based models, such as, Source Channel Model (Lee and Choi, 1998), Maximum Entropy Model (Goto et al., 2003), Conditional Random Fields (Veeravalli et al., 2008) and Decision Trees (Kang and Choi, 2000) treat transliteration as an orthographic process and try to map the source language graphemes directly to the target language graphemes. Phoneme based models, such as, the ones based on Weighted Finite State

Transducers (WFST) (Knight and Graehl, 1997) and extended Markov window (Jung et al., 2000) treat transliteration as a phonetic process rather than an orthographic process. Under such frameworks, transliteration is treated as a conversion from source grapheme to source phoneme followed by a conversion from source phoneme to target grapheme. Hybrid models either use a combination of a grapheme based model and a phoneme based model (Stalls and Knight, 1998) or capture the correspondence between source graphemes and source phonemes to produce target language graphemes (Oh and Choi, 2002).

A significant shortcoming of all the previous works was that none of them addressed the issue of performing transliteration in a resource scarce scenario, as there was always an implicit assumption of availability of data between a pair of languages. In particular, none of the above approaches address the problem of developing transliteration functionality between a pair of languages when no direct data exists between them but sufficient data is available between each of these languages and an intermediate language. Some work on similar lines has been done in Machine Translation (Wu and Wang, 2007) wherein an intermediate bridge language (say, Z) is used to fill the data void that exists between a given language pair (say, X and Y). In fact, recently it has been shown that the accuracy of a $X \rightarrow Z$ Machine Translation system can be improved by using additional $X \rightarrow Y$ data provided Z and Y share some common vocabulary and cognates (Nakov and Ng, 2009). However, no such effort has been made in the area of Machine Transliteration. To the best of our knowledge, this work is the first attempt at providing a practical solution to the problem of transliteration in the face of resource scarcity.

3 Bridge Transliteration Systems

In this section, we explore the salient question *"Is it possible to develop a practical machine transliteration system between X and Y, by composing two intermediate $X \rightarrow Z$ and $Z \rightarrow Y$ transliteration systems?"* We use a standard transliteration methodology based on orthography for all experiments (as outlined in section 3.1), to ensure the applicability of the methodology to a variety of languages.

3.1 CRF based transliteration engine

Conditional Random Fields ((Lafferty et al., 2001)) are undirected graphical models used for labeling sequential data. Under this model, the conditional probability distribution of the target word given the source word is given by,

$$P(Y|X;\lambda) = \frac{1}{N(X)} \cdot e^{\sum_{t=1}^{T}\sum_{k=1}^{K}\lambda_k f_k(Y_{t-1},Y_t,X,t)} \tag{1}$$

where,

$$\begin{aligned} X &= source\ word \\ Y &= target\ word \\ T &= length\ of\ source\ word \\ K &= number\ of\ features \\ \lambda_k &= feature\ weight \\ N(X) &= normalization\ constant \end{aligned}$$

CRF++ [1], an open source implementation of CRF was used for training and decoding (*i.e.* transliterating the names). GIZA++ (Och and Ney, 2003), a freely available implementation of the IBM alignment models (Brown et al., 1993) was used to get character level alignments for the name pairs in the parallel names training corpora. Under this alignment, each character in the source word is aligned to zero or more characters in the corresponding target word. The following features are then generated using this character-aligned data (here e_i and h_i form the ***i***-th pair of aligned characters in the source word and target word respectively):

- h_i and e_j such that $i-2 \leq j \leq i+2$
- h_i and source character bigrams ($\{e_{i-1}, e_i\}$ or $\{e_i, e_{i+1}\}$)
- h_i and source character trigrams ($\{e_{i-2}, e_{i-1}, e_i\}$ or $\{e_{i-1}, e_i, e_{i+1}\}$ or $\{e_i, e_{i+1}, e_{i+2}\}$)
- h_i, h_{i-1} and e_j such that $i-2 \leq j \leq i+2$
- h_i, h_{i-1} and source character bigrams
- h_i, h_{i-1} and source character trigrams

[1] http://crfpp.sourceforge.net/

3.2 Bridge Transliteration Methodology

In this section, we outline our methodology for composing transitive transliteration systems between X and Y, using a bridge language Z, by chaining individual direct transliteration systems. Our approach of using bridge transliteration for finding the best target string (Y^*), given the input string X can be represented by the following probabilistic expression:

$$\begin{aligned} Y^* &= \arg\max_Y P(Y|X) \\ &= \sum_Z P(Y,Z|X) \\ &= \sum_Z P(Y|Z,X) * P(Z|X) \end{aligned} \tag{2}$$

We simplify the above expression, by assuming that Y is independent of X given Z; the linguistic intuition behind this assumption is that the *top-k* outputs of the $X \rightarrow Z$ system corresponding to a string in X, capture all the transliteration information necessary for transliterating to Y. Subsequently, in section 5 we discuss the characteristics of the effective bridge languages to maximize the capture of necessary information for the second stage of the transliteration, namely for generating correct strings of Z. Thus,

$$Y^* = \sum_Z P(Y|Z) * P(Z|X) \tag{3}$$

The probabilities $P(Y|Z)$ and $P(Z|X)$ in Equation (3) are derived from the two stages of the bridge system. Specifically, we assume that the parallel names corpora are available between the language pair, X and Z, and the language pair, Z and Y. We train two baseline CRF based transliteration systems (as outlined in Section 3.1), between the language X and Z, and Z and Y. Each name in language X was provided as an input into $X \rightarrow Z$ transliteration system, and the top-10 candidate strings in language Z produced by this first stage system were given as an input into the second stage system $Z \rightarrow Y$. The results were merged using Equation (2). Finally, the top-10 outputs of this system were selected as the output of the bridge system.

4 Experiments

It is a well known fact that transliteration is lossy, and hence the transitive systems may be expected to suffer from the accumulation of errors in each stage, resulting in a system that is of much poorer quality than a direct transliteration system. In this section, we set out to quantify this expected loss in accuracy, by a series of experiments in a set of languages using bridge transliteration systems and a baseline direct systems. We conducted a comprehensive set of experiments in a diverse set of languages, as shown in Figure 1, that include English, Indic (Hindi and Kannada), Slavic (Russian) and Semitic (Arabic and Hebrew) languages. The datasets and results are described in the following subsections.

4.1 Datasets

To be consistent, for training each of these systems, we used approximately 15K name pairs corpora (as this was the maximum data available for some language pairs). While we used the NEWS 2009 training corpus (Li et al., 2009) as a part of our training data, we enhanced the data set to about 15K by adding more data of similar characteristics (such as, name origin, domain, length of the name strings, *etc.*), taken from the same source as the original NEWS 2009 data. For languages such as Arabic and Hebrew which were not part of the NEWS 2009 shared task, the data was created along the same lines. All results are reported on the standard NEWS 2009 test set, wherever applicable. The test set consists of about 1,000 name pairs in languages X and Y; to avoid any bias, it was made sure that there is no overlap between the test set with the training sets of both the $X \rightarrow Z$ and $Z \rightarrow Y$ systems. To establish a baseline, the same CRF based transliteration system (outlined in Section 3.1) was trained with a 15K name pairs corpora between the languages $X \rightarrow Y$. The same test set used for testing the transitive systems was used for testing the direct system as well. As before, to avoid any bias, we made sure that there is no overlap between the test set and the training set for the direct system as well.

4.2 Results

We produce top-10 outputs from the bridge system as well from the direct system and compare their performance. The performance is measured using the following standard measures, *viz.*, top-1 accuracy (ACC-1) and Mean F-score. These measures are described in detail in (Li et al., 2009). Table 1

Language Pair	ACC-1	Relative change in ACC-1	Mean F-score	Relative change in Mean F-score
Hin-Rus	0.507	-8.08%	0.903	-1.88%
Hin-Eng-Rus	0.466		0.886	
Hin-Ara	0.458	-8.29%	0.897	-2.34%
Hin-Eng-Ara	0.420		0.876	
Eng-Heb	0.544	0%	0.917	0%
Eng-Ara-Heb	0.544		0.917	
Hin-Eng	0.422	-9.51%	0.884	-1.47%
Hin-Kan-Eng	0.382		0.871	

Table 1: Stepping through an intermediate language

presents the performance measures, both for a direct system (say, Hin-Rus), and a transitional system (say, Hin-Eng-Rus), in 4 different transitional systems, between English, Indic, Semitic and Slavic languages. In each case, we observe that the transitional systems have a slightly lower quality, with an absolute drop in accuracy (ACC-1) of less than 0.05 (relative drop under 10%), and an absolute drop in Mean F-Score of 0.02 (relative drop under 3%).

4.3 Analysis of Results

Intuitively, one would expect that the errors of the two stages of the transitive transliteration system (i.e., $X \rightarrow Z$, and $Z \rightarrow Y$) to compound, leading to a considerable loss in the overall performance of the system. Given that the accuracies of the direct transliteration systems are as given in Table 2, the transitive systems are expected to have accuracies close to the product of the accuracies of the individual stages, for independent systems.

Language Pair	ACC-1	Mean F-Score
Hin-Eng	0.422	0.884
Eng-Rus	0.672	0.935
Eng-Ara	0.514	0.905
Ara-Heb	1.000	1.000
Hin-Kan	0.433	0.879
Kan-Eng	0.434	0.886

Table 2: Performance of Direct Transliteration Systems

However, as we observe in Table 1, the relative drop in the accuracy (ACC-1) is less than 10% from that of the direct system, which goes against our intuition. To identify the reasons for the better than expected performance, we performed a detailed error analysis of each stage of the bridge transliteration systems, and the results are reported in Tables 3 – 5. We draw attention to two interesting facts which account for the better than expected performance of the bridge system:

Improved 2nd stage performance on correct inputs: In each one of the cases, as expected, the ACC-1 of the first stage is same as the ACC-1 of the $X \rightarrow Z$ system. However, we notice that the ACC-1 of the second stage *on the correct strings output in the first stage*, is significantly better than the the ACC-1 of the $Z \rightarrow Y$ system! For example, the ACC-1 of the Eng-Rus system is 67.2% (see Table 2), but, that of the 2nd stage Eng-Rus system is 77.8%, namely, on the strings that are transliterated correctly by the first stage. Our analysis indicate that there are two reasons for such improvement: First, the strings that get transliterated correctly in the first stage are typically shorter or less ambiguous and hence have a better probability of correct transliterations in the both stages. This phenomenon could be verified empirically: Names like गोपाल {Gopal}, रमेश {Ramesh}, राम {Ram} are shorter and in general have less ambiguity on target orthography. Second, also significantly, the use of top-10 outputs from the first stage as input to the second stage provides a better opportunity for the second stage to produce correct string in Z. Again, this phenomenon is verified by providing increasing number of *top-n* results to the 2nd stage.

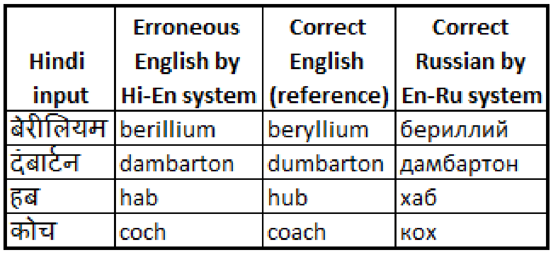
Hi→En→Ru		**En → Ru (Stage-2)**		**Stage-2 Acc.**
		Correct	**Error**	
Hi→En (Stage-1)	**Correct**	263	75	**77.81%**
	Error	**119**	362	**24.74%**

Table 3: Error Analysis for Hi→En→Ru

Hi→En→Ar		**En → Ar (Stage-2)**		**Stage-2 Acc.**
		Correct	**Error**	
Hi→En (Stage-1)	**Correct**	221	127	**63.50%**
	Error	**119**	340	**25.70%**

Table 4: Error Analysis for Hi→En→Ar

2nd stage error correction on incorrect inputs: The last rows in each of the above tables 3 – 5 report the performance of the second stage system on strings that were transliterated incorrectly by the first stage. While we expected the second row to produce incorrect transliterations nearly for all inputs (as the input themselves were incorrect in Z), we find to our surprise that upto 25% of the erroneous strings in Z were getting transliterated correctly in Y! This provides credence to our hypothesis that sufficient transliteration information is captured in the 1st stage output (*even when incorrect*) that may be exploited in the 2nd stage. Empirically, we verified that in most cases (nearly 60%) the errors were due to the incorrectly transliterated vowels, and in many cases, they get corrected in the second stage, and re-ranked higher in the output. Figure 2 shows a few examples of such error corrections in the second stage.



Hindi input	Erroneous English by Hi-En system	Correct English (reference)	Correct Russian by En-Ru system
बेरीलियम	berillium	beryllium	бериллий
दंबार्टन	dambarton	dumbarton	дамбартон
हब	hab	hub	хаб
कोच	coch	coach	кох

5 Characteristics of the bridge language

An interesting question that we explore in this section is *"how the choice of bridge language influence the performance of the bridge system?"*. The underlying assumption in transitive transliteration systems (as expressed in Equation 3), is that *"Y is independent of X given Z"*. In other words, we assume that the representations in the language will Z *"capture sufficient transliteration information from X to produce correct strings in Y"*. We hypothesize that two parameters of the bridge language, namely, the orthography inventory and the phoneme-to-grapheme entropy, that has most influence on the quality of the transitional systems, and provide empirical evidence for this hypothesis.

5.1 Richer Orthographic Inventory

In each of the successful bridge systems (that is, those with a relative performance drop of less than 10%), presented in Table 1, namely, *Hin-Eng-Ara*, *Eng-Ara-Heb* and *Hin-Kan-Eng*, the bridge language has, in general, richer orthographic inventory than the target language. Arabic has a reduced set of vowels, and hence poorer orthographic inventory compared with English. Similarly, between the closely related Semitic languages Arabic-Hebrew, there is a many-to-one mapping from Arabic to Hebrew, and between Kannada-English, Kannada has nearly a superset of vowels and consonants as compared to English or Hindi.

As an example for a poor choice of Z, we present a transitional system, *Hindi → Arabic → English*, in Table 6, in which the transitional language z (Arabic) has smaller orthographic inventory than Y (English).

Arabic has a reduced set of vowels and, unlike English, in most contexts short vowels are optional. As a result, when Arabic is used as the bridge language the loss of information (in terms of vowels) is large

Language Pair	**ACC-1**	**Relative change in ACC-1**
Hin-Eng	0.422	-64.28%
Hin-Ara-Eng	0.155	

Table 6: Incorrect choice of bridge language

and the second stage system has no possibility of recovering from such a loss. The performance of the bridge system confirms such a drastic drop in ACC-1 of nearly 64% compared with the direct system.

5.2 Higher Phoneme-Grapheme Entropy

We also find that the entropy in phoneme - grapheme mapping of a language indicate a good correlation with a good choice for a transition language. In a good transitional system (say, *Hin-Eng-Rus*), English has a more ambiguous phoneme-to-grapheme mapping than Russian; for example, in English the phoneme ‘s’ as in *Sam* or *Cecilia* can be represented by the graphemes ‘c’ and ‘s’, whereas Russian uses only a single character to represent this phoneme. In such cases, the ambiguity introduced by the bridge language helps in recovering from errors in the $X \rightarrow Z$ system. The relative loss of ACC-1 for this transitional system is only about 8%. The Table 7 shows another transitional system, in which a poor choice was for the transitional language was made.

Language Pair	**ACC-1**	**Relative change in ACC-1**
Hin-Eng	0.422	-45.26%
Hin-Tam-Eng	0.231	

Table 7: Incorrect choice of bridge language

Tamil has a reduced set of consonants compared with Hindi or English. For example, the Hindi consonants (k, kh, g, gh) are represented by a single character in Tamil. As a result, when Tamil is used as the bridge language it looses information (in terms of consonants) and results in a significant drop in performance (nearly a 45% drop in ACC-1) for the bridge system.

6 Effectiveness of Bridge Transliteration on CLIR System

In this section, we demonstrate the effectiveness of our bridge transliteration system on a downstream application, namely, a Crosslingual Information Retrieval system. We used the standard document collections from CLEF 2006 (Nardi and Peters, 2006), CLEF 2007 (Nardi and Peters, 2007) and FIRE 2008 (FIRE, 2008). We used Hindi as the query language. All the three fields (title, description and narration) of the topics were used for the retrieval. Since the collection and topics are from the previous years, their relevance judgments were also available as a reference for automatic evaluation.

6.1 Experimental Setup

We used primarily the statistical dictionaries generated by training statistical word alignment models on an existing Hindi-English parallel corpora. As with any CLIR system that uses translation lexicon, we faced the problem of out-of-vocabulary (OOV) query terms that need to be transliterated, as they are typically proper names in the target language. First, for comparison, we used the above mentioned CLIR system with no transliteration engine (*Basic*), and measured the crosslingual retrieval performance. Clearly, the OOV terms would not be converted into target language, and hence contribute nothing to the retrieval performance. Second, we integrated a direct machine transliteration system between Hindi and English (*D-HiEn*), and calibrated the improvement in performance. Third, we integrate, instead of a direct system, a bridge transliteration system between Hindi and English, transitioning through Kannada (*B-HiKaEn*). For both, direct as well as bridge transliteration, we retained the top-5 transliterations generated by the appropriate system, for retrieval.

6.2 Results and Discussion

The results of the above experiments are given in Table 7. The current focus of these experiments is to answer the question of *whether the bridge machine transliteration systems used to transliterate the OOV words in Hindi queries to English* (by stepping through Kannada) *performs at par with a direct transliteration system*. As expected, enhancing the CLIR system with a machine transliteration sys-

Collection	CLIR System	MAP	Relative MAP change from *Basic*	Recall	Relative Recall change from *Basic*
CLEF 2006	Basic	0.1463	-	0.4952	-
	D-HiEn	0.1536	+4.98%	0.5151	+4.01%
	B-HiKaEn	0.1529	+4.51%	0.5302	+7.06%
CLEF 2007	Basic	0.2521	-	0.7156	-
	D-HiEn	0.2556	+1.38%	0.7170	+ 0.19%
	B-HiKaEn	0.2748	+9.00%	0.7174	+ 0.25%
FIRE 2008	Basic	0.4361	-	0.8457	-
	D-HiEn	0.4505	+3.30%	0.8506	+0.57%
	B-HiKaEn	0.4573	+4.86%	0.8621	+1.93%

Table 8: CLIR Experiments with bridge transliteration systems

tem (*D-HiEn*) gives better results over a CLIR system with no transliteration functionality (*Basic*). On the standard test collections, the bridge transliteration system performs in par or better than the direct transliteration system in terms of MAP as well as recall. Even though, the bridged system is of slightly lesser quality in ACC-1 in Hi-Ka-En, compared to Hi-En (see Table 1), the top-5 results had captured the correct transliteration, as shown in our analysis. A detailed analysis of the query translations produced by the above systems showed that in some cases the bridge systems does produce a better transliteration thereby leading to a better MAP. As an illustration, consider the OOV terms वेटिकन {Vatican} and नेस्ले {Nestle} and the corresponding transliterations generated by the different systems. The Direct-HiEn system was unable to generate the correct transliteration in the top-5 results whereas the B-HiKaEn was able to produce the correct transliteration in the top-5 results thereby resulting in an improvement in MAP for these queries.

OOV term	D-HiEn	B-HiKaEn
वेटिकन (vatican)	vetican	vetican
	veticon	vettican
	vettican	**vatican**
	vetticon	watican
	wetican	wetican
नेस्ले (nestle)	nesle	**nestle**
	nesly	nesle
	nesley	nesley
	nessle	nestley
	nesey	nesly

Table 9: Sample output in direct and bridge systems

7 Conclusions

In this paper, we introduced the idea of bridge transliteration systems that were developed employing well-studied orthographic approaches between constituent languages. We empirically established the quality of such bridge transliteration systems and showed that quite contrary to our expectations, the quality of such systems does not degrade drastically as compared to the direct systems. Our error analysis showed that these better-than-expected results can be attributed to (i) Better performance ($\sim$10-12%) of the second stage system on the strings transliterated correctly by the first stage system and (ii) Significant ($\sim$25%) error correction in the second stage. Next, we highlighted that the performance of such bridge systems will be satisfactory as long as the orthographic inventory of the bridge language is either richer or more ambiguous as compared to the target language. We showed that our results are consistent with this hypothesis and provided two examples where there is a significant drop in the accuracy when the bridge language violates the above constraints. Finally, we showed that a state of the art CLIR system integrated with a bridge transliteration system performs in par with the same CLIR system integrated with a direct transliteration system, vindicating our claim that such bridge transliteration systems can be use in real-world applications to alleviate the resource requirement of $^{n}C_{2}$ parallel names corpora.

Abstract

This paper proposes a general learning framework for a class of problems that require learning over latent intermediate representations. Many natural language processing (NLP) decision problems are defined over an expressive intermediate representation that is not explicit in the input, leaving the algorithm with both the task of recovering a good intermediate representation and learning to classify correctly. Most current systems separate the learning problem into two stages by solving the first step of recovering the intermediate representation heuristically and using it to learn the final classifier. This paper develops a novel joint learning algorithm for both tasks, that uses the final prediction to guide the selection of the best intermediate representation. We evaluate our algorithm on three different NLP tasks – transliteration, paraphrase identification and textual entailment – and show that our joint method significantly improves performance.

1 Introduction

Many NLP tasks can be phrased as decision problems over complex linguistic structures. Successful learning depends on correctly encoding these (often latent) structures as features for the learning system. Tasks such as transliteration discovery (Klementiev and Roth, 2008), recognizing textual entailment (RTE) (Dagan et al., 2006) and paraphrase identification (Dolan et al., 2004) are a few prototypical examples. However, the input to such problems does not specify the latent structures and the problem is defined in terms of surface forms only. Most current solutions transform the raw input into a meaningful intermediate representation[1], and then encode its structural properties as features for the learning algorithm.

Consider the RTE task of identifying whether the meaning of a short text snippet (called the *hypothesis*) can be inferred from that of another snippet (called the *text*). A common solution (MacCartney et al., 2008; Roth et al., 2009) is to begin by defining an alignment over the corresponding entities, predicates and their arguments as an intermediate representation. A classifier is then trained using features extracted from the intermediate representation. The idea of using a intermediate representation also occurs frequently in other NLP tasks (Bergsma and Kondrak, 2007; Qiu et al., 2006).

While the importance of finding a good intermediate representation is clear, emphasis is typically placed on the later stage of extracting features over this intermediate representation, thus separating learning into **two stages** – specifying the latent representation, and then extracting features for learning. The latent representation is obtained by an inference process using predefined models or well-designed heuristics. While these approaches often perform well, they ignore a useful resource when generating the latent structure – the labeled data for the final learning task. As we will show in this paper, this results in degraded performance for the actual classification task at hand. Several works have considered this issue (McCallum et al., 2005; Goldwasser and Roth, 2008b; Chang et al., 2009; Das and Smith, 2009); however, they provide solutions

[1] In this paper, the phrases “intermediate representation” and “latent representation” are used interchangeably.

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 429–437,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

that do not easily generalize to new tasks.

In this paper, we propose a unified solution to the problem of learning to make the classification decision **jointly** with determining the intermediate representation. Our *Learning Constrained Latent Representations (***LCLR***) framework* is guided by the intuition that there is *no* intrinsically good intermediate representation, but rather that a representation is good only to the extent to which it improves performance on the final classification task. In the rest of this section we discuss the properties of our framework and highlight its contributions.

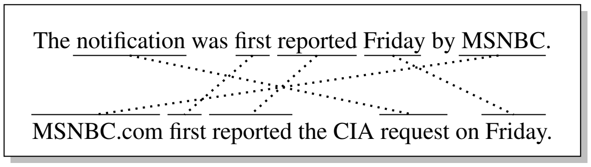
Learning over Latent Representations This paper formulates the problem of *learning over latent representations* and presents a novel and general solution applicable to a wide range of NLP applications. We analyze the properties of our learning solution, thus allowing new research to take advantage of a well understood learning and optimization framework rather than an ad-hoc solution. We show the generality of our framework by successfully applying it to three domains: transliteration, RTE and paraphrase identification.

Joint Learning Algorithm In contrast to most existing approaches that employ domain specific heuristics to construct intermediate representations to learn the final classifier, our algorithm learns to construct the optimal intermediate representation to support the learning problem. Learning to represent is a difficult structured learning problem however, unlike other works that use labeled data at the intermediate level, our algorithm only uses the binary supervision supplied for the final learning problem.

Flexible Inference Successful learning depends on constraining the intermediate representation with task-specific knowledge. Our framework uses the declarative Integer Linear Programming (ILP) inference formulation, which makes it easy to define the intermediate representation and to inject knowledge in the form of *constraints*. While ILP has been applied to structured output learning, to the best of our knowledge, this is the first work that makes use of ILP in formalizing the general problem of learning intermediate representations.

2 Preliminaries

We introduce notation using the Paraphrase Identification task as a running example. This is the binary classification task of identifying whether one sentence is a paraphrase of another. A paraphrase pair from the MSR Paraphrase corpus (Quirk et al., 2004) is shown in Figure 1. In order to identify that the sentences paraphrase each other , we need to align constituents of these sentences. One possible alignment is shown in the figure, in which the dotted edges correspond to the aligned constituents. An alignment can be specified using binary variables corresponding to every edge between constituents, indicating whether the edge is included in the alignment. Different activations of these variables induce the space of *intermediate representations.*



The notification was first reported Friday by MSNBC.
MSNBC.com first reported the CIA request on Friday.

Figure 1: The dotted lines represent a possible intermediate representation for the paraphrase identification task. Since different representation choices will impact the binary identification decision directly, our approach chooses the representation that facilitates the binary learning task.

To formalize this setting, let $\mathbf{x}$ denote the input to a decision function, which maps $\mathbf{x}$ to $\{-1, 1\}$. We consider problems where this decision depends on an intermediate representation (for example, the collection of all dotted edges in Figure 1), which can be represented by a binary vector $\mathbf{h}$.

In the literature, a common approach is to separate the problem into two stages. First, a generation stage predicts $\mathbf{h}$ for each $\mathbf{x}$ using a pre-defined model or a heuristic. This is followed by a learning stage, in which the classifier is trained using $\mathbf{h}$. In our example, if the generation stage predicts the alignment shown, then the learning stage would use the features computed based on the alignments. Formally, the two-stage approach uses a pre-defined inference procedure that finds an intermediate representation $\mathbf{h}'$. Using features $\Phi(\mathbf{x}, \mathbf{h}')$ and a learned weight vector θ, the example is classified as positive if $\theta^T \Phi(\mathbf{x}, \mathbf{h}') \geq 0$.

However, in the two stage approach, the latent representation, which is provided to the learning algorithm, is determined before learning starts, and without any feedback from the final task. It is dictated by the intuition of the developer. This approach makes two implicit assumptions: first, it assumes the existence of a "correct" latent representation and, second, that the model or heuristic used to generate it is the correct one for the learning problem at hand.

3 Joint Learning with an Intermediate Representation

In contrast to two-stage approaches, we use the annotated data for the final classification task to learn a suitable intermediate representation which, in turn, helps the final classification.

Choosing a good representation is an optimization problem that selects which of the elements (features) of the representation best contribute to successful classification given some legitimacy constraints; therefore, we (1) set up the optimization framework that finds legitimate representations (Section 3.1), and (2) learn an objective function for this optimization problem, such that it makes the best final decision (Section 3.2.)

3.1 Inference

Our goal is to correctly predict the final label rather than matching a "gold" intermediate representation. In our framework, attempting to learn the final decision drives both the selection of the intermediate representation and the final predictions.

For each $\mathbf{x}$, let $\Gamma(\mathbf{x})$ be the set of all substructures of all possible intermediate representations. In Figure 1, this could be the set of all alignment edges connecting the constituents of the sentences. Given a vocabulary of such structures of size N, we denote intermediate representations by $\mathbf{h} \in \{0,1\}^N$, which "select" the components of the vocabulary that constitute the intermediate representation. We define $\phi_s(\mathbf{x})$ to be a feature vector over the substructure s, which is used to describe the characteristics of s, and define a weight vector $\mathbf{u}$ over these features.

Let $\mathcal{C}$ denote the set of feasible intermediate representations $\mathbf{h}$, specified by means of linear constraints over $\mathbf{h}$. While $\Gamma(\mathbf{x})$ might be large, the set of those elements in $\mathbf{h}$ that are active can be constrained by controlling $\mathcal{C}$. After we have learned a weight vector $\mathbf{u}$ that scores intermediate representations for the final classification task, we define our decision function as

$$f_{\mathbf{u}}(\mathbf{x}) = \max_{\mathbf{h}\in\mathcal{C}} \mathbf{u}^T \sum_{s\in\Gamma(\mathbf{x})} h_s \phi_s(\mathbf{x}), \qquad (1)$$

and classify the input as positive if $f_{\mathbf{u}}(\mathbf{x}) \geq 0$.

In Eq. (1), $\mathbf{u}^T\phi_s(\mathbf{x})$ is the score associated with the substructure s, and $f_{\mathbf{u}}(\mathbf{x})$ is the score for the entire intermediate representation. Therefore, our decision function $f_{\mathbf{u}}(\mathbf{x}) \geq 0$ makes use of the intermediate representation and its score to classify the input. An input is labeled as positive if its underlying intermediate structure allows it to cross the decision threshold. The intermediate representation is chosen to maximize the overall score of the input. This design is especially beneficial for many phenomena in NLP, where only positive examples have a meaningful underlying structure. In our paraphrase identification example, good alignments generally exist only for positive examples.

One unique feature of our framework is that we treat Eq. (1) as an Integer Linear Programming (ILP) instance. A concrete instantiation of this setting to the paraphrase identification problem, along with the actual ILP formulation is shown in Section 4.

3.2 Learning

We now present an algorithm that learns the weight vector $\mathbf{u}$. For a loss function $\ell : \mathbb{R} \to \mathbb{R}$, the goal of learning is to solve the following optimization problem:

$$\min_{\mathbf{u}} \frac{\lambda}{2}\|\mathbf{u}\|^2 + \sum_i \ell\left(-y_i f_{\mathbf{u}}(\mathbf{x}_i)\right) \qquad (2)$$

Here, λ is the regularization parameter. Substituting Eq. (1) into Eq. (2), we get

$$\min_{\mathbf{u}} \frac{\lambda}{2}\|\mathbf{u}\|^2 + \sum_i \ell\left(-y_i \max_{\mathbf{h}\in\mathcal{C}} \mathbf{u}^T \sum_{s\in\Gamma(\mathbf{x})} h_s \phi_s(\mathbf{x}_i)\right) \qquad (3)$$

Note that there is a maximization term inside the global minimization problem, making Eq. (3) a non-convex problem. The minimization drives $\mathbf{u}$ towards smaller empirical loss while the maximization uses $\mathbf{u}$ to find the best representation for each example.

The algorithm for Learning over Constrained Latent Representations (LCLR) is listed in Algorithm 1. In each iteration, first, we find the best feature representations for all positive examples (lines 3-5). This step can be solved with an off-the-shelf ILP solver. Having fixed the representations for the positive examples, we update the $\mathbf{u}$ by solving Eq. (4) at line 6 in the algorithm. It is important to observe

Algorithm 1 *LCLR* :The algorithm that optimizes (3)

```
1: initialize: $\mathbf{u} \leftarrow \mathbf{u}_0$
2: repeat
3:     for all positive examples $(\mathbf{x}_i, y_i = 1)$ do
4:         Find $\mathbf{h}_i^* \leftarrow \arg\max_{\mathbf{h}\in\mathcal{C}} \sum_s h_s \mathbf{u}^T \phi_s(\mathbf{x}_i)$
5:     end for
6:     Update $\mathbf{u}$ by solving
       $$\min_{\mathbf{u}} \frac{\lambda}{2}\|\mathbf{u}\|^2 + \sum_{i:y_i=1} \ell(-\mathbf{u}^T \sum_s h_{i,s}^* \phi_s(\mathbf{x}_i)) + \sum_{i:y_i=-1} \ell(\max_{\mathbf{h}\in\mathcal{C}} \mathbf{u}^T \sum_s h_s \phi_s(\mathbf{x}_i)) \quad (4)$$
7: until convergence
8: return $\mathbf{u}$
```

Algorithm 2 Cutting plane algorithm to optimize Eq. (4)

```
1: for each negative example $x_j$, $H_j \leftarrow \emptyset$
2: repeat
3:     for each negative example $x_j$ do
4:         Find $\mathbf{h}_j^* \leftarrow \arg\max_{\mathbf{h}\in\mathcal{C}} \sum_s h_s \mathbf{u}^T \phi_s(\mathbf{x}_j)$
5:         $H_j \leftarrow H_j \cup \{\mathbf{h}_j^*\}$
6:     end for
7:     Solve
       $$\min_{\mathbf{u}} \frac{\lambda}{2}\|\mathbf{u}\|^2 + \sum_{i:y_i=1} \ell(-\mathbf{u}^T \sum_s h_{i,s}^* \phi_s(\mathbf{x}_i)) + \sum_{i:y_i=-1} \ell(\max_{\mathbf{h}\in H_j} \mathbf{u}^T \sum_s h_s \phi_s(\mathbf{x}_i)) \quad (5)$$
8: until no new element is added to any $H_j$
9: return $\mathbf{u}$
```

that for positive examples in Eq. (4), we use the intermediate representations $\mathbf{h}^*$ from line 4.

Algorithm 1 satisfies the following property:

Theorem 1 *If the loss function ℓ is a non-decreasing function, then the objective function value of Eq.* (3) *is guaranteed to decrease in every iteration of Algorithm 1. Moreover, if the loss function is also convex, then Eq.* (4) *in Algorithm 1 is convex.*

Due to the space limitation, we omit the proof.

Theoretically, we can use any loss function that satisfies the conditions of the theorem. In the experiments in this paper, we use the squared-hinge loss function: $\ell(-yf_{\mathbf{u}}(\mathbf{x})) = \max(0, 1 - yf_{\mathbf{u}}(\mathbf{x}))^2$.

Recall that Eq. (4) is not the traditional SVM or logistic regression formulation. This is because inside the inner loop, the best representation for each negative example must be found. Therefore, we need to perform inference for every negative example when updating the weight vector solution. Instead of solving a difficult non-convex optimization problem (Eq. (3)), LCLR iteratively solves a series of easier problems (Eq. (4)). This is especially true for our loss function because Eq. (4) is convex and can be solved efficiently.

We use a cutting plane algorithm to solve Eq. (4). A similar idea has been proposed in (Joachims et al., 2009). The algorithm for solving Eq. (4) is presented as Algorithm 2. This algorithm uses a "cache" H_j to store all intermediate representations for negative examples that have been seen in previous iterations (lines 3-6) [2]. The difference between Eq. (5) in line 7 of Algorithm 2 and Eq. (4) is that in Eq. (5), we do not search over the entire space of intermediate representations. The search space for the minimization problem Eq. (5) is restricted to the cache H_j. Therefore, instead of solving the minimization problem Eq. (4), we can now solve several simpler problems shown in Eq. (5). The algorithm is guaranteed to stop (line 8) because the space of intermediate representations is finite. Furthermore, in practice, the algorithm needs to consider only a small subset of "hard" examples before it converges.

Inspired by (Hsieh et al., 2008), we apply an efficient coordinate descent algorithm for the *dual* formulation of (5) which is guaranteed to find its global minimum. Due to space considerations, we do not present the derivation of dual formulation and the details of the optimization algorithm.

4 Encoding with ILP: A Paraphrase Identification Example

In this section, we define the latent representation for the paraphrase identification task. Unlike the earlier example, where we considered the alignment of lexical items, we describe a more complex intermediate representation by aligning graphs created using semantic resources.

An input example is represented as two acyclic

[2] In our implementation, we keep a global cache H_j for each negative example x_j. Therefore, in Algorithm 2, we start with a non-empty cache improving the speed significantly.

graphs, G_1 and G_2, corresponding to the first and second input sentences. Each vertex in the graph contains word information (lemma and part-of-speech) and the edges denote dependency relations, generated by the Stanford parser (Klein and Manning, 2003). The intermediate representation for this task can now be defined as an alignment between the graphs, which captures lexical and syntactic correlations between the sentences.

We use $V(G)$ and $E(G)$ to denote the set of vertices and edges in G respectively, and define four hidden variable types to encode vertex and edge mappings between G_1 and G_2.

- The **word-mapping** variables, denoted by h_{v_1,v_2}, define possible pairings of vertices, where $v_1 \in V(G_1)$ and $v_2 \in V(G_2)$.
- The **edge-mapping** variables, denoted by h_{e_1,e_2}, define possible pairings of the graphs edges, where $e_1 \in E(G_1)$ and $e_2 \in E(G_2)$.
- The **word-deletion** variables $h_{v_1,*}$ (or h_{*,v_2}) allow for vertices $v_1 \in V(G_1)$ (or $v_2 \in V(G_2)$) to be deleted. This accounts for omission of words (like function words).
- The **edge-deletion** variables, $h_{e_1,*}$ (or h_{*,e_2}) allow for deletion of edges from G_1 (or G_2).

Our inference problem is to find the optimal set of hidden variable activations, restricted according to the following set of linear constraints

- Each vertex in G_1 (or G_2) can either be mapped to a single vertex in G_2 (or G_1) or marked as deleted. In terms of the **word-mapping** and **word-deletion** variables, we have

$$\forall v_1 \in V(G_1); h_{v_1,*} + \sum_{v_2 \in V(G_2)} h_{v_1,v_2} = 1 \quad (6)$$

$$\forall v_2 \in V(G_2); h_{*,v_2} + \sum_{v_1 \in V(G_1)} h_{v_1,v_2} = 1 \quad (7)$$

- Each edge in G_1 (or G_2) can either be mapped to a single edge in G_2 (or G_1) or marked as deleted. In terms of the **edge-mapping** and **edge-deletion** variables, we have

$$\forall e_1 \in E(G_1); h_{e_1,*} + \sum_{e_2 \in E(G_2)} h_{e_1,e_2} = 1 \quad (8)$$

$$\forall e_2 \in E(G_2); h_{*,e_2} + \sum_{e_1 \in E(G_1)} h_{e_1,e_2} = 1 \quad (9)$$

- The edge mappings can be active if, and only if, the corresponding node mappings are active. Suppose $e_1 = (v_1, v_1') \in E(G_1)$ and $e_2 = (v_2, v_2') \in E(G_2)$, where $v_1, v_1' \in V(G_1)$ and $v_2, v_2' \in V(G_2)$. Then, we have

$$h_{v_1,v_2} + h_{v_1',v_2'} - h_{e_1,e_2} \leq 1 \quad (10)$$

$$h_{v_1,v_2} \geq h_{e_1,e_2}; h_{v_1',v_2'} \geq h_{e_1,e_2} \quad (11)$$

These constraints define the feasible set for the inference problem specified in Equation (1). This inference problem can be formulated as an ILP problem with the objective function from Equation (1):

$$\begin{aligned} \max_{\mathbf{h}} \quad & \sum_s h_s \mathbf{u}^T \phi_s(\mathbf{x}) \\ \text{subject to} \quad & \text{(6)-(11)}; \ \forall s; h_s \in \{0,1\} \quad (12) \end{aligned}$$

This example demonstrates the use of integer linear programming to define intermediate representations incorporating domain intuition.

5 Experiments

We applied our framework to three different NLP tasks: transliteration discovery (Klementiev and Roth, 2008), RTE (Dagan et al., 2006), and paraphrase identification (Dolan et al., 2004).

Our experiments are designed to answer the following research question: "Given a binary classification problem defined over latent representations, will the joint LCLR algorithm perform better than a two-stage approach?" To ensure a fair comparison, both systems use the same feature functions and definition of intermediate representation. We use the same ILP formulation in both configurations, with a single exception – the objective function parameters: the two stage approach uses a task-specific heuristic, while LCLR learns it iteratively.

The ILP formulation results in very strong two stage systems. For example, in the paraphrase identification task, even our two stage system is the current state-of-the-art performance. In these settings, the improvement obtained by our joint approach is non-trivial and can be clearly attributed to the superiority of the joint learning algorithm. Interestingly, we find that our more general approach is better than specially designed joint approaches (Goldwasser and Roth, 2008b; Das and Smith, 2009).

Since the objective function (3) of the joint approach is not convex, a good initialization is required. We use the weight vector learned by the two stage approach as the starting point for the joint approach. The algorithm terminates when the relative improvement of the objective is smaller than 10^{-5}.

5.1 Transliteration Discovery

Transliteration discovery is the problem of identifying if a word pair, possibly written using two different character sets, refers to the same underlying entity. The intermediate representation consists of all possible character mappings between the two character sets. Identifying this mapping is not easy, as most writing systems do not perfectly align phonetically and orthographically; rather, this mapping can be context-dependent and ambiguous.

For an input pair of words (w_1, w_2), the intermediate structure $\mathbf{h}$ is a mapping between their characters, with the latent variable h_{ij} indicating if the i^{th} character in w_1 is aligned to the j^{th} character in w_2. The feature vector associated with the variable h_{ij} contains unigram character mapping, bigram character mapping (by considering surrounding characters). We adopt the *one-to-one mapping* and *non-crossing* constraint used in (Chang et al., 2009).

We evaluated our system using the English-Hebrew corpus (Goldwasser and Roth, 2008a), which consists of 250 positive transliteration pairs for training, and 300 pairs for testing. As negative examples for training, we sample 10% from random pairings of words from the positive data. We report two evaluation measurements – (1) the Mean Reciprocal Rank (MRR), which is the average of the multiplicative inverse of the rank of the correct answer, and (2) the accuracy (Acc), which is the percentage of the top rank candidates being correct.

We initialized the two stage inference process as detailed in (Chang et al., 2009) using a Romanization table to assign uniform weights to prominent character mappings. This initialization procedure resembles the approach used in (Bergsma and Kondrak, 2007). An alignment is first built by solving the constrained optimization problem. Then, a support vector machine with squared-hinge loss function is used to train a classifier using features extracted from the alignment. We refer to this two stage approach as *Alignment+Learning*.

The results summarized in Table 1 show the significant improvement obtained by the joint approach (95.4% MRR) compared to the two stage approach (85.7%). Moreover, LCLR outperforms the joint system introduced in (Goldwasser and Roth, 2008b).

Transliteration System	**Acc**	**MRR**
(Goldwasser and Roth, 2008b)	N/A	89.4
Alignment + Learning	80.0	85.7
LCLR	**92.3**	**95.4**

Table 1: Experimental results for transliteration. We compare a *two-stage* system: "Alignment+Learning" with LCLR, our *joint* algorithm. Both "Alignment+Learning" and LCLR use the same features and the same intermediate representation definition.

5.2 Textual Entailment

Recognizing Textual Entailment (RTE) is an important textual inference task of predicting if a given *text* snippet, entails the meaning of another (the *hypothesis*). In many current RTE systems, the entailment decision depends on successfully aligning the constituents of the text and hypothesis, accounting for the internal linguistic structure of the input.

The raw input – the text and hypothesis – are represented as directed acyclic graphs, where vertices correspond to words. Directed edges link verbs to the head words of semantic role labeling arguments produced by (Punyakanok et al., 2008). All other words are connected by dependency edges. The intermediate representation is an alignment between the nodes and edges of the graphs. We used three hidden variable types from Section 4 – **word-mapping**, **word-deletion** and **edge-mapping**, along with the associated constraints as defined earlier. Since the text is typically much longer than the hypothesis, we create **word-deletion** latent variables (and features) only for the hypothesis.

The second column of Table 2 lists the resources used to generate features corresponding to each hidden variable type. For word-mapping variables, the features include a WordNet based metric (WNSim), indicators for the POS tags and negation identifiers. We used the state-of-the-art coreference resolution system of (Bengtson and Roth, 2008) to identify the canonical entities for pronouns and extract features accordingly. For word deletion, we use only the POS tags of the corresponding tokens (generated by the LBJ POS tagger[3]) to generate features. For edge

[3] http://L2R.cs.uiuc.edu/~cogcomp/software.php

Hidden Variable	RTE features	Paraphrase features
word-mapping	WordNet, POS, Coref, Neg	WordNet, POS, NE, ED
word-deletion	POS	POS, NE
edge-mapping	NODE-INFO	NODE-INFO, DEP
edge-deletion	N/A	DEP

Table 2: Summary of latent variables and feature resources for the entailment and paraphrase identification tasks. See Section 4 for an explanation of the hidden variable types. The linguistic resources used to generate features are abbreviated as follows – POS: Part of speech, Coref: Canonical coreferent entities; NE: Named Entity, ED: Edit distance, Neg: Negation markers, DEP: Dependency labels, NODE-INFO: corresponding node alignment resources, N/A: Hidden variable not used.

Entailment System	**Acc**
Median of TAC 2009 systems	61.5
Alignment + Learning	65.0
LCLR	**66.8**

Table 3: Experimental results for recognizing textual entailment. The first row is the median of best performing systems of all teams that participated in the RTE5 challenge (Bentivogli et al., 2009). *Alignment + Learning* is our two-stage system implementation, and LCLR is our joint learning algorithm. Details about these systems are provided in the text.

mapping variables, we include the features of the corresponding word mapping variables, scaled by the word similarity of the words forming the edge.

We evaluated our system using the RTE-5 data (Bentivogli et al., 2009), consisting of 600 sentence pairs for training and testing respectively, in which positive and negative examples are equally distributed. In these experiments the joint LCLR algorithm converged after 5 iterations.

For the two stage system, we used WN-Sim to score alignments during inference. The word-based scores influence the edge variables via the constraints. This two-stage system (the Alignment+Learning system) is significantly better than the median performance of the RTE-5 submissions. Using LCLR further improves the result by almost 2%, a substantial improvement in this domain.

5.3 Paraphrase Identification

Our final task is Paraphrase Identification, discussed in detail at Section 4. We use all the four hidden variable types described in that section. The features used are similar to those described earlier for the RTE system and are summarized in Table 2.

Paraphrase System	**Acc**
Experiments using (Dolan et al., 2004)	
(Qiu et al., 2006)	72.00
(Das and Smith, 2009)	73.86
(Wan et al., 2006)	75.60
Alignment + Learning	76.23
LCLR	**76.41**
Experiments using **Extended data set**	
Alignment + Learning	72.00
LCLR	**72.75**

Table 4: Experimental Result For Paraphrasing Identification. Our joint LCLR approach achieves the best results compared to several previously published systems, and our own two stage system implementation (*Alignment + Learning*). We evaluated the systems performance across two datasets: (Dolan et al., 2004) dataset and the Extended dataset, see the text for details. Note that LCLR outperforms (Das and Smith, 2009), which is a specifically designed joint approach for this task.

We used the MSR paraphrase dataset of (Dolan et al., 2004) for empirical evaluation. Additionally, we generated a second corpus (called the *Extended dataset*) by sampling 500 sentence pairs from the MSR dataset for training and using the entire test collection of the original dataset. In the Extended dataset, for every sentence pair, we extended the longer sentence by concatenating it with itself. This results in a more difficult inference problem because it allows more mappings between words. Note that the performance on the original dataset sets the ceiling on the second one.

The results are summarized in Table 4. The first part of the table compares the LCLR system with a two stage system (*Alignment + Learning*) and three published results that use the MSR dataset. (We only list single systems in the table[4]) Interestingly, although still outperformed by our joint LCLR algorithm, the two stage system is able perform significantly better than existing systems for that dataset (Qiu et al., 2006; Das and Smith, 2009; Wan et al., 2006). We attribute this improvement, consistent across both the ILP based systems, to the intermediate representation we defined.

We hypothesize that the similarity in performance between the joint LCLR algorithm and the two stage

[4] Previous work (Das and Smith, 2009) has shown that combining the results of several systems improves performance.

(*Alignment* + *Learning*) systems is due to the limited intermediate representation space for input pairs in this dataset. We evaluated these systems on the more difficult *Extended* dataset. Results indeed show that the margin between the two systems increases as the inference problem becomes harder.

6 Related Work

Recent NLP research has largely focused on two-stage approaches. Examples include RTE (Zanzotto and Moschitti, 2006; MacCartney et al., 2008; Roth et al., 2009); string matching (Bergsma and Kondrak, 2007); transliteration (Klementiev and Roth, 2008); and paraphrase identification (Qiu et al., 2006; Wan et al., 2006).

(MacCartney et al., 2008) considered constructing a latent representation to be an independent task and used manually labeled *alignment* data (Brockett, 2007) to tune the inference procedure parameters. While this method identifies alignments well, it does not improve entailment decisions. This strengthens our intuition that the latent representation should be guided by the final task.

There are several exceptions to the two-stage approach in the NLP community (Haghighi et al., 2005; McCallum et al., 2005; Goldwasser and Roth, 2008b; Das and Smith, 2009); however, the intermediate representation and the inference for constructing it are closely coupled with the application task. In contrast, LCLR provides a general formulation that allows the use of expressive constraints, making it applicable to many NLP tasks.

Unlike other latent variable SVM frameworks (Felzenszwalb et al., 2009; Yu and Joachims, 2009) which often use task-specific inference procedure, LCLR utilizes the declarative inference framework that allows using *constraints* over intermediate representation and provides a general platform for a wide range of NLP tasks.

The optimization procedure in this work and (Felzenszwalb et al., 2009) are quite different. We use the coordinate descent and cutting-plane methods ensuring we have fewer parameters and the inference procedure can be easily parallelized. Our procedure also allows different loss functions. (Cherry and Quirk, 2008) adopts the Latent SVM algorithm to define a language model. Unfortunately, their implementation is not guaranteed to converge.

In CRF-like models with latent variables (McCallum et al., 2005), the decision function marginalizes over the all hidden states when presented with an input example. Unfortunately, the computational cost of applying their framework is prohibitive with constrained latent representations. In contrast, our framework requires only the *best* hidden representation instead of marginalizing over all possible representations, thus reducing the computational effort.

7 Conclusion

We consider the problem of learning over an intermediate representation. We assume the existence of a latent structure in the input, relevant to the learning problem, but not accessible to the learning algorithm. Many NLP tasks fall into these settings and each can consider a different hidden input structure. We propose a unifying thread for the different problems and present a novel framework for Learning over Constrained Latent Representations (LCLR). Our framework can be applied to many different latent representations such as parse trees, orthographic mapping and tree alignments. Our approach contrasts with existing work in which learning is done over a *fixed* representation, as we advocate *jointly* learning it with the final task.

We successfully apply the proposed framework to three learning tasks – Transliteration, Textual Entailment and Paraphrase Identification. Our joint LCLR algorithm achieves superior performance in all three tasks. We attribute the performance improvement to our novel training algorithm and flexible inference procedure, allowing us to encode domain knowledge. This presents an interesting line of future work in which more linguistic intuitions can be encoded into the learning problem. For these reasons, we believe that our framework provides an important step forward in understanding the problem of learning over hidden structured inputs.

Some Empirical Evidence for Annotation Noise in a Benchmarked Dataset

Beata Beigman Klebanov
Kellogg School of Management
Northwestern University
beata@northwestern.edu

Eyal Beigman
Washington University in St. Louis
beigman@wustl.edu

Abstract

A number of recent articles in computational linguistics venues called for a closer examination of the type of noise present in annotated datasets used for benchmarking (Reidsma and Carletta, 2008; Beigman Klebanov and Beigman, 2009). In particular, Beigman Klebanov and Beigman articulated a type of noise they call *annotation noise* and showed that in worst case such noise can severely degrade the generalization ability of a linear classifier (Beigman and Beigman Klebanov, 2009). In this paper, we provide quantitative empirical evidence for the existence of this type of noise in a recently benchmarked dataset. The proposed methodology can be used to zero in on unreliable instances, facilitating generation of cleaner gold standards for benchmarking.

1 Introduction

Traditionally, studies in computational linguistics use few trained annotators. Lately this might be changing, as inexpensive annotators are available in large numbers through projects like Amazon Mechanical Turk or through online games where annotations are produced as a by-product (Poesio et al., 2008; von Ahn, 2006), and, at least for certain tasks, the quality of multiple non-expert annotations is close to that of a small number of experts (Snow et al., 2008; Callison-Burch, 2009).

Apart from the reduced costs, mass annotation is a promising way to get detailed information about the dataset, such as the level of difficulty of the difference instances. Such information is important both from the linguistic and from the machine learning perspective, as the existence of a group of instances difficult enough to look like they have been labeled by random guesses can in the worst case induce the machine learner training on the dataset to misclassify a constant proportion of easy, non-controversial instances, as well as produce incorrect comparative results in a benchmarking setting (Beigman Klebanov and Beigman, 2009; Beigman and Beigman Klebanov, 2009) .

In this article, we employ annotation generation models to estimate the types of instances in a multiply annotated dataset for a binary classification task. We provide the first quantitative empirical demonstration, to our knowledge, of the existence of what Beigman Klebanov and Beigman (2009) call "annotation noise" in a benchmarked dataset, that is, for a case where instances cannot be plausibly assigned to just two classes, and where instances in the third class can be plausibly described as having been annotated by flips of a nearly fair coin. The ability to identify such instances helps improve the gold standard by eliminating them, and allows further empirical investigation of their impact on machine learning for the task in question.

2 Generative models of annotation

We present a graphical model for the generation of annotations. The basic idea is that there are different types of instances that induce different responses from annotators. Each instance may have a true label of "0" or "1", however, the researcher's access to it is mediated by annotators who are guessing the true label by flipping a coin, where the bias of the coin depends on the type of the instance. The bias of the coin essentially models the difficulty of label-

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 438–446,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

ing the instance; coins biased close to 0 and 1 correspond to instances that are easy to classify; a fair coin represents instances that are very difficult if not impossible to classify correctly with the given pool of annotators. The model presented in Beigman Klebanov and Beigman (2009) is a special case with 3 types (A,B,C) where p_A=0, p_C=1 (easy cases), and 0<p_B<1 represents the hard cases, the harder the closer p_B is to 0.5. Models used here are a type of latent class models (McCutcheon, 1987) widely used in the *Biometrics* community (Espeland and Handelman, 1989; Yang and Becker, 1997; Albert et al., 2001; Albert and Dodd, 2004).

The goal of modeling is to determine whether more than two types of instances need to be postulated, to estimate how difficult each type is, and to identify the troublemaking instances.

The graphical model is presented in figure 1. We assume the dataset of size N is a mixture of k different types of instances. The proportion of types is given by $\theta = (\theta_1, \ldots, \theta_k)$, and coin biases for each type are given by $p = (p_1, \ldots, p_k)$. Each instance is annotated by n i.i.d coinflips, and random variable $x \in \{0, \ldots, n\}$ counts the number of "1"s in the n annotations given to an instance. Each instance belongs to a type $t \in \{1, ..., k\}$, characterized by a coin with the probability p_t of annotating with the label "1". Conditioned on t, the number of "1"s in n annotations has a binomial distribution with parameter p_t: $\Pr(x = j|t) = \binom{n}{j} p_t^j (1 - p_t)^{n-j}$.

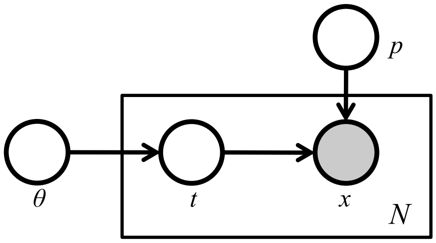

Figure 1: A graphical model of annotation generation.

The probability of observing j "1"s out of n annotations for an instance given θ and p is therefore $\Pr(x = j|\theta, p) = \sum_{t=1}^{k} \Pr(t|\theta) \cdot \Pr(x = j|t) = = \binom{n}{j} \sum_{t=1}^{k} \theta_t p_t^j (1 - p_t)^{n-j}$. The annotations are thus generated by a superposition of k binomials.

3 Data

3.1 Recognizing Textual Entailment -1

For the experiments reported here we use the 800 item test data of the first Recognizing Textual Entailment benchmark (RTE-1) from Dagan et al. (2006). This task drew a lot of attention in the community, with a series of benchmarks in 2005-2007.

The task is defined as follows: "... *textual entailment* is defined as a directional relationship between pairs of text expressions, denoted by *T* - the entailing "Text", and *H* - the entailed "Hypothesis". We say that *T* entails *H* if the meaning of *H* can be inferred from the meaning of T, as would typically be interpreted by people. This somewhat informal definition is based on (and assumes) common human understanding of language as well as common background knowledge" (Dagan et al., 2006). Further guidelines included an instruction to disregard tense differences, to accept cases where the inference is "very probable (but not completely certain)" and to avoid cases where the inference "has some positive probability that is not clearly very high." An example of a true entailment is the pair *T-H*: (T) Cavern Club sessions paid the Beatles £15 evenings and £5 lunchtime. (H) The Beatles perform at Cavern.

Although annotated by a small number of experts for the benchmark, the RTE-1 dataset has been later transferred to a mass annotation framework by Snow et al. (2008), who submitted simplified guidelines to the Amazon Mechanical Turk workplace (henceforth, AMT), collected 10 annotations per item from the total of 164 annotators, and showed that majority vote by Turkers agreed with expert annotation in 89.7% of the cases. We call the Snow et al. (2008) Turker annotations SRTE dataset, and use it in section 6. The instructions, followed by two examples, read: "Please state whether the second sentence (the Hypothesis) is implied by the information in the first sentence (the Text), i.e., please state whether the Hypothesis can be determined to be true given that the Text is true. Assume that you do not know anything about the situation except what the Text itself says. Also, note that every part of the Hypothesis must be implied by the Text in order for it to be true." The guidelines for Turkers are somewhat different from the original, not mentioning the issue of highly probable though not certain inference or a special treatment of tense mismatch between *H* and *T*, as well as discouraging reliance on background knowledge.

Using Snow et al. (2008) instructions, we collected 20 annotations for each of the 800 items through AMT from the total of 441 annotators. Each annotator did the minimum of 2 items, and was paid $0.01 for 2 items, for the total annotator cost of $80. We used only annotators with prior AMT approval rate of at least 95%, that is, only people whose performance in previous tasks on AMT was almost always approved by the requester of the task. Our design is thus somewhat different from Snow et al. (2008), as we paid more and selected annotators with a stake in their AMT reputation.

3.2 Preparing the data for model fitting

We collected the annotations in two separate batches of 10 annotations per item, using the same set of instructions, incentives, and examples. We hypothesized that controlling for these elements, we would get two random samples from the same distribution of Turkers, and hence will have two samples to make sure a model fitted on one sample generalized to the other. It turned out, however, that a 3-Binomial model with a good fit on one of the samples was rejected with high probability for the other.[1] Thus, on the one hand, the variations between annotators in each sample were not as high as to preclude a model that captures only instance variability from fitting well; on the other hand, evidently, the two samples did not come from the same annotator distribution, but differed systematically due to factors we did not control for.[2] In order for our models not to inherit a systematic bias of any of the two samples, we mixed the two samples, and constructed two sets, BRTEa and BRTEb, each with 10 annotations per item, by randomly splitting the 20 answers per item into two groups, allowing the same annotator to contribute to different groups on different instances. Indeed, after the randomization, a model fitted for BRTEa produced excellent generalization on BRTEb, as we will see in section 4.2.

4 Fitting a model to BRTE data

Using the model template presented in section 2, we successively attempt to fit a model with $k = 2, 3, \ldots$ until a model with a good fit is found or no degrees of freedom are left. For a given k, we fit the parameters θ and p using non-linear least squares trust-region method as implemented in the default version of MATLAB's *lsqnonlin* function. We then use χ^2 to measure goodness of fit; a model that cannot be rejected with 95% confidence (p>0.05) would be considered a good fit. In all cases N=800, n=10, as we use 10 annotations for each instance.

4.1 Mixture of 2 Binomials

Suppose k=2, with types t_0 and t_1. The best fit yields p_0=0.237, p_1=0.867, $\theta_0=\frac{431}{800}$, θ_1=1-θ_0. The model (shown in figure 2) is a poor fit, with χ^2=73.66 well above the critical value of 14.07 for df=7, p=0.05.[3]

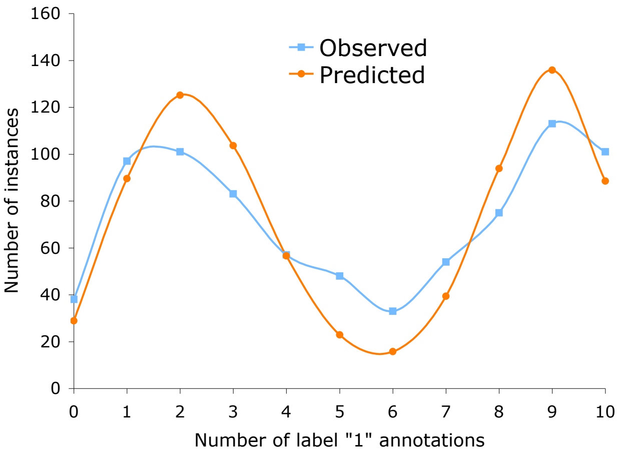

Figure 2: Fitting the model B1+B2 to BRTEa data. B1∼ $\mathcal{B}$(10,0.237) on 431 instances, B2∼ $\mathcal{B}$(10,0.867) on 369 instances. The point (x,y) means that there are y instances given label "1" in exactly x out of 10 annotations.

4.2 Model M: Mixture of 3 Binomials

Suppose now k=3. The best fitting model M=B1+B2+B3 is specified in figure 3; M fits the data very well. Assuming B1 and B3 reflect items

[1] For details of the model fitting procedure, see section 4.

[2] Such factors could be the hour and day of assignment, as the composition of AMT's global 24/7 workforce could differ systematically by day and hour.

[3] For degrees of freedom, we take the number of datapoints being fitted (11), take one degree of freedom off for knowing in advance the total number of instances, and take off additional 3 degrees of freedom for estimating p_0, p_1, and θ_0 from the data. We are therefore left with 7 degrees of freedom in this case.

with uncontroversial labels “0” and “1”, respectively, the model suggests that detecting “0” (no textual entailment) is somewhat more difficult for non-experts than detecting “1” (there is textual entailment) in this dataset, with the rate of incorrect predictions of about 20% and 10%, respectively.[4] The model also predicts that $\frac{159}{800} \approx 20\%$ of the data are difficult cases, with annotators flipping a close-to-a-fair coin (p=0.5487).

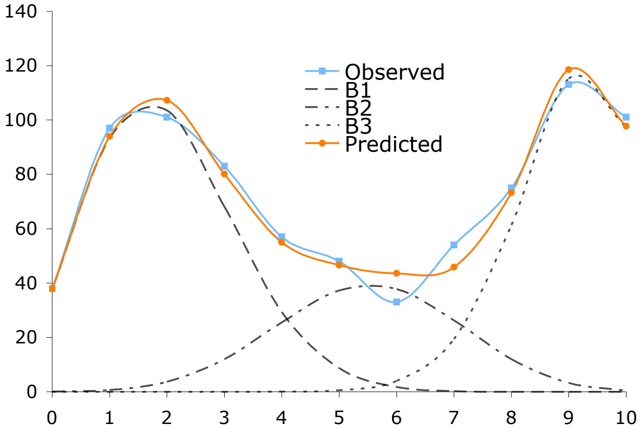

Figure 3: Fitting the model M=B1+B2+B3 to BRTEa data. B1∼ $\mathcal{B}$(10,0.1978) on 343 instances, B2∼ $\mathcal{B}$(10,0.5487) on 159 instances, B3∼ $\mathcal{B}$(10,0.8942) on 298 instances. The binomials are shown in grey lines. The model M fits with χ^2=5.091; for df=5, this corresponds to p=0.4.

We use the dataset BRTEb to test the model developed on BRTEa. The model fits with χ^2=13.13, which, for df=10,[5] corresponds to p=0.2154.

We therefore conclude that, after eliminating systematic differences between annotators, we were unable to fit a model with two types of instances, whereas a model with three types of instances provides a good fit both for the dataset on which it is estimated and for a new dataset. This constitutes empirical evidence for the existence of a group of instances with near-random labels in this recently benchmarked dataset, at least for our pool of more than 400 non-expert annotators.

5 Could annotator heterogeneity provide an alternative explanation?

In the previous section, we established that instance heterogeneity can explain the observations. We might however ask whether a different model could provide a similarly fitting explanation. Specifically, heterogeneity among annotators has been seen as a major source of noise in the aggregate data and there are several works attempting to separate high quality annotators from low quality ones (Raykar et al., 2009; Donmez et al., 2009; Sheng et al., 2008; Carpenter, 2008). Could we explain the observed behavior with a model with only two types of instances that allows for annotator heterogeneity?

In this section we construct such a model. We show that this model entails an instance distribution that is a superposition of two normal distributions. We subsequently show that the best fitting two-Gaussian model does not provide a good fit.

We use a generation model similar to those in (Raykar et al., 2009; Carpenter, 2008) but with weaker parametric assumptions. The graphical model is given in figure 4.

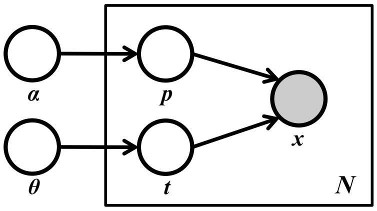

Figure 4: Annotation generation model with annotator heterogeneity.

We assume there are two types of instances $t \in \{0,1\}$ with the proportions $\theta = (\theta_0, \theta_1)$. The $2n$ probabilities $p = (p_{t1}, \ldots, p_{tn})$ for $t = 0, 1$ correspond to coins drawn independently from some distribution with parameter $\alpha = (\alpha_1, \ldots, \alpha_n)$. We make no assumption on the functional form apart from a positive probability to draw a value between 0 and 1, this in particular is true for the beta distribution used in (Raykar et al., 2009; Carpenter, 2008). As before, the number of “1”s attributed to an instance of type t is a random variable x, determined

[4] We note that any conclusions from the model hold for the particular 800 item dataset in question, and not for the task of recognizing textual entailment in general, as the dataset is not necessarily a representative sample. In fact, we know from Dagan et al. (2006) that these 800 items are not a random sample, but rather what remained after some 400 instances were removed due to disagreements between expert annotators or due to the judgment of one of organizers of the RTE-1 challenge.

[5] No parameters are fitted using the BRTEb data.

by independent flips of the n coins that correspond to the value of t. The marginal distribution of x is:

$$Pr(x = j|\theta, \alpha) =$$

$$= \sum_{t=0,1} \Pr(t|\theta) \int_{[0,1]^n} \Pr(p_t|\alpha) \cdot \Pr(x = j|p_t, t, \alpha) dp_t$$

$$= \sum_{t=0,1} \theta_t \int_{[0,1]^n} \Pr(p_t|\alpha) \left(\sum_{|S|=j} \prod_{i \in S} p_{ti} \prod_{i \notin S} (1 - p_{ti}) \right) dp_t$$

Let $x_1, \ldots, x_N$ be the random variables corresponding to the number of "1"s attributed to instances $1, \ldots, N$. W.l.g we assume instances $1, \ldots, N'$ are all of type t_0 ($N' = \theta_0 \cdot N$) and the rest of type t_1. Since $0 \leq x_j \leq n$ it follows that $\mathbb{E}(x_j), \mathit{Var}(x_j) < \infty$ for $j = 1, \ldots, N$. If for each instance the coin-flips are independent, we can think of this as a two step process where we first draw the coins and then flip them. Thus, $x_1, \ldots, x_{N'}$ are i.i.d and the central limit theorem implies that the average number of "1"s on t_0 instances, namely the random variable $y_0 = \frac{1}{N'} \sum_{j=1}^{N'} x_j$ has an approximately normal distribution.[6] Making the same argument for the distribution of y_1 for instances of type t_1, it follows that the number of "1"s attributed to an instance of any type $y = y_0 + y_1$ would have a distribution that is a superposition of two Gaussians.

The best least-squares fit of all two-Gaussian models to BRTEa data is produced by G=N1+N2, N1$\sim$ $\mathcal{N}$(2.22, 1.73) on 418 instances, N2$\sim$ $\mathcal{N}$(9.07,1.41) on 382 instances; G is shown in figure 5. G fits with χ^2=36.77, much above the critical value χ^2=11.07 for df=5, p=0.05. We can thus rule out annotator heterogeneity as the only explanation of the observed pattern of responses.

6 Testing M on SRTE data

We further test M on the annotations collected by Snow et al. (2008) for the same 800 item dataset. While the instructions and the task were identical in BRTEa, BRTEb, and BRTE datasets, and in all cases each item was given 10 annotations, the incentive design was different (see section 3).

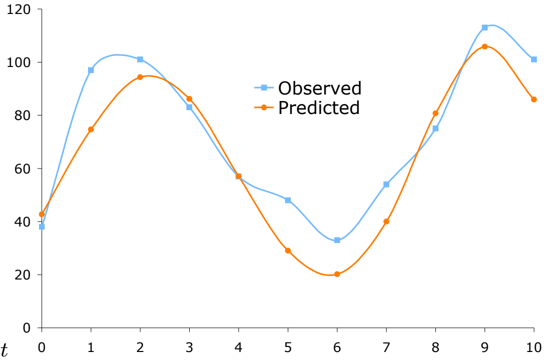

Figure 5: Model G's fit to BRTEa data, G= N1+N2, a mixture of two Gaussians.

Figure 6 shows that model M=B1+B2+B3 does not fit well, as SRTE dataset exhibits a rather different distribution from both BRTE datasets. In particular, it is clear that had a model been fitted on SRTE data, the coin flipping probabilities for the clear types, B1 and B3, would have to be moved towards 0.5; that is, an average annotator in SRTE dataset had worse ability to detect clear 0s and clear 1s than an average BRTE annotator. We note that BRTEa and BRTEb agreed with expert annotation in 92.5% and 90.8% of the instances, respectively, both better than 89.7% in SRTE.[7] Since we offered somewhat better incentives in BRTE, it is tempting to attribute the observed better quality of BRTE annotations to the improved incentives, although it is possible that some other uncontrolled AMT-related factor is responsible for the difference between the datasets, just as we found for our original two collected samples (see section 3.2).

Supposing the main source of misfit is difference in incentives, we conjecture that the difference between the 441 BRTE annotators and the 164 SRTE ones is due to the existence in SRTE of unmotivated, or "lazy" annotators, that is, people who flipped the same coin on every instance, no matter what type. Our hypothesis is that once an annotator is diligent (and motivated) enough to pay attention to the data, her annotations can be described by model M, but some annotators are not sufficiently diligent.

[6] It can be shown that $y_0 \sim \mathcal{N}(\mu, \sigma)$ for $\mu = n \cdot \mathbb{E}_{\mathit{Dist}(\alpha)}(p)$ and $\sigma = \sqrt{\mathit{Var}_{\mathit{Dist}(\alpha)}(p) \cdot n}$, using the expectation and variance of the coin parameter for type t_0 instances. For example, for a beta distribution with parameters α and β these would be $\mu = \frac{\alpha}{\alpha+\beta} n$ and $\sigma = \sqrt{\frac{\alpha\beta}{\alpha+\beta}} n$.

[7] Turker annotations were aggregated using majority vote, as in Snow et al. (2008) section 4.3.

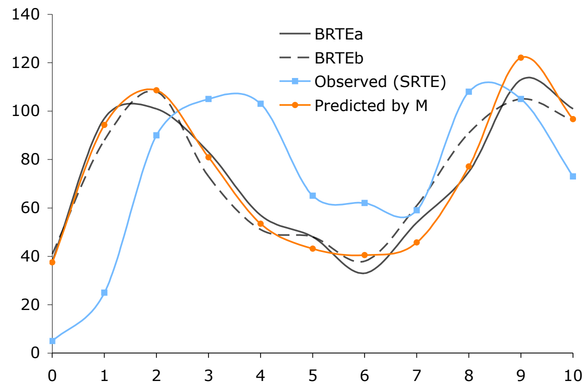

Figure 6: Model M's fit to SRTE data. BRTEa and BRTEb are shown in grey lines.

In this model we assume there are three types of instances as before, and two types of annotators $a \in \{D, L\}$, for Diligent and Lazy, with their proportions in the population $\xi = (\xi_D, \xi_L)$. The corresponding graphical model is shown in figure 7.

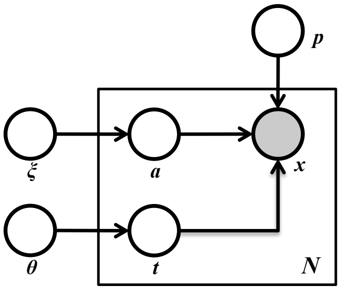

Figure 7: Annotation generation with diligent and lazy annotators.

We assume that diligent annotators flip coins corresponding to the types of instances, whereas lazy annotators always flip the same coin p_L.

Let n_D and n_L=$n - n_D$ be the number of diligent and lazy annotations given to a certain instance, thus $\Pr(n_D{=}r|\xi){=}\binom{n}{r}\xi_D^r\xi_L^{n-r}$, and the probability of observing j label "1" annotations for an instance of type t is given by:

$$\Pr(x = j|t, \xi, p) = \sum_{r=1}^{n}\Bigg[\binom{n}{r}\xi_D^r\xi_L^{n-r}\times$$

$$\times\Bigg[\sum_{(j_1,j_2)\in S}\binom{r}{j_1}p_t^{j_1}(1-p_t)^{r-j_1}\times$$

$$\times\binom{n-r}{j_2}p_L^{j_2}(1-p_L)^{n-r-j_2}\Bigg]\Bigg]$$

where S=$\{(j_1, j_2){:}j_1{+}j_2{=}j; j_1{\leq}\text{r};j_2{\leq}\text{n-r}\}$. Finally, $\Pr(x{=}j|\theta,\xi,p){=}\sum_{t=1}^{k}\theta_t \Pr(x{=}j|t,\xi,p)$.

We assume that model M provides the values for θ and p for all diligent annotators, and estimate ξ and p_L, the proportion of the lazy annotators and the coin they flip. The best fitting model yields ξ=(0.79,0.21), and p_L=0.74, predicting that about one-fifth of SRTE annotators are lazy.[8] This model fits with χ^2=14.63, which is below the critical level of χ^2=15.51 for df=8,p=0.05, hence a hypothesis that model M behavior for the diligent annotators and flipping a coin with bias 0.74 for the lazy ones generated the SRTE data cannot be rejected with high confidence. We note that Carpenter (2008) arrived at a similar conclusion – that there are quite a few annotators making random guesses in SRTE dataset – by means of jointly estimating annotator accuracies.

7 Discussion

To summarize our findings: With systematic differences between annotators smoothed out, there is evidence that non-expert annotators performing RTE task on RTE-1 test data tend to flip a close-to-fair coin on about 20% of instances, according to the best fitting model.[9] This constitutes, to our knowledge, the first empirical evidence for the existence of the kind of noise termed annotation noise in Beigman Klebanov and Beigman (2009). Given Beigman Klebanov and Beigman (2009) warning against annotation noise in test data and their finding in Beigman and Beigman Klebanov (2009) that annotation noise in training data can potentially devastate a linear classifier learning from the data, the immediate usefulness of our result is that instances of this difficult type can be identified, removed from the dataset before further benchmarking, and pos-

[8] A more precise statement is that there are about one-fifth lazy potential annotators in the SRTE pool for any given item. It is possible that the length of stay of an annotator in the pool is not independent of her diligence; for example, Callison-Burch (2009) found in his AMT experiments with tasks related to machine translation that lazy annotators tended to stay longer and do more annotations.

[9] Beigman Klebanov and Beigman (2009) discuss the connection between noise models and inter-annotator agreement.

sibly used in a controlled fashion for subsequent studies of the impact of annotation noise on specific learning algorithms and feature spaces for this task.

The current literature on generating benchmarking data from AMT annotations overwhelmingly considers annotator heterogeneity as the source of observed discrepancies, with instances falling into two classes only. Our results suggest that, at least in RTE data, instance heterogeneity cannot be ignored.

It also transpired that small variations in incentives (as between SRTE and BRTE), and even unknown factors possibly related to differences in the composition of AMT's workforce can lead to systematic differences in the resulting annotator pools, which results in annotations that are described by models with somewhat different parameter values. This can potentially limit the usefulness of our main finding, because it is not clear how reliable the identification of hard cases is using any particular group of Turkers. While this is a valid concern in general, we show in section 7.1 that many items consistently found to be hard by different groups of Turkers warrant at least an additional examination, as they often represent borderline cases of highly or not-so-highly probable inferences, corruption of meaning by ungrammaticality, or difficulties related to the treatment of time references and background knowledge.

Finally, our findings seem to be at odds with the fact that the 800 items analyzed here were left after all items on which two experts disagreed and all items that looked controversial to the arbiter were removed (see section 3). One potential explanation is that things that are hard for Turkers are not necessarily hard for experts. Yet it is possible that two or three annotators, graduate students or faculty in computational linguistics, are an especially homogenous and small pool of people to base gold standard annotations of the way things are "typically interpreted by people" upon. Furthermore, there is some evidence from additional expert re-annotations of this dataset that some controversies remain; we discuss relation to expert annotations in section 7.2.

7.1 Hard cases

We examine some of the instances that in all likelihood belong to the difficult type, according to Turkers. We focus on items that received between 4 and 7 class "1" annotations in SRTE and in each of our two datasets (before randomization).

(1) **T**: Saudi Arabia, the biggest oil producer in the world, was once a supporter of Osama bin Laden and his associates who led attacks against the United States. **H**: Saudi Arabia is the world's biggest oil exporter.

(2) **T**: Seiler was reported missing March 27 and was found four days later in a marsh near her campus apartment. **H**: Abducted Audrey Seiler found four days after missing.

(3) **T**: The spokesman for the rescue authorities, Linart Ohlin, said that the accident took place between 01:00 and dawn today, Friday (00:00 GMT) in a disco behind the theatre, where "hundreds" of young people were present. **H**: The fire happened in the early hours of Friday morning, and hundreds of young people were present.

(4) **T**: William Leonard Jennings sobbed loudly as was charged with killing his 3-year-old son, Stephen, who was last seen alive on Dec.12, 1962. **H**: William Leonard Jennings killed his 3-year-old son, Stephen.

Labeling of examples 1-4 seems to hinge on the assessment of the likelihood of an alternative explanation. Thus, it is possible that the biggest producer of oil is not the biggest exporter, because, for example, its internal consumption is much higher than in the second-biggest producer. In 2, abduction is a possible cause for being missing, but how relatively probable is it? Similarly, fire is a kind of accident, but can we infer that there was fire from a report about an accident? In 4, could the man have sobbed because on top of loosing his son he was also being falsely accused of having killed him? Experts marked all five as true entailments, while many Turkers had reservations.

(5) **T**: Bush returned to the White House late Saturday while his running mate was off campaigning in the West. **H**: Bush left the White House.

(6) **T**: De la Cruz's family said he had gone to Saudi Arabia a year ago to work as a driver after a long period of unemployment. **H**: De la Cruz was unemployed.

(7) **T**: Measurements by ground-based instruments around the world have shown a decrease of up to 10 percent in sunlight from the late 1950s to the early 1990s. **H**: The world is about 10 per cent darker than half a century ago.

In examples 5-7 time seems to be an issue. If Bush returned to White House, he must have left it beforehand, but does this count as entailment, or is the hypothesis referencing a time concurrent with the text, in which case *T* and *H* are in contradiction? In 6, can *H* be seen as referring to some time more than a year ago? In 7, if the hypothesis is taken to be stated in mid- or late-2000s, the time of annotation, half a century ago would reach to late 1950s, but it is possible that further substantial reduction occurred between early 1990s mentioned in the text and mid 2000s, amounting to much more than 10%. Experts labeled example 5 as false, 6 and 7 as true.

(8) **T**: On 2 February 1990, at the opening of Parliament, he declared that apartheid had failed and that the bans on political parties, including the ANC, were to be lifted. **H**: Apartheid in South Africa was abolished in 1990.

(9) **T**: Kennedy had just won California's Democratic presidential primary when Sirhan shot him in Los Angeles on June 5, 1968. **H**: Sirhan killed Kennedy.

Labeling examples 8 and 9 (both true according to the experts) requires knowledge about South African and American politics, respectively. Was the ban on ANC the only or the most important manifestation of apartheid? Was abolishing apartheid merely an issue of declaring that it failed? In 9, killing is a potential but not necessary outcome of shooting, so details of Robert Kennedy's case need to be known to the annotator to render the case-specific judgment.

(10) **T**: The version for the PC has essentially the same packaging as those for the big game consoles, but players have been complaining that it offers significantly less versatility when it comes to swinging through New York. **H**: Players have been complaining that it sells significantly less versatility when it comes to swinging through New York.

(11) **T**: During his trip to the Middle East that took three days, Clinton made the first visit by an American president to the Palestinian Territories and participated in a three-way meeting with Israeli Prime Minister Benjamin Netanyahu and Palestinian President Yasser Arafat. **H**: During his trip to the east of the Middle which lasted three days, the Clinton to first visit to American President to the occupied Palestinian territories and participated in meeting tripartite cooperation with Israeli Prime Minister Benjamin Netanyahu and Palestinian President, Yasser Arafat.

(12) **T**: The ISM non-manufacturing index rose to 64.8 in July from 59.9 in June. **H**: The non-manufacturing index of the ISM raised 64.8 in July from 59.9 in June.

(13) **T**: Henryk Wieniawski, a Polish-born musician, was known for his special preference for resurrecting neglected or lost works for the violin. **H**: Henryk Wieniawski was born in Polish.

Examples 10-13 were labeled as false by experts, possibly betraying over-sensitivity to the failings of language technology. *Sells* is not an ideal substitution for *offers*, but in a certain sense versatility is sold as part of a product. In 11-13, some Turkers felt the hypothesis is not too bad a rendition of the text or of its part, while experts seemed to hold MT to a higher standard.

7.2 Turkers vs experts

Model M puts 159 items in the difficult type B2. While M is the best fitting model, it is possible to find a model that still fits with p>0.05 but places a smaller number of items in B2, in order to obtain a conservative estimate on the number of difficult cases. The model with B1$\sim \mathcal{B}(10, 0.21)$ on 373 items, B2$\sim \mathcal{B}(10,0.563)$ on 110 items, B3$\sim \mathcal{B}(10,0.89)$ on 327 items still produces a fit with p>0.05, but going down to 100 instances in B2 makes it impossible to find a good fit with a 3 type model. There are therefore about 110 difficult cases by a conservative estimate. Assuming there remain 110 hard cases in the 800 item dataset for which even experts flip a fair coin, we expect about 55 disagreements between the 800 item gold standard from RTE-1 and a replication by a new expert, or an agreement of $\frac{745}{800}$=93% on average. This estimate is consistent with reports of 91% to 96% replication accuracy for the expert annotations on various subsets of the data by different groups of experts (see section 2.3 in Dagan et al. (2006)).

Acknowledgments

We would like to thank the anonymous reviewers of this and the previous draft for helping us improve the paper significantly. We also thank Amar Cheema for his advice on AMT.

Abstract

We describe a Bayesian inference algorithm that can be used to train any cascade of weighted finite-state transducers on end-to-end data. We also investigate the problem of automatically selecting from among multiple training runs. Our experiments on four different tasks demonstrate the genericity of this framework, and, where applicable, large improvements in performance over EM. We also show, for unsupervised part-of-speech tagging, that automatic run selection gives a large improvement over previous Bayesian approaches.

1 Introduction

In this paper, we investigate Bayesian inference for weighted finite-state transducers (WFSTs). Many natural language models can be captured by weighted finite-state transducers (Pereira et al., 1994; Sproat et al., 1996; Knight and Al-Onaizan, 1998; Clark, 2002; Kolak et al., 2003; Mathias and Byrne, 2006), which offer several benefits:

- WFSTs provide a uniform knowledge representation.
- Complex problems can be broken down into a cascade of simple WFSTs.
- Input- and output-epsilon transitions allow compact designs.
- Generic algorithms exist for doing inferences with WFSTs. These include best-path decoding, *k*-best path extraction, composition, intersection, minimization, determinization, forward-backward training, forward-backward pruning, stochastic generation, and projection.
- Software toolkits implement these generic algorithms, allowing designers to concentrate on novel models rather than problem-specific inference code. This leads to faster scientific experimentation with fewer bugs.

Weighted tree transducers play the same role for problems that involve the creation and transformation of tree structures (Knight and Graehl, 2005). Of course, many problems do not fit either the finite-state string or tree transducer framework, but in this paper, we concentrate on those that do.

Bayesian inference schemes have become popular recently in natural language processing for their ability to manage uncertainty about model parameters and to allow designers to incorporate prior knowledge flexibly. Task-accuracy results have generally been favorable. However, it can be time-consuming to apply Bayesian inference methods to each new problem. Designers typically build custom, problem-specific sampling operators for exploring the derivation space. They may factor their programs to get some code re-use from one problem to the next, but highly generic tools for string and tree processing are not available.

In this paper, we marry the world of finite-state machines with the world of Bayesian inference, and we test our methods across a range of natural language problems. Our contributions are:

- We describe a Bayesian inference algorithm that can be used to train any cascade of WFSTs on end-to-end data.
- We propose a method for automatic *run selec-*

tion, i.e., how to automatically select among multiple training runs in order to achieve the best possible task accuracy.

The natural language applications we consider in this paper are: (1) unsupervised part-of-speech (POS) tagging (Merialdo, 1994; Goldwater and Griffiths, 2007), (2) letter substitution decipherment (Peleg and Rosenfeld, 1979; Knight et al., 2006; Ravi and Knight, 2008), (3) segmentation of space-free English (Goldwater et al., 2009), and (4) Japanese/English phoneme alignment (Knight and Graehl, 1998; Ravi and Knight, 2009a). Figure 1 shows how each of these problems can be represented as a cascade of finite-state acceptors (FSAs) and finite-state transducers (FSTs).

2 Generic EM Training

We first describe forward-backward EM training for a single FST M. Given a string pair (v, w) from our training data, we transform v into an FST M_v that just maps v to itself, and likewise transform w into an FST M_w. Then we compose M_v with M, and compose the result with M_w. This composition follows Pereira and Riley (1996), treating epsilon input and output transitions correctly, especially with regards to their weighted interleaving. This yields a derivation lattice D, each of whose paths transforms v into w.[1] Each transition in D corresponds to some transition in the FST M. We run the forward-backward algorithm over D to collect fractional counts for the transitions in M. After we sum fractional counts for all examples, we normalize with respect to competing transitions in M, assign new probabilities to M, and iterate. Transitions in M compete with each other if they leave the same state with the same input symbol, which may be empty (ϵ).

In order to train an FSA on observed string data, we convert the FSA into an FST by adding an input-epsilon to every transition. We then convert each training string v into the string pair (ϵ, v). After running the above FST training algorithm, we can remove all input-ϵ from the trained machine.

It is straightforward to modify generic training to support the following controls:

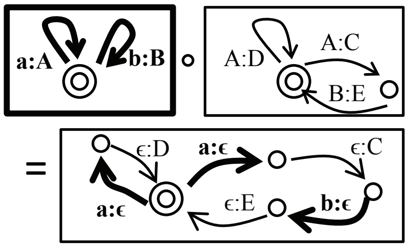

Figure 2: Composition of two FSTs maintaining separate transitions.

Maximum iterations and early stopping. We specify a maximum number of iterations, and we halt early if the ratio of $\log P(\text{data})$ from one iteration to the next exceeds a threshold (such as 0.99999).

Initial point. Any probabilities supplied on the pre-trained FST are interpreted as a starting point for EM's search. If no probabilities are supplied, EM begins with uniform probabilities.

Random restarts. We can request n random restarts, each from a different, randomly-selected initial point.

Locking and tying. Transitions on the pre-trained FST can be marked as locked, in which case EM will not modify their supplied probabilities. Groups of transitions can be tied together so that their fractional counts are pooled, and when normalization occurs, they all receive the same probability.

Derivation lattice caching. If memory is available, training can cache the derivation lattices computed in the first EM iteration for all training pairs. Subsequent iterations then run much faster. In our experiments, we observe an average 10-fold speedup with caching.

Next we turn to training a *cascade* of FSTs on end-to-end data. The algorithm takes as input: (1) a sequence of FSTs, and (2) pairs of training strings (v, w), such that v is accepted by the first FST in the cascade, and w is produced by the last FST. The algorithm outputs the same sequence of FSTs, but with trained probabilities.

To accomplish this, we first compose the supplied FSTs, taking care to keep the transitions from different machines separate. Figure 2 illustrates this with a small example. It may thus happen that a single transition in an input FST is represented multiple times in the composed device, in which case their prob-

[1] Throughout this paper, we do not assume that lattices are acyclic; the algorithms described work on general graphs.

abilities are tied together. Next, we run FST training on the end-to-end data. This involves creating derivation lattices and running forward-backward on them. After FST training, we de-compose the trained device back into a cascade of trained machines.

When the cascade's first machine is an FSA, rather than an FST, then the entire cascade is viewed as a generator of strings rather than a transformer of strings. Such a cascade is trained on observed strings rather than string pairs. By again treating the first FSA as an FST with empty input, we can train using the FST-cascade training algorithm described in the previous paragraph.

Once we have our trained cascade, we can apply it to new data, obtaining (for example) the k-best output strings for an input string.

3 Generic Bayesian Training

Bayesian learning is a wide-ranging field. We focus on training using Gibbs sampling (Geman and Geman, 1984), because it has been popularly applied in the natural language literature, e.g., (Finkel et al., 2005; DeNero et al., 2008; Blunsom et al., 2009).

Our overall plan is to give a generic algorithm for Bayesian training that is a "drop-in replacement" for EM training. That is, we input an FST cascade and data and output the same FST cascade with trained weights. This is an approximation to a purely Bayesian setup (where one would always integrate over all possible weightings), but one which makes it easy to deploy FSTs to efficiently decode new data. Likewise, we do not yet support non-parametric approaches—to create a drop-in replacement for EM, we require that all parameters be specified in the initial FST cascade. We return to this issue in Section 5.

3.1 Particular Case

We start with a well-known application of Bayesian inference, unsupervised POS tagging (Goldwater and Griffiths, 2007). Raw training text is provided, and each potential corpus tagging corresponds to a hidden derivation of that data. Derivations are created and probabilistically scored as follows:

1. $i \leftarrow 1$
2. Choose tag t_1 according to $P_0(t_1)$
3. Choose word w_1 according to $P_0(w_1 \mid t_1)$
4. $i \leftarrow i + 1$
5. Choose tag t_i according to
$$\frac{\alpha P_0(t_i \mid t_{i-1}) + c_1^{i-1}(t_{i-1}, t_i)}{\alpha + c_1^{i-1}(t_{i-1})} \quad (1)$$
6. Choose word w_i according to
$$\frac{\beta P_0(w_i \mid t_i) + c_1^{i-1}(t_i, w_i)}{\beta + c_1^{i-1}(t_i)} \quad (2)$$
7. With probability P_{quit}, quit; else go to 4.

This defines the probability of any given derivation. The base distribution P_0 represents prior knowledge about the distribution of tags and words, given the relevant conditioning context. The c_1^{i-1} are the counts of events occurring before word i in the derivation (the "cache").

When α and β are large, tags and words are essentially generated according to P_0. When α and β are small, tags and words are generated with reference to previous decisions inside the cache.

We use Gibbs sampling to estimate the distribution of tags given words. The key to efficient sampling is to define a sampling operator that makes some small change to the overall corpus derivation. With such an operator, we derive an incremental formula for re-scoring the probability of an entire new derivation based on the probability of the old derivation. Exchangeability makes this efficient—we pretend like the area around the small change occurs at the end of the corpus, so that both old and new derivations share the same cache. Goldwater and Griffiths (2007) choose the re-sampling operator "change the tag of a single word," and they derive the corresponding incremental scoring formula for unsupervised tagging. For other problems, designers develop different sampling operators and derive different incremental scoring formulas.

3.2 Generic Case

In order to develop a generic algorithm, we need to abstract away from these problem-specific design choices. In general, hidden derivations correspond to paths through derivation lattices, so we first

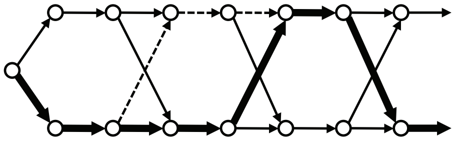

Figure 3: Changing a decision in the derivation lattice. All paths generate the observed data. The bold path represents the current sample, and the dotted path represents a sidetrack in which one decision is changed.

compute derivation lattices for our observed training data through our cascade of FSTs. A random path through these lattices constitutes the initial sample, and we calculate its derivation probability directly.

One way to think about a generic small change operator is to consider a single transition in the current sample. This transition will generally compete with other transitions. One possible small change is to "sidetrack" the derivation to a competing derivation. Figure 3 shows how this works. If the sidetrack path quickly re-joins the old derivation path, then an incremental score can be computed. However, sidetracking raises knotty questions. First, what is the proper path continuation after the sidetracking transition is selected? Should the path attempt to re-join the old derivation as soon as possible, and if so, how is this efficiently done? Then, how can we compute new derivation scores for all possible sidetracks, so that we can choose a new sample by an appropriate weighted coin flip? Finally, would such a sampler be reversible? In order to satisfy theoretical conditions for Gibbs sampling, if we move from sample A to sample B, we must be able to immediately get back to sample A.

We take a different tack here, moving from pointwise sampling to blocked sampling. Gao and Johnson (2008) employed blocked sampling for POS tagging, and the approach works nicely for arbitrary derivation lattices. We again start with a random derivation for each example in the corpus. We then choose a training example and exchange its entire derivation lattice to the end of the corpus. We create a weighted version of this lattice, called the *proposal lattice*, such that we can approximately sample whole paths by stochastic generation. The probabilities are based on the event counts from the rest of the sample (the cache), and on the base distribution, and are computed in this way:

$$P(r \mid q) = \frac{\alpha P_0(r \mid q) + c(q, r)}{\alpha + c(q)} \qquad (3)$$

where q and r are states of the derivation lattice, and the $c(\cdot)$ are counts collected from the corpus minus the entire training example being resampled. This is an approximation because we are ignoring the fact that $P(r \mid q)$ in general depends on choices made earlier in the lattice. The approximation can be corrected using the Metropolis-Hastings algorithm, in which the sample drawn from the proposal lattice is accepted only with a certain probability α; but Gao and Johnson (2008) report that $\alpha > 0.99$, so we skip this step.

3.3 Choosing the best derivations

After the sampling run has finished, we can choose the best derivations using two different methods. First, if we want to find the MAP derivations of the training strings, then following Goldwater and Griffiths (2007), we can use *annealing*: raise the probabilities in the sampling distribution to the $\frac{1}{T}$ power, where T is a temperature parameter, decrease T towards zero, and take a single sample.

But in practice one often wants to predict the MAP derivation for a new string w' not contained in the training data. To approximate the distribution of derivations of w' given the training data, we average the transition counts from all the samples (after burn-in) and plug the averaged counts into (3) to obtain a single proposal lattice.[2] The predicted derivation is the Viterbi path through this lattice. Call this method *averaging*. An advantage of this approach is that the trainer, taking a cascade of FSAs as input, outputs a weighted version of the same cascade, and this trained cascade can be used on unseen examples without having to rerun training.

3.4 Implementation

That concludes the generic Bayesian training algorithm, to which we add the following controls:

[2] A better approximation might have been to build a proposal lattice for each sample (after burn-in), and then construct a single FSA that computes the average of the probability distributions computed by all the proposal lattices. But this FSA would be rather large.

Number of Gibbs sampling iterations. We execute the full number specified.

Base distribution. Any probabilities supplied on the pre-trained FST are interpreted as base distribution probabilities. If no probabilities are supplied, then the base distribution is taken to be uniform.

Hyperparameters. We supply a distinct α for each machine in the FST cascade. We do not yet support different α values for different states within a single FST.

Random restarts. We can request multiple runs from different, randomly-selected initial samples.

EM-based initial point. If random initial samples are undesirable, we can request that the Gibbs sampler be initialized with the Viterbi path using parameter values obtained by n iterations of EM.

Annealing schedule. If annealing is used, it follows a linear annealing schedule with starting and stopping temperature specified by the user.

EM and Bayesian training for arbitrary FST cascades are both implemented in the finite-state toolkit Carmel, which is distributed with source code.[3] All controls are implemented as command-line switches. We use Carmel to carry out the experiments in the next section.

4 Run Selection

For both EM and Bayesian methods, different training runs yield different results. EM's objective function (probability of observed data) is very bumpy for the unsupervised problems we work on—different initial points yield different trained WFST cascades, with different task accuracies. Averaging task accuracies across runs is undesirable, because we want to deploy a particular trained cascade in the real world, and we want an estimate of its performance. Selecting the run with the best task accuracy is illegal in an unsupervised setting. With EM, we have a good alternative: select the run that maximizes the objective function, i.e., the likelihood of the observed training data. We find a decent correlation between this value and task accuracy, and we are generally able to improve accuracy using this run selection method. Figure 4 shows a scatterplot of 1000 runs for POS tagging. A single run with a uniform start yields 81.8% accuracy, while automatic selection from 1000 runs yields 82.4% accuracy.

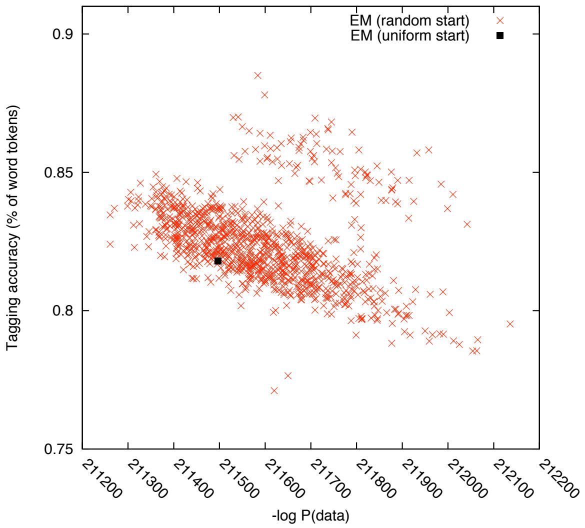

Figure 4: Multiple EM restarts for POS tagging. Each point represents one random restart; the y-axis is tagging accuracy and the x-axis is EM's objective function, $-\log P(\text{data})$.

Gibbs sampling runs also yield WFST cascades with varying task accuracies, due to random initial samples and sampling decisions. In fact, the variation is even larger than what we find with EM. It is natural to ask whether we can do automatic run selection for Gibbs sampling. If we are using annealing, it makes sense to use the probability of the final sample, which is supposed to approximate the MAP derivation. When using averaging, however, choosing the final sample would be quite arbitrary. Instead, we propose choosing the run that has the highest average log-probability (that is, the lowest entropy) after burn-in. The rationale is that the runs that have found their way to high-probability peaks are probably more representative of the true distribution, or at least capture a part of the distribution that is of greater interest to us.

We find that this method works quite well in practice. Figure 5 illustrates 1000 POS tagging runs for annealing with automatic run selection, yielding 84.7% accuracy. When using averaging, however, automatic selection from 1000 runs (Figure 6) produces a much higher accuracy of 90.7%. This is better than accuracies reported previously using

Bayesian methods (85.2% from Goldwater and Griffiths (2007), who use a trigram model) and close to the best accuracy reported on this task (91.8% from Ravi and Knight (2009b), who use an integer linear program to minimize the model directly).

5 Experiments and Results

We run experiments for various natural language applications and compare the task accuracies achieved by the EM and Bayesian learning methods. The tasks we consider are:

Unsupervised POS tagging. We adopt the common problem formulation for this task described by Merialdo (1994), in which we are given a raw 24,115-word sequence and a dictionary of legal tags for each word type. The tagset consists of 45 distinct grammatical tags. We use the same modeling approach as as Goldwater and Griffiths (2007), using a probabilistic tag bigram model in conjunction with a tag-to-word model.

Letter substitution decipherment. Here, the task is to decipher a 414-letter substitution cipher and uncover the original English letter sequence. The task accuracy is defined as the percent of ciphertext tokens that are deciphered correctly. We work on the same standard cipher described in previous literature (Ravi and Knight, 2008). The model consists of an English letter bigram model, whose probabilities are fixed and an English-to-ciphertext channel model, which is learnt during training.

Segmentation of space-free English. Given a space-free English text corpus (e.g., `iwalkedtothe...`), the task is to segment the text into words (e.g., `i walked to the ...`). Our input text corpus consists of 11,378 words, with spaces removed. As illustrated in Figure 1, our method uses a unigram FSA that models every letter sequence seen in the data, which includes both words and non-words (at most 10 letters long) composed with a deterministic spell-out model. In order to evaluate the quality of our segmented output, we compare it against the gold segmentation and compute the word token f-measure.

Japanese/English phoneme alignment. We use the problem formulation of Knight and Graehl (1998). Given an input English/Japanese katakana phoneme sequence pair, the task is to produce an alignment that connects each English

	MLE	Bayesian		
	EM	prior	VB-EM	Gibbs
POS tagging	82.4	$\alpha = 10^{-2}, \beta = 10^{-1}$	84.1	90.7
Letter decipherment	83.6	$\alpha = 10^{6}, \beta = 10^{-2}$	83.6	88.9
Re-spacing English	0.9	$\alpha = 10^{-8}, \beta = 10^{4}$	0.8	42.8
Aligning phoneme strings*	100	$\alpha = 10^{-2}$	99.9	99.1

Table 1: Gibbs sampling for Bayesian inference outperforms both EM and Variational Bayesian EM. *The output of EM alignment was used as the gold standard.

phoneme to its corresponding Japanese sounds (a sequence of one or more Japanese phonemes). For example, given a phoneme sequence pair ((AH B AW T) → (a b a u t o)), we have to produce the alignments ((AH → a), (B → b), (AW → a u), (T → t o)). The input data consists of 2,684 English/Japanese phoneme sequence pairs. We use a model that consists of mappings from each English phoneme to Japanese phoneme sequences (of length up to 3), and the mapping probabilities are learnt during training. We manually analyzed the alignments produced by the EM method for this task and found them to be nearly perfect. Hence, for the purpose of this task we treat the EM alignments as our gold standard, since there are no gold alignments available for this data.

In all the experiments reported here, we run EM for 200 iterations and Bayesian for 5000 iterations (the first 2000 for burn-in). We apply automatic run selection using the objective function value for EM and the averaging method for Bayesian.

Table 1 shows accuracy results for our four tasks, using run selection for both EM and Bayesian learning. For the Bayesian runs, we compared two inference methods: Gibbs sampling, as described above, and Variational Bayesian EM (Beal and Ghahramani, 2003), both of which are implemented in Carmel. We used the hyperparameters (α, β) as shown in the table. Setting a high value yields a final distribution that is close to the original one (P_0). For example, in letter decipherment we want to keep the language model probabilities fixed during training, and hence we set the prior on that model to be very strong ($\alpha = 10^6$). Table 1 shows that the Bayesian methods consistently outperform EM for all the tasks (except phoneme alignment, where EM was taken as the gold standard). Each iteration of Gibbs sampling was 2.3 times slower than EM for POS tagging, and in general about twice as slow.

6 Discussion

We have described general training algorithms for FST cascades and their implementation, and examined the problem of run selection for both EM and Bayesian training. This work raises several interesting points for future study.

First, is there an efficient method for performing pointwise sampling on general FSTs, and would pointwise sampling deliver better empirical results than blocked sampling across a range of tasks?

Second, can generic methods similar to the ones described here be developed for cascades of tree transducers? It is straightforward to adapt our methods to train a single tree transducer (Graehl et al., 2008), but as most types of tree transducers are not closed under composition (Gécseg and Steinby, 1984), the compose/de-compose method cannot be directly applied to train cascades.

Third, what is the best way to extend the FST formalism to represent non-parametric Bayesian models? Consider the English re-spacing application. We currently take observed (un-spaced) data and build a giant unigram FSA that models every letter sequence seen in the data of up to 10 letters, both words and non-words. This FSA has 207,253 transitions. We also define P_0 for each individual transition, which allows a preference for short words. This set-up works fine, but in a nonparametric approach, P_0 is defined more compactly and without a word-length limit. An extension of FSTs along the lines of recursive transition networks may be appropriate, but we leave details for future work.

Distributed Training Strategies for the Structured Perceptron

Abstract

Perceptron training is widely applied in the natural language processing community for learning complex structured models. Like all structured prediction learning frameworks, the structured perceptron can be costly to train as training complexity is proportional to inference, which is frequently non-linear in example sequence length. In this paper we investigate distributed training strategies for the structured perceptron as a means to reduce training times when computing clusters are available. We look at two strategies and provide convergence bounds for a particular mode of distributed structured perceptron training based on iterative parameter mixing (or averaging). We present experiments on two structured prediction problems – named-entity recognition and dependency parsing – to highlight the efficiency of this method.

1 Introduction

One of the most popular training algorithms for structured prediction problems in natural language processing is the perceptron (Rosenblatt, 1958; Collins, 2002). The structured perceptron has many desirable properties, most notably that there is no need to calculate a partition function, which is necessary for other structured prediction paradigms such as CRFs (Lafferty et al., 2001). Furthermore, it is robust to approximate inference, which is often required for problems where the search space is too large and where strong structural independence assumptions are insufficient, such as parsing (Collins and Roark, 2004; McDonald and Pereira, 2006; Zhang and Clark, 2008) and machine translation (Liang et al., 2006). However, like all structured prediction learning frameworks, the structure perceptron can still be cumbersome to train. This is both due to the increasing size of available training sets as well as the fact that training complexity is proportional to inference, which is frequently non-linear in sequence length, even with strong structural independence assumptions.

In this paper we investigate distributed training strategies for the structured perceptron as a means of reducing training times when large computing clusters are available. Traditional machine learning algorithms are typically designed for a single machine, and designing an efficient training mechanism for analogous algorithms on a computing cluster – often via a map-reduce framework (Dean and Ghemawat, 2004) – is an active area of research (Chu et al., 2007). However, unlike many batch learning algorithms that can easily be distributed through the gradient calculation, a distributed training analog for the perceptron is less clear cut. It employs online updates and its loss function is technically non-convex.

A recent study by Mann et al. (2009) has shown that distributed training through parameter mixing (or averaging) for maximum entropy models can be empirically powerful and has strong theoretical guarantees. A parameter mixing strategy, which can be applied to any parameterized learning algorithm, trains separate models in parallel, each on a disjoint subset of the training data, and then takes an average of all the parameters as the final model. In this paper, we provide results which suggest that the perceptron is ill-suited for straight-forward parameter mixing, even though it is commonly used for large-scale structured learning, e.g., Whitelaw et al. (2008) for named-entity recognition. However, a slight mod-

ification we call *iterative parameter mixing* can be shown to: 1) have similar convergence properties to the standard perceptron algorithm, 2) find a separating hyperplane if the training set is separable, 3) reduce training times significantly, and 4) produce models with comparable (or superior) accuracies to those trained serially on all the data.

2 Related Work

Distributed cluster computation for many batch training algorithms has previously been examined by Chu et al. (2007), among others. Much of the relevant prior work on online (or sub-gradient) distributed training has been focused on asynchronous optimization via gradient descent. In this scenario, multiple machines run stochastic gradient descent simultaneously as they update and read from a shared parameter vector asynchronously. Early work by Tsitsiklis et al. (1986) demonstrated that if the delay between model updates and reads is bounded, then asynchronous optimization is guaranteed to converge. Recently, Zinkevich et al. (2009) performed a similar type of analysis for online learners with asynchronous updates via stochastic gradient descent. The asynchronous algorithms in these studies require shared memory between the distributed computations and are less suitable to the more common cluster computing environment, which is what we study here.

While we focus on the perceptron algorithm, there is a large body of work on training structured prediction classifiers. For batch training the most common is conditional random fields (CRFs) (Lafferty et al., 2001), which is the structured analog of maximum entropy. As such, its training can easily be distributed through the gradient or sub-gradient computations (Finkel et al., 2008). However, unlike perceptron, CRFs require the computation of a partition function, which is often expensive and sometimes intractable. Other batch learning algorithms include M^{3}Ns (Taskar et al., 2004) and Structured SVMs (Tsochantaridis et al., 2004). Due to their efficiency, online learning algorithms have gained attention, especially for structured prediction tasks in NLP. In addition to the perceptron (Collins, 2002), others have looked at stochastic gradient descent (Zhang, 2004), passive aggressive algorithms (McDonald et al., 2005; Crammer et al., 2006), the recently introduced confidence weighted learning (Dredze et al., 2008) and coordinate descent algorithms (Duchi and Singer, 2009).

3 Structured Perceptron

The structured perceptron was introduced by Collins (2002) and we adopt much of the notation and presentation of that study. The structured percetron algorithm – which is identical to the multi-class perceptron – is shown in Figure 1. The perceptron is an online learning algorithm and processes training instances one at a time during each epoch of training. Lines 4-6 are the core of the algorithm. For a input-output training instance pair $(\mathbf{x}_t, \mathbf{y}_t) \in \mathcal{T}$, the algorithm predicts a structured output $\mathbf{y}' \in \mathcal{Y}_t$, where $\mathcal{Y}_t$ is the space of permissible structured outputs for input $\mathbf{x}_t$, e.g., parse trees for an input sentence. This prediction is determined by a linear classifier based on the dot product between a high-dimensional feature representation of a candidate input-output pair $\mathbf{f}(\mathbf{x}, \mathbf{y}) \in \mathbb{R}^M$ and a corresponding weight vector $\mathbf{w} \in \mathbb{R}^M$, which are the parameters of the model[1]. If this prediction is incorrect, then the parameters are updated to add weight to features for the corresponding correct output $\mathbf{y}_t$ and take weight away from features for the incorrect output $\mathbf{y}'$. For structured prediction, the inference step in line 4 is problem dependent, e.g., CKY for context-free parsing.

A training set $\mathcal{T}$ is separable with margin $\gamma > 0$ if there exists a vector $\mathbf{u} \in \mathbb{R}^M$ with $\|\mathbf{u}\| = 1$ such that $\mathbf{u} \cdot \mathbf{f}(\mathbf{x}_t, \mathbf{y}_t) - \mathbf{u} \cdot \mathbf{f}(\mathbf{x}_t, \mathbf{y}') \geq \gamma$, for all $(\mathbf{x}_t, \mathbf{y}_t) \in \mathcal{T}$, and for all $\mathbf{y}' \in \mathcal{Y}_t$ such that $\mathbf{y}' \neq \mathbf{y}_t$. Furthermore, let $R \geq ||\mathbf{f}(\mathbf{x}_t, \mathbf{y}_t) - \mathbf{f}(\mathbf{x}_t, \mathbf{y}')||$, for all $(\mathbf{x}_t, \mathbf{y}_t) \in \mathcal{T}$ and $\mathbf{y}' \in \mathcal{Y}_t$. A fundamental theorem

[1] The perceptron can be kernalized for non-linearity.

of the perceptron is as follows:

Theorem 1 (Novikoff (1962)). *Assume training set $\mathcal{T}$ is separable by margin γ. Let k be the number of mistakes made training the perceptron (Figure 1) on $\mathcal{T}$. If training is run indefinitely, then $k \leq \frac{R^2}{\gamma^2}$.*

Proof. See Collins (2002) Theorem 1. □

Theorem 1 implies that if $\mathcal{T}$ is separable then 1) the perceptron will converge in a finite amount of time, and 2) will produce a $\mathbf{w}$ that separates $\mathcal{T}$. Collins also proposed a variant of the structured perceptron where the final weight vector is a weighted average of all parameters that occur during training, which he called the *averaged perceptron* and can be viewed as an approximation to the voted perceptron algorithm (Freund and Schapire, 1999).

4 Distributed Structured Perceptron

In this section we examine two distributed training strategies for the perceptron algorithm based on parameter mixing.

4.1 Parameter Mixing

Distributed training through parameter mixing is a straight-forward way of training classifiers in parallel. The algorithm is given in Figure 2. The idea is simple: divide the training data $\mathcal{T}$ into S disjoint *shards* such that $\mathcal{T} = \{\mathcal{T}_1, \ldots, \mathcal{T}_S\}$. Next, train perceptron models (or any learning algorithm) on each shard in parallel. After training, set the final parameters to a weighted mixture of the parameters of each model using mixture coefficients $\boldsymbol{\mu}$. Note that we call this strategy *parameter mixing* as opposed to *parameter averaging* to distinguish it from the averaged perceptron (see previous section). It is easy to see how this can be implemented on a cluster through a map-reduce framework, i.e., the map step trains the individual models in parallel and the reduce step mixes their parameters. The advantages of parameter mixing are: 1) that it is parallel, making it possibly to scale to extremely large data sets, and 2) it is resource efficient, in particular with respect to network usage as parameters are not repeatedly passed across the network as is often the case for exact distributed training strategies.

```
PerceptronParamMix($\mathcal{T} = \{(\mathbf{x}_t, \mathbf{y}_t)\}_{t=1}^{|\mathcal{T}|}$)
    Shard $\mathcal{T}$ into $S$ pieces $\mathcal{T} = \{\mathcal{T}_1, \ldots, \mathcal{T}_S\}$
    $\mathbf{w}^{(i)}$ = Perceptron($\mathcal{T}_i$)                      †
    $\mathbf{w} = \sum_i \mu_i \mathbf{w}^{(i)}$                             ‡
    return $\mathbf{w}$
```

Figure 2: Distributed perceptron using a parameter mixing strategy. † Each $\mathbf{w}^{(i)}$ is computed in parallel. ‡ $\boldsymbol{\mu} = \{\mu_1, \ldots, \mu_S\}$, $\forall \mu_i \in \boldsymbol{\mu} : \mu_i \geq 0$ and $\sum_i \mu_i = 1$.

For maximum entropy models, Mann et al. (2009) show it is possible to bound the norm of the difference between parameters trained on all the data serially versus parameters trained with parameter mixing. However, their analysis requires a stability bound on the parameters of a regularized maximum entropy model, which is not known to hold for the perceptron. In Section 5, we present empirical results showing that parameter mixing for distributed perceptron can be sub-optimal. Additionally, Dredze et al. (2008) present negative parameter mixing results for confidence weighted learning, which is another online learning algorithm. The following theorem may help explain this behavior.

Theorem 2. *For a any training set $\mathcal{T}$ separable by margin γ, the perceptron algorithm trained through a parameter mixing strategy (Figure 2) does not necessarily return a separating weight vector* $\mathbf{w}$.

Proof. Consider a binary classification setting where $\mathcal{Y} = \{0, 1\}$ and $\mathcal{T}$ has 4 instances. We distribute the training set into two shards, $\mathcal{T}_1 = \{(\mathbf{x}_{1,1}, \mathbf{y}_{1,1}), (\mathbf{x}_{1,2}, \mathbf{y}_{1,2})\}$ and $\mathcal{T}_2 = \{(\mathbf{x}_{2,1}, \mathbf{y}_{2,1}), (\mathbf{x}_{2,2}, \mathbf{y}_{2,2})\}$. Let $\mathbf{y}_{1,1} = \mathbf{y}_{2,1} = 0$ and $\mathbf{y}_{1,2} = \mathbf{y}_{2,2} = 1$. Now, let $\mathbf{w}, \mathbf{f} \in \mathbb{R}^6$ and using block features, define the feature space as,

$$\begin{array}{ll}
\mathbf{f}(\mathbf{x}_{1,1}, 0) = [1\,1\,0\,0\,0\,0] & \mathbf{f}(\mathbf{x}_{1,1}, 1) = [0\,0\,0\,1\,1\,0] \\
\mathbf{f}(\mathbf{x}_{1,2}, 0) = [0\,0\,1\,0\,0\,0] & \mathbf{f}(\mathbf{x}_{1,2}, 1) = [0\,0\,0\,0\,0\,1] \\
\mathbf{f}(\mathbf{x}_{2,1}, 0) = [0\,1\,1\,0\,0\,0] & \mathbf{f}(\mathbf{x}_{2,1}, 1) = [0\,0\,0\,0\,1\,1] \\
\mathbf{f}(\mathbf{x}_{2,2}, 0) = [1\,0\,0\,0\,0\,0] & \mathbf{f}(\mathbf{x}_{2,2}, 1) = [0\,0\,0\,1\,0\,0]
\end{array}$$

Assuming label 1 tie-breaking, parameter mixing returns $\mathbf{w}^1$=[1 1 0 -1 -1 0] and $\mathbf{w}^2$=[0 1 1 0 -1 -1]. For any $\boldsymbol{\mu}$, the mixed weight vector $\mathbf{w}$ will not separate all the points. If both μ_1/μ_2 are non-zero, then all examples will be classified 0. If μ_1=1 and μ_2=0, then $(\mathbf{x}_{2,2}, \mathbf{y}_{2,2})$ will be incorrectly classified as 0 and $(\mathbf{x}_{1,2}, \mathbf{y}_{1,2})$ when μ_1=0 and μ_2=1. But there is a separating weight vector $\mathbf{w}$ = [-1 2 -1 1 -2 1]. □

This counter example does not say that a parameter mixing strategy will not converge. On the contrary, if $\mathcal{T}$ is separable, then each of its subsets is separable and converge via Theorem 1. What it does say is that, independent of $\boldsymbol{\mu}$, the mixed weight vector produced after convergence will not necessarily separate the entire data, even when $\mathcal{T}$ is separable.

4.2 Iterative Parameter Mixing

Consider a slight augmentation to the parameter mixing strategy. Previously, each parallel perceptron was trained to convergence before the parameter mixing step. Instead, shard the data as before, but train a single epoch of the perceptron algorithm for each shard (in parallel) and mix the model weights. This mixed weight vector is then re-sent to each shard and the perceptrons on those shards reset their weights to the new mixed weights. Another single epoch of training is then run (again in parallel over the shards) and the process repeats. This *iterative parameter mixing* algorithm is given in Figure 3.

Again, it is easy to see how this can be implemented as map-reduce, where the map computes the parameters for each shard for one epoch and the reduce mixes and re-sends them. This is analogous to batch distributed gradient descent methods where the gradient for each shard is computed in parallel in the map step and the reduce step sums the gradients and updates the weight vector. The disadvantage of iterative parameter mixing, relative to simple parameter mixing, is that the amount of information sent across the network will increase. Thus, if network latency is a bottleneck, this can become problematic. However, for many parallel computing frameworks, including both multi-core computing as well as cluster computing with high rates of connectivity, this is less of an issue.

Theorem 3. *Assume a training set $\mathcal{T}$ is separable by margin γ. Let $k_{i,n}$ be the number of mistakes that occurred on shard i during the nth epoch of training. For any N, when training the perceptron with iterative parameter mixing (Figure 3),*

$$\sum_{n=1}^{N}\sum_{i=1}^{S}\mu_{i,n}k_{i,n} \leq \frac{R^2}{\gamma^2}$$

Proof. Let $\mathbf{w}^{(i,n)}$ to be the weight vector for the ith shard after the nth epoch of the main loop and let $\mathbf{w}^{([i,n]-k)}$ be the weight vector that existed on shard i in the nth epoch k errors before $\mathbf{w}^{(i,n)}$. Let

```
PerceptronIterParamMix($\mathcal{T} = \{(\mathbf{x}_t, \mathbf{y}_t)\}_{t=1}^{|\mathcal{T}|}$)
  1.  Shard $\mathcal{T}$ into $S$ pieces $\mathcal{T} = \{\mathcal{T}_1, \ldots, \mathcal{T}_S\}$
  2.  $\mathbf{w} = \mathbf{0}$
  3.  for $n : 1..N$
  4.      $\mathbf{w}^{(i,n)} = $ OneEpochPerceptron($\mathcal{T}_i, \mathbf{w}$)    †
  5.      $\mathbf{w} = \sum_i \mu_{i,n}\mathbf{w}^{(i,n)}$    ‡
  6.  return $\mathbf{w}$

OneEpochPerceptron($\mathcal{T}$, $\mathbf{w}^*$)
  1.  $\mathbf{w}^{(0)} = \mathbf{w}^*$; $k = 0$
  2.  for $t : 1..T$
  3.      Let $\mathbf{y}' = \arg\max_{\mathbf{y}'} \mathbf{w}^{(k)} \cdot \mathbf{f}(\mathbf{x}_t, \mathbf{y}')$
  4.      if $\mathbf{y}' \neq \mathbf{y}_t$
  5.          $\mathbf{w}^{(k+1)} = \mathbf{w}^{(k)} + \mathbf{f}(\mathbf{x}_t, \mathbf{y}_t) - \mathbf{f}(\mathbf{x}_t, \mathbf{y}')$
  6.          $k = k + 1$
  7.  return $\mathbf{w}^{(k)}$
```

Figure 3: Distributed perceptron using an iterative parameter mixing strategy. † Each $\mathbf{w}^{(i,n)}$ is computed in parallel. ‡ $\boldsymbol{\mu}_n = \{\mu_{1,n}, \ldots, \mu_{S,n}\}$, $\forall \mu_{i,n} \in \boldsymbol{\mu}_n$: $\mu_{i,n} \geq 0$ and $\forall n$: $\sum_i \mu_{i,n} = 1$.

$\mathbf{w}^{(\text{avg},n)}$ be the mixed vector from the weight vectors returned after the nth epoch, i.e.,

$$\mathbf{w}^{(\text{avg},n)} = \sum_{i=1}^{S} \mu_{i,n}\mathbf{w}^{(i,n)}$$

Following the analysis from Collins (2002) Theorem 1, by examining line 5 of OneEpochPerceptron in Figure 3 and the fact that $\mathbf{u}$ separates the data by γ:

$$\begin{aligned}
\mathbf{u}\cdot\mathbf{w}^{(i,n)} &= \mathbf{u}\cdot\mathbf{w}^{([i,n]-1)} \\
&\quad + \mathbf{u}\cdot(\mathbf{f}(\mathbf{x}_t,\mathbf{y}_t) - \mathbf{f}(\mathbf{x}_t,\mathbf{y}')) \\
&\geq \mathbf{u}\cdot\mathbf{w}^{([i,n]-1)} + \gamma \\
&\geq \mathbf{u}\cdot\mathbf{w}^{([i,n]-2)} + 2\gamma \\
\ldots &\geq \mathbf{u}\cdot\mathbf{w}^{(\text{avg},n-1)} + k_{i,n}\gamma \quad \text{(A1)}
\end{aligned}$$

That is, $\mathbf{u}\cdot\mathbf{w}^{(i,n)}$ is bounded below by the average weight vector for the n-1st epoch plus the number of mistakes made on shard i during the nth epoch times the margin γ. Next, by OneEpochPerceptron line 5, the definition of R, and $\mathbf{w}^{([i,n]-1)}(\mathbf{f}(\mathbf{x}_t,\mathbf{y}_t) - \mathbf{f}(\mathbf{x}_t,\mathbf{y}')) \leq 0$ when line 5 is called:

$$\begin{aligned}
\|\mathbf{w}^{(i,n)}\|^2 &= \|\mathbf{w}^{([i,n]-1)}\|^2 \\
&\quad + \|\mathbf{f}(\mathbf{x}_t,\mathbf{y}_t) - \mathbf{f}(\mathbf{x}_t,\mathbf{y}')\|^2 \\
&\quad + 2\mathbf{w}^{([i,n]-1)}(\mathbf{f}(\mathbf{x}_t,\mathbf{y}_t) - \mathbf{f}(\mathbf{x}_t,\mathbf{y}')) \\
&\leq \|\mathbf{w}^{([i,n]-1)}\|^2 + R^2 \\
&\leq \|\mathbf{w}^{([i,n]-2)}\|^2 + 2R^2 \\
\ldots &\leq \|\mathbf{w}^{(\text{avg},n-1)}\|^2 + k_{i,n}R^2 \quad \text{(A2)}
\end{aligned}$$

That is, the squared L2-norm of a shards weight vector is bounded above by the same value for the average weight vector of the n-1st epoch and the number of mistakes made on that shard during the nth epoch times R^2.

Using A1/A2 we prove two inductive hypotheses:

$$\mathbf{u} \cdot \mathbf{w}^{(\text{avg},N)} \geq \sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} \gamma \qquad \text{(IH1)}$$

$$\|\mathbf{w}^{(\text{avg},N)}\|^2 \leq \sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} R^2 \qquad \text{(IH2)}$$

IH1 implies $\|\mathbf{w}^{(\text{avg},N)}\| \geq \sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} \gamma$ since $\mathbf{u} \cdot \mathbf{w} \leq \|\mathbf{u}\|\|\mathbf{w}\|$ and $\|\mathbf{u}\| = 1$.

The base case is $\mathbf{w}^{(\text{avg},1)}$, where we can observe:

$$\mathbf{u} \cdot \mathbf{w}^{\text{avg},1} = \sum_{i=1}^{S} \mu_{i,1} \mathbf{u} \cdot \mathbf{w}^{(i,1)} \geq \sum_{i=1}^{S} \mu_{i,1} k_{i,1} \gamma$$

using A1 and the fact that $\mathbf{w}^{(\text{avg},0)} = \mathbf{0}$ for the second step. For the IH2 base case we can write:

$$\begin{aligned} \|\mathbf{w}^{(\text{avg},1)}\|^2 &= \left\| \sum_{i=1}^{S} \mu_{i,1} \mathbf{w}^{(i,1)} \right\|^2 \\ &\leq \sum_{i=1}^{S} \mu_{i,1} \|\mathbf{w}^{(i,1)}\|^2 \leq \sum_{i=1}^{S} \mu_{i,1} k_{i,1} R^2 \end{aligned}$$

The first inequality is Jensen's inequality, and the second is true by A2 and $\|\mathbf{w}^{(\text{avg},0)}\|^2 = 0$.

Proceeding to the general case, $\mathbf{w}^{(\text{avg},N)}$:

$$\begin{aligned} \mathbf{u} \cdot \mathbf{w}^{(\text{avg},N)} &= \sum_{i=1}^{S} \mu_{i,N} (\mathbf{u} \cdot \mathbf{w}^{(i,N)}) \\ &\geq \sum_{i=1}^{S} \mu_{i,N} (\mathbf{u} \cdot \mathbf{w}^{(\text{avg},N-1)} + k_{i,N} \gamma) \\ &= \mathbf{u} \cdot \mathbf{w}^{(\text{avg},N-1)} + \sum_{i=1}^{S} \mu_{i,N} k_{i,N} \gamma \\ &\geq \left[\sum_{n=1}^{N-1} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} \gamma \right] + \sum_{i=1}^{S} \mu_{i,N} k_{i,N} \\ &= \sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} \gamma \end{aligned}$$

The first inequality uses A1, the second step $\sum_i \mu_{i,N} = 1$ and the second inequality the inductive hypothesis IH1. For IH2, in the general case, we can write:

$$\begin{aligned} \|\mathbf{w}^{(\text{avg},N)}\|^2 &\leq \sum_{i=1}^{S} \mu_{i,N} \|\mathbf{w}^{(i,N)}\|^2 \\ &\leq \sum_{i=1}^{S} \mu_{i,N} (\|\mathbf{w}^{(\text{avg},N-1)}\|^2 + k_{i,N} R^2) \\ &= \|\mathbf{w}^{(\text{avg},N-1)}\|^2 + \sum_{i=1}^{S} \mu_{i,N} k_{i,N} R^2 \\ &\leq \left[\sum_{n=1}^{N-1} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} R^2 \right] + \sum_{i=1}^{S} \mu_{i,N} k_{i,N} R^2 \\ &= \sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} R^2 \end{aligned}$$

The first inequality is Jensen's, the second A2, and the third the inductive hypothesis IH2. Putting together IH1, IH2 and $\|\mathbf{w}^{(\text{avg},N)}\| \geq \mathbf{u} \cdot \mathbf{w}^{(\text{avg},N)}$:

$$\left[\sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} \right]^2 \gamma^2 \quad \leq \quad \left[\sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} \right] R^2$$

which yields: $\sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n} \leq \frac{R^2}{\gamma^2}$ □

4.3 Analysis

If we set each $\boldsymbol{\mu}_n$ to be the uniform mixture, $\mu_{i,n} = 1/S$, then *Theorem 3 guarantees convergence to a separating hyperplane*. If $\sum_{i=1}^{S} \mu_{i,n} k_{i,n} = 0$, then the previous weight vector already separated the data. Otherwise, $\sum_{n=1}^{N} \sum_{i=1}^{S} \mu_{i,n} k_{i,n}$ is still increasing, but is bounded and cannot increase indefinitely. Also note that if $S = 1$, then $\mu_{1,n}$ must equal 1 for all n and this bound is identical to Theorem 1.

However, we are mainly concerned with how fast convergence occurs, which is directly related to the number of training epochs each algorithm must run, i.e., N in Figure 1 and Figure 3. For the non-distributed variant of the perceptron we can say that $N_{\text{non\_dist}} \leq R^2/\gamma^2$ since in the worst case a single mistake happens on each epoch.[2] For the distributed case, consider setting $\mu_{i,n} = k_{i,n}/k_n$, where $k_n = \sum_i k_{i,n}$. That is, we mix parameters proportional to the number of errors each made during the previous epoch. Theorem 3 still implies convergence to a separating hyperplane with this choice. Further, we can

[2] It is not hard to derive such degenerate cases.

bound the required number of epochs N_{dist}:

$$N_{\text{dist}} \leq \sum_{n=1}^{N_{\text{dist}}} \prod_{i=1}^{S} [k_{i,n}]^{\frac{k_{i,n}}{k_n}} \leq \sum_{n=1}^{N_{\text{dist}}} \sum_{i=1}^{S} \frac{k_{i,n}}{k_n} k_{i,n} \leq \frac{R^2}{\gamma^2}$$

Ignoring when all $k_{i,n}$ are zero (since the algorithm will have converged), the first inequality is true since either $k_{i,n} \geq 1$, implying that $[k_{i,n}]^{k_{i,n}/k_n} \geq 1$, or $k_{i,n} = 0$ and $[k_{i,n}]^{k_{i,n}/k_n} = 1$. The second inequality is true by the generalized arithmetic-geometric mean inequality and the final inequality is Theorem 3. Thus, the worst-case number of epochs is identical for both the regular and distributed perceptron – but the distributed perceptron can theoretically process each epoch S times faster. This observation holds only for cases where $\mu_{i,n} > 0$ when $k_{i,n} \geq 1$ and $\mu_{i,n} = 0$ when $k_{i,n} = 0$, which does not include uniform mixing.

5 Experiments

To investigate the distributed perceptron strategies discussed in Section 4 we look at two structured prediction tasks – named entity recognition and dependency parsing. We compare up to four systems:

1. **Serial (All Data)**: This is the classifier returned if trained serially on all the available data.
2. **Serial (Sub Sampling)**: Shard the data, select one shard randomly and train serially.
3. **Parallel (Parameter Mix)**: Parallel strategy discussed in Section 4.1 with uniform mixing.
4. **Parallel (Iterative Parameter Mix)**: Parallel strategy discussed in Section 4.2 with uniform mixing (Section 5.1 looks at mixing strategies).

For all four systems we compare results for both the standard perceptron algorithm as well as the averaged perceptron algorithm (Collins, 2002).

We report the final test set metrics of the converged classifiers to determine whether any loss in accuracy is observed as a consequence of distributed training strategies. We define convergence as either: 1) the training set is separated, or 2) the training set performance measure (accuracy, f-measure, etc.) does not change by more than some pre-defined threshold on three consecutive epochs. As with most real world data sets, convergence by training set separation was rarely observed, though in both cases training set accuracies approached 100%. For both tasks we also plot test set metrics relative to the user wall-clock taken to obtain the classifier. The results were computed by collecting the metrics at the end of each epoch for every classifier. All experiments used 10 shards (Section 5.1 looks at convergence relative to different shard size).

Our first experiment is a named-entity recognition task using the English data from the CoNLL 2003 shared-task (Tjong Kim Sang and De Meulder, 2003). The task is to detect entities in sentences and label them as one of four types: people, organizations, locations or miscellaneous. For our experiments we used the entire training set (14041 sentences) and evaluated on the official development set (3250 sentences). We used a straight-forward IOB label encoding with a 1st order Markov factorization. Our feature set consisted of predicates extracted over word identities, word affixes, orthography, part-of-speech tags and corresponding concatenations. The evaluation metric used was micro f-measure over the four entity class types.

Results are given in Figure 4. There are a number of things to observe here: 1) training on a single shard clearly provides inferior performance to training on all data, 2) the simple parameter mixing strategy improves upon a single shard, but does not meet the performance of training on all data, 3) iterative parameter mixing achieves performance as good as or better than training serially on all the data, and 4) the distributed algorithms return better classifiers much quicker than training serially on all the data. This is true regardless of whether the underlying algorithm is the regular or the averaged perceptron. Point 3 deserves more discussion. In particular, the iterative parameter mixing strategy has a higher final f-measure than training on all the data serially than the standard perceptron (f-measure of 87.9 vs. 85.8). We suspect this happens for two reasons. First, the parameter mixing has a bagging like effect which helps to reduce the variance of the per-shard classifiers (Breiman, 1996). Second, the fact that parameter mixing is just a form of parameter averaging perhaps has the same effect as the averaged perceptron.

Our second set of experiments looked at the much more computationally intensive task of dependency parsing. We used the Prague Dependency Treebank (PDT) (Hajič et al., 2001), which is a Czech

	Reg. Perceptron F-measure	Avg. Perceptron F-measure
Serial (All Data)	85.8	88.2
Serial (Sub Sampling)	75.3	76.6
Parallel (Parameter Mix)	81.5	81.6
Parallel (Iterative Parameter Mix)	87.9	88.1

Figure 4: NER experiments. Upper figures plot test data f-measure versus wall clock for both regular perceptron (left) and averaged perceptron (right). Lower table is f-measure for converged models.

language treebank and currently one of the largest dependency treebanks in existence. We used the CoNLL-X training (72703 sentences) and testing splits (365 sentences) of this data (Buchholz and Marsi, 2006) and dependency parsing models based on McDonald and Pereira (2006) which factors features over pairs of dependency arcs in a tree. To parse all the sentences in the PDT, one must use a non-projective parsing algorithm, which is a known NP-complete inference problem when not assuming strong independence assumptions. Thus, the use of approximate inference techniques is common in order to find the highest weighted tree for a sentence. We use the approximate parsing algorithm given in McDonald and Pereira (2006), which runs in time roughly cubic in sentence length. To train such a model is computationally expensive and can take on the order of days to train on a single machine.

Unlabeled attachment scores (Buchholz and Marsi, 2006) are given in Figure 5. The same trends are seen for dependency parsing that are seen for named-entity recognition. That is, iterative parameter mixing learns classifiers faster and has a final accuracy as good as or better than training serially on all data. Again we see that the iterative parameter mixing model returns a more accurate classifier than the regular perceptron, but at about the same level as the averaged perceptron.

5.1 Convergence Properties

Section 4.3 suggests that different weighting strategies can lead to different convergence properties, in particular with respect to the number of epochs. For the named-entity recognition task we ran four experiments comparing two different mixing strategies – uniform mixing ($\mu_{i,n}{=}1/S$) and error mixing ($\mu_{i,n}{=}k_{i,n}/k_n$) – each with two shard sizes – $S = 10$ and $S = 100$. Figure 6 plots the number of training errors per epoch for each strategy.

We can make a couple observations. First, the mixing strategy makes little difference. The reason being that the number of observed errors per epoch is roughly uniform across shards, making both strategies ultimately equivalent. The other observation is that increasing the number of shards can slow down convergence when viewed relative to epochs[3]. Again, this appears in contradiction to the analysis in Section 4.3, which, at least for the case of error weighted mixtures, implied that the number of epochs to convergence was independent of the number of shards. But that analysis was based on worst-case scenarios where a single error occurs on a single shard at each epoch, which is unlikely to occur in real world data. Instead, consider the uni-

[3] As opposed to raw wall-clock/CPU time, which benefits from faster epochs the more shards there are.

	Reg. Perceptron	Avg. Perceptron
	Unlabeled Attachment Score	Unlabeled Attachment Score
Serial (All Data)	81.3	84.7
Serial (Sub Sampling)	77.2	80.1
Parallel (Iterative Parameter Mix)	83.5	84.5

Figure 5: Dependency Parsing experiments. Upper figures plot test data unlabeled attachment score versus wall clock for both regular perceptron (left) and averaged perceptron (right). Lower table is unlabeled attachment score for converged models.

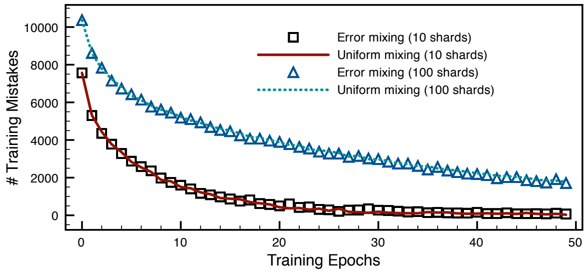

Figure 6: Training errors per epoch for different shard size and parameter mixing strategies.

form mixture case. Theorem 3 implies:

$$\sum_{n=1}^{N}\sum_{i=1}^{S}\frac{k_{i,n}}{S} \leq \frac{R^2}{\gamma^2} \quad\implies\quad \sum_{n=1}^{N}\sum_{i=1}^{S} k_{i,n} \leq S \times \frac{R^2}{\gamma^2}$$

Thus, for cases where training errors are uniformly distributed across shards, it is possible that, in the worst-case, convergence may slow proportional the the number of shards. This implies a trade-off between slower convergence and quicker epochs when selecting a large number of shards. In fact, we observed a tipping point for our experiments in which increasing the number of shards began to have an adverse effect on training times, which for the named-entity experiments occurred around 25-50 shards. This is both due to reasons described in this section as well as the added overhead of maintaining and summing multiple high-dimensional weight vectors after each distributed epoch.

It is worth pointing out that a linear term S in the convergence bound above is similar to convergence/regret bounds for asynchronous distributed online learning, which typically have bounds linear in the asynchronous delay (Mesterharm, 2005; Zinkevich et al., 2009). This delay will be on average roughly equal to the number of shards S.

6 Conclusions

In this paper we have investigated distributing the structured perceptron via simple parameter mixing strategies. Our analysis shows that an iterative parameter mixing strategy is both guaranteed to separate the data (if possible) and significantly reduces the time required to train high accuracy classifiers. However, there is a trade-off between increasing training times through distributed computation and slower convergence relative to the number of shards. Finally, we note that using similar proofs to those given in this paper, it is possible to provide theoretical guarantees for distributed online passive aggressive learning (Crammer et al., 2006), which is a form of large-margin perceptron learning. Unfortunately space limitations prevent exploration here.

Abstract

Many implementations of Latent Dirichlet Allocation (LDA), including those described in Blei et al. (2003), rely at some point on the removal of stopwords, words which are assumed to contribute little to the meaning of the text. This step is considered necessary because otherwise high-frequency words tend to end up scattered across many of the latent topics without much rhyme or reason. We show, however, that the 'problem' of high-frequency words can be dealt with more elegantly, and in a way that to our knowledge has not been considered in LDA, through the use of appropriate weighting schemes comparable to those sometimes used in Latent Semantic Indexing (LSI). Our proposed weighting methods not only make theoretical sense, but can also be shown to improve precision significantly on a non-trivial cross-language retrieval task.

1 Introduction

Latent Dirichlet Allocation (LDA) (Blei et al., 2003), like its more established competitors Latent Semantic Indexing (LSI) (Deerwester et al., 1990) and Probabilistic Latent Semantic Indexing (PLSI) (Hofmann, 1999), is a model which is applicable to the analysis of text corpora. It is claimed to differ from LSI in that LDA is a generative Bayesian model (Blei et al., 2003), although this may depend upon the manner in which one approaches LSI (see for example Chew et al. (2010)). In LDA as applied to text analysis, each document in the corpus is modeled as a mixture over an underlying set of topics, and each topic is modeled as a probability distribution over the terms in the vocabulary.

As the newest among the above-mentioned techniques, LDA is still in a relatively early stage of development. It is also sufficiently different from LSI, probably the most popular and well-known compression technique for information retrieval (IR), that many practitioners of LSI may perceive a 'barrier to entry' to LDA. This in turn perhaps explains why notions such as term weighting, which have been commonplace in LSI for some time (Dumais, 1991), have not yet found a place in LDA. In fact, it is often assumed that weighting is unnecessary in LDA. For example, Blei et al. (2003) contrast the use of tf-idf weighting in both non-reduced space (Salton and McGill, 1983) and LSI on the one hand with PLSI and LDA on the other, where no mention is made of weighting. Ramage et al. (2008) propose a simple term-frequency weighting scheme for tagged documents within the framework of LDA, although term weighting is not their focus and their scheme is intended to incorporate document tags into the same model that represents the documents themselves.

In this paper, we produce evidence that term weighting should be given consideration within LDA. First and foremost, this is shown empirically through a non-trivial multilingual retrieval task which has previously been used as the basis for tests of variants of LSI. We also show that term weighting allows one to avoid maintenance of stoplists, which can be awkward especially for multilingual data. With appropriate term weighting, high-frequency words (which might otherwise be eliminated as stopwords) are assigned naturally to topics

Human Language Technologies: The 2010 Annual Conference of the North American Chapter of the ACL, pages 465–473,
Los Angeles, California, June 2010. ©2010 Association for Computational Linguistics

by LDA, rather than dominating and being scattered across many topics as happens with the standard uniform weighting. Our approach belies the usually unstated, but widespread, assumption in papers on LDA that the removal of stopwords is a necessary pre-processing step (see e.g. Blei et al. (2003); Griffiths and Steyvers (2004)).

It might seem that to demonstrate this it would be necessary to perform a test that directly compares the results when stoplists are used to those when weighting are used. However, we believe that stopwords are highly ad-hoc to begin with. Assuming a vocabulary of n words and a stoplist of x items, there are (at least in theory) $\binom{n}{x}$ possible stoplists. To be sure that *no* stoplist improves on a particular term weighting scheme we would have to test every one of these. In addition, our tests are with a multilingual dataset, which raises the issue that a domain-appropriate stoplist for a particular corpus and language may not be available. This is even more true if we pre-process the dataset morphologically (for example, with stemming). Therefore, rather than attempting a direct comparison of this type, we take the position that it is possible to sidestep the need for stoplists and to do so in a non-ad-hoc way.

The paper is organized as follows. Section 2 describes the general framework of LDA, which has only very recently been applied to cross-language IR. In Section 3, we look at alternatives to the 'standard' uniform weighting scheme (i.e., lack of weighting scheme) commonly used in LDA. Section 4 discusses the framework we use for empirical testing of our hypothesis that a weighting scheme would be beneficial. We present the results of this comparison in Section 5 along with an impressionistic comparison of the output of the different alternatives. We conclude in Section 6.

2 Latent Dirichlet Allocation

Our IR framework is multilingual Latent Dirichlet Allocation (LDA), first proposed by Blei et al. (2003) as a general Bayesian framework with initial application to topic modeling. It is only very recently that variants of LDA have been applied to cross-language IR: examples are Cimiano et al. (2009) and Ni et al. (2009).

As an approach to topic modeling, LDA relies on the idea that the tokens in a document are drawn independently from a set of topics where each topic is a distribution over types (words) in the vocabulary. The mixing coefficients for topics within each document and weights for types in each topic can be specified *a priori* or learned from a training corpus. Blei et al. initially proposed a variational model (2003) for learning topics from data. Griffiths and Steyvers (2004) later developed a Markov chain Monte Carlo approach based on collapsed Gibbs sampling.

In this model, the mixing weights for topics within each document and the multinomial coefficients for terms within each topic are hidden (latent) and must be learned from a training corpus. Blei et al. (2003) proposed LDA as a general Bayesian framework and gave a variational model for learning topics from data. Griffiths and Steyvers (2004) subsequently developed a stochastic learning algorithm based on collapsed Gibbs sampling. In this paper we will focus on the Gibbs sampling approach.

2.1 Generative Document Model

The LDA algorithm models the D documents in a corpus as mixtures of K topics where each topic is in turn a distribution over W terms. Given $\boldsymbol{\theta}$, the matrix of mixing weights for topics within each document, and $\boldsymbol{\phi}$, the matrix of multinomial coefficients for each topic, we can use this formulation to describe a generative model for documents (Alg. 1).

Restating the LDA model in linear-algebraic terms, we can say that the product of $\boldsymbol{\phi}$ (the $K \times W$ column-stochastic topic-by-type matrix) and $\boldsymbol{\theta}$ (the $D \times K$ column-stochastic topic-by-document matrix) is the original $D \times W$ term-by-document matrix. In this sense, LDA computes a matrix factorization of the term-by-document matrix in the same way that LSI or non-negative matrix factorization (NMF) do. In fact, LDA is a special case of NMF, but unlike in NMF, there is a unique factorization in LDA. We see this as a feature recommending LDA above NMF.

Our objective is to reverse the generative model to learn the contents of $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ given a training corpus D, a number of topics K, and symmetric Dirichlet prior distributions over both $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ with hyperparameters α and β, respectively.

```
for $k = 1$ to $K$ do
  Draw $\phi^k \sim$ Dirichlet($\beta$)
end for
for $d = 1$ to $D$ do
  Draw $\theta \sim$ Dirichlet($\alpha$)
  Draw $N \sim$ Poisson($\xi$)
  for $i = 1$ to $N$ do
    Draw $z \sim$ Multinomial($\theta$)
    Draw $w \sim$ Multinomial($\phi^{(z)}$)
  end for
end for
```

Algorithm 1: Generative algorithm for LDA. This will generate D documents with N tokens each. Each token is drawn from one of K topics. The distributions over topics and terms have Dirichlet hyperparameters α and β respectively. The Poisson distribution over the token count may be replaced with any other convenient distribution.

2.2 Learning Topics via Collapsed Gibbs Sampling

Rather than learn $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ directly, we use collapsed Gibbs sampling (Geman et al. (1993), Chatterji and Pachter (2004)) to learn the latent assignment of tokens to topics **z** given the observed tokens **x**.

The algorithm operates by repeatedly sampling each z_{ij} from a distribution conditioned on the values of all other elements of **z**. This requires maintaining counts of tokens assigned to topics globally and within each document. We use the following notation for these sums:

N_{ijk}**:** Number of tokens of type w_i in document d_j assigned to topic k

N^{-st}_{ijk}**:** The sum N_{ijk} with the contribution of token x_{st} excluded

We indicate summation over all values of an index with $(\cdot)$.

Given the current state of **z** the conditional probability of z_{ij} is:

$$\begin{aligned} p(z_{ij} = k|\mathbf{z}^{-ij}, \mathbf{x}, d, \alpha, \beta) &= \\ p(x_{ij}|\phi^k) \quad p(k|d_j) \quad &\propto \\ \frac{N^{-ij}_{i(\cdot)k} + \beta}{N^{-ij}_{(\cdot)(\cdot)k} + W\beta} \; \frac{N^{-ij}_{(\cdot)jk} + \alpha}{N_{(\cdot)j(\cdot)} + T\alpha} & \end{aligned} \tag{1}$$

As Griffiths and Steyvers (2004) point out, this is an intuitive result. The first term, $p(x_{ij}|\phi^k)$, indicates the importance of term x_{ij} in topic k. The second term, $p(k|d_j)$, indicates the importance of topic k in document j. The sum of the terms is normalized implicitly to 1 when we draw each new z_{ij}.

We sample a new value for z_{ij} for every token x_{ij} during each iteration of Gibbs sampling. We run the sampler for a burn-in period of a few hundred iterations to allow it to reach its converged state and then estimate $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ from **z** as follows:

$$\theta_{jk} = \frac{N_{(\cdot)jk} + \alpha}{N_{(\cdot)j(\cdot)} + T\alpha} \tag{2}$$

$$\phi_{ki} = \frac{N_{i(\cdot)k} + \beta}{N_{(\cdot)(\cdot)k} + W\beta} \tag{3}$$

2.3 Classifying New Documents

In LSI, new documents not in the original training set can be ‘projected’ into the semantic space of the training set. The equivalent process in LDA is one of *classification*: given a corpus D' of one or more new documents we use the existing topics $\boldsymbol{\phi}$ to compute a maximum a posteriori estimate of the mixing coefficients $\boldsymbol{\theta}'$. This follows the same Monte Carlo process of repeatedly resampling a set of token-to-topic assignments **z′** for the tokens **x′** in the new documents. These new tokens are used to compute the first term $p(k|d_j)$ in Eq. 1. We re-use the topic assignments **z** from the training corpus to compute the second term $p(x_{ij}|\phi_k)$. Tokens with new types that were not present in the vocabulary of the training corpus do not participate in classification.

The resulting distribution $\boldsymbol{\theta}'$ essentially encodes how likely each new document is to relate to each of the K topics. We can use this matrix to compute pairwise similarities between any two documents from either corpus (training or newly-classified). Whereas in LSI it may make sense to compute similarity between documents using the cosine metric (since the ‘dimensions’ defining the space are orthogonal), we compute similarities in LDA using either the symmetrized Kullback-Leibler (KL) or Jensen-Shannon (JS) divergences (Kullback and Leibler (1951), Lin (2002)) since these are methods of measuring the similarity between probability distributions.

3 Term Weighting Schemes and LDA

The standard approach presented above assumes, effectively, that each token is equally important in calculating the conditional probabilities. From both an information-theoretic and a linguistic point of view, however, it is clear that this is not the case. In English, a term such as ‘the’ which occurs with high frequency in many documents does not contribute as much to the meaning of each document as a lower-frequency term such as ‘corpus’. It is an axiom of information theory that an event a’s information content (in bits) is equal to $\log_2 \frac{1}{p(a)} = -\log_2 p(a)$.

Treating tokens as events, we can say that the information content of a particular token of type t is $-\log_2 p(t)$. Furthermore, as is well-known, we can estimate $p(t)$ from observed frequencies in a corpus: it is simply the number of tokens of type t in the corpus, divided by the total number of tokens in the corpus. For high-probability terms such as ‘the’, therefore, $-\log_2 p(t)$ is low. Our basic hypothesis is that recalculating $p(z_{ij}|\mathbf{z}, \mathbf{x}, \alpha, \beta)$ to take the information content of each token into account will improve the results of LDA. Specifically, we have incorporated a weighting term into Eq. 1 by replacing the counts denoted N with weights denoted M.

$$p(z_{ij} = k|\mathbf{z}^{-ij}, \mathbf{x}, d, \alpha, \beta) \propto \frac{M_{i(\cdot)k}^{-ij} + \beta}{M_{(\cdot)(\cdot)k}^{-ij} + W\beta} \frac{M_{(\cdot)jk}^{-ij} + \alpha}{M_{(\cdot)j(\cdot)} + T\alpha} \tag{4}$$

Here M_{ijk} is the total *weight* of tokens of type i in document j assigned to topic k instead of the total *number* of tokens. All of the machinery for Gibbs sampling and the estimation of $\boldsymbol{\theta}$ and $\boldsymbol{\phi}$ from $\mathbf{z}$ remains unchanged.

We appeal to an urn model to explain the intuition behind this approach. In the original LDA formulation, each topic ϕ can be modeled as an urn containing a large number of balls of uniform size. Each ball assumes one of W different colors (one color for each term in the vocabulary). The frequency of occurrence of each color in the urn is proportional to the corresponding term’s weight in topic ϕ. We incorporate a term weighting scheme by making the size of each ball proportional to the weight of its corresponding term. This makes the probability of drawing the ball for a term w proportional to both the term weight $m(w)$ and its multinomial weight ϕ^w:

$$p(w|\phi, \beta, m) = \frac{\phi^w \, m(w)}{\sum_{w \in W} m(w)} \tag{5}$$

We can now expand Eq. 4 to obtain a new sampling equation for use with the Gibbs sampler.

$$p(z_{ij} = k|\mathbf{z}^{-ij}, \mathbf{x}, \mathbf{d}, m, \alpha, \beta) = \frac{m(x_i) N_{i(\cdot)k}^{-ij} + \beta}{\sum_w m(w) N_{w(\cdot)k}^{-ij} + W\beta} \frac{\sum_w m(w) N_{wjk}^{-ij} + \alpha}{\sum_w m(w) N_{wj(\cdot)} + T\alpha} \tag{6}$$

If all weights $m(w) = 1$ this reduces immediately to the standard LDA formulation in Eq. 1.

The information measure we describe above is constant for a particular term across the entire corpus, but it is possible to conceive of other, more sophisticated weighting schemes as well, for example those where term weights vary by document. Pointwise mutual information (PMI) is one such weighting scheme which has a solid basis in information theory and has been shown to work well in the context of LSI (Chew et al., 2010). According to PMI, the weight of a given term w in a given document d is the pointwise mutual information of the term and document, or $-\log_2 \frac{p(w|d)}{p(w)}$. Extending the LDA model to accommodate PMI is straightforward. We replace $m(x_i)$ and $m(w)$ in Eq. 4 with $m(x_i, d)$ as follows.

$$\begin{aligned} m(x_i, d) &= -\log_2 \frac{p(x_i|d)}{p(x_i)} \\ &= -\log_2 \frac{\#[\text{tokens of type } x_i \text{ in } d]}{\#[\text{tokens of type } x_i]} \end{aligned} \tag{7}$$

It is possible for PMI of a term within a document to be negative. When this happens, we clamp the weight of the offending term to zero in that document. In practice, we observe this only with common words (e.g. ‘and’, ‘in’, ‘of’, ‘that’, ‘the’ and ‘to’ in English) that are assigned very low weight everywhere else in the corpus. This clamping does not noticeably affect the results.

In the next sections, we describe tests which have enabled us to evaluate empirically which of these formulations works best in practice.

4 Testing Framework

In this paper, we chose to test our hypotheses with the same cross-language retrieval task used in a number of previous studies of LSI (e.g. Chew and Abdelali (2007)). Briefly, the task is to train an IR model on one particular multilingual corpus, then deploy it on a separate multilingual corpus, using a document in one language to retrieve related documents in other languages. This task is difficult because of the size of the datasets involved. Its usefulness becomes apparent when we consider the following two use cases: a human wishing (1) to use a search engine to retrieve relevant documents in many languages regardless of the language in which the query is posed; or (2) to produce a clustering or visualization of documents according to their topics even when the documents are in different languages.

The training corpus consists of the text of the Bible in 31,226 parallel chunks, corresponding generally to verses, in Arabic, English, French, Russian and Spanish. These data were obtained from the Unbound Bible project (Biola University (2006)). The test data, obtained from `http://www.kuran.gen.tr/`, is the text of the Quran in the same 5 languages, in 114 parallel chunks corresponding to suras (chapters). The task, in short, is to use the training data to inform whatever linguistic, semantic, or statistical model is being tested, and then to infer characteristics of the test data in such a way that the test documents can automatically be matched with their translations in other languages. Though the documents come from a specific domain (scriptural texts), what is of interest is comparative results using different weighting schemes, holding the datasets and other settings constant. The training and test datasets are large enough to allow statistically significant observations to be made, and if a significant difference is observed between experiments using two settings, it is to be expected that similar basic differences would be observed with any other set of training and test data. In any case, it should be noted that the Bible and Quran were written centuries apart, and in different original languages; we believe this contributes to a clean separation of training and test data, and makes for a non-trivial retrieval task.

In our framework, a term-by-document matrix is formed from the Bible as a parallel verse-aligned corpus. We employed two different approaches to tokenization, one (word-based tokenization) in which text was tokenized at every non-word character, and the other (unsupervised morpheme-based tokenization) in which after word-based tokenization, a further pre-processing step (based on Goldsmith (2001)) was performed to add extra breaks at every morpheme. It is shown elsewhere (Chew et al., 2010) that this step leads to improved performance with LSI. In each verse, all languages are concatenated together, allowing terms (either morphemes or words) from all languages to be represented in every verse. Cross-language homographs such as 'mien' in English and French are treated as distinct terms in our framework. Thus, if there are L languages, D documents (each of which is translated into each of the L languages), and W distinct linguistic terms across all languages, then the term-by-document matrix is of dimensions W by D (not W by $D \times L$); with the Bible as a training corpus, the actual numbers in our case are 160,345 × 31,226. As described in Sec. 2.2, we use this matrix as the input to a collapsed Gibbs sampling algorithm to learn the latent assignment of tokens in all five languages to language-independent topics, as well as the latent assignment of language-independent topics to the multilingual (parallel) documents. In general, we specified, arbitrarily but consistently across all tests, that the number of topics to be learned should be 200. Other parameters for the Gibbs sampler held constant were the number of iterations for burn-in (200) and the number of iterations for sampling (1).

To evaluate our different approaches to weighting, we use classification as described in Sec. 2.3 to obtain, for each document from the Quran test corpus, a probability distribution across the topics learned from the Bible. While in training we have D multilingual documents, in testing we have $D' \times L$ documents, each in a specific language, for which a distribution is computed. For the Quran data, this amounts to 114 × 5 = 570 documents. This is because our goal is to match documents with their translations in other languages using just the probability distributions. For each source-language/target-language pair L_1 and L_2, we obtain the similarity of each of the 114 documents in L_1 to each of the 114 documents in L_2. We found that similarity here is best computed using the Jensen-Shannon divergence

	Tokenization	
Weighting Scheme	Word	Morpheme
Unweighted	0.505	0.544
$\log p(w\|L)$	0.616	0.641
PMI	0.612	**0.686**

Table 1: Summary of comparison results. This table shows the average precision at one document (P1) for each of the tokenization and weighting schemes we evaluated. Detailed results are presented in Table 2.

(Lin, 2002) and so this measure was used in all tests. Ultimately, the measure of how well a particular method performs is average precision at 1 document (P1). Among the various measurements for evaluating the performance of IR systems (Salton and McGill (1983), van Rijsbergen (1979)), this is a fairly standard measure. For a particular source-target pair, this is the percentage (out of 114 cases) where a document in L_1 is most similar to its mate in L_2. With 5 languages, there are 25 source-target pairs, and we can also calculate average P1 across all language pairs. Here, we average across 114 × 25 (or 2,850) cases. This is why even small differences in P1 can be statistically significant.

5 Results

First, we present a summary of our results in Table 1 which clearly demonstrates that it is better in LDA to use some kind of weighting scheme rather than the uniform weights in the standard LDA formulation from Eq. 1. This is true whether tokenization is by word or by morpheme. All increases from the baseline precision at 1 document (0.505 and 0.544 respectively), whether under log or PMI weighting, are highly significant (p $< 10^{-11}$). Furthermore, all increases in precision when moving from word-based to morphology-based tokenization are also highly significant (p $< 5 \times 10^{-5}$ without weighting, p $< 5 \times 10^{-3}$ with log-weighting, and p $< 2 \times 10^{-15}$ with PMI weighting). The best result overall, where P1 is 0.686, is obtained with morphological tokenization and PMI weighting (parallel to the results in (Chew et al., 2010) with LSI), and again the difference between this result and its nearest competitor of 0.641 is highly significant (p $< 3 \times 10^{-6}$). We return to comment below on lack of an increase in P1 when moving from log-weighting to PMI-weighting under word-based tokenization.

These results can also be broken out by language pair, as shown in Table 2. Here, it is apparent that Arabic, and to a lesser extent Russian, are harder languages in the IR problem at hand. Our intuition is that this is connected with the fact that these two languages have a more complex morphological structure: words are formed by a process of agglutination. A consequence of this is that single Arabic and Russian tokens can less frequently be mapped to single tokens in other languages, which appears to "confuse" LDA (and also, as we have found, LSI). The complex morphology of Russian and Arabic is also reflected in the type-token ratios for each language: in our English Bible, there are 12,335 types (unique words) and 789,744 tokens, a type-token ratio of 0.0156. The ratios for French, Spanish, Russian and Arabic are 0.0251, 0.0404, 0.0843 and 0.1256 respectively. Though the differences may not be explicable in purely statistical terms (there may be linguistic factors at play which cannot be reduced to statistics), it seems plausible that choosing a suboptimal term-weighting scheme could exacerbate any intrinsic problems of statistical imbalance. Considering this, it is interesting to note that the greatest gains, when moving from unweighted LDA to either form of weighted LDA, are often to be found where Russian and/or Arabic are involved. This, to us, shows the value of using a multilingual dataset as a testbed for our different formulations of LDA: it allows problems which may not be apparent when working with a monolingual dataset to come more easily to light.

We have mentioned that the best results are with PMI and morphological tokenization, and also that there is an increase in precision for many language of the pairs when morphological (as opposed to word-based) tokenization is employed. To us, the results leave little doubt that both weighting and morphological tokenization are independently beneficial. It appears, though, that morphology and weighting are also complementary and synergistic strategies for improving the results of LDA: for example, a suboptimal approach in tokenization may at best place an upper bound on the overall precision achievable, and perhaps at worst undo the benefits of a good weighting scheme. This may explain the one apparently anomalous result, which is the lack of an increase in

Table 2: Full results for precision at one document for all combinations of LDA, Log-WLDA, PMI-WLDA, word tokenization and morphological tokenization.

precision moving from log-WLDA to PMI-WLDA under word-based tokenization: if word-based tokenization is suboptimal, PMI weighting cannot compensate for that. Effectively, for best results, the right strategies have to be pursued with respect *both* to morphology *and* to weighting.

Finally, we can illustrate the differences between weighted and unweighted LDA in another way. As discussed earlier, each topic in LDA is a probability distribution over terms. For each topic, we can list the most probable terms in decreasing order of probability; this gives a sense of what each topic is 'about' and whether the groupings of terms appear reasonable. Since we use 200 topics, an exhaustive listing is impractical here, but in Table 3 we present some representative examples from unweighted LDA and PMI-WLDA that we judged to be of interest. It appears to us that the groupings are not perfect under either LDA or PMI-WLDA; under both methods, we find examples of rather heterogeneous topics, whereas we would like each topic to be semantically focused. Still, a comparison of the output with LDA and PMI-WLDA sheds some light on why PMI-WLDA makes it less necessary to remove stopwords. Note that all words listed for the top two topics under LDA would commonly be considered stopwords. This might also be true of the words in topic 1 for PMI-WLDA, but in the latter case, the topic is actually one of the most semantically focused in that the top words have a clear semantic connection to one another. This cannot be said of topics 1 and 2 in LDA. For one thing, many of the same terms that appear in topic 1 reappear in topic 2, making the two topics hard to distinguish from one another. Secondly, the terms have only a loose semantic connection to one another: 'the', 'and', and 'of' are all high-frequency and likely to co-occur, but they are different parts of speech and have very different functions in English. One might say that topics 1 and 2 in LDA are a rag-bag of high-frequency words, and it is unsurprising that these topics do little to help characterize documents in our cross-language IR task. The same cannot be said of any of the top 5 topics in PMI-WLDA. We believe this illustrates well, and at a fundamental level, why weighted forms of LDA work better in practice than unweighted LDA.

6 Conclusion

We have conducted a series of experiments to evaluate the effect of different weighting schemes on Latent Dirichlet Allocation. Our results demonstrate, perhaps contrary to the conventional wisdom that weighting is unnecessary in LDA, that weighting schemes (and other pre-processing strategies) simi-

lar to those commonly employed in other approaches to IR (such as LSI) can significantly improve the performance of a system. Our approach also runs counter to the standard position in LDA that it is necessary or desirable to remove stopwords as a preprocessing step, and we have presented an alternative approach of applying an appropriate weighting scheme within LDA. This approach is preferable because it is considerably less ad-hoc than the construction of stoplists. We have shown mathematically how alternative weighting schemes can be incorporated into the Gibbs sampling model. We have also demonstrated that, far from being arbitrary, the introduction of weighting into the LDA model has a solid and rational basis in information and probability theory, just as the basic LDA model itself has.

In future work, we would like to explore further enhancements to weighting in LDA. There are many variants which can be considered: one example is the incorporation of word order and context through an n-gram model based on conditional probabilities. We also aim to evaluate LDA against LSI with a view to establishing whether one can be said to outperform the other consistently in terms of precision, with appropriate settings held constant. Finally, we would like to determine whether other techniques which have been shown to benefit LSI can also be usefully brought to bear in LDA, just as we have shown here in the case of term weighting.

Abstract

The goal of this work is to integrate query similarity metrics as features into a dense model that can be trained on large amounts of query log data, in order to rank query rewrites. We propose features that incorporate various notions of syntactic and semantic similarity in a generalized edit distance framework. We use the implicit feedback of user clicks on search results as weak labels in training linear ranking models on large data sets. We optimize different ranking objectives in a stochastic gradient descent framework. Our experiments show that a pairwise SVM ranker trained on multipartite rank levels outperforms other pairwise and listwise ranking methods under a variety of evaluation metrics.

1 Introduction

Measures of query similarity are used for a wide range of web search applications, including query expansion, query suggestions, or listings of related queries. Several recent approaches deploy user query logs to learn query similarities. One set of approaches focuses on user reformulations of queries that differ only in one phrase, e.g., Jones et al. (2006). Such phrases are then identified as candidate expansion terms, and filtered by various signals such as co-occurrence in similar sessions, or log-likelihood ratio of original and expansion phrase. Other approaches focus on the relation of queries and search results, either by clustering queries based on their search results, e.g., Beeferman and Berger (2000), or by deploying the graph of queries and results to find related queries, e.g., Sahami and Heilman (2006).

The approach closest to ours is that of Jones et al. (2006). Similar to their approach, we create a training set of candidate query rewrites from user query logs, and use it to train learners. While the dataset used in Jones et al. (2006) is in the order of a few thousand query-rewrite pairs, our dataset comprises around 1 billion query-rewrite pairs. Clearly, manual labeling of rewrite quality is not feasible for our dataset, and perhaps not even desirable. Instead, our intent is to learn from large amounts of user query log data. Such data permit to learn smooth models because of the effectiveness of large data sets to capture even rare aspects of language, and they also are available as *in the wild*, i.e., they reflect the actual input-output behaviour that we seek to automate (Halevy et al., 2009). We propose a technique to automatically create weak labels from co-click information in user query logs of search engines. The central idea is that two queries are related if they lead to user clicks on the same documents for a large amount of documents. A manual evaluation of a small subset showed that a determination of positive versus negative rewrites by thresholding the number of co-clicks correlates well with human judgements of similarity, thus justifying our method of eliciting labels from co-clicks.

Similar to Jones et al. (2006), the features of our models are not based on word identities, but instead on general string similarity metrics. This leads to dense rather than sparse feature spaces. The dif-

ference of our approach to Jones et al. (2006) lies in our particular choice of string similarity metrics. While Jones et al. (2006) deploy "syntactic" features such as Levenshtein distance, and "semantic" features such as log-likelihood ratio or mutual information, we combine syntactic and semantic aspects into generalized edit-distance features where the cost of each edit operation is weighted by various term probability models.

Lastly, the learners used in our approach are applicable to very large datasets by an integration of linear ranking models into a stochastic gradient descent framework for optimization. We compare several linear ranking models, including a log-linear probability model for bipartite ranking, and pairwise and listwise SVM rankers. We show in an experimental evaluation that a pairwise SVM ranker trained on multipartite rank levels outperforms state-of-the-art pairwise and listwise ranking methods under a variety of evaluation metrics.

2 Query Similarity Measures

2.1 Semantic measures

In several of the similarity measures we describe below, we employ *pointwise mutual information* (PMI) as a measure of the association between two terms or queries. Let w_i and w_j be two strings that we want to measure the amount of association between. Let $\mathrm{p}(w_i)$ and $\mathrm{p}(w_j)$ be the probability of observing w_i and w_j in a given model; e.g., relative frequencies estimated from occurrence counts in a corpus. We also define $\mathrm{p}(w_i, w_j)$ as the joint probability of w_i and w_j; i.e., the probability of the two strings occurring together. We define PMI as follows:

$$\mathrm{PMI}(w_i, w_j) = \log \frac{\mathrm{p}(w_i, w_j)}{\mathrm{p}(w_i)\mathrm{p}(w_j)}. \qquad (1)$$
