WEXEA: Wikipedia EXhaustive Entity Annotation

Michael Strobl, Amine Trabelsi, Osmar R. Zaïane

University of Alberta, Edmonton, Canada

Abstract

Building predictive models for information extraction from text, such as named entity recognition or the extraction of semantic relationships between named entities in text, requires a large corpus of annotated text. Wikipedia is often used as a corpus for these tasks where the annotation is a named entity linked by a hyperlink to its article. However, editors on Wikipedia are only expected to link these mentions in order to help the reader to understand the content, but are discouraged from adding links that do not add any benefit for understanding an article. Therefore, many mentions of popular entities (such as countries or popular events in history), or previously linked articles, as well as the article's entity itself, are not linked. In this paper, we discuss WEXEA, a Wikipedia EXhaustive Entity Annotation system, to create a text corpus based on Wikipedia with exhaustive annotations of entity mentions, i.e. linking all mentions of entities to their corresponding articles. This results in a huge potential for additional annotations that can be used for downstream NLP tasks, such as Relation Extraction. We show that our annotations are useful for creating distantly supervised datasets for this task. Furthermore, we publish all code necessary to derive a corpus from a raw Wikipedia dump, so that it can be reproduced by everyone.

Keywords: Wikipedia, Knowledge Graphs, Relation Extraction, Information Extraction, Annotated Data, Distant Supervision

1. Introduction

Understanding factual knowledge from text data is a crucial skill towards mastering several high-level NLP tasks, such as Response Generation for conversational agents (Logan et al., 2019) or Question Answering (Yih et al., 2015). Elements of factual knowledge can include the following items:

- What are the entities in context?

- What is happening? Typically an event about how entities are interacting with or related to each other or what they are doing. ("John married Lisa", "John was born in New York City")

- When is this happening? Events have a timestamp or a period of time is attached. ("John was born on November 11th, 1976")

Apart from these three elements, text can also contain other numerical data, e.g. quantities with units, that express something of interest and are not just a sequence of distinct words as usually assumed in Language Modeling.
In order to achieve the task of extracting factual knowledge from text or conversations, several subtasks have to be mastered (either pipelined or in an end-to-end fashion):

1. Entity Recognition (ER) (Lample et al., 2016): Typically formulated as Named Entity Recognition (NER) task aiming to find all named entities in text. Different tagging schemes are possible, although the most common scheme is the CoNLL-2003 scheme (Sang and De Meulder, 2003) with 4 classes: Person, Organization, Location and Miscellaneous (entities that are related to entities from other classes, e.g. events).

2. Entity Linking (EL) (Sil et al., 2018): Linking known entities to unique identifiers in a Knowledge Graph (KG), such as Wikipedia[1].

3. Co-reference Resolution (CR) (Lee et al., 2018): Finding mentions of entities in text that refer to named entities, such as *he*, *she*, *it* or *the company*, *the prince*.

4. Relation Extraction (RE) (Takanobu et al., 2019): Finding interactions between entities either using a fixed set of relations or words from text. For example, potential relations to extract include family relations, such as *spouse* or *son_of*.

5. Creating a Knowledge Graph (KG): Assuming every entity has a unique identifier attached (either from a known KG or internally), a graph can be created using the KG identifiers and the extracted relations connecting them, using, for example, the Resource Description Framework (RDF)[2].

Once created, the KG can be used for downstream tasks, such as fact-aware language modeling (Logan et al., 2019). However, corpora with labeled data including all of the aforementioned subtasks are hard to come by since manual annotation of entities (with KG identifiers, if available), co-references and their relations to each other, is time-consuming, and therefore only limited amounts of data exist. Typically, the higher level the task is, the less data is available.
Our goal in this paper is to present WEXEA, Wikipedia EXhaustive Entity Annotation, a system aiming to create a large annotated corpus based on Wikipedia, which already contains millions of annotations (i.e. mentions in text, linked to their article name in Wikipedia) created by humans. We show that many more can be extracted to increase the number of annotations per entity. This is crucial for tasks such as RE, in which more context for specific entities is desirable in order to create a KG with as much knowledge about an entity as possible. We are applying an extensive set of rules in order to create more annotations through finding co-references of already annotated entities

---

[1] https://www.wikipedia.org/

[2] https://www.w3.org/RDF/

as well as finding entities that are not linked or do not exist in Wikipedia. If conflicts appear (several entity candidates for a single mention), we use a modified version of existing neural-network-based Entity Linker for linking these mentions to their Wikipedia articles.

The corpus created with WEXEA can later be used in order to extract datasets for RE using Distant Supervision (DS) (Bunescu and Mooney, 2007; Mintz et al., 2009).

Our research contributions consist of:

- devising a new approach to exhaustively annotate all mentions in Wikipedia to create an annotated text corpus that can be more useful in downstream tasks, than solely relying on already existing links or using an NER and EL to find and link more mentions, which introduces unnecessary errors;

- highlighting the usefulness of our approach for the task of creating datasets for RE using DS. Many more sentences, for more relations, can be extracted, following our approach, than using a basic Wikipedia-based corpus without additional annotations;

- providing a publicly available code base[3] of WEXEA. Whenever a new dump is released, a newly updated corpus can be created.

It is possible to apply WEXEA to Wikipedia for all languages since only minimal language-dependent assumptions are made (only regarding frequent words starting English sentences). However, we only show the creation of such a corpus based on the English version of Wikipedia.

The remainder of this article is organized as follows. In Section 2., Wikipedia and related statistics are presented. In Section 3., we present related work, including similar corpora based on the English Wikipedia. Section 4. describes WEXEA and the steps necessary to create an annotated corpus. In Section 5., we report experimental results indicating why this corpus can be useful to the community. Section 6. concludes the paper and introduces potential future work.

2. Wikipedia

Wikipedia is a free encyclopedia that exists for 307 languages[4] of varying content size. Table 2 shows statistics about the 10 largest versions (the Swedish and Cebuano Wikipedias were largely created by a bot[5]). Although Wikipedia exists for 307 languages, only $\approx$ 5% of all Wikipedias contain more than 1,000,000 articles and $\approx$ 37% contain only 1,000 to 9,999 articles. Nevertheless, Wikipedia is a Knowledge Base of impressive size with almost 6 million articles in the English version. This leads to a huge potential for NLP research, as shown by Ghaddar and Langlais (2017) for NER.

Wikipedia contains many more pages than articles, such as redirect or disambiguation pages as seen in Table 3. In the following, we explain certain features of Wikipedia and the annotation scheme proposed for editors, which we deem important for a proper understanding of our approach:

10+	0
1+	8
0	2

Table 2: Distribution of number of articles and language versions.

- Redirect pages: Wikipedia contains many redirect pages, e.g. *NYC* or *The City of New York* referring to the article of *New York City*. Editors can create these pages through adding alternative names for an article or they are created automatically, e.g. in case the name of an article changes and therefore broken links can be avoided through creating a redirect page.

- Disambiguation pages: Wikipedia contains many disambiguation pages, which are similar to redirect pages, except they deal with mentions that are knowingly referring to several different articles. For example, the disambiguation page of *New York*[6] refers to a whole list of articles including the city, state and many sports clubs located in New York City or the state of New York.

- Typically, entities are only linked once in an article when they are mentioned first. Subsequent mentions should not be linked anymore.[7] In addition, pages do not contain links to themselves, e.g. there is no link to

Disambiguations (geo)	38,507
Disambiguations (human)	59,988

Table 3: Number of important pages other than articles.

the article of *Barack Obama* within itself, although he is mentioned in there many times.

- Links can consist of two parts: (1) The article name that the link refers to (mandatory), and (2) an alias for that article since it is not always convenient to include the linked article's full name. This could look like the following link (following the linking scheme of Wikipedia): *[[Barack Obama|Obama]]*, resulting in a hyperlink with anchor text *Obama*, linking to article *Barack Obama*.

- Links, in general, should help the reader to understand the article and therefore should only be added if helpful (over-linking is to be avoided). This also means that articles, most readers are familiar with, such as countries, locations, languages, etc., are typically not linked.

Wikipedia's linking scheme aims for the best readability, but in order to be useful for NLP tasks, more annotations can be beneficial and we show in this article that it is possible to add more annotations automatically. Therefore, WEXEA aims for an exhaustively annotated corpus, based on Wikipedia. By exhaustively annotated we mean that all mentions of entities, whether or not they have an article in Wikipedia, and their co-references, are annotated.

3. Background and Related Work

There are two main lines of previous work that are important to our method: (1) Datasets with annotations similar to ours (mostly for NER) and (2) semi-automatically extracted datasets for Relation Extraction (RE) using Distant Supervision (DS). Both are described below.

3.1. Wikipedia Annotated Corpora for NER

In (Nothman et al., 2008), entities in Wikipedia are classified into one of the CoNLL-2003 classes, i.e. Person, Organization, Location or Miscellaneous, in order to create a large annotated corpus based on the English Wikipedia. Already linked entities are classified and additional links are identified through the use of 3 different rules:

1. The title of an article and all redirects are used to find more links of this article.

2. If article A is of type PER, the first and last word are considered as alternative title for article A.

3. The text of all links linking to article A is used as alternative title as well.

Their work is based on a 2008 Wikipedia dump. Co-references such as *he* or *she* or others that can be used to refer to certain entities are not considered, if not already in Wikipedia (typically it is not the case).

Ghaddar and Langlais (2017) created the WiNER corpus and follow a similar approach using a 2013 Wikipedia dump. Their annotation pipeline mainly follows the one of (Nothman et al., 2008), although conflicts (certain words may refer to multiple entities) are resolved through linking such a mention to the closest already linked article before or after. While easy to implement, this rule does not hold in general.

The resulting corpora of both systems are evaluated using common NER approaches and corpora, and showed a slightly better result than training an NER system on other typically smaller datasets. Even though both datasets are publicly available, classifying entities into one of the 4 CoNLL-2003 classes introduces errors. Moreover, the original annotations are removed and cannot be obtained anymore. This removes valuable information, e.g. for creating distantly supervised RE corpora or training CR systems, since it is not clear which annotation refers to which Wikipedia article.

The closest to our approach is the work of Klang and Nugues (2018). It uses an Entity Linking (EL) system with a pruning strategy based on link counts in order to keep the number of candidates per mention low (after running a mention detection algorithm). It also uses PageRank (Brin and Page, 1998) combined with a neural network classifier to link mentions to their Wikipedia articles. Furthermore, articles with all linked mentions are indexed and visualized online.[8] The authors did not publish the code, and the data is not downloadable, to work with it offline. Therefore, it is not possible to compare against this approach. In addition to that, co-references are not resolved.

Another similar but smaller dataset is the *Linked WikiText-2* dataset from (Logan et al., 2019), which is publicly available[9]. It consists of only 720 articles (600 train, 60 dev, 60 test). It was created using a neural EL system (Gupta et al., 2017) and a CR system (Manning et al., 2014) to generate additional annotations to the ones given by the editors of the articles. However, using automatic tools introduce additional errors, especially since both tools are trained on non-annotated data. Conversely, Wikipedia can be considered as partially annotated data, and therefore it would certainly be beneficial to consider these annotations, as our work and others in the literature suggest (Nothman et al., 2008; Ghaddar and Langlais, 2017). The main issue with using an Entity Linker in such an unrestricted way is that it tries to link all mentions of entities, regardless of whether they have an article in Wikipedia or not.

3.2. Distant Supervision

Another line of work, relevant to ours, is extracting datasets from large text corpora for RE using Distant Supervision (DS), a boostraping method that uses an existing knowledge graph and a corpus of text to label sentences with relations. Due to the lack of large datasets with entities as well as their relations annotated, Mintz et al. (2009) proposed to link entities in text corpora to their corresponding entries in a KG, e.g. Freebase (Bollacker et al., 2008), and whenever two entities that are linked in the KG appear in the same sentence, this sentence is considered as expressing this relationship in some ways. They created a dataset with 10,000 instances and 102 Freebase relations using Wikipedia, although entities are tagged with an NER and existing anno-

---

[8] `http://vilde.cs.lth.se:9001/en-hedwig/` for the English Wikipedia.
[9] `https://rloganiv.github.io/linked-wikitext-2`

tations are ignored. The reported human-evaluated precision of the extracted instances is 67.7%. Using Wikipedia annotations may help here, instead of relying on an NER. Riedel et al. (2010), follow a similar approach, except that their assumption is slightly different. Instead of assuming every sentence expresses a certain relation, they hypothesized that given a set of sentences mentioning two specific entities, at least one of them expresses the relation of interest. They created an RE corpus based on the New York Times Annotated Corpus[10] with 430 Freebase relations. However, they run a manual inspection on a dataset based on Wikipedia as well as the New York Times corpus comparing the number of violations of the distant supervision assumption on three relations and found that it is a lot less often violated in Wikipedia ($\approx 31\%$ vs. $\approx 13\%$). This indicates that Wikipedia can indeed provide DS data for RE systems and high-quality annotations presumably lead to better extractions. As we show in Section 5., WEXEA is capable of extracting many more relevant sentences than only using Wikipedia without additional annotations.

4. Method

In this section we present WEXEA, which annotates as many mentions as possible in Wikipedia articles.

In order to illustrate the problem that our approach aims to solve, consider the following sentence from *Tony Hawk*'s Wikipedia article[11] (original annotations in blue):

> "Tony Hawk was born on May 12, 1968 in **San Diego, California** to Nancy and Frank Peter Rupert Hawk, and was raised in San Diego."

Apart from the entity "San Diego, California", a few other non-annotated mentions of entities appear in this sentence: (1) *Tony Hawk*, the entity of the current article, (2) his parents *Nancy Hawk* and *Frank Peter Rupert Hawk* (both currently not in Wikipedia), as well as (3) another mention of *San Diego, California*. Therefore, if correctly annotated, this sentence includes 5 mentions of entities, although only a single one is already annotated.

In general, editors should avoid to link mentions if they refer to entities that were already linked before or if they refer to very popular entities, and linking them would not contribute to understanding the meaning of a sentence[12]. However, WEXEA aims to exhaustively annotate all mentions in Wikipedia in order to create an annotated text corpus that can be more useful in downstream tasks, than solely relying on already existing links or using an NER and EL to find and link more mentions, which introduces unnecessary errors.

In order to achieve this task, it can be broken down into several subtasks, including (1) dictionary generations for linking mentions to articles, (2) initial annotations, (3) coreference resolution and (4) candidate conflict resolution, which are described below.

4.1. Dictionary Creation

We are focusing only on Named Entities (similar to (Ghaddar and Langlais, 2017)) and therefore we only keep entities and their articles that typically start with a capital letter (considering the most frequent anchor text of incoming links of an article).

The first step of our approach is to create the following dictionaries that help with the initial Mention Detection (MD) and EL, considering the hyperlinks that are added by the editors of the article:

- Redirects dictionary: Wikipedia contains many redirect pages, e.g. *NYC*[13] or *The City of New York*[14] referring to the article of *New York City*. These redirects are useful alternative titles that, presumably, solely refer to a certain entity (otherwise it would not be a redirect page, it could be a disambiguation page instead if several candidate articles are possible). Redirect pages can be either created by an editor to provide alternative titles or they are created automatically in case the title of an article changes.[15]

- Alias dictionary: This is another dictionary containing alternative names for articles, created through collecting anchor texts of hyperlinks referring to an article, e.g. *U.S.* and *USA* are both included in the alias dictionary since they appear in other Wikipedia articles linking to the article of the *United States*. Overlaps with the redirects dictionary are possible, but typically the alias dictionary contains more ambiguous aliases, e.g. *New York* referring to the articles *New York City*, *New York (state)* and many more. We only keep aliases that start with a capital letter, since only these can refer to Named Entities, and we ignore alias-entity links that only appear once in Wikipedia, since these are often not meaningful and can introduce unnecessary errors.

- Disambiguation page dictionaries: Wikipedia contains many disambiguation pages, which are similar to redirect pages, except they deal with mentions that knowingly refer to several different articles, e.g. the disambiguation page *New York* refers to a whole list of articles including the city, state and many sports clubs located in New York City or the state of New York. Often, these disambiguation pages have a certain type attached, mainly *human*[16] for persons or *geo*[17] for geopolitical entities. In case the page contains several types of entities, such as "New York", it typically does not fall under one of these two categories. However, if it does, at least we can infer that the mention type is

---

[15]https://en.wikipedia.org/wiki/Wikipedia:Redirect
[16]https://en.wikipedia.org/wiki/Template:Human_name_disambiguation
[17]https://en.wikipedia.org/wiki/Template:Place_name_disambiguation

person or geopolitical entity, even if we cannot link it to a specific article.

- We are ignoring stub articles[18], which are articles that are very short and do not contain a lot of information. Usually, these are articles that are just started, but none of the editors has taken a closer look into it, and therefore the expected quality could be lower than the more popular and longer articles.

- Frequent sentence starter words: We collected a list of frequent sentence starter words that should not be considered for starting a mention at the beginning of a sentence, similarly to (Nothman et al., 2008). We used the PUNKT sentence tokenizer (Kiss and Strunk, 2006) from the NLTK Python package (Bird et al., 2009) in order to tokenize each article and collect the most frequent sentence starter words. We ended up with a list of 1760 words that, if starting a sentence and are not part of a multi-word mention, should not be considered as entity mention that should be linked to an article.

- We compiled a list of persons from the Yago KG (Mahdisoltani et al., 2015) in order to figure out whether an article refers to a person, in which case the first and last word of the name can be also considered as alternative name for that person, again, as done in (Nothman et al., 2008).

- Often very popular entities, such as countries or certain events (e.g. "World War II") are mentioned in text without being linked. In order to link these mentions with high confidence we kept a dictionary of the 10,000 most popular articles (regarding the number of incoming hyperlinks found in all of Wikipedia) that can be linked to mentions, without being linked in the text at all.

- Wikipedia contains many articles about given names. We collect all articles for this dictionary through looking for the categories "Given names", "Masculine given names" or "Feminine given names".

4.2. Direct Mention Annotations

We apply a relatively extensive set of rules in order to annotate mentions in Wikipedia articles, compared to just 3 or 4 as done in (Ghaddar and Langlais, 2017) or (Nothman et al., 2008). Apart from keeping the links corresponding to articles mostly starting with capital letters, we are detecting new potential mentions of articles using the following rules (applied to text between already annotated mentions):

1. The first line of an article often contains mentions of the article entity in **bold**, representing alternative names and are therefore annotated with the article entity.

2. At any time throughout processing an article, we are keeping an alias dictionary of alternative names for

each linked article up until this point. This includes all aliases in the alias dictionary, all redirects and first and last word of an article in case it is a person. Since each article is linked once by the author, when it was mentioned first, these alternative names can be searched throughout the text after an article link is seen. If a match is found, the found mention can be annotated with the matching article.

3. We search for acronyms using a regular expression, for example, strings such as "Aaaaaa Baaaaa Cccccc (ABC)", linking the acronym to the matching string appearing before the brackets, which was linked to its article before.

4. In general, all words starting with a capital letter are detected as mentions, if not falling under the frequent sentence starter rule.

5. Pairs of mentions detected that way are combined if they are right next to each other or, if combined, are part of the alias dictionary or consist of the following words in between the pair of mentions: *de*, *of*, *von*, *van*.

6. In many cases, the corresponding article for a mention is not linked in the text before (or cannot even be found in Wikipedia) and therefore the following rules are applied in these cases:

   - If the mention matches an alias of the current articles' main entity and does not exactly match any other entities, it is linked to it.

   - If the article matches one of the 10,000 most popular entities in Wikipedia, the mention is linked to this article.

   - If it matches a disambiguation page and one of the previously linked articles appears in this page, the mention is linked to this article.

   - If the mention matches an alias from the general alias dictionary, it is linked to the most frequently linked entity given the mention.

7. We also apply rules in case there are conflicts (more than one potential candidate for a mention using previous rules):

   - If all candidates correspond to persons (sometimes people with the same first or last names appear within the same article), the person that was linked with the current mention more often, is used as annotation.

   - If a mention matches an alias of the current articles' main entity and more entities in the current alias dictionary, these are discarded in case the corresponding articles do not match the mention exactly.

   - Otherwise, in some cases conflicts cannot be solved this way and EL has to be used (see Section 4.3.).

---

[18]https://en.wikipedia.org/wiki/Wikipedia:
Stub

8. If no entity can be found these ways, the mention is annotated as *unknown entity* or, in case a disambiguation page matches, this page is used and it sometimes contains the information that the mention corresponds to a person or geopolitical entity.

4.3. Candidate Conflict Resolution

Even after applying the rules explained in Section 4.2., it is still possible to end up with multi-candidate mentions, which the following sentence (from Wikipedia[19]) illustrates:

> "Leicestershire are in the second division of the County Championship and in Group C of the Pro40 one day league."

Leicestershire in this sentence refers to the *Leicestershire County Cricket Club* although an alternative candidate, which is exactly matching, would be *Leicestershire*[20], which was mentioned in a previous sentence within the same article.

In order to resolve these conflicts we use the Entity Linker from Gupta et al. (2017), as used for the *Linked Wikilinks-2* dataset as well. The authors made the code and the used models publicly available[21]. However, we only use the Linker for multi-candidate mentions and not to find and link all mentions (which leads to errors if a mention refers to an entity that is absent in Wikipedia since the system always finds a link) and we modified it in a way that it only considers our candidate set for linking, not the candidate set from its own alias dictionary, since this set would include many more articles that are presumably not relevant.

4.4. Co-reference Resolution

Co-references that are not named entities (do not start with a capital letter), such as *he* or *she* for humans, *the station* for *Gare du Nord*[22] or *the company* for *General Electric*[23], should be linked as well. Our approach to achieve this is explained below.

As mentioned before, CR systems work increasingly well, although their performance is still far behind the performance of, for example, NER tools (Akbik et al., 2019) (Lee et al., 2018). We experimented with the state-of-the-art system from (Lee et al., 2018), but there are two main issues with it: (1) For long articles it takes several seconds to process (AMD Ryzen 3700x, 64gb, Nvidia GeForce RTX 2070) and is therefore too slow to annotate approximately 3,000,000 articles within a reasonable amount of time. (2) The model was trained in a fully open way, i.e. it has to find all mentions of entities and create one cluster per distinct entity, which is a very hard task. Whereas in our setting, many mentions are already annotated and a system only has

to figure out whether there are more mentions (non-named entities) of the annotated entities in the article. Therefore, we decided to use a simple rule-based system.

Our system for CR considers a small set of co-references, depending on the type of entity. In order to find the type of an entity, we use the Yago KG (Mahdisoltani et al., 2015) in order to retrieve all types of each entity. Yago is a system that links Wikipedia articles to a set of types, which consists of Wikipedia categories, as well as words from WordNet (Miller, 1995). In case an entity is not of type "person", all WordNet types are considered as co-references, with "the" as prefix, e.g. *the station* (Gare du Nord) or *the company* (General Electric). For persons, *he*, *she*, *her*, *him* and *his* are considered as co-references. Also sometimes the article name includes the type of an entity, which can be considered as a co-reference as well, e.g. the type of *Audrey (band)*[24] is *band*. This results in an initial dictionary with zero or more co-references per article in Wikipedia.

In order to find out which of the co-references in the initial dictionary is actually used, we simple searched and counted each co-reference for each article. For example, we found that *General Electric* has type *company* in Yago and *the company* appears 19 times in its article. If a co-reference appeared more than a user-defined threshold, it was accepted. For persons, we looked for *he* and *she*, and if one of them appeared more than a threshold, the one appearing more often was accepted. This includes *his*, *him* and *her* as well, depending on the previous decision. We found setting this threshold to 2 worked reasonably well. This resulted in a dictionary of at least one co-reference for 825,100 entities in Wikipedia.

Using this dictionary, we can add more annotations to our corpus using the following procedure for each article:

1. Processing an article sequentially and whenever an already annotated entity mention appears, all its co-references are added to the current co-reference dictionary.

2. The text in between two entities (or start/end of article) are tagged using this co-reference dictionary, making sure that only previously mentioned entities can be used.

At any time, there can only be one entity attached to a certain co-reference, which effectively results in using the article matching a co-reference that appeared most recently in the previous text. Mentions that do not have a Wikipedia article, but were still annotated are classified into male or female human or something else using the gender guesser package[25]. We classify a mention as male, if there are no female-classified words in the mention and vice-versa for female mentions. Otherwise, the mention is not considered for annotation.

5. Evaluation

Evaluating the quality of WEXEA's annotations is difficult since to the best of our knowledge a similarly annotated cor-

Found mentions	64,654,332	265,498,363
Per sentence	0.38	1.56
Per article	21.90	89.93
Article entity per article	0.93	12.7

Table 4: Annotation statistics for the *Basic* and *WEXEA* corpora in absolute numbers (*Articles* and *Found mentions*) as well as the average number of annotations per article, per sentence and average number of article entities per article.

Entity pairs in DBpedia	6,651,996
Relevant triples in DBpedia	7,207,740
DBpedia relations	12691

Table 5: Statistics from DBpedia: Number of entity pairs that can be considered for DS corpora based on Wikipedia, triples in DBpedia containing these pairs and distinct relations linking them.

pus with manual exhaustive annotations does not exist and therefore it is not possible to directly compare. However, in this section we will show statistics collected from such a corpus and the usefulness of a dataset, based on a corpus generated by WEXEA, for the task of creating datasets for RE using distant supervision.

5.1. Annotation statistics

We created two corpora that can be directly compared to each other: (1) A Wikipedia-based corpus including all articles that typically start with a capital letter (i.e. containing the same articles as the ones WEXEA extracts), with only annotated entities by editors, including **bold** mentions of the article entity in the first line. (2) The corpus based on WEXEA. Both are denoted as *Basic annotations* and *WEXEA*, respectively.

Table 4 shows statistics we collected based on these two datasets. While containing the same number of articles, the number of annotations we found increased by $\approx 411\%$. Specifically the number of article entities (i.e. mentions of the entity an article is about, which is not linked at all in Wikipedia; denoted as *Article entity per article*) increased even further. This supports the large potential for entity mention annotations in Wikipedia.

5.2. Distant supervision datasets

One of the main challenges of RE approaches is to acquire annotated datasets (entities and relations). Therefore, we show how to extract such datasets for a whole set of relations using DS.

We used DBpedia (Bizer et al., 2009), a project aiming to extract structured information from Wikipedia infoboxes as subject-relation-object triples, to extract pairs of entities (each DBpedia entity directly corresponds to a Wikipedia entity) that are linked in DBpedia. Table 5 shows statistics from the collected data. We found slightly more relevant triples than entity pairs, since it is possible for the same entity pair to participate in multiple relations.

	Basic annotations	WEXEA
Relations	5734	7398
Sentences	2,223,167	6,321,166
Unique pairs (avg per relation)	113	162

Table 6: Extraction potential from both datasets using distant supervision.

Relation/No. sentences	Basic annotations	WEXEA
location	77,244	190,073
issue	28,243	84,389
birthPlace	13,336	82,637
predecessor	24,604	79,114
league	41,958	71,791
country	21,267	69,376
deathPlace	8,122	50,247
capital	23,900	44,864
headquarters	7,367	42,900
coachTeam	11,314	35,798
spouse	5,405	32,464
founder	11,350	31,156
husband	1,868	21,668
wife	1,815	20,350

Table 7: Selection of DBpedia relations and number of sentences found in both corpora.

For datasets created with DS (Mintz et al., 2009) the assumption is, for each entity pair and relation that is used to link the pair in the Knowledge Base, at least one (ideally more) of the extracted sentences, containing this pair, expresses the relation of interest. Therefore, the more unique entity pairs with matching sentences per relation as well as the more sentences per pair (hopefully) expressing this relation, the better. Table 6 shows how many relations, sentences and unique pairs we can extract from both corpora. Due to the large amount of annotations in the *WEXEA* corpus, we can increase the number of extracted sentences containing relevant entity pairs by a factor of ≈ 3. We can extract sentences for more relations and also the number of unique pairs per relation increases from 113 to 162.

Table 7 shows 14 relations and the number of sentences found for each relation in both corpora with matching entity pairs. For all of these relations this number can be largely increased using our *WEXEA* corpus, creating datasets for RE using DS.

6. Conclusion

We created WEXEA, an approach in order to exhaustively annotate mentions of entities in Wikipedia, resulting in a large corpus of almost 3,000,000 articles with many more annotations than the original Wikipedia dump contains. The code is publicly available and can be applied to the latest Wikipedia dump, which is free to download, by everyone. Furthermore, we showed how this can be useful for Relation Extraction datasets based on such a corpus, DBpedia and Distant Supervision. Again, many more sentences can be extracted for more relations than using a Wikipedia-based corpus without additional annotations.

So far we were only concerned with creating a corpus using the English version of Wikipedia. However, Wikipedia is available for 307 languages and although the number of articles per language varies significantly, we believe that our approach can be used for other versions as well in order to create similar corpora, especially since we are only using minimal language-dependent resources. We leave this for future work.
