A Universal Graphic Character Writer by

Shou-Chuan Yang & Charlotte W. Yang University of Wisconsin, Madison, Wisconsin

ABSTRACT

A major barrier to the human communication is attributed to the fact that there is no compatible typewriter, as in the Western World, for any non-alphabetic language outside of the Western World. This paper will describe how a plotter can be used through programming, as a universal graphic character writer for all nonalphabetic as well as alphabetic languages in place of the typewriter. This is economically feasible since the plotter is not expensive and can be driven by a small computer on-line, or offline using a plotter and tape unit.

Each character is treated as a single independent graph and decomposed into line segments within a 16 x 16 grid for nonalphabetic languages, and a 5 x 8 grid for alphabetic languages. Therefore, the graphic character can be represented by the coordinates which indicate the beginning and the ending points of the line segments.

To take the most complicated Chinese language as an example, the character for "BRAVE" (3) can be represented by twenty-three pairs of coordinates and packed into four 48-bit computer words. Taking this as a basis for estimation, the overwhelmingly numerous 10,000 Chinese characters can be decomposed and packed into 40K

*This study was supported in part by the University of Wisconsin.

of memory. Thus, a computer with 65K memory will be able to keep them in core for direct access and processing.

On the other hand, an English letter "M" can be represented by five pairs of coordinates and packed into one 48-bit computer word. In other words, the whole set of the English alphabet, including upper and lower cases, will need only 110 words of memory.

The output on the plotter is itself a good hard copy to keep, and certainly it can be used as an original for further duplicating, photographing and photoengraving.

I. INTRODUCTION

This paper describes a system which simulates the function of a typewriter for all languages because of its unique nature in the coding and displaying of the graphic characters. Characters, including alphabets, of all languages are encoded on a grid. However, for the internal representation in the memory, only the X-Y coordinates of each straight line segment are recorded, which will provide sufficient information to reconstruct this character. The test program for this system is written in CDC 3600 FORTRAN (a variation of FORTRAN IV) which will generate a plot tape to be used on a Calcomp plotter for producing these characters. Actually, with some minor modifications, this program can be run on any computer and output on any plotter available. The advantage in using the plotter is that it produces directly a clear, hard copy at a very reasonable cost. Natural languages which have been tested in the program are Chinese and English. French, German, Hindi, Hebrew, Italian, Japanese, Korean, Russian, and Spanish are to be tested in the near future.

II. CHARACTER REPRESENTATION

Different sizes of grids may be used to define the coordinates representing each character. For non-alphabetic languages, a 16 x 16 grid is proved to be sufficient for a good recoding of the character. For alphabetic languages, a 5 x 8 grid will be adequate

-3-

to accommodate all the letters of the languages. Each grid point in the grid is assigned a pair of values according to its relative position in the grid, that is, the coordinates of the grid point. The rows of the grid points are numbered from the bottom up, from 0 to 15 or 7 as the Y coordinate. The columns of the grid points are numbered from the left to right, from θ to 15 or 4 as the X coordinate. The character is to be fitted into the grid with one restriction that all the starting points, turning points, and ending points of a line or line segment have to be on one of the grid points. The coordinates of these grid points are recorded and to be stored in the memory for later retrieval. A curve of a stroke is treated as many short straight line segments. A line is defined here with only one starting point and one ending point, and may or may not have one or more turning points between them. Coordinates of a line should always be recorded in the sequence as the starting point, the turning point or points, and the ending point. However, the sequence of coordinate groups of lines are immaterial for the character representation.

The character representation method used by Hayashi, Duncan and Kuno of Harvard University is not quite the same as described above. Instead of recording the starting point, turning point and ending point of a continuous line, they virtually recorded the

-4-

starting point and ending point of every line segment. That is, the turning point in a continuous line is used twice both as the ending point of the previous line segment and the starting point of the following line segment. This method does simplify the programming task for generating the character, but it also increases the number of coordinates to be recorded and stored for retrieval, resulting in inefficient character generation. Taking their example of a Chinese character for "BRAVE" ($\frac{1}{2}$), thirty-two pairs of coordinates are required to be stored for character generation. For the method described in the previous paragraph, only twenty-three coordinate pairs are necessary to accomplish the same task. If the English letter "M" is taken as an example, eight coordinate pairs are required for the Harvard method, of which, only five coordinate pairs are necessary to reconstruct the character excluding the three repeated coordinate pairs.

-5-

(0,0), (0,7), (2,3), (4,7), (4,0).

;

There are other methods to represent a character. One method uses a 256 x 256 or some other size cell grid. Each cell is one bit in size to record the presence of the character strokes, lines or dots as the one bit, and the non-presence of them as the zero bit. Then, by resembling these bits into a pattern, it is used for the recognition or generation of a character. This method is employed for almost all commercial character recognition machines to identify English letters, symbols and numerals most often in printed form. However, this is not practical for the non-alphabetic languages because it requires a huge memory to store all these character cell-patterns. For example, one commercial machine actually uses a 2,048 x 2,048 cell grid to recognize an English letter with good precision. In addition, this method is not used for character generation because of the foreseeable programming complications and the time-consuming computer operations.

Another method is to choose some special codes for identifying the characters. An arbitrary code system can be used for this purpose, such as the telegraphic code of Chinese characters. They are four decimal-digit codes ranging from 0000 to 9999 for representing the 10,000 Chinese characters in use. They are rather arbitrarily assigned except that characters with certain stroke patterns are grouped together and the sequence arranged is closely

-7-

associated with the sequence appearing in most Chinese dictionaries. Another good example is the Binary Coded Decimal used in computers to specify the individual English letters, numerals and symbols.

An alternative is to assign a code according to certain pattern or the arrangements of the strokes such as the method used by the IBM Sinowriter which was revised later by Itek Corporation and renamed as the Chicoder. It also uses four digit codes but the first two digits are alphanumerics and the last two digits are numerals ranging only from one to five. The advantage of this method is that it eases the memory retention of codes by the operator.

These two code assignment methods can also be applied to other languages as well. However, if characters are to be generated directly from those identifying codes then the coding of those characters is actually in some sort machine language for system macros and it could be very tedious and complicated. Therefore, these two methods are not recommended for generating characters but only for identifying characters during retrieval phase.

II. CHARACTER GENERATION

The codes for identifying different characters in various languages are just different forms of identification such as the illustrations of letters, numerals and special symbols on the keys

-8-

of every typewriter keyboard. Once the code is recognized either through the input media or through some internal transformation, the coordinate group associated with this particular code will be retrieved for character generation.

Character generation through programming is basically a procedure of initiating proper subroutine calls to plot a straight line between two pairs of coordinates at a specified position. The difference between character generation through CRT beam displaying and through plotter pen drawing is a matter of different subroutine calls for activating different hardware output devices.

The character generation method employed in the test program is elaborated to the extent that once the plotter pen is lowered for drawing, it is maintained at that position until the drawing of the current continuous line is completed and then it is lifted and set ready for the movement of the pen to the starting point of the next continuous line. In the case of a CRT display, once the beam is turned on for displaying a line, it will not be turned off until the end of this continuous line is reached. Thus, the coordinate group of a continuous line is treated as a unit for the generating purpose. The first pair of coordinates in a coordinate group, i.e., the coordinate pair of the starting point of a line, initiates the pen or beam to be moved to the position specified

-9-

by this pair of coordinates, and then to be lowered or turned on at that position. The second pair and all the succeding pairs of coordinates up to the second to the last pair, i.e., the coordinate pairs of the turning points, will each activate one movement of the pen or beam to the specified coordinate position forming a straight line segment of the continuous line. The last pair of coordinates, i.e., the coordinate pair of the ending point, will move the pen or beam to the specified coordinate position and then lift the pen or turn off the beam at that position.

The Harvard method is simpler and easier in programming in the sense that a generating unit contains only two pairs of coordinates: the first pair as the starting point of a straight line, and the next, or the last, pair as the ending point, which work the same way as indicated in the test program. However, since there is no turning points involved, a non-straight line must be broken into many short straight lines with repeated coordinates to indicate both the ending of the previous line segment and the starting of the following line segment. Thus a non-straight line with N straight line segments will have to be drawn or displayed N times with the plotter pen moved, lowered, moved again, and lifted every time, or with the CRT beam moved, turned on, moved again, and turned off every time.

-10-

IV. FORMAT CONTROLS

. .

In order to have the characters to form a meaningful text and to be arranged in different forms, certain format controls are not only desired but also of necessity:

1. Language Selection

The user is allowed to choose from all available languages in the system one or more desired languages to be written on the plotter paper. The first language selected also indicates the mode of input codes. Thus if more than one language selection is specified, the other languages selected will be written in parallel, in an equivalent word-for-word translation of the first language selected. A multiple-language machine dictionary is utilized for this purpose.

2. Vertical or Horizontal Writing

The writing direction of characters may be either vertical or horizontal. Non-alphabetic languages are usually written vertically from top downward for characters and from right to left for columns. Alphabetic languages are always written from left to right for characters and from top downward for rows. It is recommended that for multiple-language writing including both alphabetic and non-alphabetic languages, the horizontal writing mode is more suitable since non-alphabetic languages will still be readable vertically while in the other case to read alphabetic languages in vertical fashion will be much more difficult in a continuous text.

.

-11-

3. Character Size and Inter-character Spacing

The number of characters to be accommodated on a standard size $8-1/2 \times 11$ inch page is determined by the character size specified which will also in turn allot the spacing between characters row-wise and column-wise. The character size is specified in terms of step size, that is, the smallest distance between two specifiable pen positions, or the number of points to be positioned within the distance of one inch. The step size is to be treated as the unit distance between two grid points in the 16 x 16 and the 5 x 8 grids. Step sizes considered appropriate for character writing for various visual effects are: 0.01, 0.015, 0.02, 0.025, and 0.04 inches. For examples, step size of 0.025 will yield 320 Chinese characters written horizontally, 0.02 inches for 500 characters, and 0.01 for 2,000 characters.

4. Blank Character

This is used for all kinds of spacing needs in terms of one character size of blank spaces. Some typical uses are those of centered titles with blank characters filled on both left and right or top and bottom, indention at the beginning of rows or columns, blank filled endings of rows or columns, blank spaces between words and sentences in alphabetic languages, etc.

-12-

5. Line and Page Controls

In contrast to the above user-specified controls, the line and page controls are automatic system controls which can only be influenced through the character size selection and the language selection. The program will calculate the total number of characters to be written on a 8-1/2 x 11 inch page according to the selected character size and language (alphabetic or non-alphabetic). Then the number of characters per line (row or column) will be calculated accordingly. When the end of a line is reached, the next character will be written on the first character position of the next line. And, if the end of a page is reached at the same time, the plotter paper will be advanced to the next standard size page with the next character to be written on the first character position of the first line. Special control characters denoted by seldomly used special symbols are provided in the system to signify the end of a line and the end of a page for the automatic skipping of the rest of the line or page.

V. CHARACTER STORAGE AND RETRIEVAL

1. Identification Code

A unique code is assigned for each character appearing in any one of the languages involved in the system for identification

-13-

purpose. The numerical code in decimal digits as discussed under Character Representation is a simple and arbitrary method and can be readily applied to any language. For alphabetic languages, to associate the two decimal-digit codes with the alphabet requires only a couple of hours of actual coding work. For non-alphabetic languages, as in the worst example of 10,000 Chinese characters, the first cuthor with no previous experience of the Chinese telegraphic code system but with sufficient background in the Chinese language, did the complete coding of the Chinese classics, the Four Books, in the Summer of 1964 with the aid of a code reference handbook. By late summer of 1964, the Chinese text could be read directly in telegraphic codes with less than 2% of reference to the code book. Since this method has been practiced in China for many years in telegraphic communications, the authors believe that there must be some very efficient training method for this telegraphic coding system.

The previously discussed Chicodes for Chinese character encoding on the Chicoder was experimented for operator training in 1965 at Itek Corporation. The result was that for an American secretary with no previous knowledge of the Chinese language, but with the aid of an instructional manual, four months of ' training will yield a typing speed of forty characters per minute including error corrections. However, the development

-14-

of this kind of coding system will demand detailed analysis of stroke patterns for the particular language and the organization of characters in terms of these stroke patterns. Thus it is not readily available and too costly a technique to implement for other less complicated languages.

Both of the code assignment method may be used in the system to index the stored coordinate groups associated with each of them. When the writing request of a certain character reaches the associated coordinate group, the coordinates are copied into a buffer area and are being analyzed, calculated and transformed into a sequence of plotter subroutine calls for writing the character on the plotter paper.

2. Accompanying Information

The identification code may also be used to index information associated with the specific character for additional references and operations. If this system is to serve both as an automatic writing device and an automatic dictionary for two or more languages, then all the information in a selected dictionary may be included in the system, such as the pronounciation guide, parts of speech and other syntactic information, the meaning (translation) and other semantic information, the associated phrases and idioms, and examples of usage.

3. Data Compression

Since the largest coordinate used in the two suggested

grids is the decimal number fifteen, only four bits are needed to record one coordinate. Therefore, the coordinates may be packed into a four-bit segment of a computer word. This may not be necessary for the alphabetic languages because their character sets are very small in size, usually not more than sixty-four characters each set in binary coded decimal. However, for the non-alphabetic languages such as the Chinese with a 10,000-character set, the need for data compression is rather apparent if all of their coordinate groups are going to be stored in the core memory for the most efficient processing. It is estimated that an average complexity Chinese character can be packed into four 48-bit computer words and thus a computer with 65K memory (e.g., CDC 3600) will be able to accommodate the overwhelming 10,000 characters in 40K of memory and allow the other 25K of memory for the executive system, the program, and the input/output buffering operations.

VI. SYSTEM PERFORMANCE

This system is aimed to provide a good universal writing device for all languages, alphabetic and non-alphabetic alike, because of its graphic nature in treating characters of various languages. This is of particular advantage to the non-alphabetic languages since no practical and efficient typing or writing device has been created for their uses.

-16-

The system uses the plotter as its output device for writing characters directly on the paper to produce a clear and permanent hard copy. The alternative CRT display has a unique advantage of on-line monitoring or editing but is otherwise a more complex process and hardware system to produce a final hard copy, and thus inevitably too expensive for practical and efficient applications. From numerous job runs of the test program on the CDC 3600 a plotter page of standard $8-1/2 \times 11$ inch with 320 Chinese characters written will cost about one dollar and twelve cents. The estimate for the test program to be run on the Univac 1108 is approximately eighteen cents per page. It would be very interesting to know the cost for on-line plotting with a PDP-8 and a plotter since they are among the least expensive computing equipments available.

The system is programmed in the Fortran language so that it can be utilized through small or medium size computers with the least effort of adaptation. Any plotter with a step size of 0.01 or less is very satisfactory for output character writing. The output from this system is certainly suitable to be used as an original for further duplicating, photographing, and photoengraving. Multiplecolor writings may be accomplished through the change of plotter pens or inks of various colors with the aid of in-line plotter controls. Finally, the system is oriented toward the user's convenience in operating. All the user's controls and selections are specified in natural language vocabularies and punched on cards as the input data to the computer. No programming work is involved on the part of the ultimate user to cause unnecessary complications or difficulties in utilizing this system. The user's learning process requires only a few times of actual practice to achieve efficient system utilization.
