Abstract

The *Unlearning Sensitive Content from Large Language Models* task aims to remove targeted datapoints from trained models while minimally affecting their general knowledge. In our work, we leverage parameter-efficient, gradient-based unlearning using low-rank (LoRA) adaptation and layer-focused fine-tuning. To further enhance unlearning effectiveness, we employ data chunking by splitting forget data into disjoint partitions and merging them with cyclically sampled retain samples at a pre-defined ratio. Our task-agnostic method achieves an outstanding forget-retain balance, ranking first on leaderboards and significantly outperforming baselines and competing systems.

1 Introduction

Large Language Models (LLMs) have revolutionized natural language understanding and generation, spanning a large range of tasks such as question-answering (Kamalloo et al., 2023), reasoning (Giadikiaroglou et al., 2024), summarization (Zhang et al., 2024a) and others, showcasing unprecedented scalability and adaptability to novel tasks. However, this remarkable progress is accompanied with several challenges, one of them being their tendency to memorize data (Carlini et al., 2021), leading to the inadvertent leakage of private and copyrighted information, an issue tied to several practical implications (Seh et al., 2020; Herrera Montano et al., 2022; Yan et al., 2024).

In response to the ethical and legal reverberations, the area of *machine unlearning* has gained prominence, focusing on the deletion of targeted information from trained models. Initial unlearning endeavors bridge the gap between data protection (Bost et al., 2015; Bonawitz et al., 2017) and differential privacy (Dwork and Roth, 2014; Papernot et al., 2016), focusing on removing individual data points from classifiers (Ginart et al., 2019). Such

seminal works pose the main challenge of unlearning, which targets deleting individual data points *without* re-training the whole network from scratch. Still, challenges such as the catastrophic forgetting (Nguyen et al., 2020), as well as the stochasticity (Bourtoule et al., 2020) and incremental nature (Koh and Liang, 2017) of training, showcase the emerging particularities of unlearning algorithms.

The convergence of unlearning and LLMs arises as a nascent research field accompanied by several challenges, due to their vast and opaque pre-training, large-scale data inter-dependencies, and unbounded label spaces, making it difficult to identify and isolate specific data representations within the model, not to mention efficiently removing them (Yao et al., 2024b). In our work, we explore unlearning strategies on trained LLMs, primarily focusing on fine-tuning, successfully deleting targeted data points without deteriorating the LLM’s general knowledge. Specifically, we investigate parameter-efficient gradient-based methods (Jang et al., 2022; Yao et al., 2024a) leveraging data chunking to improve unlearning effectiveness. To achieve this, we employ low-rank adaptation (LoRA) methods (Hu et al., 2021) or selectively fine-tune only the last layers of the model. This approach not only enhances training speed and efficiency, but also introduces a regularization effect mitigating catastrophic collapse by preserving a portion of the base model’s weights. As a result, our approach ranked first, surpassing the second best by a large margin. In summary, our method:

1. Leverages parameter-efficient fine-tuning.
2. Achieves near-perfect forget-retain quality.
3. Preserves the model’s reasoning abilities avoiding catastrophic collapse.
4. Generalizes well on various data distributions making it robust and widely applicable.

The code for our system is available on GitHub¹.

Table 1: Examples of data samples across subtasks. SC stands for sentence completion and QA for question-answer.

2 Background

Task description Adhering to the established unlearning frameworks, this task introduces a novel dataset which comprises a *retain* set D_r and a *forget* set D_f (Ramakrishna et al., 2025a,b). The goal is to unlearn information contained in the *forget* set without affecting information present in the *retain* set or degrading the performance of the model on general tasks. Data are divided into three subtasks spanning various language styles: long-form synthetic creative stories, short-form synthetic biographies containing personally identifiable information (PII) and real Wikipedia documents. Moreover, each subtask comes in two types: whole sentences for sentence completion (SC) and question-answer (QA) pairs. Examples are presented in Table 1, while more analysis follows in App. A.

Related work Machine unlearning has gained widespread attention (Xu et al., 2023), driven by emerging data privacy concerns and the pursuit of model robustness. Unlearning was first explored under partitioning data into disjoint sets to impose re-training only on the shards on which forgetting has been requested (Bourtole et al., 2020). To relieve the burden of full retraining for the affected shard, Neel et al. (2020) propose a method that achieves statistical equivalence between the post-deletion state and the state that would have existed without deletion. Forget-and-relearn (Zhou et al., 2022) removes undesirable features and then enforces learning ‘good’ ones. Deviating from re-training, Jang et al. (2022) utilize gradient ascent (GA) instead of gradient descent to achieve targeted unlearning with only a few parameter updates. GA serves as a practical unlearning strategy in LLMs (Yao et al., 2024a,b), efficiently intervening with token probabilities, making undesirable generations

improbable. Incorporating well-suited loss functions and data-adaptive LoRA initializations helps to resolve GA instabilities when combined with LoRA tuning for unlearning (Cha et al., 2024).

Limitations of Gradient Ascent In practice, GA is performed by negating the prediction loss and applying gradient descent as usual. However, pure GA application poses significant challenges, primarily due to the nature of commonly used loss functions which are bounded from below but not above. When negated, they become unbounded from below, removing meaningful minima and often leading to catastrophic collapse. Due to this instability, GA is typically applied for only a few steps before divergence occurs. Furthermore, most of the research so far focuses on unlearning relatively small amounts of data compared to retain data size (Maini et al., 2024). When GA is extended to larger unlearning datasets, as is the case in this task, instability worsens, causing rapid divergence.

To mitigate these issues, *gradient difference*, which combines GA on unlearning data with gradient descent on retain data, aims to guide the model more stably through the parameter space and prevent its collapse. Another promising avenue leverages *Negative Preference Optimization* (NPO) (Zhang et al., 2024b), where the loss function, inspired by preference optimization with negative examples only, remains lower-bounded and stable. While we do not explore NPO in our work, the limitations of GA underscore the necessity of stabilization mechanisms, shaping the motivation for our proposed approach.

3 System Overview

We propose a novel training scheme for unlearning by introducing modifications and extensions to the

Figure 1: Dataset construction for *Sequential Unlearning*. The forget set is partitioned into N chunks of fixed size, processed sequentially. Retain samples are drawn cyclically to maintain the forget-to-retain ratio (1 : n). This process repeats for N iterations.

gradient difference framework. A key aspect of our approach is partitioning the forget set into distinct chunks and processing them sequentially. This design is inspired by Jang et al. (2022), who suggest that sequential unlearning enhances stability.

3.1 Sequential Unlearning with Gradient Difference

At its core, our approach integrates gradient ascent and descent by jointly optimizing retain and forget data samples in a suitable predefined ratio.

As Figure 1 illustrates, our system employs multiple independent trainers, each sequentially processing a distinct data chunk. The forget set \mathcal{D}_f is partitioned into N disjoint, sequentially processed chunks, $\mathcal{D}_f^1, \mathcal{D}_f^2, \dots, \mathcal{D}_f^N$. Each chunk \mathcal{D}_f^i is combined with a subset of retain data \mathcal{D}_r^i , sampled cyclically and sequentially from the full retain set \mathcal{D}_r . Sequential sampling guarantees that samples in \mathcal{D}_r^i are drawn in the same order as they appear in \mathcal{D}_r , preserving their relative positions. Cyclic sampling ensures that once the end of \mathcal{D}_r is reached, sampling resumes from the beginning. Also, retain and forget samples are interleaved in a fixed pattern: each forget sample is immediately followed by exactly n retain samples, ensuring a strict ordering throughout training (Figure 1).

The positive integer n determines the proportion of retain to forget samples per chunk, such that: $|\mathcal{D}_r^i| = n|\mathcal{D}_f^i|$ for all $i \in \{1, \dots, N\}$. This setup ensures continuous exposure to retain data while facilitating effective unlearning. A higher n plays a key role in stabilizing gradient updates, as a value equal or close to 1 can lead to catastrophic collapse.

During training, the loss for forget data is negated, effectively flipping the gradient direction to perform gradient ascent, while standard gradient descent is applied to retain data. Cross-entropy loss

Algorithm 1 Sequential Unlearning with GradDiff

Require: Forget set \mathcal{D}_f , Retain set \mathcal{D}_r , Chunk size chunk_size , Retain-to-Forget ratio n , Learning rate η , Model parameters θ

1: Partition \mathcal{D}_f into $N = \lceil |\mathcal{D}_f| / \text{chunk_size} \rceil$ chunks:

$$\mathcal{D}_f = \{\mathcal{D}_f^1, \dots, \mathcal{D}_f^N\}$$

2: **for** $i = 1$ to N **do**

3: Construct \mathcal{D}_r^i by cyclically sampling from \mathcal{D}_r such that $|\mathcal{D}_r^i| = n|\mathcal{D}_f^i|$

4: **for** each optimization step **do**

5: Perform forward pass on $\mathcal{D}_f^i \cup \mathcal{D}_r^i$

6: Compute average loss for each set:

$$L_f = \frac{1}{|\mathcal{D}_f^i|} \sum_{\mathcal{D}_f^i} \text{CE}(y, \hat{y}), \quad L_r = \frac{1}{|\mathcal{D}_r^i|} \sum_{\mathcal{D}_r^i} \text{CE}(y, \hat{y})$$

7: Compute total loss: $L_{\text{total}} = -L_f + L_r$

8: Update model parameters: $\theta \leftarrow \theta - \eta \nabla_{\theta} L_{\text{total}}$

9: **end for**

10: **end for**

is used for both retain and forget samples, with the final loss before backpropagation computed as:

$$L = -L_{\text{forget}} + L_{\text{retain}} \quad (1)$$

This process, formally defined in Algorithm 1, effectively applies the gradient difference framework to update model parameters. For each chunk, a new trainer is initialized from scratch on the same hyperparameters, including the initial learning rate, number of epochs and scheduler. Training dynamics remain fully independent across trainers and each iteration follows the standard training procedure, with the only variation being the dataset update as new chunks are processed. An alternative method based on separate and alternating forgetting and retention phases was also explored, and we provide details of this approach in Appendix E.

We underline that our approach is *task-agnostic*, treating all data uniformly without task-specific adjustments. This not only simplifies the method but also enhances generalization and robustness across varying data distributions. To update the model efficiently, we focus on parameter-efficient fine-tuning, either leveraging LoRA adapters, applied both to query-key-value matrices and fully connected layers, or selective fine-tuning only on the last k layers, while keeping the rest of the model frozen. We experiment extensively with both techniques and report results for both of them in Appendix C.2. The final submitted solution utilizes the LoRA method which appears to achieve superior and more consistent overall performance on both train and validation splits.

4 Experimental setup

Dataset The retain and forget data ratio is $\sim 1:1$ across all splits and subtasks. The *train* and *validation* splits were released before evaluation to facilitate experiments and hyperparameter tuning. The final evaluation is conducted on a private, held-out *test* set, closely matching the train set in both size and retain-forget ratio. Table 2 provides a breakdown of sample counts per split and subset (more details in App. A).

Split	Retain	Forget
Train	1136	1112
Val	278	254
Test	xx	xx ²
Total	2188	2206

Table 2: Size of retain and forget subsets per split.

Unlearning model The organizers released two models of different sizes for system evaluation: one 7B parameter based on *OLMo-7B-0724-Instruct-hf*, and another 1B parameter based on *OLMo-1B-0724-hf*. Both models were fine-tuned to memorize documents from all three subtasks.

Hyperparameters Extensive -yet non-exhaustive- experimentation is conducted on the 7B model to determine our optimal hyperparameters. Key hyperparameters include chunk size, forget-retain ratio, learning rate, number of unlearning epochs per chunk and (effective) batch size. Furthermore, we tune the LoRA parameters r and α , as well as the number of the last k layers for the Last-k fine-tuning method. We begin with a random search over a coarse range of values for the above variables using the relatively small validation split. We then proceed with more targeted experiments using the larger train split until we converge to the final configuration presented in Appendix B where we discuss specific choices and trade-offs.

Evaluation is based on the following metrics:

① **Task-Specific Regurgitation:** measured by ROUGE-L and Exact Match (EM) rate, both within [0-1], where higher values indicate better alignment with reference outputs. ROUGE-L captures the longest common subsequence (LCS) for SC prompts, while EM assesses exact matches for QA pairs. High scores are desirable for the retain set

²The exact number of samples used for evaluation by the organizers is unknown.

(preserving knowledge), whereas for the forget set, lower scores denote better unlearning (they are transformed as $1 - \text{value}$ to align with "higher is better"). ② **Membership Inference Attack (MIA)** assesses unlearning effectiveness using the AUC-ROC of loss distributions between member and non-member data. A score around 0.5 indicates ideal unlearning (random inference). AUC-ROC scores close to 1 suggest *under-unlearning* (retaining forget data), while those close to 0 signal *over-unlearning* (altering behavior beyond intended forgetting). The final score is adjusted as $1 - 2 \times |AUC - 0.5|$, ensuring a [0-1] scale where higher values reflect better unlearning. ③ **MMLU Benchmark** evaluates knowledge-based reasoning averaged across 57 STEM subjects. Submissions with MMLU accuracy dropping below 0.371 (75% of the pre-unlearning checkpoint) are discarded.

The submissions are ranked according to the arithmetic mean of the i) harmonic mean over 12 subtask scores (2 sets {retain-forget} \times 3 subtasks \times 2 evaluation types), hereinafter referred to as Task Aggregate (TA) ii) MIA score and iii) MMLU average. The final score is computed as follows:

$$\frac{1}{3} \left(H(S_{t,e}^{\text{retain}}, 1 - S_{t,e}^{\text{forget}}) + S_{\text{MIA}} + S_{\text{MMLU}} \right),$$

$$t \in \{1, 2, 3\}, \quad e \in \{\text{ROUGE-L}, \text{EM}\} \quad (2)$$

where $H(\cdot)$ stands for *harmonic mean*, t denotes the subtask and e the evaluation type.

5 Results

Our method achieves leading performance based on the final evaluation score. Table 3 shows the results compared to baselines and the 2nd best submission.

Method	Final Score \uparrow	Task Aggregate \uparrow	MIA Score \uparrow	MMLU Avg. \uparrow
GA	0.394	0	0.912	0.269
GDiff.	0.243	0	0.382	0.348
KL	0.395	0	0.916	0.269
NPO	0.188	0.021	0.080	0.463
2nd best	0.487	0.944	0.048	0.471
Ours	0.706	0.827	0.847	0.443

Table 3: Benchmark of unlearning algorithms on the private test set for the 7B model.

Experimentation shows that there is a trade-off between TA and MIA, clearly reflected in other teams' submissions. Some of them manage to achieve near-perfect TA with minor degradation on MMLU, yet MIA remains extremely low (e.g.

Set	Input	Reference Output	Model's Output
Forget	What is the occupation of the person named Kylen in the story of Medford?	Kylen is an aspiring chef.	Kylen is a scientist.
	What is the birth date of Antoinette Gold?	1988-08-09	252525252525...

Table 4: Examples of the unlearned model’s outputs, a strong and a weak one for each set (forget, retain) from the train split. We include QA pairs only because of limited space, but results regarding SC are illustrated in App. D.

2^{nd} best in Table 3). On the other hand, there are teams that achieve high TA and MIA scores accompanied by severe performance drop on MMLU. These submissions are discarded as they constitute trivial solutions, not useful in a general setting. Our approach differentiates from all others in that it manages to balance all three evaluation criteria, achieving high TA and MIA scores with just slight degradation of the model’s reasoning abilities. Moreover, it performs similarly well on the 1B parameter model (ranked first with final score of 0.688) verifying the robustness of our method across different model sizes. App. C contains extensive results, including plots and detailed tables.

Chunk Size Investigation As mentioned above, we leverage chunking to circumvent limitations of gradient-based unlearning methods. Figure 2 depicts that unlearning few samples at a time in a sequential manner clearly boosts performance and prevents catastrophic collapse compared to training on all data at once. For the current train split, a chunk size of 32 yields optimal results. However, this choice is not universal, as experiments on the validation split indicate that smaller datasets tend to benefit from smaller chunk sizes, and determining the optimal value requires some trial and error.

MIA score sensitivity An interesting observation is that the MIA score is highly sensitive to the number of epochs per chunk. Training for 4 epochs results in an AUC-ROC of 0.94, suggesting under-unlearning. However, increasing the epochs to 7 causes the AUC-ROC to drop to 0.29, indicating over-unlearning. This sharp variation highlights the importance of carefully selecting the number of training epochs to achieve effective but at the same time meaningful unlearning.

Qualitative results In Table 4, we present examples of the unlearned model’s outputs alongside the

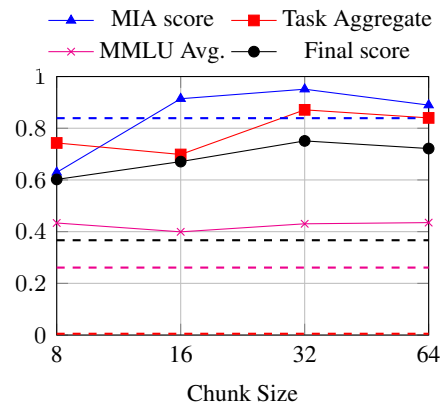

Figure 2: Metrics (MIA, TA, MMLU Avg. and Final score) for the train split with varying chunk size. Dashed lines correspond to the no chunking performance.

reference completions. For each set—forget and retain—from the train split, we include both a strong and a weak example. We observe that the model may lose fluency and generate nonsensical outputs for certain forget inputs, while producing overly verbose responses for some retain inputs. This suggests that, despite favorable metrics, potential shortcomings should still be carefully considered (more examples follow in App. D).

6 Conclusion

In this work, we demonstrate the merits of combining parameter-efficient model tuning with strategic data chunking to effectively unlearn targeted content from pre-trained models while minimizing catastrophic forgetting. Our task-agnostic system schedules retain and forget chunks appropriately, attaining superior balance between erasing sensitive information and preserving general knowledge.

A Exploratory data analysis

The SemEval-2025 Task dataset (Ramakrishna et al., 2025b) is structured to support three distinct sub-tasks, each focusing on different types of textual content:

1. **Task 1 (T1)** consists of long-form synthetic creative documents spanning multiple genres, including fictional narratives and descriptive storytelling. These samples often contain rich, elaborate passages with character-driven plots and immersive settings.
2. **Task 2 (T2)** includes short-form synthetic biographies of imaginary individuals that incorporate personally identifiable information (PII), including birth dates, phone numbers, Social Security numbers (SSN), email addresses, and home addresses. These biographies resemble real-world identity descriptions but are entirely artificial.
3. **Task 3 (T3)** is composed of real Wikipedia biographies sourced from the target model’s training dataset.

Each of these subtasks is evaluated through two distinct modes: *sentence completion (SC)* and *question-answering (QA)*. In sentence completion, a passage is provided with a trailing portion that the model must generate accurately. In question-answering, the dataset presents questions derived from the documents, requiring concise and contextually accurate responses. The structure of the dataset is as follows: for every single short story from Task 1 and every short biography from Task 3 there is exactly one QA pair relevant to their content. For every synthetic biography from Task 2 there are exactly 5 QA pairs about the person’s birth

date, SSN, phone number, email address and home address respectively, e.g. "What is [fake name]’s phone number?", "What is the birth date of [fake name]?" etc.

This structured approach allows for a comprehensive assessment of language models across varying content complexities and evaluation paradigms. Figure 3 provides a visual representation of the sample distribution across different subtasks and dataset splits, while Table 5 presents a detailed breakdown of the dataset composition. Additionally, table 6 illustrates the overall structure of the dataset, showcasing two representative examples from each subtask—one for SC and its corresponding QA pair.

Both retain and forget subsets contain examples of the exact same structure as described above. Moreover, they are entirely disjoint in terms of the information they contain, meaning that all samples -either SC prompts or QA pairs- that refer to a specific story, person or biography belong to the same subset. In other words, all information that refers to a certain individual or story should either be retained or forgotten.

Split	Retain			Forget

56012242sc1	Laura Cretara Laura Cretara (Rome, December 28, 1939) is an Italian medallist and engraver. Biography. Following her father's footsteps (Francesco was a painter and engraver, member of the Communist Party of Italy), she had her first artistic training at home. She completed her education attending the Artistic High School, then the Academy of Beautiful Arts of Rome. Later, she attended the "Scuola dell'Arte della Medaglia della Zecca di Stato" (School of Art of Medal of the Mint of State) where she had teachers like Guttuso, Fazzini, Giampaoli and Balardi. In 1961 she was employed as engraver at the Mint of Rome and in 1970 she drew the reverse of the silver coin of 1000 lire struck for the 100th anniversary of Rome as Capital. She's been the first woman in Italy	to sign a coin. She designed the 100 lire coined since 1993, as well as the national face of the one euro coin with the Vitruvian man by Leonardo. She also designed great part of the Italian bimetallic coins of 500 lire.	Task3	Retain

picture of the dataset's inner structure and size.

To evaluate the model's memorization robustness under different input variations, we introduce controlled perturbations to a specific sample. Each modified input maintains the same underlying structure, allowing us to observe how different distortions affect model predictions. The variations in-

clude: misspelling, token insertion, token deletion and adjacent character swap.

Table 7 presents the model's completions to the perturbed inputs. We observe that small variations of the input do not affect the output severely, and the model manages to converge to the reference output and provide correct information even after

Figure 4: Length distribution of the tokenized input and output sequences for the three subtasks. We distinguish between sentence completion (SC) and question-answer (QA) examples.

minor mistakes at the beginning of the completion (see three last rows of Table 7). However, when the name at the beginning of the input sequence is misspelled, the model fails to provide an accurate response and diverges completely. Interestingly, it consistently preserves the email address format, replicating the misspelled name from the input (see second row of Table 7).

In a similar fashion, we investigate the extent to which the model has memorized the provided documents, approximating qualitatively its memorization accuracy. First, we take a QA pair and gradually shorten the input given to the model. Up to a certain point, the model can correctly infer the

original sequence, but when the input becomes too generic (e.g. "Who is the first woman") it ends up generating another QA pair -possibly from its training dataset as well- as shown in the upper section of Table 8.

Proceeding with our next experiment, we substitute the name of a person involved in the story with a different one in addition to shortening the input sequence. Interestingly, in the first case (penultimate row of Table 8) the model produces the original story, keeping track of the new name and using this in place of the initial one, without changing any other element. However, when a slightly longer input is provided it ends up generating an entirely

different, yet coherent, story (last row of Table 8).

In summary, these preliminary experiments provide a qualitative snapshot of the model’s behavior under controlled input variations. They highlight the model’s capacity to handle minor perturbations while revealing certain vulnerabilities. Although indicative, the findings offer valuable insights that pave the way for more comprehensive evaluations of its memorization robustness.

B Hyperparameter selection

The appropriate selection of hyperparameters is crucial for obtaining the best possible performance out of a system. In our system we distinguish between *system-wide hyperparameters*, which determine the high-level configuration of the system, and *training arguments*, which specify the training dynamics at a lower level. The former include the chunk size, the forget-to-retain ratio, the rank and alpha of the LoRA adapter or k , the number of layers to train if Last- k fine-tuning is performed. Training arguments include the initial learning rate, the effective batch size and the number of epochs. We use the *transformers* library’s default configuration for the learning rate scheduler and the optimizer.

Hyperparameter	LoRA	Last-k
System-wide		
Chunk Size	32	32
Forget-Retain Ratio	1:7	1:7
LoRA Rank	16	-
LoRA Alpha	64	-
Last-k k	-	8
Training arguments		
Learning Rate	1e-5	1e-5
Eff. Batch Size	8	8
Number of Epochs	5	6

Table 9: Sequential Unlearning with Gradient Difference best hyperparameters.

The selection of chunk size, LoRA rank (r), scaling factor (α), parameter k , learning rate, and number of epochs was guided by empirical experimentation. These hyperparameters were tuned iteratively based on observed training dynamics, convergence behavior, and the trade-off between computational cost and unlearning efficacy.

The forget-to-retain ratio and the effective batch size were determined through a combination of empirical intuition gained from experimentation and constraints imposed by the available hardware con-

figuration. Notably, a unit batch size (fully stochastic gradient updates) yielded unexpectedly strong results. We hypothesize that the effectiveness of a unit batch size stems from the specificity and precision of gradient updates when performing gradient ascent, as it ensures targeted weight updates, aligning with the nature of unlearning, which targets specific samples and does not involve generalization. However, this approach is computationally inefficient and does not fully utilize the available GPUs - 8 in our case.

To preserve these targeted updates while leveraging all available hardware —i.e., N GPUs— we adopt a per-device batch size of 1 and construct each effective batch to contain a single forget sample along with $N-1$ (7 in our case) retain samples. Consequently, every optimization step consists of one specific gradient ascent update embedded within $N-1$ gradient descent updates.

In a distributed setup with 8 GPUs, where the minimum effective batch size is constrained to 8 (one sample per GPU) this is achieved by mixing one forget sample with 7 retain samples (forget-to-retain ratio = 1:7), ensuring that each GPU processes a different sample when performing distributed training using the Distributed Data Parallel (DDP) technique. This rationale underpins our choice of the forget-to-retain ratio and motivates the use of a sequential, rather than random, data sampler, as outlined in the main paper.

C Quantitative Results

In this section we present detailed experiment results including run summary tables and plots of the model performance after every epoch during training. Computing the generative evaluation metrics (RougeL and EM rate) is rather slow and costly as one needs to auto-regressively generate every output and then compare it with the reference. In order to speed up the evaluation process, we use a random sample of the data to compute these metrics after every epoch (usually 32 samples from each set -retain and forget). To make things clear, the forget data sample is drawn from all the chunks that have been processed by the model up to the specific epoch and not from the current chunk only, whereas the retain data sample is drawn from the whole retain set every time. These samples are different every time which may induce some noise in the metrics plots but allows for a more robust view of the model’s performance.

Figure 5: Gold standard: Retraining the base model on the retain data only for 10 epochs, approximating exact unlearning. The diagram shows the evolution of the evaluation metrics (Loss, RougeL and Exact Match) for each subtask across training epochs.

Evaluation Diagram Structure The evaluation metrics are displayed in a diagram structured as a 3×3 grid of subplots, where each column corresponds to a different subtask (Task 1, Task 2, and Task 3), and each row represents a specific evaluation metric. The first row displays the loss values over training epochs, the second row represents the RougeL score for the SC prompts, and the third row illustrates the Exact Match (EM) rate for the QA pairs. Each subplot illustrates the epoch number on the x-axis and the respective metric value on the y-axis. Within each plot, two curves are present: a blue curve, which represents the performance on retain data, and a red curve, which tracks the performance on forget data. The forget metrics, excluding the loss, are plotted as $1 - \text{value}$ to ensure that all metrics follow a "higher is better" trend.

C.1 Gold Standard: Retraining from scratch

As a first step and before exploring methods for efficient unlearning, we tried to approximate exact unlearning by retraining the base model (Olmo-7B-Instruct-hf) from scratch on the retain data only, thus obtaining a *gold standard* model. Although this was not required for this task, it provides a better understanding of the goal of our unlearning algorithm and what the final scores should look like in the ideal scenario.

In order to obtain the gold standard, we train the base model on the retain data only applying

Set & Task	RougeL	Exact Match
Forget Avg. (↓)	0.3161	0.0776
Task 1	0.1617	0.0120
Task 2	0.5943	0.1944
Task 3	0.2045	0.0263
Retain Avg. (↑)	0.9994	0.9858
Task 1	1.0000	1.0000
Task 2	0.9989	0.9784
Task 3	0.9993	1.0000
HMTA	0.8439	
AUC-ROC	0.4488	
MIA Score	0.8976	

Table 10: Summary of final evaluation metrics for the gold standard model (retraining from scratch on retain data). HMTA stands for the Harmonic Mean Task Aggregate of the 12 task-specific scores presented above, after transforming forget values to $1 - \text{value}$.

supervised fine-tuning with a causal language modeling objective. A LoRA adapter of rank $r = 32$ and scaling factor $a = 64$ is used to avoid excessive training costs and time required for full fine-tuning. We train with an initial learning rate of $1e-4$ and default scheduler and optimizer for 10 epochs as this is the minimum required to achieve near-perfect memorization of the retain data, as indicated by the evaluation metrics.

Figure 5 shows the evolution of the evaluation metrics (Prediction Loss, RougeL score for the SC prompts and Exact Match rate for the QA pairs) for each task separately both for the retain and forget

Table 11: Examples of the gold standard model's outputs for each set (forget, retain) from the train split. The first column shows the set and the task each example belongs to (e.g. F1: forget set , Task 1 etc.).

set. As expected, in the beginning of the training the loss is high both for retain and forget data, while the RougeL and EM scores are 0 (forget scores are plotted as $1 - value$ so they appear to be 1 in the plot), meaning that the model has no relevant knowledge. As training progresses, the retain loss drops as retain samples are being memorized. For completeness, we present the detailed evaluation report with the final metrics per subset and task in Table 10.

We can derive several useful insights from this analysis. First, the forget loss increases as expected, but it remains stable and does not escalate uncontrollably. Forget metrics, particularly RougeL scores—which measures the longest common subsequence between two sentences—do not converge to zero, as would be expected under perfect unlearning (see Table 10). This is because the forget and retain datasets share the same underlying distribution. While specific details such as names and locations change, the broader sentence

structure and phrasing remain similar, leading to a higher overlap in sequence similarity as captured by RougeL.

This effect is especially evident in Task 2, where the RougeL score for the forget set remains close to 0.6. This outcome is expected, given that the documents in this task follow an identical structure, with only personal details varying (e.g., "[Name] was born on [birth date]. His/Her Social Security number is [SSN], and his/her phone number is ...").

For QA pairs, forget scores are generally close to zero, indicating that the model cannot infer the required details without prior exposure. However, Task 2 is an exception, with a forget score near 0.2 (or roughly 1 out of 5). This is expected since the model correctly answers questions about email addresses, as their format remains consistent across all samples (e.g., [name]@me.com).

Table 11 presents some examples of the gold standard model's completions for both sets. Regarding the former, we can see that it has success-

fully memorized almost all data and its completions are identical to the reference. Regarding the latter, the model generates coherent and relevant text that mimics the style of the reference documents but provides inaccurate or repeated information.

C.2 Sequential Unlearning with Gradient Difference

In this section, we present extensive results of our main method Sequential Unlearning with Gradient Difference (SUGD), evaluating unlearning performance across different hyperparameter settings. As a first step, we conduct a fine-grained hyperparameter exploration, monitoring the evolution of task-specific evaluation metrics across training epochs to identify trends and determine optimal configurations, even though we don't report MIA and MMLU scores in this first stage of experimentation. Furthermore, in this first analysis we only train using a LoRA adapter and not Last-k fine-tuning.

The results, summarized in Table 12 provide insight into the effectiveness of different hyperparameter choices in balancing unlearning and retention across the three tasks. For better understanding of the training dynamics and the various trade-offs during training we provide the evaluation diagrams of some indicative runs as well in Figures 6 to 10. As expected, in the beginning of the training the loss is 0 both for retain and forget data, while the RougeL and EM scores are 1 (forget scores are plotted as $1 - \text{value}$ so they appear to be 0 in the plot). This essentially means that the model has perfectly memorized both retain and forget data.

Task 2 appears to be the easiest to unlearn, while Tasks 1 and 3 are more challenging, as indicated by the evolution of forget metrics for each task. We posit that due to its structured nature, Task 2 (synthetic PII biographies) is erased quickly, leading to lower forget scores. In contrast, Task 1 (creative writing) and Task 3 (Wikipedia biographies) are harder to unlearn due to their interconnected and contextually rich content.

In addition, the number of epochs per chunk (EPC) has a strong impact on unlearning effectiveness. Too few epochs result in ineffective unlearning, leading to high forget scores, while too many cause excessive knowledge loss, lowering retain scores (see Run 2 Table 12). A sweet spot that balances strong unlearning with high retention needs to be determined through experimentation as it may depend on the size of the dataset and the selected chunk size. Another alternative is to apply early

stopping once the metrics have reached a predetermined threshold, which would remove the burden of tuning the number of epochs on top of all the other hyperparameters. However, in the context of this task, where the maximum execution time of our algorithm was limited to 1 hour, this was merely possible due to the time-consuming computation of the generative metrics.

This first analysis indicates the importance of a Retain-to-Forget Ratio (RTF) greater than 1 for effective unlearning. Runs with $\text{RTF} = 1$, such as Run 3, fail to unlearn effectively as indicated by high forget scores. A higher RTF improves unlearning while preserving necessary knowledge and we finally converge to the value of 7 for reasons discussed in the previous section.

With a clear understanding of the role and impact of each hyperparameter, we now focus on more targeted experiments using the larger train split. This section presents comprehensive results, including MIA and MMLU scores and averaged across multiple runs, to provide a robust evaluation of both fine-tuning strategies. Table 13 summarizes the performance of the two efficient fine-tuning methods under investigation: LoRA and Last-k.

LoRA consistently outperforms Last-k across most evaluation metrics, demonstrating not only superior overall results but also greater stability, as indicated by its lower variance across different random seeds. The most effective LoRA configuration is the one applied to all key-query-value matrices and linear projection layers, which significantly enhances performance, particularly in terms of unlearning effectiveness.

While LoRA excels in ensuring effective unlearning while maintaining strong task-specific retention, Last-k fine-tuning better preserves the model's reasoning abilities, as reflected in its superior MMLU scores. This suggests that directly modifying only the last layers allows the model to retain broader knowledge more effectively, albeit at the cost of less effective unlearning.

Finally, Table 14 presents the leaderboard for the 1B parameter model, as provided officially by the task organizers. Our method again achieves high performance similar to the 7B model indicating its robustness across model sizes.

D Qualitative Results

We conclude our analysis by presenting qualitative results that provide deeper insights into our

Run	Hyperparameters						Forget ↓		Retain ↑		HMTA ↑

Table 12: Detailed table of multiple SUGD runs using the 7B model and the validation split. For every run we report the hyperparameters along with the final task-specific evaluation metrics, stacked vertically with the first row corresponding to Task 1 etc. Regarding the table’s notation CS: Chunk Size, RTF: Retain-to-Forget ratio, LoRA: (r , α), LR: Learning rate, BS: Effective Batch Size, EPC: Epochs per Chunk, RL: RougeL score, EM: Exact Match rate, HMTA: Harmonic Mean Task Aggregate

Figure 6: Run 1 SUGD evaluation diagram. Here no chunking is applied. The hyperparameters used are *Retain-to-Forget ratio=1*, $(r, \alpha) = (16, 32)$, *learning rate=6e-05*, *eff. batch size=16*, *epochs=5*.

Figure 7: Run 2 SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=3, $(r, \alpha) = (16, 32)$, *learning rate*=5e-05, *eff. batch size*=16, *epochs per chunk*=5.

Figure 8: Run 3 SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=1, $(r, \alpha) = (16, 32)$, *learning rate*=5e-05, *eff. batch size*=16, *epochs per chunk*=3.

method’s performance and its limitations. Despite achieving strong quantitative metrics, our best-performing method struggles with fluency. While the MMLU scores indicate that the model does not suffer from catastrophic collapse, it frequently generates incoherent responses—particularly for forget samples and, more critically, for general queries. Table 15 presents sentence completion prompts that complement the QA pairs shown in the main paper. These examples confirm a significant loss of fluency when responding to forget inputs. Even if

we disregard this aspect given that information that needs to be forgotten is actually hidden, the model also exhibits fluency issues in general queries, most of the times generating repetitive outputs (strangely enough it converges to a specific number, e.g. 10).

This issue is further reflected in task-specific metrics, where forget scores drop to nearly zero across all tasks and evaluation types. This suggests that the model produces nonsensical outputs, as Rouge-L scores would otherwise be higher (e.g., 0.2–0.3, as observed with the gold standard model,

Figure 9: Run 5 SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=3, $(r, \alpha) = (16, 32)$, *learning rate*=5e-05, *eff. batch size*=16, *epochs per chunk*=3.

Figure 10: Run 6 SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=3, $(r, \alpha) = (16, 32)$, *learning rate*=5e-05, *eff. batch size*=16, *epochs per chunk*=4.

Table 10). This behavior may improve unlearning metrics but it does not necessarily translate to effective quality unlearning.

In order to circumvent these limitations, we explored the effect of using a unit batch size, as discussed above, by running experiments on a single GPU with fully stochastic gradient updates (batch size = 1). Due to the significantly increased execution time, this configuration was not considered for submission, yet we believe that it is crucial to be presented here as it provides a comprehensive

conclusion to our method and analysis. The hyperparameters used in this case are: *chunk size*=32, *Retain-to-Forget ratio*=3, $(r, \alpha) = (16, 64)$, *learning rate*=5e-05, *eff. batch size*=1 and *epochs per chunk*=3.

In Figure 11, we observe that the forget metrics (Rouge-L and EM) start near-perfect from the beginning of training. This is because, after every epoch, evaluation is performed only on forget samples that have already been processed by the model. The high forget scores indicate that these

Table 13: Summary metrics of SUGD runs using the 7B model and the train split, averaged across 3 random seeds. For every experiment, we report the hyperparameters along with the final evaluation metrics (MIA, HMTA, MMLU average and Final aggregate score) as well as the execution time and the number of floating point operations. Hyperparameters not mentioned in the table remain constant across runs: *chunk size*=32, *retain-to-forget ratio*=7, *learning rate*= $1e-5$ and *batch size*=8 (1 per device \times 8 GPUs). As for LoRA experiments the adapter is applied only to *query-value* matrices and linear layers, except run [†] where it’s applied to the *key* matrix as well.

Figure 11: Fully stochastic SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=3, $(r, \alpha) = (16, 64)$, *learning rate*= $5e-05$, ***effective batch size***=1, *epochs per chunk*=3.

Table 14: Final leaderboard for the 1B model. Our method consistently outperforms other teams’ submissions across model sizes.

processed samples have been successfully removed from memory, demonstrating the effectiveness of

the forgetting mechanism.

Examining the loss curves, we note that the forget loss remains relatively stable for Task 1 and Task 3, with only minor fluctuations. This suggests that the forgetting mechanism is mostly stable across training. However, in Task 2, forget loss shows a noticeable increase as training progresses, implying potential instability or difficulty in forgetting certain samples. The retain loss remains close to zero throughout training for all tasks, indicating that the model effectively retains relevant information without significant degradation.

Table 15: Qualitative examples for sentence completion prompts (drawn from the train split) complementing the QA pairs presented in the main paper. For each subtask we intentionally pick a sample our best model (the submitted configuration) struggles with (*Best Model's output* column). Next to its completion we provide the response of a model trained in a fully stochastic way, i.e. using a unit batch size (*Fully Stochastic* column). The latter evidently smooths out many of the other model's pain points, failing to provide a coherent response only for Task 2.

From a qualitative perspective, as shown in Table 15, this training approach significantly improves coherence, correcting nearly all cases where the

submitted model fails. Additionally, the MMLU average, which reflects the model's reasoning ability has increased from 0.494 at the pre-unlearning

Set & Task	RougeL	Exact Match

Table 16: Summary of final evaluation metrics for the model trained with a batch size of 1. The values closely match those of the gold standard indicating quite successful unlearning. Note that the MMLU average improves compared to the model’s performance prior unlearning (0.4946).

checkpoint to 0.519 (see Table 16 for detailed metrics of the fully stochastic run).

E Alternating Gradient Ascent - Descent

E.1 Method

Part of our experimentation focuses on an alternative approach designed to maintain training stability while ensuring effective unlearning by alternating between gradient ascent and descent. The forget set \mathcal{D}_f is partitioned into N chunks of a predefined size:

$$\mathcal{D}_f = \{\mathcal{D}_f^1, \dots, \mathcal{D}_f^N\}$$

Each chunk \mathcal{D}_f^i undergoes gradient ascent (GA) steps to maximize loss on forget data, inducing unlearning (*forgetting phase*). To counteract potential instability from repeated forgetting, a subset of the retain set \mathcal{D}_r is sampled and used for gradient descent (GD), reinforcing retained knowledge (*annealing phase*).

The size of the subset \mathcal{D}_r^i is controlled by the *annealing fraction* $\alpha \in (0, 1]$, which determines what proportion of the retain set is used for stabilization. The goal of the annealing phase is not to retrain the model on all retained samples—since they have already been memorized—but rather to smooth out potential instabilities introduced by the forgetting process. Using a smaller subset ($\alpha < 1$) speeds up training while potentially still providing sufficient stabilization.

Annealing phases are interleaved at a frequency dictated by the *interleaving factor* $\lambda \in [0, 1]$, which

Algorithm 2 Alternating GA-GD

Require: Forget set \mathcal{D}_f , Retain set \mathcal{D}_r , Chunk size chunk_size , Interleaving Factor λ , Annealing Fraction α , Learning rate η , Model parameters θ

1: Partition \mathcal{D}_f into $N = \lceil |\mathcal{D}_f| / \text{chunk_size} \rceil$ chunks:

$$\mathcal{D}_f = \{\mathcal{D}_f^1, \dots, \mathcal{D}_f^N\}$$

2: **for** $i = 1$ to N **do**

3: **for** each optimization step **do**

4: Perform forward pass on \mathcal{D}_f^i

5: Compute average forget loss:

$$L_f = \frac{1}{|\mathcal{D}_f^i|} \sum_{\mathcal{D}_f^i} \text{CE}(y, \hat{y})$$

6: Update model parameters via GA:

$$\theta \leftarrow \theta + \eta \nabla_{\theta} L_f$$

7: **end for**

8: **if** $(i \bmod \frac{1}{\lambda}) == 0$ **then**

9: Sample subset $\mathcal{D}_r^i \subset \mathcal{D}_r$ such that $|\mathcal{D}_r^i| = \alpha |\mathcal{D}_r|$

10: **for** each optimization step **do**

11: Perform forward pass on \mathcal{D}_r^i

12: Compute average retain loss:

$$L_r = \frac{1}{|\mathcal{D}_r^i|} \sum_{\mathcal{D}_r^i} \text{CE}(y, \hat{y})$$

13: Update model parameters via GD:

$$\theta \leftarrow \theta - \eta \nabla_{\theta} L_r$$

14: **end for**

15: **end if**

16: **end for**

17: **if** final annealing **then**

18: Perform final GD step on full retain set \mathcal{D}_r

$$\theta \leftarrow \theta - \eta \nabla_{\theta} L_r$$

19: **end if**

regulates how often stabilization is applied during the unlearning process. For example, when $\lambda = 0$, no intermediate annealing is performed, and the model undergoes all forgetting phases without stabilization. When $\lambda = 0.2$, annealing occurs after every 5 forgetting phases, when $\lambda = 0.5$ every 2 etc. Finally, when $\lambda = 1$, every forgetting phase is immediately followed by an annealing phase, ensuring continuous stabilization.

After completing all forgetting phases, an optional final annealing step is applied, where the model is trained on the full retain set \mathcal{D}_r to further mitigate unintended degradation of retained knowledge. The steps of this approach are outlined in Algorithm 2.

Additionally, the forgetting and annealing phases can be configured with different training arguments, such as learning rate, number of epochs, or op-

Run	Forget ↓						Retain ↑						HMTA ↑
	Task 1		Task 2		Task 3		Task 1		Task 2		Task 3

Table 17: Final evaluation metrics for some *Alternating GA-GD* runs on the 7B model using the validation split. Every run is accompanied by the detailed evaluation diagram in Figures 13, 14 and 15 respectively, where the hyperparameters of each run are also mentioned. RL stands for RougeL score computed for the sentence completion pairs, EM stands for Exact Match rate computed for the question-answer pairs and HMTA stands for Harmonic Mean Task Aggregate of the 12 task-specific metrics.

timization settings. This flexibility allows each phase to be handled in a way that best suits its objective. For instance, the forgetting phase often requires more controlled updates to prevent excessive or unstable modifications to the model, which can be achieved by using a smaller learning rate or fewer epochs. In contrast, the annealing phase primarily acts as a stabilizer, meaning it can often tolerate larger learning rates or more epochs to efficiently smooth out instabilities introduced by forgetting. By tuning these hyperparameters independently, the method ensures a balanced trade-off between effective unlearning and model stability.

E.2 Results

In order to get some insights of the method’s effectiveness, we conduct experiments using the validation split and evaluate the model after every epoch during training. In Table 17 we present the detailed evaluation metrics for three indicative runs. For every run reported here we also provide the corresponding evaluation diagram for completeness in Figures 13, 14 and 15 respectively. All these experiments are conducted using the 7B model and the validation split. A small-scale experimentation with this method reveals moderate performance, therefore we did not proceed with extensive experiments. However, these results offer useful insights and disclose limitations which our main method aims to resolve.

Regarding some key findings of the presented alternating gradient ascent-descent method, we observe that frequent annealing is almost mandatory to prevent loss explosion and catastrophic collapse. Forgetting, especially when processing later chunks, causes retain loss to increase as well, even though it is not applied on retain data at all. This means that the gradient ascent steps lead to partial catastrophic collapse deteriorating the model’s general performance instead of just acting selectively

on the forget data samples. In a similar fashion, annealing interestingly lowers forget loss along with its intended function to stabilize retain loss. This hints that annealing forces the model to return somewhere close to its initial state -speaking in terms of the model’s parameter space-, on the one hand reversing a potential divergence, but at the same time failing to actually forget the data that need to be forgotten.

F Submission details

Participants are tasked to submit a PyTorch function that performs unlearning on the trained model utilizing the private *test* split. The unlearned model is then evaluated as described above. This code is executed on an AWS EC2 p4d.24xlarge node (8 A100 40GB GPUs), allowing maximum execution time of 1 hour. Throughout our experimentation, we develop our algorithms in the same computational environment, as offered by Amazon Web Services (AWS).
