higher-level purpose of the data that they are trained on. As a community, we have been optimizing an utterance excerpting task, we have been moderately successful at it, but this task in at least one important respect bears no resemblance to what we could convincingly call speech summarization.

These four results provide us with valuable insight into the current state of the art in speech summarization: it is not summarization, the aspiration to measure the relative merits of knowledge sources has masked the prominence of some very simple baselines, and the Zechner & Waibel pipe-ASR-output-into-text-summarizer model is still very competitive — what seems to matter more than having access to the raw spoken data is simply knowing that it is spoken data, so that the most relevant, still textually available features can be used. Section 2 describes the background and further details of the experiments that we conducted to arrive at these conclusions. Section 3 presents the results that we obtained. Section 4 concludes by outlining an ecologically valid alternative for evaluating real summarization in light of these results.

## 2 Setting of the experiment

### 2.1 Provenance of the data

Speech summarizers are generally trained to summarize either broadcast news or meetings. With the exception of one paper that aspires to compare the “styles” of spoken and written language *ceteris paribus* (Christensen et al., 2004), the choice of broadcast news as a source of data in more recent work is rather curious. Broadcast news, while open in principle in its range of topics, typically has a range of closely parallel, written sources on those same topics, which can either be substituted for spoken source material outright, or at the very least be used corroboratively alongside them. Broadcast news is also read by professional news readers, using high quality microphones and studio equipment, and as a result has very lower WER — some even call ASR a solved problem on this data source. Broadcast news is also very text-like at a deeper level. Relative position within a news story or dialogue, the dreaded baseline of text summarization, works extremely well in spoken broadcast news summarization, too. Within the operating region of the receiver

operating characteristics (ROC) curve most relevant to summarizers (0.1–0.3), Christensen et al. (2004) showed that position was by far the best feature in a read broadcast news system with high WER, and that position and length of the extracted utterance were the two best with low WER. Christensen et al. (2004) also distinguished read news from “spontaneous news,” broadcasts that contain interviews and/or man-in-the-field reports, and showed that in the latter variety position is not at all prominent at any level of WER, but length is. Maskey & Hirschberg’s (2005) broadcast news is a combination of read news and spontaneous news.

Spontaneous speech, in our view, particularly in the lecture domain, is our best representative of what needs to be summarized. Here, the positional baseline performs quite poorly (although length does extremely well, as discussed below), and ASR performance is far from perfect. In the case of lectures, there are rarely exact transcripts available, but there are bulleted lines from presentation slides, related research papers on the speaker’s web page and monographs on the same topic that can be used to improve the language models for speech recognition systems. Lectures have just the right amount of props for realistic ASR, but still very open domain vocabularies and enough spontaneity to make this a problem worth solving. As discussed further in Section 4, the classroom lecture genre also provides us with a task that we hope to use to conduct a better grounded evaluation of real summarization quality.

To this end, we use a corpus of lectures recorded at the University of Toronto to train and test our summarizer. Only the lecturer is recorded, using a head-worn microphone, and each lecture lasts 50 minutes. The lectures in our experiments are all undergraduate computer science lectures. The results reported in this paper used four different lectures, each from a different course and spoken by a different lecturer. We used a leave-one-out cross-validation approach by iteratively training on three lectures worth of material and testing on the one remaining. We combine these iterations by averaging. The lectures were divided at random into 8–15 minute intervals, however, in order to provide a better comparison with the SWITCHBOARD dialogues. Each interval was treated as a separate document and was summarized separately. So the four lectures together actually

provide 16 SWITCHBOARD-sized samples of material, and our cross-validation leaves on average four of them out in a turn.

We also use part of the SWITCHBOARD corpus in one of our comparisons. SWITCHBOARD is a collection of telephone conversations, in which two participants have been told to speak on a certain topic, but with no objective or constructive goal to proceed towards. While the conversations are locally coherent, this lack of goal-orientation is acutely apparent in all of them — they may be as close as any speech recording can come to being about nothing.<sup>2</sup> We randomly selected 27 conversations, containing a total of 3665 utterances (identified by pause length), and had three human annotators manually label each utterance as in- or out-of-summary. Interestingly, the interannotator agreement on SWITCHBOARD ( $\kappa = 0.383$ ) is higher than on the lecture corpus (0.372) and higher than the  $\kappa$ -score reported by Galley (2006) for the ICSI meeting data used by Murray et al. (2005; 2006), in spite of the fact that Murray et al. (2005) primed their annotators with a set of questions to consider when annotating the data.<sup>3</sup> This does not mean that the SWITCHBOARD summaries are qualitatively better, but rather that annotators are apt to agree more on which utterances to include in them.

## 2.2 Summarization task

As with most work in speech summarization, our strategy involves considering the problem as one of utterance extraction, which means that we are not synthesizing new text or speech to include in summaries, nor are we attempting to extract small phrases to sew together with new prosodic contours. Candidate utterances are identified through pause-length detection, and the length of these pauses has been experimentally calibrated to 200 msec, which results in roughly sentence-sized utterances. Summarization then consists of choosing the best N% of these utterances for the summary, where N is typ-

<sup>2</sup>It should be noted that the meandering style of SWITCHBOARD conversations does have correlates in text processing, particularly in the genres of web blogs and newsgroup- or wiki-based technical discussions.

<sup>3</sup>Although we did define what a summary was to each annotator beforehand, we did not provide questions or suggestions on content for either corpus.

ically between 10 and 30. We will provide ROC curves to indicate performance as a function over all N. An ROC is plotted along an x-axis of *specificity* (true-negative-rate) and a y-axis of *sensitivity* (true-positive-rate). A larger area under the ROC corresponds to better performance.

## 2.3 Utterance isolation

The framework for our extractive summarization experiments is depicted in Figure 1. With the exception of disfluency removal, it is very similar in its overall structure to that of Zechner’s (2001). The summarizer takes as input either manual or automatic transcripts together with an audio file, and has three modules to process disfluencies and extract features important to identifying sentences.

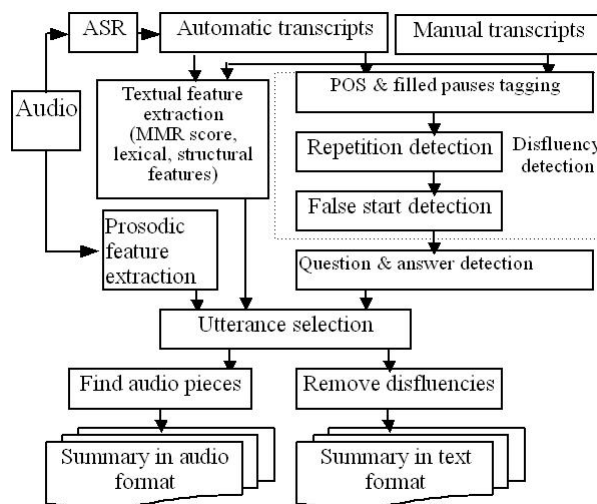

Figure 1: Experimental framework for summarizing spontaneous conversations.

During sentence boundary detection, words that are likely to be adjacent to an utterance boundary are determined. We call these words *trigger words*.

False starts are very common in spontaneous speech. According to Zechner’s (2001) statistics on the SWITCHBOARD corpus, they occur in 10-15% of all utterances. A decision tree (C4.5, Release 8) is used to detect false starts, trained on the POS tags and trigger-word status of the first and last four words of sentences from a training set. Once false starts are detected, these are removed.

We also identify repetitions as a sequence of between 1 and 4 words which is consecutively re-

peated in spontaneous speech. Generally, repetitions are discarded. Repetitions of greater length are extremely rare statistically and are therefore ignored.

Question-answer pairs are also detected and linked. Question-answer detection is a two-stage process. The system first identifies the questions and then finds the corresponding answer. For (both WH- and Yes/No) question identification, another C4.5 classifier was trained on 2,000 manually annotated sentences using utterance length, POS bigram occurrences, and the POS tags and trigger-word status of the first and last five words of an utterance. After a question is identified, the immediately following sentence is labelled as the answer.

## 2.4 Utterance selection

To obtain a trainable utterance selection module that can utilize and compare rich features, we formulated utterance selection as a standard binary classification problem, and experimented with several state-of-the-art classifiers, including linear discriminant analysis LDA, support vector machines with a radial basis kernel (SVM), and logistic regression (LR), as shown in Figure 2 (computed on SWITCHBOARD data). MMR, Zechner’s (2001) choice, is provided as a baseline. MMR linearly interpolates a relevance component and a redundancy component that balances the need for new vs. salient information. These two components can just as well be mixed through LR, which admits the possibility of adding more features and the benefit of using LR over held-out estimation.

Figure 2: Precision-recall curve for several classifiers on the utterance selection task.

As Figure 2 indicates, there is essentially no difference in performance among the three classifiers we tried, nor between MMR and LR restricted to the two MMR components. This is important, since we will be comparing MMR to LR-trained classifiers based on other combinations of features below. The ROC curves in the remainder of this paper have been prepared using the LR classifier.

## 2.5 Features extracted

While there is very little difference realized across pattern recognition methods, there is much more at stake with respect to which features the methods use to characterize their input. We can extract and use the features in Figure 3, arranged there according to their knowledge source.

We detect disfluencies in the same manner as Zechner (2001)). Taking ASR transcripts as input, we use the Brill tagger (Brill, 1995) to assign POS tags to each word. There are 42 tags: Brill’s 38 plus four which identify filled-pause disfluencies:

- empty coordinating conjunctions (CO),
- lexicalized filled pauses (DM),
- editing terms (ET), and
- non-lexicalized filled pauses (UH).

Our disfluency features include the number of each of these, their total, and also the number of repetitions. Disfluencies adjacent to a speaker turn are ignored, however, because they occur as a normal part of turn coordination between speakers.

Our preliminary experiments suggest that speaker meta-data do not improve on the quality of summarization, and so this feature is not included.

We indicate with bold type the features that indicate some quantity of length, and we will consider these as members of another class called “length,” in addition to their given class above. In all of the data on which we have measured, the correlation between time duration and number of words is nearly 1.00 (although pause length is not).

## 2.6 Evaluation of summary quality

We plot receiver operating characteristic (ROC) curves along a range of possible compression parameters, and in one case, ROUGE scores. ROUGE

1. Lexical features
    - MMR score<sup>4</sup>,
    - **utterance length (in words)**,
  2. Named entity features — number of:
    - person names,
    - location names
    - organization names
    - the sum of these
  3. Structural features
    - utterance position, labelled as first, middle, or last one-third of the conversation
    - a Boolean feature indicating whether an utterance is adjacent to a speaker turn
1. Acoustic features — min, max and avg. of:<sup>5</sup>
    - pitch
    - energy
    - speaking rate
    - **(unfilled) pause length**
    - **time duration (in msec)**
  2. “Spoken language” features
    - disfluencies
    - given/new information
    - question/answer pair identification

Figure 3: Features available for utterance selection by knowledge source. Features in bold type quantify length. In our experiments, we exclude these from their knowledge sources, and study them as a separate length category.

and F-measure are both widely used in speech summarization, and they have been shown by others to be broadly consistent on speech summarization tasks (Zhu and Penn, 2005).

### 3 Results and analysis

#### 3.1 Lecture corpus

The results of our evaluation on the lecture data appear in Figure 4. As is evident, there is very little difference among the combinations of features with this data source, apart from the positional baseline, “lead,” which simply chooses the first N% of the utterances. This performs quite poorly. The best performance is achieved by using all of the features together, but the length baseline, which uses only those features in bold type from Figure 3, is very close (no statistically significant difference), as is MMR.<sup>6</sup>

<sup>4</sup>When evaluated on its own, the MMR interpolating parameter is set through experimentation on a held-out dataset, as in Zechner (2001). When combined with other features, its relevance and redundancy components are provided to the classifier separately.

<sup>5</sup>All of these features are calculated on the word level and normalized by speaker.

<sup>6</sup>We conducted the same evaluation without splitting the lectures into 8–15 minute segments (so that the summaries summarize an entire lecture), and although space here precludes the presentation of the ROC curves, they are nearly identical

Figure 4: ROC curve for utterance selection with the lecture corpus with several feature combinations.

#### 3.2 SWITCHBOARD corpus

The corresponding results on SWITCHBOARD are shown in Figure 5. Again, length and MMR are very close to the best alternative, which is again all of features combined. The difference with respect to either of these baselines is statistically significant within the popular 10–30% compression range, as is the classifier trained on all features but acoustic to those on the segments shown here.

Figure 5: ROC curve for SWITCHBOARD utterance selection with several feature combinations.

(not shown). The classifier trained on all features but spoken language features (not shown) is not significantly better, so it is the spoken language features that make the difference, not the acoustic features. The best score is also significantly better than on the lecture data, however, particularly in the 10–30% range. Our analysis of the difference suggests that the much greater variance in utterance length in SWITCHBOARD is what accounts for the overall better performance of the automated system as well as the higher human interannotator agreement. This also goes a long way to explaining why the length baseline is so good.

Still another perspective is to classify features as either “what-is-said” (MMR, length and NE features) or “how-it-is-said” (structural, acoustic and spoken-language features), as shown in Figure 6. What-is-said features are better, but only barely so within the usual operating region of summarizers.

### 3.3 Impact of WER

Word error rates (WERs) arising from speech recognition are usually much higher in spontaneous conversations than in read news. Having trained ASR models on SWITCHBOARD section 2 data with our sample of 27 conversations removed, the WER on that sample is 46%. We then train a language model on SWITCHBOARD section 2 without removing the 27-conversation sample so as to delib-

Figure 6: ROC curves for textual and non-textual features.

erately overfit the model. This pseudo-WER is then 39%. We might be able to get less WER by tuning the ASR models or by using more training data, but that is not the focus here. Summarizing the automatic transcripts generated from both of these systems using our LR-based classifier with all features, as well as manual (perfect) transcripts, we obtain the ROUGE-1 scores in Table 1.

WER	10%	15%	20%	25%	30%
0.46	.615	.591	.556	.519	.489
0.39	.615	.591	.557	.526	.491
0	.619	.600	.566	.530	.492

Table 1: ROUGE-1 of LR system with all features under different WERs.

Table 1 shows that WERs do not impact summarization performance significantly. One reason is that the acoustic and structural features are not affected by word errors, although WERs can affect the MMR, spoken language, length and NE features. Figures 7 and 8 present the ROC curves of the MMR and spoken language features, respectively, under different WERs. MMR is particularly resilient, even on SWITCHBOARD. Keywords are still often correctly recognized, even in the presence of high WER, although possibly because the same topic is discussed in many SWITCHBOARD conversations.

Figure 7: ROC curves for the effectiveness of MMR scores on transcripts under different WERs.

Figure 8: ROC curves for the effectiveness of spoken language features on transcripts under different WERs.

When some keywords are misrecognized (e.g. hat), furthermore, related words (e.g. dress, wear) still may identify important utterances. As a result, a high WER does not necessarily mean a worse transcript for bag-of-keywords applications like summarization and classification, regardless of the data source. Utterance length does not change very much when WERs vary, and in addition, it is often a latent variable that underlies some other features' role, e.g., a long utterance often has a higher MMR score than a short utterance, even when the WER changes.

Note that the effectiveness of spoken language features varies most between manually and automatically generated transcripts just at around the typi-

cal operating region of most summarization systems. The features of this category that respond most to WER are disfluencies. Disfluency detection is also at its most effective in this same range with respect to any transcription method.

#### 4 Future Work

In terms of future work in light of these results, clearly the most important challenge is to formulate an experimental alternative to measuring against a subjectively classified gold standard in which annotators are forced to commit to relative salience judgements with no attention to goal orientation and no requirement to synthesize the meanings of larger units of structure into a coherent message. It is here that using the lecture domain offers us some additional assistance. Once these data have been transcribed and outlined, we will be able to formulate examinations for students that test their knowledge of the topics being lectured upon: both their higher-level understanding of goals and conceptual themes, as well as factoid questions on particular details. A group of students can be provided with access to a collection of entire lectures to establish a theoretical limit. Experimental and control groups can then be provided with access only to summaries of those lectures, prepared using different sets of features, or different modes of delivery (text vs. speech), for example. This task-based protocol involves quite a bit more work, and at our university, at least, there are regulations that preclude us placing a group of students in a class at a disadvantage with respect to an examination for credit that need to be dealt with. It is, however, a far better means of assessing the quality of summaries in an ecologically valid context.

It is entirely possible that, within this protocol, the baselines that have performed so well in our experiments, such as length or, in read news, position, will utterly fail, and that less traditional acoustic or spoken language features will genuinely, and with statistical significance, add value to a purely transcript-based text summarization system. To date, however, that case has not been made. He et al. (1999) conducted a study very similar to the one suggested above and found no significant difference between using pitch and using slide transition boundaries. No ASR transcripts or length features were used.

## Abstract

Despite its long history, and a great deal of research producing many useful algorithms and observations, research in cooperative response generation has had little impact on the recent commercialization of dialogue technologies, particularly within the spoken dialogue community. We hypothesize that a particular type of cooperative response, *intensional summaries*, are effective for when users are unfamiliar with the domain. We evaluate this hypothesis with two experiments with CRUISER, a DS for in-car or mobile users to access restaurant information. First, we compare CRUISER with a baseline system-initiative DS, and show that users prefer CRUISER. Then, we experiment with four algorithms for constructing *intensional summaries* in CRUISER, and show that two summary types are equally effective: summaries that maximize domain coverage and summaries that maximize utility with respect to a user model.

## 1 Introduction

Research in cooperative response generation has had a long history and produced many useful algorithms and observations (Mays 1980; Pollack et al.1982; Joshi et al., 1986; Kalita et al., 1986) *inter alia*. However, it has had little impact on the recent commercialization of dialogue technologies, particularly within the spoken dialogue community. We believe that this lack of interest in cooperative response generation arises from two limitations of previous work: (1) There has been relatively little empirical research showing that cooperative responses lead

<i>U1:</i>	Tell me about restaurants in London.
<i>SI1:</i>	What kind of cuisine are you interested in?
<i>C1:</i>	I know of 596 restaurants in London. I know of 3 inexpensive vegetarian restaurants and 14 inexpensive Chinese restaurants. I also know of 4 inexpensive Greek restaurants.
<i>U2:</i>	Chinese.
<i>SI2:</i>	Do you have a price range in mind?
<i>C2:</i>	I know of 27 restaurants in London that serve Chinese food. There are 8 inexpensive Chinese restaurants in Chinatown and 2 inexpensive Chinese restaurants in Hampstead/Kilburn. I also know of 1 inexpensive Chinese restaurant in Soho.
<i>U3:</i>	How about a cheap one?
<i>SI3:</i>	What neighborhood would you like?
<i>C3:</i>	I know of 1 inexpensive Chinese restaurant in Hampstead/Kilburn with very good food quality and 1 in Bayswater with good food quality. I also know of 2 in Chinatown with medium food quality.

Figure 1: Intensional summaries (C = CRUISER) as compared with a *system initiative* (SI) strategy in the London restaurant domain. U = User

to more natural, effective, or efficient dialogues (Litman et al.1998; Demberg and Moore, 2006); and (2) Previous work has hand-crafted such responses, or hand-annotated the database to support them (Kaplan, 1984; Kalita et al., 1986; Cholvy, 1990; Polifroni et al., 2003; Benamara, 2004), which has made it difficult to port and scale these algorithms.

Moreover, we believe that there is an even greater need today for cooperative response generation. Larger and more complex datasets are daily being created on the Web, as information

is integrated across multiple sites and vendors. Many users will want to access this information from a mobile device and will have little knowledge of the domain. We hypothesize that these users will need cooperative responses that select and generalize the information provided.

In particular, we hypothesize that a particular type of cooperative response, *intensional summaries*, when provided incrementally during a dialogue, are effective for large or complex domains, or when users are unfamiliar with the domain. These intensional summaries have the ability to describe the data that forms the knowledge base of the system, as well as relationships among the components of that database. We have implemented *intensional summaries* in CRUISER (Cooperative Responses Using Intensional Summaries of Entities and Relations), a DS for in-car or mobile users to access restaurant information (Becker et al.2006; Weng et al.2005; Weng et al.2006). Figure 1 contrasts our proposed *intensional summary* strategy with the *system initiative* strategy used in many dialogue systems (Walker et al., 2002; VXML, 2007).

Previous research on cooperative responses has noted that summary strategies should vary according to the context (Sparck Jones, 1993), and the interests and preferences of the user (Gaasterland et al., 1992; Carenini and Moore, 2000; Demberg and Moore, 2006). A number of proposals have emphasized the importance of making generalizations (Kaplan, 1984; Kalita et al., 1986; Joshi et al., 1986). In this paper we explore different methods for constructing intensional summaries and investigate their effectiveness. We present fully automated algorithms for constructing intensional summaries using knowledge discovery techniques (Acar, 2005; Lesh and Mitzenmacher, 2004; Han et al., 1996), and decision-theoretic user models (Carenini and Moore, 2000).

We first explain in Sec. 2 our fully automated, domain-independent algorithm for constructing intensional summaries. Then we evaluate our intensional summary strategy with two experiments. First, in Sec. 3, we test the hypothesis that users prefer summary responses in dialogue

systems. We also test a refinement of that hypothesis, i.e., that users prefer summary type responses when they are unfamiliar with a domain. We compare several versions of CRUISER with the system-initiative strategy, exemplified in Fig. 1, and show that users prefer CRUISER. Then, in Sec. 4, we test four different algorithms for constructing *intensional summaries*, and show in Sec. 4.1 that two summary types are equally effective: summaries that maximize domain coverage and summaries that maximize utility with respect to a user model. We also show in Sec. 4.2 that we can predict with 68% accuracy which summary type to use, a significant improvement over the majority class baseline of 47%. We sum up in Sec. 5.

## 2 Intensional Summaries

This section describes algorithms which result in the four types of intensional summaries shown in Fig. 2. We first define *intensional summaries* as follows. Let  $D$  be a domain comprised of a set  $R$  of database records  $\{r_1, \dots, r_n\}$ . Each record consists of a set of attributes  $\{A_1, \dots, A_n\}$ , with associated values  $v$ :  $D(A_i) = \{v_{i,1}, v_{i,2}, \dots, v_{i,n}\}$ . In a dialogue system, a constraint is a value introduced by a user with either an explicit or implied associated attribute. A constraint  $c$  is a function over records in  $D$  such that  $c_j(R)$  returns a record  $r$  if  $r \subseteq D$  and  $r : A_i = c$ . The set of all dialogue constraints  $\{c_1, \dots, c_n\}$  is the *context*  $C$  at any point in the dialogue. The set of records  $R$  in  $D$  that satisfy  $C$  is the *focal information*:  $R$  is the *extension* of  $C$  in  $D$ . For example, the attribute *cuisine* in a restaurant domain has values such as “French” or “Italian”. A user utterance instantiating a constraint on cuisine, e.g., “I’m interested in Chinese food”, results in a set of records for restaurants serving Chinese food. *Intensional summaries* as shown in Fig. 2 are descriptions of the focal information, that highlight particular subsets of the focal information and make generalizations over these subsets.

The algorithm for constructing intensional summaries takes as input the focal information  $R$ , and consists of the following steps:

- Rank attributes in context  $C$ , using one of two ranking methods (Sec. 2.1);

Type	Ranking	#atts	Clusters	Scoring	Summary
<b>Ref-Sing</b>	Refiner	3	Single value	Size	<i>I know of 35 restaurants in London serving Indian food. All price ranges are represented. Some of the neighborhoods represented are Mayfair, Soho, and Chelsea. Some of the nearby tube stations are Green Park, South Kensington and Piccadilly Circus.</i>
<b>Ref-Assoc</b>	Refiner	2	Associative	Size	<i>I know of 35 restaurants in London serving Indian food. There are 3 medium-priced restaurants in Mayfair and 3 inexpensive ones in Soho. There are also 2 expensive ones in Chelsea.</i>
<b>UM-Sing</b>	User model	3	Single value	Utility	<i>I know of 35 restaurants in London serving Indian food. There are 6 with good food quality. There are also 12 inexpensive restaurants and 4 with good service quality.</i>
<b>UM-Assoc</b>	User model	2	Associative	Utility	<i>I know of 35 restaurants in London serving Indian food. There are 4 medium-priced restaurants with good food quality and 10 with medium food quality. There are also 4 that are inexpensive but have poor food quality.</i>

Figure 2: Four intensional summary types for a task specifying restaurants with Indian cuisine in London.

- Select top- $N$  attributes and construct clusters using selected attributes (Sec. 2.2);
- Score and select top- $N$  clusters (Sec. 2.3);
- Construct frames for generation, perform aggregation and generate responses.

## 2.1 Attribute Ranking

We explore two candidates for attribute ranking: User model and Refiner.

**User model:** The first algorithm utilizes decision-theoretic user models to provide an attribute ranking specific to each user (Carenini and Moore, 2000). The database contains 596 restaurants in London, with up to 19 attributes and their values. To utilize a user model, we first elicit user ranked preferences for domain attributes. Attributes that are unique across all entities, or missing for many entities, are automatically excluded, leaving six attributes: *cuisine*, *decor quality*, *food quality*, *price*, *service*, and *neighborhood*. These are ranked using the SMARTER procedure (Edwards and Barron, 1994). Rankings are converted to weights ( $w$ ) for each attribute, with a formula which guarantees that the weights sum to 1:

$$w_k = \frac{1}{K} \sum_{i=k}^K \frac{1}{i}$$

where  $K$  equals the number of attributes in the ranking. The absolute rankings are used to select attributes. The weights are also used for cluster scoring in Sec. 2.3. User model ranking is used to produce **UM-Sing** and **UM-Assoc** in Fig. 2.

**Refiner method:** The second attribute ranking method is based on the Refiner algorithm for summary construction (Polifroni et al., 2003). The Refiner returns values for every attribute in the focal information in frames ordered by frequency. If the counts for the top- $N$  (typically, 4) values for a particular attribute, e.g., *cuisine*, exceeded  $M\%$  (typically 80%) of the total counts for all values, then that attribute is selected. For example, 82% of Indian restaurants in the London database are in the neighborhoods Mayfair, Soho, and Chelsea. *Neighborhood* would, therefore, be chosen as an attribute to speak about for Indian restaurants. The thresholds  $M$  and  $N$  in the original Refiner were set *a priori*, so it was possible that no attribute met or exceeded the thresholds for a particular subset of the data. In addition, some entities could have many unknown values for some attributes.

Thus, to insure that all user queries result in some summary response, we modify the Refiner

method to include a ranking function for attributes. This function favors attributes that contain fewer unknown values but always returns a ranked set of attributes. Refiner ranking is used to produce **Ref-Sing** and **Ref-Assoc** in Fig. 2.

## 2.2 Subset Clustering

Because the focal information is typically too large to be enumerated, a second parameter attempts to find interesting clusters representing subsets of the focal information to use for the content of intensional summaries. We assume that the *coverage* of the summary is important, i.e., the larger the cluster, the more general the summary.

The simplest algorithm for producing clusters utilizes a specified number of the top-ranked attributes to define a cluster. Single attributes, as in the **Ref-Sing** and **UM-Sing** examples in Fig. 2, typically produce large clusters. Thus one algorithm uses the top three attributes to produce clusters, defined by either a single value (e.g., **UM-Sing**) or by the set of values that comprise a significant portion of the total (e.g., **Ref-Sing**).

Figure 3: A partial tree for Indian restaurants in London, using price range as the predictor variable and food quality as the dependent variable. The numbers in parentheses are the size of the clusters described by the path from the root.

However, we hypothesize that more informative and useful intensional summaries might be constructed from clusters of discovered *associations* between attributes. For example, associations between *price* and *cuisine* produce summaries such as *There are 49 medium-priced*

*restaurants that serve Italian cuisine*. We apply c4.5 decision tree induction to compute associations among attributes (Kamber et al., 1997; Quinlan, 1993). Each attribute in turn is designated as the dependent variable, with other attributes used as predictors. Thus, each branch in the tree represents a cluster described by the attribute/value pairs that predict the leaf node. Fig. 3 shows clusters of different sizes induced from Indian restaurants in London. The cluster size is determined by the number of attributes used in tree induction. With two attributes, the average cluster size at the leaf node is 60.4, but drops to 4.2 with three attributes. Thus, we use two attributes to produce associative clusters, as shown in Fig. 2 (i.e., the **Ref-Assoc** and **UM-Assoc** responses), to favor larger clusters.

## 2.3 Cluster Scoring

The final parameter scores the clusters. One scoring metric is based on cluster size. Single attributes produce large clusters, while association rules produce smaller clusters.

The second scoring method selects clusters of high utility according to a user model. We first assign scalar values to the six ranked attributes (Sec. 2.1), using clustering methods as described in (Polifroni et al., 2003). The weights from the user model and the scalar values for the attributes in the user model yield an overall utility  $U$  for a cluster  $h$ , similar to utilities as calculated for individual entities (Edwards and Barron, 1994; Carenini and Moore, 2000):

$$U_h = \sum_{k=1}^K w_k(x_{hk})$$

We use cluster size scoring with Refiner ranking and utility scoring with user model ranking. For conciseness, all intensional summaries are based on the three highest scoring clusters.

## 2.4 Summary

The algorithms for attribute selection and cluster generation and scoring yield the four summary types in Table 2. Summary **Ref-Sing** is constructed using (1) the Refiner attribute ranking; and (2) no association rules. (The quantifier (e.g., *some*, *many*) is based on the cover-

age.) Summary **Ref-Assoc** is constructed using (1) the Refiner attribute ranking; and (2) association rules for clustering. Summary **UM-Sing** is constructed using (1) a user model with ranking as above; and (2) no association rules. Summary **UM-Assoc** is constructed using (1) a user model with ranking of price, food, cuisine, location, service, and decor; and (2) association rules.

### 3 Experiment One

This experiment asks whether subjects prefer intensional summaries to a baseline system-initiative strategy. We compare two types of intensional summary responses from Fig. 2, **Ref-Assoc** and **UM-Assoc** to system-initiative.

The 16 experimental subjects are asked to assume three personas, in random order, chosen to typify a range of user types, as in (Demberg and Moore, 2006). Subjects were asked to read the descriptions of each persona, which were available for reference, via a link, throughout the experiment.

The first persona is the *Londoner*, representing someone who knows London and its restaurants quite well. The Londoner persona typically knows the specific information s/he is looking for. We predict that the system-initiative strategy in Fig. 1 will be preferred by this persona, since our hypothesis is that users prefer intensional summaries when they are *unfamiliar* with the domain.

The second persona is the *Generic tourist* (GT), who doesn't know London well and does not have strong preferences when it comes to selecting a restaurant. The GT may want to *browse* the domain, i.e. to learn about the structure of the domain and retrieve information by recognition rather than specification (Belkin et al., 1994). We hypothesize that the **Ref-Assoc** strategy in Fig. 2 will best fit the GT, since the corresponding clusters have good domain coverage.

The third persona is the *UM tourist* (UMT). This persona may also want to *browse* the database, since they are unfamiliar with London. However, this user has expressed preferences about restaurants through a previous interaction. The UMT in our experiment is con-

cerned with price and food quality (in that order), and prefers restaurants in Central London. After location, the UMT is most concerned with cuisine type. The intensional summary labelled **Um-Assoc** in Fig. 2 is based on this user model, and is computed from discovered associations among preferred attributes.

As each persona, subjects rate responses on a Likert scale from 1-7, for each of four dialogues, each containing between three and four query/response pairs. We do not allow tie votes among the three choices.

#### 3.1 Experimental results

The primary hypothesis of this work is that users prefer summary responses in dialogue systems, without reference to the context. To test this hypothesis, we first compare Londoner responses (average rating 4.64) to the most highly rated of the two intensional summaries (average rating 5.29) for each query/response pair. This difference is significant ( $df = 263, p < .0001$ ), confirming that over users prefer an intensional summary strategy to a system-initiative strategy.

Table 1 shows ratings as a function of persona and response type. Overall, subjects preferred the responses tailored to their persona. The Londoner persona significantly preferred Londoner over UMT responses ( $df = 95, p < .05$ ), but not more than GT responses. This confirms our hypothesis that users prefer incremental summaries in dialogue systems. Further, it disconfirms our refinement of that hypothesis, that users prefer summaries only when they are unfamiliar with the domain. The fact that no difference was found between Londoner and GT responses indicates that GT responses contain information that is perceived as useful even when users are familiar with the domain.

The Generic Tourist persona also preferred the GT responses, significantly more than the Londoner responses ( $df = 95, p < .05$ ), but not significantly more than the UMT responses. We had hypothesized that the optimal summary type for users completely new to a domain would describe attributes that have high coverage of the focal information. This hypothesis is disconfirmed by these findings, that indicate that user

Persona	Response Type		
	London	GT	UMT
London	5.02	4.55	4.32
GT	4.14	4.67	4.39
UM tourist	3.68	4.86	5.23

Table 1: Ratings by persona assumed. London = Londoner persona, GT = Generic tourist, UMT = User Model tourist

model information is helpful when constructing summaries for any user interested in browsing.

Finally, the UM Tourist persona overwhelmingly preferred UMT responses over Londoner responses ( $df = 95, p < .0001$ ). However, UMT responses were not significantly preferred to GT responses. This confirms our hypothesis that users prefer summary responses when they are unfamiliar with the domain, but disconfirms the hypothesis that users will prefer summaries based on a user model. The results for both the Generic Tourist and the UM Tourist show that both types of intensional summaries contain useful information.

## 4 Experiment Two

The first experiment shows that users prefer intensional summaries; the purpose of the second experiment is to investigate what makes a good intensional summary. We test the different ways of constructing such summaries described in Sec. 2, and illustrated in Fig. 2.

Experimental subjects were 18 students whose user models were collected as described in Sec. 2.3. For each user, the four summary types were constructed for eight tasks in the London restaurant domain, where a task is defined by a query instantiating a particular attribute/value combination in the domain (e.g., *I'm interested in restaurants in Soho*). The tasks were selected to utilize a range of attributes. The focal information for four of the tasks (*large set tasks*) were larger than 100 entities, while the focal information for the other four tasks were smaller than 100 entities (*small set tasks*). Each task was presented to the subject on its own web page with the four intensional summaries presented as text on the web page. Each subject was asked to carefully read and rate each al-

	User model	Refiner
Association rules	3.4	2.9
Single attributes	3.0	3.4
	User model	Refiner
Small dataset	3.1	3.4
Large dataset	3.2	2.9

Table 2: User ratings showing the interaction between clustering method, attribute ranking, and dataset size in summaries.

ternative summary response on a Likert scale of 1...5 in response to the statement, *This response contains information I would find useful when choosing a restaurant*. The subjects were also asked to indicate which response they considered the best and the worst, and to provide free-text comments about each response.

### 4.1 Hypothesis Testing Results

We performed an analysis of variance with attribute ranking (user model vs. refiner), clustering method (association rules vs. single attributes), and set size (large vs. small) as independent variables and user ratings as the dependent variable. There was a main effect for set size ( $df = 1, f = 6.7, p < .01$ ), with summaries describing small datasets (3.3 average rating) rated higher than those for large datasets (3.1 average rating).

There was also a significant interaction between attribute ranking and clustering method ( $df = 1, f = 26.8, p < .001$ ). Table 2 shows ratings for the four summary types. There are no differences between the two highest rated summaries: **Ref-Sing** (average 3.4) and **UM-Assoc** (average 3.4). See Fig. 2. This suggests that discovered associations provide useful content for intensional summaries, but only for attributes ranked highly by the user model.

In addition, there was another significant interaction between ranking method and setsize ( $df = 1, f = 11.7, p < .001$ ). The ratings at the bottom of Table 2 shows that overall, users rate summaries of small datasets higher, but users rate summaries higher for large datasets when a user model is used. With small datasets, users prefer summaries that don't utilize user model information.

We also calculate the average utility for each response (Sec. 2.1) and find a strong correlation between the rating and its utility ( $p < .005$ ). When considering this correlation, it is important to remember that utility can be calculated for all responses, and there are cases where the Refiner responses have high utility scores.

## 4.2 Summary Type Prediction

Our experimental data suggest that characteristics associated with the set of restaurants being described are important, as well as utility information derived from application of a user model. The performance of a classifier in predicting summary type will indicate if trends we discovered among user judgements carry over to an automated means of selecting which response type to use in a given context.

In a final experiment, for each task, we use the highest rated summary as a class to be predicted using C4.5 (Quinlan, 1993). Thus we have 4 classes: **Ref-Sing**, **Ref-Assoc**, **UM-Sing**, and **UM-Assoc**. We derive two types of feature sets from the responses: features derived from each user model and features derived from attributes of the query/response pair itself. The five feature sets for the user model are:

- *umInfo*: 6 features for the rankings for each attribute for each user’s model, e.g. a summary whose user had rated *food quality* most highly would receive a ’5’ for the feature *food quality*;
- *avgUtility*: 4 features representing an average utility score for each alternative summary response, based on its clusters (Sec. 2.3).
- *hiUtility*: 4 features representing the highest utility score among the three clusters selected for each response;
- *loUtility*: 4 features representing the lowest utility score among the three clusters selected for each response;
- *allUtility*: 12 features consisting of the high, low, and average utility scores from the previous three feature sets.

Three feature sets are derived from the query and response pair:

- *numRests*: 4 features for the coverage of each response. For summary **Ref-Assoc** in Table 2, *numRests* is 43; for summary **UM-Assoc**, *numrests* is 53.;

Sys	Feature Sets	Acc(%)
S1	<i>allUtility</i>	47.1
S2	<i>task, numRests</i>	51.5
S3	<i>allUtility, umInfo</i>	62.3*
S4	<i>allUtility, umInfo, numRests, task</i>	63.2*
S5	<i>avgUtility, umInfo, numRests, task</i>	62.5*
S6	<i>hiUtility, umInfo, numRests, task</i>	66.9*
S7	<i>hiUtility, umInfo, numRests, task, dataset</i>	68.4*
S8	<i>loUtility, umInfo, numRests, task</i>	60.3*
S9	<i>hiUtility, umInfo</i>	64.0*

Table 3: Accuracy of feature sets for predicting preferred summary type. \* =  $p < .05$  as compared to the Baseline (S1).

- *task*: A feature for the type of constraint used to generate the focal information (e.g., *cuisine, price range*).
- *dataset*: A feature for the size of the focal information subset (i.e., *big, small*), for values greater and less than 100.

Table 3 shows the relative strengths of the two types of features on classification accuracy. The majority class baseline (System S1) is 47.1%. The S2 system uses only features associated with the query/response pair, and its accuracy (51.5%) is not significantly higher than the baseline (S3 in Table 3), and combining features from the query/response pair and the user model significantly increases accuracy in all cases. We experimented with using all the utility scores (S4), as well as with using just the average (S5), the high (S6), and the low (S8). The best performance (68.4%) is for the (S7) system combination of features.

The classification rules in Table 4 for the best system (S7) suggests some bases for users’ decisions. The first rule is very simple, simply stating that, if the highest utility value of the **Ref-Sing** response is lower than a particular threshold, then use the **UM-Assoc** response. In other words, if one of the two highest scoring response types has a low utility, use the other.

The second rule in Table 4 shows the effect that the number of restaurants in the response has on summary choice. In this rule, the **Ref-Sing** response is preferred when the highest util-

```

IF (HighestUtility: Ref-Sing) < 0.18
  THEN USE UM-Assoc
-----
IF (HighestUtility: Ref-Assoc) > 0.18) &&
  (NumRestaurants: UM-Assoc < 400) &&
  (HighestUtility: UM-Assoc < .47)
  THEN USE Ref-Sing
-----
IF (NumRestaurants: UM-Assoc < 400) &&
  (HighestUtility: UM-Assoc < .57) &&
  (HighestUtility: Ref-Assoc > .2)
  THEN USE Ref-Assoc

```

Table 4: Example classification rules from System 7 in Table 3.

ity value of that response is over a particular threshold.

The final rule in Table 4 predicts **Ref-Assoc**, the lowest overall scoring response type. When the number of restaurants accounted for by **UM-Assoc**, as well as the highest utility for that response, are both below a certain threshold, and the highest utility for the **Ref-Assoc** response is above a certain threshold, then use **Ref-Assoc**. The utility for any summary type using the Refiner method is usually lower than those using the user model, since overall utility is not taken into account in summary construction. However, even low utility summaries may mention attributes the user finds important. That, combined with higher coverage, could make that summary type preferable over one constructed to maximize user model utility.

## 5 Conclusion

We first compared intensional summary cooperative responses against a system initiative dialogue strategy in CRUISER. Subjects assumed three “personas”, a native Londoner, a tourist who was interacting with the system for the first time (GT), or a tourist for which the system has a user model (UMT). The personas were designed to reflect differing ends of the spectra defined by Belkin to characterize information-seeking strategies (Belkin et al., 1994). There was a significant preference for intensional summaries across all personas, but especially when the personas were unfamiliar with the domain.

This preference indicates that the benefits of intensional summaries outweigh the increase in verbosity.

We then tested four algorithms for summary construction. Results show that intensional summaries based on a user model with association rules, or on the Refiner method (Polifroni et al., 2003), are equally effective. While (Demberg and Moore, 2006) found that their user model stepwise refinement (UMSR) method was superior to the Refiner method, they also found many situations (70 out of 190) in which the Refiner method was preferred. Our experiment was structured differently, but it suggests that, in certain circumstances, or within certain domains, users may wish to hear about choices based on an analysis of focal information, irrespective of user preferences.

Our intensional summary algorithms automatically construct summaries from a database, along with user models collected via a domain-independent method; thus we believe that the methods described here are domain-independent. Furthermore, in tests to determine whether a classifier can predict the best summary type to use in a given context, we achieved an accuracy of 68% as compared to a majority class baseline of 47%, using dialogue context features. Both of these results point hopefully towards a different way of automating dialogue design, one based on a combination of user modelling and an analysis of contextual information. In future work we hope to test these algorithms in other domains, and show that intensional summaries can not only be automatically derived but also lead to reduced task times and increased task success.

## Abstract

Statistical machine learning methods are employed to train a Named Entity Recognizer from annotated data. Methods like Maximum Entropy and Conditional Random Fields make use of features for the training purpose. These methods tend to overfit when the available training corpus is limited especially if the number of features is large or the number of values for a feature is large. To overcome this we proposed two techniques for feature reduction based on word clustering and selection. A number of word similarity measures are proposed for clustering words for the Named Entity Recognition task. A few corpus based statistical measures are used for important word selection. The feature reduction techniques lead to a substantial performance improvement over baseline Maximum Entropy technique.

## 1 Introduction

Named Entity Recognition (NER) involves locating and classifying the names in a text. NER is an important task, having applications in information extraction, question answering, machine translation and in most other Natural Language Processing (NLP) applications. NER systems have been developed for English and few other languages with high accuracy. These belong to two main categories based on machine learning (Bikel et al., 1997; Borthwick, 1999; McCallum and Li, 2003) and language or domain specific rules (Grishman, 1995; Wakao et al., 1996).

In English, the names are usually capitalized which is an important clue for identifying a name. Absence of capitalization makes the Hindi NER task difficult. Also, person names are more diverse in Indian languages, many common words being used as names.

A pioneering work on Hindi NER is by Li and McCallum (2003) where they used Conditional Random Fields (CRF) and feature induction to automatically construct only the features that are important for recognition. In an effort to reduce overfitting, they use a combination of a Gaussian prior and early-stopping.

In their Maximum Entropy (MaxEnt) based approach for Hindi NER development, Saha et al. (2008) also observed that the performance of the MaxEnt based model often decreases when huge number of features are used in the model. This is due to overfitting which is a serious problem in most of the NLP tasks in resource poor languages where annotated data is scarce.

This paper is a study on effectiveness of word clustering and selection as feature reduction techniques for MaxEnt based NER. For clustering we use a number of word similarities like cosine similarity among words and co-occurrence, along with the k-means clustering algorithm. The clusters are then used as features instead of words. For important word selection we use corpus based statistical measurements to find the importance of the words in the NER task. A significant performance improvement over baseline MaxEnt was observed after using the above feature reduction techniques.

The paper is organized as follows. The MaxEnt

based NER system is described in Section 2. Various approaches for word clustering are discussed in Section 3. Next section presents the procedure for selecting the important words. In Section 5 experimental results and related discussions are given. Finally Section 6 concludes the paper.

## 2 Maximum Entropy Based Model for Hindi NER

Maximum Entropy (MaxEnt) principle is a commonly used technique which provides probability of belongingness of a token to a class. MaxEnt computes the probability  $p(o|h)$  for any  $o$  from the space of all possible outcomes  $O$ , and for every  $h$  from the space of all possible histories  $H$ . In NER, history can be viewed as all information derivable from the training corpus relative to the current token. The computation of probability ( $p(o|h)$ ) of an outcome for a token in MaxEnt depends on a set of features that are helpful in making predictions about the outcome. The features may be binary-valued or multi-valued. Given a set of features and a training corpus, the MaxEnt estimation process produces a model in which every feature  $f_i$  has a weight  $\alpha_i$ . We can compute the conditional probability as (Berger et al., 1996):

$$p(o|h) = \frac{1}{Z(h)} \prod_i \alpha_i^{f_i(h,o)} \quad (1)$$

$$Z(h) = \sum_o \prod_i \alpha_i^{f_i(h,o)} \quad (2)$$

The conditional probability of the outcome is the product of the weights of all active features, normalized over the products of all the features. For our development we have used a Java based open-nlp MaxEnt toolkit<sup>1</sup>. A beam search algorithm is used to get the most probable class from the probabilities.

### 2.1 Training Corpus

The training data for the Hindi NER task is composed of about 243K words which is collected from the popular daily Hindi newspaper ‘‘Dainik Jagaran’’. This corpus has been manually annotated and contains about 16,491 Named Entities (NEs). In this study we have considered 4 types

<sup>1</sup><http://sourceforge.net/projects/maxent/>

Type	Features
Word	$w_i, w_{i-1}, w_{i-2}, w_{i+1}, w_{i+2}$
NE Tag	$t_{i-1}, t_{i-2}$
Digit information	Contains digit, Only digit, Four digit, Numerical word
Affix information	Fixed length suffix, Suffix list, Fixed length prefix
POS information	POS of words, Coarse-grained POS, POS based binary features

Table 1: Features used in the MaxEnt based Hindi NER system

of NEs, these are *Person* (Per), *Location* (Loc), *Organization* (Org) and *Date* (Dat). To recognize entity boundaries each name class  $N$  has 4 types of labels:  $N\_Begin$ ,  $N\_Continue$ ,  $N\_End$  and  $N\_Unique$ . For example, *Kharagpur* is annotated as *Loc\_Unique* and *Atal Bihari Vajpeyi* is annotated as *Per\_Begin Per\_Continue Per\_End*. Hence, there are a total of 17 classes including one class for not-name. The corpus contains 6298 person, 4696 location, 3652 organization and 1845 date entities.

### 2.2 Feature Description

We have identified a number of candidate features for the Hindi NER task. Several experiments were conducted with the identified features, individually and in combination. Some of the features are mentioned below. They are summarized in Table 1.

**Static Word Feature:** Recognition of NE is highly dependent on contexts. So the surrounding words of a particular word ( $w_i$ ) are used as features. During our experiments different combinations of previous 3 words ( $w_{i-3}...w_{i-1}$ ) to next 3 words ( $w_{i+1}...w_{i+3}$ ) are treated as features. This is represented by  $L$  binary features where  $L$  is the size of lexicon.

**Dynamic NE tag:** NE tags of the previous words ( $t_{i-m}...t_{i-1}$ ) are used as features. During decoding, the value of this feature for a word ( $w_i$ ) is obtained only after the computation of the NE tag for the previous word ( $w_{i-1}$ ).

**Digit Information:** If a word ( $w_i$ ) contains digit(s) then the feature *ContainsDigit* is set to 1. This feature is used with some modifications also. *OnlyDigit*, which is set to 1 if the word contains

Feature Id	Feature	Per	Loc	Org	Dat	Total
F1	$w_i, w_{i-1}, w_{i+1}$	61.36	68.29	52.12	88.9	67.26
F2	$w_i, w_{i-1}, w_{i-2}, w_{i+1}, w_{i+2}$	64.10	67.81	58	92.30	69.09
F3	$w_i, w_{i-1}, w_{i-2}, w_{i-3}, w_{i+1}, w_{i+2}, w_{i+3}$	60.42	67.81	51.48	90.18	66.84
F4	$w_i, w_{i-1}, w_{i-2}, w_{i+1}, w_{i+2}, t_{i-1}, t_{i-2}, \text{Suffix}$	66.67	73.36	58.58	89.09	71.2
F5	$w_i, w_{i-1}, w_{i+1}, t_{i-1}, \text{Suffix}$	69.65	75.8	59.31	89.09	73.42
F6	$w_i, w_{i-1}, w_{i+1}, t_{i-1}, \text{Prefix}$	66.67	71	58.58	87.8	70.02
F7	$w_i, w_{i-1}, w_{i+1}, t_{i-1}, \text{Prefix}, \text{Suffix}$	70.61	71	59.31	89.09	72.5
F8	$w_i, w_{i-1}, w_{i+1}, t_{i-1}, \text{Suffix}, \text{Digit}$	70.61	75.8	60.54	93.8	74.26
F9	$w_i, w_{i-1}, w_{i+1}, t_{i-1}, \text{POS (28 tags)}$	64.25	71	60.54	89.09	70.39
F10	$w_i, w_{i-1}, w_{i+1}, t_{i-1}, \text{POS (coarse grained)}$	69.65	75.8	59.31	92.82	74.16
F11	$w_i, w_{i-1}, w_{i+1}, T_{i-1}, \text{Suffix}, \text{Digit}, \text{NomPSP}$	72.26	78.6	61.36	92.82	75.6
F12	$w_i, w_{i-1}, w_{i+1}, w_{i-2}, w_{i+2}, T_{i-1}, \text{Prefix}, \text{Suffix}, \text{Digit}, \text{NomPSP}$	65.26	78.01	52.12	93.33	72.65

Table 2: F-values for different features in the MaxEnt based Hindi NER system

only digits, *4Digit*, which is set to 1 if the word contains only 4 digits, etc. are some modifications of the feature which are helpful.

**Numerical Word:** For a word ( $w_i$ ) if it is a numerical word i.e. word denoting a number (e.g. *eka*<sup>2</sup> (one), *do* (two), *tina* (three) etc.) then the feature *NumWord* is set to 1.

**Word Suffix:** Word suffix information is helpful to identify the NEs. Two types of suffix features have been used. Firstly a fixed length word suffix (set of characters occurring at the end of the word) of the current and surrounding words are used as features. Secondly we compiled list of common suffixes of place names in Hindi. For example, *pura*, *bAda*, *nagara* etc. are location suffixes. We used binary feature corresponding to the list - whether a given word has a suffix from the list.

**Word Prefix:** Prefix information of a word may be also helpful in identifying whether it is a NE. A

fixed length word prefix (set of characters occurring at the beginning of the word) of current and surrounding words are treated as features. List of important prefixes, which are used frequently in the NEs, are also effective.

**Parts-of-Speech (POS) Information:** The POS of the current word and the surrounding words are used as feature for NER. We have used a Hindi POS tagger developed at IIT Kharagpur, India which has an accuracy about 90%. We have used the POS values of the current and surrounding words as features.

We realized that the detailed POS tagging is not very relevant. Since NEs are noun phrases, the noun tag is very relevant. Further the postposition following a name may give a clue to the NE type. So we decided to use a coarse-grained tagset with only three tags - nominal (Nom), postposition (PSP) and other (O).

The POS information is also used by defining several binary features. An example is the *NomPSP* binary feature. The value of this feature is defined to be 1 if the current word is nominal and the next

<sup>2</sup>All Hindi words are written in italics using the ‘Itrans’ transliteration.

word is a PSP.

### 2.3 Performance of Hindi NER using MaxEnt Method

The performance of the MaxEnt based Hindi NER using the above mentioned features is reported here as a baseline. We have evaluated the system using a blind test corpus of 25K words. The test corpus contains 521 person, 728 location, 262 organization and 236 date entities. The accuracies are measured in terms of the f-measure, which is the weighted harmonic mean of precision and recall. Precision is the fraction of the correct annotations and recall is the fraction of the total NEs that are successfully annotated. The general formula for measuring the f-measure or f-value is,  $F_{\beta} = (1 + \beta^2) \cdot (\text{precision} \cdot \text{recall}) \setminus (\beta^2 \cdot \text{precision} + \text{recall})$ . Here the value of  $\beta$  is taken as 1. In Table 2 we have shown the accuracy values for few feature sets.

While experimenting with static word features, we have observed that a window of previous and next two words ( $w_{i-2} \dots w_{i+2}$ ) gives best result (69.09) using the word features only. But when  $w_{i-3}$  and  $w_{i+3}$  are added with it, the f-value is reduced to 66.84. Again when  $w_{i-2}$  and  $w_{i+2}$  are deducted from the feature set (i.e. only  $w_{i-1}$  and  $w_{i+1}$  as feature), the f-value is reduced to 67.26. This demonstrates that  $w_{i-2}$  and  $w_{i+2}$  are helpful features in NE identification.

When suffix, prefix and digit information are added to the feature set, the f-value is increased upto 74.26. The value is obtained using the feature set F8 [ $w_i$ ,  $w_{i-1}$ ,  $w_{i+1}$ ,  $t_{i-1}$ , Suffix, Digit]. It is observed that when  $w_{i-2}$  and  $w_{i+2}$  are added with the feature, the accuracy decreases by 2%. It contradicts the results using the word features only. Another interesting observation is that prefix information are helpful features in NE identification as these increase accuracy when separately added with the word features (F6). Similarly the suffix information helps in increasing the accuracy. But when both the suffix and prefix information are used in combination along with the word features, the f-value is decreased. From Table 2, a f-value of 73.42 is obtained using F5 [ $w_i$ ,  $w_{i-1}$ ,  $w_{i+1}$ ,  $t_{i-1}$ , Suffix] but when prefix information are added with it (F7), the f-value is reduced to 72.5.

POS information are important features in NER. In general it is observed that coarse grained POS information performs better than the finer grained POS information. The best accuracy (75.6 f-value) of the baseline system is obtained using the binary NomPSP feature along with word feature ( $w_{i-1}$ ,  $w_{i+1}$ ), suffix and digit information. It is noted that when  $w_{i-2}$ ,  $w_{i+2}$  and prefix information are added with the best feature, the f-value is reduced to 72.65.

From the above discussion it is clear that the system suffers from overfitting if a large number of features are used to train the system. Note that the surrounding word ( $w_{i-2}$ ,  $w_{i-1}$ ,  $w_{i+1}$ ,  $w_{i+2}$  etc.) features can take any value from the lexicon and hence are of high dimensionality. These cause the degradation of performance of the system. However it is obvious that few words in the lexicon are important in identification of NEs.

To solve the problem of high dimensionality we use clustering to group the words present in the corpus into much smaller number of clusters. Then the word clusters are used as features instead of the word features (for surrounding words). For example, our Hindi corpus contains 17,456 different words, which are grouped into  $N$  (say 100) clusters. Then for a particular word, it is assigned to a cluster and the corresponding cluster-id is used as feature. Hence the number of features is reduced to 100 instead of 17,456.

Similarly, selection of important words can also solve the problem of high dimensionality. As some of the words in the lexicon play important role in the NE identification process, we aim to select these particular words. Only these important words are used in NE identification instead of all words in the corpus.

## 3 Word Clustering

Clustering is the process of grouping together objects based on their similarity. The measure of similarity is critical for good quality clustering. We have experimented with some approaches to compute word-word similarity. These are described in details in the following section.

### 3.1 Cosine Similarity based on Sentence Level Co-occurrence

A word is represented by a binary vector of dimension same as the number of sentences in the corpus. A component of the vector is 1 if the word occurs in the corresponding sentence and zero otherwise. Then we measure cosine similarity between the word vectors. The cosine similarity between two word vectors ( $\vec{A}$  and  $\vec{B}$ ) with dimension  $d$  is measured as:

$$\text{CosSim}(\vec{A}, \vec{B}) = \frac{\sum_d A_d B_d}{(\sum_d A_d^2)^{\frac{1}{2}} \times (\sum_d B_d^2)^{\frac{1}{2}}} \quad (3)$$

This measures the number of co-occurring sentences.

### 3.2 Cosine Similarity based on Proximal Words

In this measure a word is represented by a vector having dimension same as the lexicon size. For ease of implementation we have taken a dimension of  $2 \times 200$ , where each component of the vector corresponds to one of the 200 most frequent preceding and following words of a token word. *List\_Prev* containing the most frequent (top 200) previous words ( $w_{i-1}$  or  $w_{i-2}$  if  $w_i$  is the first word of a NE) and *List\_Next* contains 200 most frequent next words ( $w_{i+1}$  or  $w_{i+2}$  if  $w_i$  is the last word of a NE). A particular word  $w_k$  may occur several times (say  $n$ ) in the corpus. For each occurrence of  $w_k$  find if its previous word ( $w_{k-1}$  or  $w_{k-2}$ ) matches any element of *List\_Prev*. If matches, then set 1 to the corresponding position of the vector and set zero to all other positions related to *List\_Prev*. Similarly check the next word ( $w_{k+1}$  or  $w_{k+2}$ ) in the *List\_Next* and find the values of the corresponding positions. The final word vector  $\vec{W}_k$  is obtained by taking the average of all occurrences of  $w_k$ . Then the cosine similarity is measured between the word vectors. This measures the similarity of the contexts of the occurrences of the word in terms of the proximal words.

### 3.3 Similarity based on Proximity to NE Categories

Here, for each word ( $w_i$ ) in the corpus four binary vectors are defined corresponding to two preceding

and two following positions (i-1, i-2, i+1, i+2). Each binary vector is of dimension five corresponding to four NE classes ( $C_j$ ) and one for the not-name class. For a particular word  $w_k$ , find all the words occur in a particular position (say, +1). Measure the fraction ( $P_j(w_k)$ ) of these words belonging to a class  $C_j$ . The component of the word vector  $\vec{W}_k$  for the position corresponding to  $C_j$  is  $P_j(w_k)$ .

$$P_j(w_k) = \frac{\text{No. of times } w_{k+1} \text{ is a NE of class } C_j}{\text{Total occurrence of } w_k \text{ in corpus}}$$

The Euclidean distance is used to find the similarity between the above word vectors as a similarity measure. Some of the word vectors for the +1 position are given in Table 3. In this table we have given the word vectors for a few Hindi words, which are, *sthita* (located), *shahara* (city), *jAkara* (go), *nagara* (township), *gA.nva* (village), *nivAsI* (resident), *mishrA* (a surname) and *limiTeDa* (ltd.). From the table we observe that the word vectors are close for *sthita* [0 0.478 0 0 0.522], *shahara* [0 0.585 0.001 0.024 0.39], *nagara* [0 0.507 0.019 0 0.474] and *gA.nva* [0 0.551 0 0 0.449]. So these words are considered as close.

Word	Per	Loc	Org	Dat	Not
<i>sthita</i>	0	0.478	0	0	0.522
<i>shahara</i>	0	0.585	0.001	0.024	0.39
<i>jAkara</i>	0	0.22	0	0	0.88
<i>nagara</i>	0	0.507	0.019	0	0.474
<i>gA.nva</i>	0	0.551	0	0	0.449
<i>nivAsI</i>	0.108	0.622	0	0	0.27
<i>mishrA</i>	0.889	0	0	0	0.111
<i>limiTeDa</i>	0	0	1	0	0

Table 3: Example of some word vectors for next (+1) position (see text for glosses)

### 3.4 K-means Clustering

Using the above similarity measures we have used the k-means algorithm. The seeds were randomly selected. The value of  $k$  (number of clusters) was varied till the best result is obtained.

## 4 Important Word Selection

It is noted that not all words are equally important in determining the NE category. Some of the words

in the lexicon are typically associated with a particular NE category and hence have important role to play in the classification process. We describe below a few statistical techniques that has been used to identify the important words.

#### 4.1 Class Independent Important Word Selection

We define context words as those which occur in proximity of a NE. In other words, context words are the words present in the  $w_{i-2}$ ,  $w_{i-1}$ ,  $w_{i+1}$  or  $w_{i+2}$  position if  $w_i$  is a NE. Note that only a subset of the lexicon are context words. For all the context words, its  $N\_weight$  is calculated as the ratio between the occurrence of the word as a context word and its total number of occurrence in the corpus. The context words having the higher  $N\_weight$  are considered as important words for NER. For our experiments we have considered top 500 words as important words.

$$N\_weight(w_i) = \frac{\text{Occurrence of } w_i \text{ as context word}}{\text{Total occurrence of } w_i \text{ in corpus}}$$

#### 4.2 Important Words for Each Class

Similar to the class independent important word selection from the contexts, important words are selected for individual classes also. This is an extension of the previous context word considering only NEs of a particular class. For person, location, organization and date classes we have considered top 150, 120, 50 and 50 words respectively as important words. Four binary features are also defined for these four classes. These are defined as having value 1 if any of the context words belongs to the important words list for a particular class.

#### 4.3 Important Words for Each Position

Position based important words are also selected from the corpus. Here instead of context, particular positions are considered. Four lists are compiled for two preceding and two following positions (-2, -1, +1 and +2).

### 5 Evaluation of NE Recognition

The following subsections contain the experimental results using word clustering and important word selection. The results demonstrate the effectiveness of

<b>k</b>	<b>Per</b>	<b>Loc</b>	<b>Org</b>	<b>Dat</b>	<b>Total</b>
20	66.33	74.57	43.64	91.30	69.54
50	64.13	76.35	52	93.62	71.7
80	66.33	74.57	53.85	93.62	72.08
100	70.1	73.1	57.7	96.62	<b>72.78</b>
120	66.15	73.43	54.9	93.62	71.52
150	66.88	74.94	53.06	95.65	72.33
200	66.09	73.82	52	92	71.13

Table 4: Variation of MaxEnt based system accuracy depending on number of clusters ( $k$ )

word clustering and important word selection over the baseline MaxEnt model.

#### 5.1 Using Word Clusters

To evaluate the effectiveness of the clustering approaches in Hindi NER, we have used cluster features instead of word features. For the surrounding words, corresponding cluster-ids are used as feature.

**Choice of  $k$  :** We have already mentioned that, for k-means clustering number of classes ( $k$ ) should be determined initially. To find suitable  $k$  we had conducted the following experiments. We have selected a feature F1 (mentioned in Table 2) and applied the clusters with different  $k$  as features replacing the word features. In Table 4 we have summarized the experimental results, in order to find a suitable  $k$  for clustering, the word vectors obtained using the procedure described in Section 3.3. From the table we observe that the best result is obtained when  $k$  is 100. We have used  $k = 100$  for the subsequent experiments for comparing the effectiveness of the features. Similarly when we deal with all the words in the corpus (17,465 words), we got best results when the words are clustered into 1100 clusters.  $\diamond$

The details of the comparison between the baseline word features and the reduced features obtained using clustering are given in Table 5. In general it is observed that clustering has improved the performance over baseline features. Using only cluster features the system provides a maximum f-value of 74.26 where the corresponding word features give f-value of 69.09.

Among the various similarity measures of clustering, improved results are obtained using the clus-

Feature	Using Word Features	Using Clusters (C1)	Using Clusters (C2)	Using Clusters (C3)
$w_i$ , window(-1, +1)	67.26	69.67	72.05	72.78
$w_i$ , window(-2, +2)	69.09	71.52	72.65	74.26
$w_i$ , window(-1, +1), Suffix	73.42	74.24	75.44	75.84
$w_i$ , window(-1, +1), Prefix, Suffix	72.5	74.76	75.7	76.33
$w_i$ , window(-1, +1), Prefix, Suffix, Digit	74.26	75.09	75.91	76.41
$w_i$ , window(-1, +1), Prefix, Suffix, Digit, NomPSP	75.6	77.2	77.39	77.61
$w_i$ , window(-2, +2), Prefix, Suffix, Digit, NomPSP	72.65	77.86	78.61	<b>79.03</b>

Table 5: F-values for different features in a MaxEnt based Hindi NER with clustering based feature reduction [ $window(-m, +n)$  refers to the cluster or word features corresponding to previous  $m$  positions and next  $n$  positions; C1 is the clusters which use sentence level co-occurrence based cosine similarity (3.1), C2 denotes the clusters which use proximal word based cosine similarity (3.2), C3 denotes the clusters for each positions related to NE (3.3)]

ters which uses the similarity measurement based on proximity of the words to NE categories (defined in Section 3.3).

Using clustering features the best f-value (79.03) is obtained using clusters for previous two and next two words along with the suffix, prefix, digit and POS information.

It is observed that the prefix information increases the accuracy if applied along with suffix information when cluster features are used. More interestingly, addition of cluster features for positions  $-2$  and  $+2$  over the feature [window(-1, +1), Suffix, Prefix, Digit, NomPSP] increase the f-value from 77.61 to 79.03. But in the baseline system addition of word features ( $w_{i-2}$  and  $w_{i+2}$ ) over the same feature decrease the f-value from 75.6 to 72.65.

## 5.2 Using Important Word Selection

The details of the comparison between the word feature and the reduced features based on important word selection are given in Table 6. For the surrounding word features, find whether the particular word (e.g. at position -1, -2 etc.) presents in the important words list (corresponding to the particular position if position based important words are considered). If the word occurs in the list then the word is used as features. In general it is observed that word selection also improves performance over baseline features. Among the different approaches,

the best result is obtained when important words for two preceding and two following positions (defined in Section 4.3) are selected. Using important word based features, the highest f-value of 79.85 is obtained by using the important words for previous two and next two positions along with the suffix, prefix, digit and POS information.

## 5.3 Relative Effectiveness of Clustering and Word Selection

In most of the cases clustering based features perform better than the important word based feature reduction. But the best f-value (79.85) of the system (using the clustering based and important word based features separately) is obtained by using important word based features.

Next we have made an experiment by considering both the clusters and important words combined. We have defined the combined feature as, if the word ( $w_i$ ) is in the corresponding important word list then the word is used as feature otherwise the corresponding cluster-id (in which  $w_i$  belongs to) is considered as feature. Using the combined feature, we have achieved further improvement. Here we are able to achieve the highest f-value of 80.01.

## 6 Conclusion

A hierarchical word clustering technique, where clusters are driven automatically from large unan-

Feature	Using Word Features	Using Words (I1)	Using Words (I2)	Using Words (I3)
$w_i$ , window(-1, +1)	67.26	66.31	67.53	66.8
$w_i$ , window(-2, +2)	69.09	72.04	72.9	73.34
$w_i$ , window(-1, +1), Suffix	73.42	73.85	73.12	74.61
$w_i$ , window(-1, +1), Prefix, Suffix	72.5	73.52	73.94	74.87
$w_i$ , window(-1, +1), Prefix, Suffix, Digit	74.26	73.97	74.13	74.7
$w_i$ , window(-1, +1), Prefix, Suffix, Digit, NomPSP	75.6	75.84	76.6	77.22
$w_i$ , window(-2, +2), Prefix, Suffix, Digit, NomPSP	72.65	76.69	77.42	<b>79.85</b>

Table 6: F-values for different features in a MaxEnt based Hindi NER with important word based feature reduction [ $window(-m, +n)$  refers to the important word or baseline word features corresponding to previous  $m$  positions and next  $n$  positions; I1 is the class independent important words (4.1), I2 denotes the important words for each class (4.2), I3 denotes the important words for each positions (4.3)]

notated corpus, is used by Miller et al. (2004) for augmenting annotated training data. Note that our clustering approach is different, where the clusters are obtained using some statistics derived from the annotated corpus, and also the purpose is different as we have used the clusters for feature reduction.

In this paper we propose two feature reduction techniques for Hindi NER based on word clustering and word selection. A number of word similarity measures are used for clustering. A few statistical approaches are used for the selection of important words. It is observed that significant enhancement of accuracy over the baseline system which use word features is obtained. This is probably due to reduction of overfitting. This is more important for a resource poor languages like Hindi where there is scarcity in annotated training data and other NER resources (like, gazetteer lists).

## Abstract

This paper presents an innovative, complex approach to semantic verb classification that relies on selectional preferences as verb properties. The probabilistic verb class model underlying the semantic classes is trained by a combination of the EM algorithm and the MDL principle, providing soft clusters with two dimensions (verb senses and subcategorisation frames with selectional preferences) as a result. A language-model-based evaluation shows that after 10 training iterations the verb class model results are above the baseline results.

## 1 Introduction

In recent years, the computational linguistics community has developed an impressive number of semantic verb classifications, i.e., classifications that generalise over verbs according to their semantic properties. Intuitive examples of such classifications are the MOTION WITH A VEHICLE class, including verbs such as *drive*, *fly*, *row*, etc., or the BREAK A SOLID SURFACE WITH AN INSTRUMENT class, including verbs such as *break*, *crush*, *fracture*, *smash*, etc. Semantic verb classifications are of great interest to computational linguistics, specifically regarding the pervasive problem of data sparseness in the processing of natural language. Up to now, such classifications have been used in applications such as word sense disambiguation (Dorr and Jones, 1996; Kohomban and Lee, 2005), machine translation (Prescher et al., 2000; Koehn and Hoang, 2007), document classification (Klavans and Kan, 1998), and in statistical lexical acquisition in general (Rooth et al., 1999; Merlo and Stevenson, 2001; Korhonen, 2002; Schulte im Walde, 2006).

Given that the creation of semantic verb classifications is not an end task in itself, but depends on the application scenario of the classification, we find various approaches to an automatic induction of semantic verb classifications. For example, Siegel and McKeown (2000) used several machine learning algorithms to perform an automatic aspectual classification of English verbs into event and stative verbs. Merlo and Stevenson (2001) presented an automatic classification of three types of English intransitive verbs, based on argument structure and heuristics to thematic relations. Pereira et al. (1993) and Rooth et al. (1999) relied on the Expectation-Maximisation algorithm to induce soft clusters of verbs, based on the verbs' direct object nouns. Similarly, Korhonen et al. (2003) relied on the Information Bottleneck (Tishby et al., 1999) and subcategorisation frame types to induce soft verb clusters.

This paper presents an innovative, complex approach to semantic verb classes that relies on selectional preferences as verb properties. The underlying linguistic assumption for this verb class model is that verbs which agree on their selectional preferences belong to a common semantic class. The model is implemented as a soft-clustering approach, in order to capture the polysemy of the verbs. The training procedure uses the Expectation-Maximisation (EM) algorithm (Baum, 1972) to iteratively improve the probabilistic parameters of the model, and applies the Minimum Description Length (MDL) principle (Rissanen, 1978) to induce WordNet-based selectional preferences for arguments within subcategorisation frames. Our model is potentially useful for lexical induction (e.g., verb senses, subcategorisation and selectional preferences, collocations, and verb alternations),

and for NLP applications in sparse data situations. In this paper, we provide an evaluation based on a language model.

The remainder of the paper is organised as follows. Section 2 introduces our probabilistic verb class model, the EM training, and how we incorporate the MDL principle. Section 3 describes the clustering experiments, including the experimental setup, the evaluation, and the results. Section 4 reports on related work, before we close with a summary and outlook in Section 5.

## 2 Verb Class Model

### 2.1 Probabilistic Model

This paper suggests a probabilistic model of verb classes that groups verbs into clusters with similar subcategorisation frames and selectional preferences. Verbs may be assigned to several clusters (soft clustering) which allows the model to describe the subcategorisation properties of several verb readings separately. The number of clusters is defined in advance, but the assignment of the verbs to the clusters is learnt during training. It is assumed that all verb readings belonging to one cluster have similar subcategorisation and selectional properties. The selectional preferences are expressed in terms of semantic concepts from WordNet, rather than a set of individual words. Finally, the model assumes that the different arguments are mutually independent for all subcategorisation frames of a cluster. From the last assumption, it follows that any statistical dependency between the arguments of a verb has to be explained by multiple readings.

The statistical model is characterised by the following equation which defines the probability of a verb  $v$  with a subcategorisation frame  $f$  and arguments  $a_1, \dots, a_{n_f}$ :

$$p(v, f, a_1, \dots, a_{n_f}) = \sum_c p(c) p(v|c) p(f|c) * \prod_{i=1}^{n_f} \sum_{r \in R} p(r|c, f, i) p(a_i|r)$$

The model describes a stochastic process which generates a verb-argument tuple like  $\langle \textit{speak}, \textit{subj-pp.to}, \textit{professor}, \textit{audience} \rangle$  by

1. selecting some cluster  $c$ , e.g.  $c_3$  (which might

correspond to a set of *communication* verbs), with probability  $p(c_3)$ ,

2. selecting a verb  $v$ , here the verb *speak*, from cluster  $c_3$  with probability  $p(\textit{speak}|c_3)$ ,
3. selecting a subcategorisation frame  $f$ , here *subj-pp.to*, with probability  $p(\textit{subj-pp.to}|c_3)$ ; note that the frame probability only depends on the cluster, and not on the verb,
4. selecting a WordNet concept  $r$  for each argument slot, e.g. *person* for the first slot with probability  $p(\textit{person}|c_3, \textit{subj-pp.to}, 1)$  and *social group* for the second slot with probability  $p(\textit{social group}|c_3, \textit{subj-pp.to}, 2)$ ,
5. selecting a word  $a_i$  to instantiate each concept as argument  $i$ ; in our example, we might choose *professor* for *person* with probability  $p(\textit{professor}|\textit{person})$  and *audience* for *social group* with probability  $p(\textit{audience}|\textit{social group})$ .

The model contains two *hidden variables*, namely the clusters  $c$  and the selectional preferences  $r$ . In order to obtain the overall probability of a given verb-argument tuple, we have to sum over all possible values of these hidden variables.

The assumption that the arguments are independent of the verb given the cluster is essential for obtaining a clustering algorithm because it forces the EM algorithm to make the verbs within a cluster as similar as possible.<sup>1</sup> The assumption that the different arguments of a verb are mutually independent is important to reduce the parameter set to a tractable size

The fact that verbs select for concepts rather than individual words also reduces the number of parameters and helps to avoid sparse data problems. The application of the MDL principle guarantees that no important information is lost.

The probabilities  $p(r|c, f, i)$  and  $p(a|r)$  mentioned above are not represented as atomic entities. Instead, we follow an approach by Abney

<sup>1</sup>The EM algorithm adjusts the model parameters in such a way that the probability assigned to the training tuples is maximised. Given the model constraints, the data probability can only be maximised by making the verbs within a cluster as similar to each other as possible, regarding the required arguments.

and Light (1999) and turn WordNet into a Hidden Markov model (HMM). We create a new pseudo-concept for each WordNet noun and add it as a hyponym to each synset containing this word. In addition, we assign a probability to each hypernym-hyponym transition, such that the probabilities of the hyponymy links of a synset sum up to 1. The pseudo-concept nodes emit the respective word with a probability of 1, whereas the regular concept nodes are non-emitting nodes. The probability of a path in this (a priori) WordNet HMM is the product of the probabilities of the transitions within the path. The probability  $p(a|r)$  is then defined as the sum of the probabilities of all paths from the concept  $r$  to the word  $a$ . Similarly, we create a partial WordNet HMM for each argument slot  $\langle c, f, i \rangle$  which encodes the selectional preferences. It contains only the WordNet concepts that the slot selects for, according to the MDL principle (cf. Section 2.3), and the dominating concepts. The probability  $p(r|c, f, i)$  is the total probability of all paths from the top-most WordNet concept  $entity$  to the terminal node  $r$ .

## 2.2 EM Training

The model is trained on verb-argument tuples of the form described above, i.e., consisting of a verb and a subcategorisation frame, plus the nominal<sup>2</sup> heads of the arguments. The tuples may be extracted from parsed data, or from a treebank. Because of the hidden variables, the model is trained iteratively with the Expectation-Maximisation algorithm (Baum, 1972). The parameters are randomly initialised and then re-estimated with the Inside-Outside algorithm (Lari and Young, 1990) which is an instance of the EM algorithm for training Probabilistic Context-Free Grammars (PCFGs).

The PCFG training algorithm is applicable here because we can define a PCFG for each of our models which generates the same verb-argument tuples with the same probability. The PCFG is defined as follows:

- (1) The start symbol is TOP.
- (2) For each cluster  $c$ , we add a rule  $TOP \rightarrow V_c A_c$  whose probability is  $p(c)$ .

<sup>2</sup>Arguments with lexical heads other than nouns (e.g., subcategorised clauses) are not included in the selectional preference induction.

- (3) For each verb  $v$  in cluster  $c$ , we add a rule  $V_c \rightarrow v$  with probability  $p(v|c)$ .
- (4) For each subcategorisation frame  $f$  of cluster  $c$  with length  $n$ , we add a rule  $A_c \rightarrow f R_{c,f,1,entity} \dots R_{c,f,n,entity}$  with probability  $p(f|c)$ .
- (5) For each transition from a node  $r$  to a node  $r'$  in the selectional preference model for slot  $i$  of the subcategorisation frame  $f$  of cluster  $c$ , we add a rule  $R_{c,f,i,r} \rightarrow R_{c,f,i,r'}$  whose probability is the transition probability from  $r$  to  $r'$  in the respective WordNet-HMM.
- (6) For each terminal node  $r$  in the selectional preference model, we add a rule  $R_{c,f,i,r} \rightarrow R_r$  whose probability is 1. With this rule, we “jump” from the selectional restriction model to the corresponding node in the a priori model.
- (7) For each transition from a node  $r$  to a node  $r'$  in the a priori model, we add a rule  $R_r \rightarrow R_{r'}$  whose probability is the transition probability from  $r$  to  $r'$  in the a priori WordNet-HMM.
- (8) For each word node  $a$  in the a priori model, we add a rule  $R_a \rightarrow a$  whose probability is 1.

Based on the above definitions, a partial “parse” for  $\langle speak\ subj\text{-}pp.\text{to}\ professor\ audience \rangle$ , referring to cluster 3 and one possible WordNet path, is shown in Figure 1. The connections within  $R_3$  ( $R_{3,\dots,entity} - R_{3,\dots,person/group}$ ) and within  $R$  ( $R_{person/group} - R_{professor/audience}$ ) refer to sequential applications of rule types (5) and (7), respectively.

Figure 1: Example parse tree.

The EM training algorithm maximises the likelihood of the training data.

## 2.3 MDL Principle

A model with a large number of fine-grained concepts as selectional preferences assigns a higher likelihood to the data than a model with a small number of general concepts, because in general a larger number of parameters is better in describing training data. Consequently, the EM algorithm a priori prefers fine-grained concepts but – due to sparse data problems – tends to overfit the training data. In order to find selectional preferences with an appropriate granularity, we apply the Minimum Description Length principle, an approach from Information Theory. According to the MDL principle, the model with minimal *description length* should be chosen. The description length itself is the sum of the *model length* and the *data length*, with the model length defined as the number of bits needed to encode the model and its parameters, and the data length defined as the number of bits required to encode the training data with the given model. According to coding theory, an optimal encoding uses  $-\log_2 p$  bits, on average, to encode data whose probability is  $p$ . Usually, the model length increases and the data length decreases as more parameters are added to a model. The MDL principle finds a compromise between the size of the model and the accuracy of the data description.

Our selectional preference model relies on Li and Abe (1998), applying the MDL principle to determine selectional preferences of verbs and their arguments, by means of a concept hierarchy ordered by hypernym/hyponym relations. Given a set of nouns within a specific argument slot as a sample, the approach finds the cut<sup>3</sup> in a concept hierarchy which minimises the sum of encoding both the model and the data. The *model length* ( $ML$ ) is defined as

$$ML = \frac{k}{2} * \log_2 |S|,$$

with  $k$  the number of concepts in the partial hierarchy between the top concept and the concepts in the cut, and  $|S|$  the sample size, i.e., the total frequency of the data set. The *data length* ( $DL$ ) is defined as

$$DL = - \sum_{n \in S} \log_2 p(n).$$

---

<sup>3</sup>A *cut* is defined as a set of concepts in the concept hierarchy that defines a partition of the "leaf" concepts (the lowest concepts in the hierarchy), viewing each concept in the cut as representing the set of all leaf concepts it dominates.

The probability of a noun  $p(n)$  is determined by dividing the total probability of the concept class the noun belongs to,  $p(\text{concept})$ , by the size of that class,  $|\text{concept}|$ , i.e., the number of nouns that are dominated by that concept:

$$p(n) = \frac{p(\text{concept})}{|\text{concept}|}.$$

The higher the concept within the hierarchy, the more nouns receive an equal probability, and the greater is the data length.

The probability of the concept class in turn is determined by dividing the frequency of the concept class  $f(\text{concept})$  by the sample size:

$$p(\text{concept}) = \frac{f(\text{concept})}{|S|},$$

where  $f(\text{concept})$  is calculated by upward propagation of the frequencies of the nominal lexemes from the data sample through the hierarchy. For example, if the nouns *coffee*, *tea*, *milk* appeared with frequencies 25, 50, 3, respectively, within a specific argument slot, then their hypernym concept *beverage* would be assigned a frequency of 78, and these 78 would be propagated further upwards to the next hypernyms, etc. As a result, each concept class is assigned a fraction of the frequency of the whole data set (and the top concept receives the total frequency of the data set). For calculating  $p(\text{concept})$  (and the overall data length), though, only the concept classes within the cut through the hierarchy are relevant.

Our model uses WordNet 3.0 as the concept hierarchy, and comprises one (complete) a priori WordNet model for the lexical head probabilities  $p(a|r)$  and one (partial) model for each selectional probability distribution  $p(r|c, f, i)$ , cf. Section 2.1.

## 2.4 Combining EM and MDL

The training procedure that combines the EM training with the MDL principle can be summarised as follows.

1. The probabilities of a verb class model with  $c$  classes and a pre-defined set of verbs and frames are initialised randomly. The selectional preference models start out with the most general WordNet concept only, i.e., the partial WordNet hierarchies underlying the probabilities  $p(r|c, f, i)$  initially only contain the concept  $r$  for *entity*.

2. The model is trained for a pre-defined number of iterations. In each iteration, not only the model probabilities are re-estimated and maximised (as done by EM), but also the cuts through the concept hierarchies that represent the various selectional preference models are re-assessed. In each iteration, the following steps are performed.

(a) The partial WordNet hierarchies that represent the selectional preference models are expanded to include the hyponyms of the respective leaf concepts of the partial hierarchies. I.e., in the first iteration, all models are expanded towards the hyponyms of *entity*, and in subsequent iterations each selectional preference model is expanded to include the hyponyms of the leaf nodes in the partial hierarchies resulting from the previous iteration. This expansion step allows the selection models to become more and more detailed, as the training proceeds and the verb clusters (and their selectional restrictions) become increasingly specific.

(b) The training tuples are processed: For each tuple, a PCFG parse forest as indicated by Figure 1 is done, and the Inside-Outside algorithm is applied to estimate the frequencies of the "parse tree rules", given the current model probabilities.

(c) The MDL principle is applied to each selectional preference model: Starting from the respective leaf concepts in the partial hierarchies, MDL is calculated to compare each set of hyponym concepts that share a hypernym with the respective hypernym concept. If the MDL is lower for the set of hyponyms than the hypernym, the hyponyms are left in the partial hierarchy. Otherwise the expansion of the hypernym towards the hyponyms is undone and we continue recursively upwards the hierarchy, calculating MDL to compare the former hypernym and its co-hyponyms with the next upper hypernym, etc. The recursion allows the training algorithm to remove nodes which were added in earlier iterations and are no longer relevant. It stops if the MDL is lower for the hyponyms than for the hypernym.

This step results in selectional preference models that minimally contain the top concept *entity*, and maximally contain the partial WordNet hierarchy between *entity* and the concept classes that have been expanded within this iteration.

(d) The probabilities of the verb class model are

maximised based on the frequency estimates obtained in step (b).

### 3 Experiments

The model is generally applicable to all languages for which WordNet exists, and for which the WordNet functions provided by Princeton University are available. For the purposes of this paper, we choose English as a case study.

#### 3.1 Experimental Setup

The input data for training the verb class models were derived from Viterbi parses of the whole British National Corpus, using the lexicalised PCFG for English by Carroll and Rooth (1998). We took only active clauses into account, and disregarded auxiliary and modal verbs as well as particle verbs, leaving a total of 4,852,371 Viterbi parses. Those input tuples were then divided into 90% training data and 10% test data, providing 4,367,130 training tuples (over 2,769,804 types), and 485,241 test tuples (over 368,103 types).

As we wanted to train and assess our verb class model under various conditions, we used different fractions of the training data in different training regimes. Because of time and memory constraints, we only used training tuples that appeared at least twice. (For the sake of comparison, we also trained one model on all tuples.) Furthermore, we disregarded tuples with personal pronoun arguments; they are not represented in WordNet, and even if they are added (e.g. to general concepts such as *person*, *entity*) they have a rather destructive effect. We considered two subsets of the subcategorisation frames with 10 and 20 elements, which were chosen according to their overall frequency in the training data; for example, the 10 most frequent frame types were *subj:obj*, *subj*, *subj:ap*, *subj:to*, *subj:obj:obj2*, *subj:obj:pp-in*, *subj:adv*, *subj:pp-in*, *subj:vbase*, *subj:that*.<sup>4</sup> When relying on these 10/20 subcategorisation frames, plus including the above restrictions, we were left with 39,773/158,134 and 42,826/166,303 training tuple types/tokens, respectively. The overall number of training tuples

<sup>4</sup>A frame lists its arguments, separated by ':'. Most arguments within the frame types should be self-explanatory. *ap* is an adjectival phrase.

was therefore much smaller than the generally available data. The corresponding numbers including tuples with a frequency of one were 478,717/597,078 and 577,755/701,232.

The number of clusters in the experiments was either 20 or 50, and we used up to 50 iterations over the training tuples. The model probabilities were output after each 5th iteration. The output comprises all model probabilities introduced in Section 2.1. The following sections describe the evaluation of the experiments, and the results.

### 3.2 Evaluation

One of the goals in the development of the presented verb class model was to obtain an accurate statistical model of verb-argument tuples, i.e. a model which precisely predicts the tuple probabilities. In order to evaluate the performance of the model in this respect, we conducted an evaluation experiment, in which we computed the probability which the verb class model assigns to our test tuples and compared it to the corresponding probability assigned by a baseline model. The model with the higher probability is judged the better model.

We expected that the verb class model would perform better than the baseline model on tuples where one or more of the arguments were not observed with the respective verb, because either the argument itself or a semantically similar argument (according to the selectional preferences) was observed with verbs belonging to the same cluster. We also expected that the verb class model assigns a lower probability than the baseline model to test tuples which frequently occurred in the training data, since the verb class model fails to describe precisely the idiosyncratic properties of verbs which are not shared by the other verbs of its cluster.

**The Baseline Model** The baseline model decomposes the probability of a verb-argument tuple into a product of conditional probabilities:<sup>5</sup>

$$p(v, f, a_1^{n_f}) = p(v) p(f|v) \prod_{i=1}^{n_f} p(a_i | a_1^{i-1}, \langle v, f \rangle, f_i)$$

<sup>5</sup>  $f_i$  is the label of the  $i^{\text{th}}$  slot. The verb and the subcategorisation frame are enclosed in angle brackets because they are treated as a unit during smoothing.

The probability of our example tuple  $\langle \text{*speak*, subj-pp.to, professor, audience} \rangle$  in the baseline model is then  $p(\text{*speak*}) p(\text{subj-pp.to}|\text{*speak*}) p(\text{professor}|\langle \text{*speak*, subj-pp.to} \rangle, \text{subj}) p(\text{audience}|\text{professor}, \langle \text{*speak*, subj-pp.to} \rangle, \text{pp.to})$ .

The model contains no hidden variables. Thus the parameters can be directly estimated from the training data with relative frequencies. The parameter estimates are smoothed with modified Kneser-Ney smoothing (Chen and Goodman, 1998), such that the probability of each tuple is positive.

**Smoothing of the Verb Class Model** Although the verb class model has a built-in smoothing capacity, it needs additional smoothing for two reasons: Firstly, some of the nouns in the test data did not occur in the training data. The verb class model assigns a zero probability to such nouns. Hence we smoothed the concept instantiation probabilities  $p(\text{noun}|\text{concept})$  with Witten-Bell smoothing (Chen and Goodman, 1998). Secondly, we smoothed the probabilities of the concepts in the selectional preference models where zero probabilities may occur.

The smoothing ensures that the verb class model assigns a positive probability to each verb-argument tuple with a known verb, a known subcategorisation frame, and arguments which are in WordNet. Other tuples were excluded from the evaluation because the verb class model cannot deal with them.

### 3.3 Results

The evaluation results of our classification experiments are presented in Table 1, for 20 and 50 clusters, with 10 and 20 subcategorisation frame types. The table cells provide the  $\log_e$  of the probabilities per tuple token. The probabilities increase with the number of iterations, flattening out after approx. 25 iterations, as illustrated by Figure 2. Both for 10 and 20 frames, the results are better for 50 than for 20 clusters, with small differences between 10 and 20 frames. The results vary between -11.850 and -10.620 (for 5-50 iterations), in comparison to baseline values of -11.546 and -11.770 for 10 and 20 frames, respectively. The results thus show that our verb class model results are above the baseline results after 10 iterations; this means that our statistical model then assigns higher probabilities to the test tuples than the baseline model.

No. of Clusters	Iteration									
	5	10	15	20	25	30	35	40	45	50
<i>10 frames</i>										
20	-11.770	-11.408	-10.978	-10.900	-10.853	-10.841	-10.831	-10.823	-10.817	-10.812
50	-11.850	-11.452	-11.061	-10.904	-10.730	-10.690	-10.668	-10.628	-10.625	-10.620
<i>20 frames</i>										
20	-11.769	-11.430	-11.186	-10.971	-10.921	-10.899	-10.886	-10.875	-10.873	-10.869
50	-11.841	-11.472	-11.018	-10.850	-10.737	-10.728	-10.706	-10.680	-10.662	-10.648

Table 1: Clustering results – BNC tuples.

Figure 2: Illustration of clustering results.

Including input tuples with a frequency of one in the training data with 10 subcategorisation frames (as mentioned in Section 3.1) decreases the  $\log_e$  per tuple to between -13.151 and -12.498 (for 5-50 iterations), with similar training behaviour as in Figure 2, and in comparison to a baseline of -17.988. The differences in the result indicate that the models including the hapax legomena are worse than the models that excluded the sparse events; at the same time, the differences between baseline and clustering model are larger.

In order to get an intuition about the qualitative results of the clusterings, we select two example clusters that illustrate that the idea of the verb class model has been realised within the clusters. According to our own intuition, the clusters are overall semantically impressive, beyond the examples. Future work will assess by semantics-based evaluations of the clusters (such as pseudo-word disambiguation, or a comparison against existing verb classifications), whether this intuition is justified, whether it transfers to the majority of verbs within the cluster analyses, and whether the clusters capture polysemic verbs appropriately.

The two examples are taken from the 10 frame/50 cluster verb class model, with probabilities of 0.05 and 0.04. The ten most probable verbs in the first cluster are *show*, *suggest*, *indicate*, *reveal*, *find*, *imply*, *conclude*, *demonstrate*, *state*, *mean*, with the two most probable frame types *subj* and *subj:that*, i.e., the intransitive frame, and a frame that subcategorises a *that* clause. As selectional preferences within the intransitive frame (and quite similarly in the *subj:that* frame), the most probable concept classes<sup>6</sup> are *study*, *report*, *survey*, *name*, *research*, *result*, *evidence*. The underlined nouns represent specific concept classes, because they are leaf nodes in the selectional preference hierarchy, thus referring to very specific selectional preferences, which are potentially useful for collocation induction. The ten most probable verbs in the second cluster are *arise*, *remain*, *exist*, *continue*, *need*, *occur*, *change*, *improve*, *begin*, *become*, with the intransitive frame being most probable. The most probable concept classes are *problem*, *condition*, *question*, *natural phenomenon*, *situation*. The two examples illustrate that the verbs within a cluster are semantically related, and that they share obvious subcategorisation frames with intuitively plausible selectional preferences.

## 4 Related Work

Our model is an extension of and thus most closely related to the latent semantic clustering (LSC) model (Rooth et al., 1999) for verb-argument pairs  $\langle v, a \rangle$  which defines their probability as follows:

$$p(v, a) = \sum_c p(c) p(v|c) p(a|c)$$

In comparison to our model, the LSC model only considers a single argument (such as direct objects),

<sup>6</sup>For readability, we only list one noun per WordNet concept.

or a fixed number of arguments from one particular subcategorisation frame, whereas our model defines a probability distribution over all subcategorisation frames. Furthermore, our model specifies selectional preferences in terms of general WordNet concepts rather than sets of individual words.

In a similar vein, our model is both similar and distinct in comparison to the soft clustering approaches by Pereira et al. (1993) and Korhonen et al. (2003). Pereira et al. (1993) suggested deterministic annealing to cluster verb-argument pairs into classes of verbs and nouns. On the one hand, their model is asymmetric, thus not giving the same interpretation power to verbs and arguments; on the other hand, the model provides a more fine-grained clustering for nouns, in the form of an additional hierarchical structure of the noun clusters. Korhonen et al. (2003) used verb-frame pairs (instead of verb-argument pairs) to cluster verbs relying on the Information Bottleneck (Tishby et al., 1999). They had a focus on the interpretation of verbal polysemy as represented by the soft clusters. The main difference of our model in comparison to the above two models is, again, that we incorporate selectional preferences (rather than individual words, or subcategorisation frames).

In addition to the above soft-clustering models, various approaches towards semantic verb classification have relied on hard-clustering models, thus simplifying the notion of verbal polysemy. Two large-scale approaches of this kind are Schulte im Walde (2006), who used k-Means on verb subcategorisation frames and verbal arguments to cluster verbs semantically, and Joanis et al. (2008), who applied Support Vector Machines to a variety of verb features, including subcategorisation slots, tense, voice, and an approximation to animacy. To the best of our knowledge, Schulte im Walde (2006) is the only hard-clustering approach that previously incorporated selectional preferences as verb features. However, her model was not soft-clustering, and she only used a simple approach to represent selectional preferences by WordNet's top-level concepts, instead of making use of the whole hierarchy and more sophisticated methods, as in the current paper.

Last but not least, there are other models of selectional preferences than the MDL model we used in our paper. Most such models also rely on the

WordNet hierarchy (Resnik, 1997; Abney and Light, 1999; Ciaramita and Johnson, 2000; Clark and Weir, 2002). Brockmann and Lapata (2003) compared some of the models against human judgements on the acceptability of sentences, and demonstrated that the models were significantly correlated with human ratings, and that no model performed best; rather, the different methods are suited for different argument relations.

## 5 Summary and Outlook

This paper presented an innovative, complex approach to semantic verb classes that relies on selectional preferences as verb properties. The probabilistic verb class model underlying the semantic classes was trained by a combination of the EM algorithm and the MDL principle, providing soft clusters with two dimensions (verb senses and subcategorisation frames with selectional preferences) as a result. A language model-based evaluation showed that after 10 training iterations the verb class model results are above the baseline results.

We plan to improve the verb class model with respect to (i) a concept-wise (instead of a cut-wise) implementation of the MDL principle, to operate on concepts instead of combinations of concepts; and (ii) variations of the concept hierarchy, using e.g. the sense-clustered WordNets from the Stanford WordNet Project (Snow et al., 2007), or a WordNet version improved by concepts from DOLCE (Gangemi et al., 2003), to check on the influence of conceptual details on the clustering results. Furthermore, we aim to use the verb class model in NLP tasks, (i) as resource for lexical induction of verb senses, verb alternations, and collocations, and (ii) as a lexical resource for the statistical disambiguation of parse trees.

## Abstract

We propose a succinct randomized language model which employs a *perfect hash function* to encode *fingerprints* of  $n$ -grams and their associated probabilities, backoff weights, or other parameters. The scheme can represent any standard  $n$ -gram model and is easily combined with existing model reduction techniques such as entropy-pruning. We demonstrate the space-savings of the scheme via machine translation experiments within a distributed language modeling framework.

## 1 Introduction

Language models (LMs) are a core component in statistical machine translation, speech recognition, optical character recognition and many other areas. They distinguish plausible word sequences from a set of candidates. LMs are usually implemented as  $n$ -gram models parameterized for each distinct sequence of up to  $n$  words observed in the training corpus. Using higher-order models and larger amounts of training data can significantly improve performance in applications, however the size of the resulting LM can become prohibitive.

With large monolingual corpora available in major languages, making use of all the available data is now a fundamental challenge in language modeling. Efficiency is paramount in applications such as machine translation which make huge numbers of LM requests per sentence. To scale LMs to larger corpora with higher-order dependencies, researchers

have considered alternative parameterizations such as class-based models (Brown et al., 1992), model reduction techniques such as entropy-based pruning (Stolcke, 1998), novel representation schemes such as suffix arrays (Emami et al., 2007), Golomb Coding (Church et al., 2007) and distributed language models that scale more readily (Brants et al., 2007).

In this paper we propose a novel randomized language model. Recent work (Talbot and Osborne, 2007b) has demonstrated that randomized encodings can be used to represent  $n$ -gram counts for LMs with significant space-savings, circumventing information-theoretic constraints on lossless data structures by allowing errors with some small probability. In contrast the representation scheme used by our model encodes parameters directly. It can be combined with any  $n$ -gram parameter estimation method and existing model reduction techniques such as entropy-based pruning. Parameters that are stored in the model are retrieved without error; however, *false positives* may occur whereby  $n$ -grams not in the model are incorrectly ‘found’ when requested. The false positive rate is determined by the space usage of the model.

Our randomized language model is based on the Bloomier filter (Chazelle et al., 2004). We encode *fingerprints* (random hashes) of  $n$ -grams together with their associated probabilities using a *perfect hash function* generated at random (Majewski et al., 1996). Lookup is very efficient: the values of 3 cells in a large array are combined with the fingerprint of an  $n$ -gram. This paper focuses on machine translation. However, many of our findings should transfer to other applications of language modeling.

## 2 Scaling Language Models

In statistical machine translation (SMT), LMs are used to score candidate translations in the target language. These are typically  $n$ -gram models that approximate the probability of a word sequence by assuming each token to be independent of all but  $n - 1$  preceding tokens. Parameters are estimated from monolingual corpora with parameters for each distinct word sequence of length  $l \in [n]$  observed in the corpus. Since the number of parameters grows somewhat exponentially with  $n$  and linearly with the size of the training corpus, the resulting models can be unwieldy even for relatively small corpora.

### 2.1 Scaling Strategies

Various strategies have been proposed to scale LMs to larger corpora and higher-order dependencies. *Model-based* techniques seek to parameterize the model more efficiently (e.g. latent variable models, neural networks) or to reduce the model size directly by pruning uninformative parameters, e.g. (Stolcke, 1998), (Goodman and Gao, 2000). *Representation-based* techniques attempt to reduce space requirements by representing the model more efficiently or in a form that scales more readily, e.g. (Emami et al., 2007), (Brants et al., 2007), (Church et al., 2007).

### 2.2 Lossy Randomized Encodings

A fundamental result in information theory (Carter et al., 1978) states that a random set of objects cannot be stored using constant space per object as the universe from which the objects are drawn grows in size: the space required to uniquely identify an object increases as the set of possible objects from which it must be distinguished grows. In language modeling the universe under consideration is the set of all possible  $n$ -grams of length  $n$  for given vocabulary. Although  $n$ -grams observed in natural language corpora are *not* randomly distributed within this universe no lossless data structure that we are aware of can circumvent this space-dependency on both the  $n$ -gram order and the vocabulary size. Hence as the training corpus and vocabulary grow, a model will require more space *per parameter*.

However, if we are willing to accept that occasionally our model will be unable to distinguish between distinct  $n$ -grams, then it is possible to store

each parameter in constant space independent of both  $n$  and the vocabulary size (Carter et al., 1978), (Talbot and Osborne, 2007a). The space required in such a *lossy encoding* depends only on the range of values associated with the  $n$ -grams and the desired error rate, i.e. the probability with which two distinct  $n$ -grams are assigned the same fingerprint.

### 2.3 Previous Randomized LMs

Recent work (Talbot and Osborne, 2007b) has used lossy encodings based on Bloom filters (Bloom, 1970) to represent logarithmically quantized corpus statistics for language modeling. While the approach results in significant space savings, working with corpus statistics, rather than  $n$ -gram probabilities directly, is computationally less efficient (particularly in a distributed setting) and introduces a dependency on the smoothing scheme used. It also makes it difficult to leverage existing model reduction strategies such as entropy-based pruning that are applied to final parameter estimates.

In the next section we describe our randomized LM scheme based on perfect hash functions. This scheme can be used to encode any standard  $n$ -gram model which may first be processed using any conventional model reduction technique.

## 3 Perfect Hash-based Language Models

Our randomized LM is based on the Bloomier filter (Chazelle et al., 2004). We assume the  $n$ -grams and their associated parameter values have been precomputed and stored on disk. We then encode the model in an array such that each  $n$ -gram's value can be retrieved. Storage for this array is the model's only significant space requirement once constructed.<sup>1</sup>

The model uses randomization to map  $n$ -grams to *fingerprints* and to generate a *perfect hash function* that associates  $n$ -grams with their values. The model can erroneously return a value for an  $n$ -gram that was never actually stored, but will always return the correct value for an  $n$ -gram that is in the model. We will describe the randomized algorithm used to encode  $n$ -gram parameters in the model, analyze the probability of a false positive, and explain how we construct and query the model in practice.

<sup>1</sup>Note that we do not store the  $n$ -grams explicitly and therefore that the model's parameter set cannot easily be enumerated.

### 3.1 $N$ -gram Fingerprints

We wish to encode a set of  $n$ -gram/value pairs

$$\mathcal{S} = \{(x_1, v(x_1)), (x_2, v(x_2)), \dots, (x_N, v(x_N))\}$$

using an array  $A$  of size  $M$  and a perfect hash function. Each  $n$ -gram  $x_i$  is drawn from some set of possible  $n$ -grams  $\mathcal{U}$  and its associated value  $v(x_i)$  from a corresponding set of possible values  $\mathcal{V}$ .

We do not store the  $n$ -grams and their probabilities directly but rather encode a *fingerprint* of each  $n$ -gram  $f(x_i)$  together with its associated value  $v(x_i)$  in such a way that the value can be retrieved when the model is queried with the  $n$ -gram  $x_i$ .

A fingerprint hash function  $f : \mathcal{U} \rightarrow [0, B - 1]$  maps  $n$ -grams to integers between 0 and  $B - 1$ .<sup>2</sup> The array  $A$  in which we encode  $n$ -gram/value pairs has addresses of size  $\lceil \log_2 B \rceil$  hence  $B$  will determine the amount of space used per  $n$ -gram. There is a trade-off between space and error rate since the larger  $B$  is, the lower the probability of a false positive. This is analyzed in detail below. For now we assume only that  $B$  is at least as large as the range of values stored in the model, i.e.  $B \geq |\mathcal{V}|$ .

### 3.2 Composite Perfect Hash Functions

The function used to associate  $n$ -grams with their values (Eq. (1)) combines a composite perfect hash function (Majewski et al., 1996) with the fingerprint function. An example is shown in Fig. 1. The composite hash function is made up of  $k$  independent hash functions  $h_1, h_2, \dots, h_k$  where each  $h_i : \mathcal{U} \rightarrow [0, M - 1]$  maps  $n$ -grams to locations in the array  $A$ . The lookup function is then defined as  $g : \mathcal{U} \rightarrow [0, B - 1]$  by<sup>3</sup>

$$g(x_i) = f(x_i) \otimes \left( \bigotimes_{i=1}^k A[h_i(x_i)] \right) \quad (1)$$

where  $f(x_i)$  is the fingerprint of  $n$ -gram  $x_i$  and  $A[h_i(x_i)]$  is the value stored in location  $h_i(x_i)$  of the array  $A$ . Eq. (1) is evaluated to retrieve an  $n$ -gram's parameter during decoding. To encode our model correctly we must ensure that  $g(x_i) = v(x_i)$  for all  $n$ -grams in our set  $\mathcal{S}$ . Generating  $A$  to encode this

<sup>2</sup>The analysis assumes that all hash functions are random.

<sup>3</sup>We use  $\otimes$  to denote the exclusive bitwise OR operator.

Composite hash function  $g(x)$  encodes  $v(x) = 3$

Figure 1: Encoding an  $n$ -gram's value in the array.

function for a given set of  $n$ -grams is a significant challenge described in the following sections.

### 3.3 Encoding $n$ -grams in the model

All addresses in  $A$  are initialized to zero. The procedure we use to ensure  $g(x_i) = v(x_i)$  for all  $x_i \in \mathcal{S}$  updates a single, unique location in  $A$  for each  $n$ -gram  $x_i$ . This location is chosen from among the  $k$  locations given by  $h_j(x_i), j \in [k]$ . Since the composite function  $g(x_i)$  depends on the values stored at all  $k$  locations  $A[h_1(x_i)], A[h_2(x_i)], \dots, A[h_k(x_i)]$  in  $A$ , we must also ensure that once an  $n$ -gram  $x_i$  has been encoded in the model, these  $k$  locations are not subsequently changed since this would invalidate the encoding; however,  $n$ -grams encoded later may reference earlier entries and therefore locations in  $A$  can effectively be 'shared' among parameters.

In the following section we describe a randomized algorithm to find a suitable order in which to enter  $n$ -grams in the model and, for each  $n$ -gram  $x_i$ , determine which of the  $k$  hash functions, say  $h_j$ , can be used to update  $A$  without invalidating previous entries. Given this ordering of the  $n$ -grams and the choice of hash function  $h_j$  for each  $x_i \in \mathcal{S}$ , it is clear that the following update rule will encode  $x_i$  in the array  $A$  so that  $g(x_i)$  will return  $v(x_i)$  (cf. Eq.(1))

$$A[h_j(x_i)] = v(x_i) \otimes f(x_i) \otimes \bigotimes_{i=1, i \neq j}^k A[h_i(x_i)]. \quad (2)$$

### 3.4 Finding an Ordered Matching

We now describe an algorithm (Algorithm 1; (Majewski et al., 1996)) that selects one of the  $k$  hash

functions  $h_j, j \in [k]$  for each  $n$ -gram  $x_i \in \mathcal{S}$  and an order in which to apply the update rule Eq. (2) so that  $g(x_i)$  maps  $x_i$  to  $v(x_i)$  for all  $n$ -grams in  $\mathcal{S}$ .

This problem is equivalent to finding an *ordered matching* in a bipartite graph whose LHS nodes correspond to  $n$ -grams in  $\mathcal{S}$  and RHS nodes correspond to locations in  $A$ . The graph initially contains edges from each  $n$ -gram to each of the  $k$  locations in  $A$  given by  $h_1(x_i), h_2(x_i), \dots, h_k(x_i)$  (see Fig. (2)). The algorithm uses the fact that any RHS node that has degree one (i.e. a single edge) can be safely matched with its associated LHS node since no remaining LHS nodes can be dependent on it.

We first create the graph using the  $k$  hash functions  $h_j, j \in [k]$  and store a list (`degree_one`) of those RHS nodes (locations) with degree one. The algorithm proceeds by removing nodes from `degree_one` in turn, pairing each RHS node with the unique LHS node to which it is connected. We then remove both nodes from the graph and push the pair  $(x_i, h_j(x_i))$  onto a stack (`matched`). We also remove any other edges from the matched LHS node and add any RHS nodes that now have degree one to `degree_one`. The algorithm succeeds if, while there are still  $n$ -grams left to match, `degree_one` is never empty. We then encode  $n$ -grams in the order given by the stack (i.e., first-in-last-out).

Since we remove each location in  $A$  (RHS node) from the graph as it is matched to an  $n$ -gram (LHS node), each location will be associated with at most one  $n$ -gram for updating. Moreover, since we match an  $n$ -gram to a location only once the location has degree one, we are guaranteed that any other  $n$ -grams that depend on this location are already on the stack and will therefore only be encoded once we have updated this location. Hence dependencies in  $g$  are respected and  $g(x_i) = v(x_i)$  will remain true following the update in Eq. (2) for each  $x_i \in \mathcal{S}$ .

### 3.5 Choosing Random Hash Functions

The algorithm described above is not guaranteed to succeed. Its success depends on the size of the array  $M$ , the number of  $n$ -grams stored  $|\mathcal{S}|$  and the choice of random hash functions  $h_j, j \in [k]$ . Clearly we require  $M \geq |\mathcal{S}|$ ; in fact, an argument from Majewski et al. (1996) implies that if  $M \geq 1.23|\mathcal{S}|$  and  $k = 3$ , the algorithm succeeds with high probabil-

Figure 2: The ordered matching algorithm: `matched` =  $[(a, 1), (b, 2), (d, 4), (c, 5)]$

ity. We use 2-universal hash functions (L. Carter and M. Wegman, 1979) defined for a range of size  $M$  via a prime  $P \geq M$  and two random numbers  $1 \leq a_j \leq P$  and  $0 \leq b_j \leq P$  for  $j \in [k]$  as

$$h_j(x) \equiv a_j x + b_j \pmod{P}$$

taken modulo  $M$ . We generate a set of  $k$  hash functions by sampling  $k$  pairs of random numbers  $(a_j, b_j), j \in [k]$ . If the algorithm does not find a matching with the current set of hash functions, we re-sample these parameters and re-start the algorithm. Since the probability of failure on a single attempt is low when  $M \geq 1.23|\mathcal{S}|$ , the probability of failing multiple times is very small.

### 3.6 Querying the Model and False Positives

The construction we have described above ensures that for any  $n$ -gram  $x_i \in \mathcal{S}$  we have  $g(x_i) = v(x_i)$ , i.e., we retrieve the correct value. To retrieve a value given an  $n$ -gram  $x_i$  we simply compute the fingerprint  $f(x_i)$ , the hash functions  $h_j(x_i), j \in [k]$  and then return  $g(x_i)$  using Eq. (1). Note that unlike the constructions in (Talbot and Osborne, 2007b) and (Church et al., 2007) no errors are possible for  $n$ -grams stored in the model. Hence we will not make errors for common  $n$ -grams that are typically in  $\mathcal{S}$ .

---

**Algorithm 1** Ordered Matching

---

**Input** : Set of  $n$ -grams  $\mathcal{S}$ ;  $k$  hash functions  $h_j, j \in [k]$ ; number of available locations  $M$ .  
**Output** : Ordered matching `matched` or `FAIL`.  
`matched`  $\leftarrow []$   
**for all**  $i \in [0, M - 1]$  **do**  
   $r2l_i \leftarrow \emptyset$   
**end for**  
**for all**  $x_i \in \mathcal{S}$  **do**  
   $l2r_i \leftarrow \emptyset$   
  **for all**  $j \in [k]$  **do**  
     $l2r_i \leftarrow l2r_i \cup h_j(x_i)$   
     $r2l_{h_j(x_i)} \leftarrow r2l_{h_j(x_i)} \cup x_i$   
  **end for**  
**end for**  
`degree_one`  $\leftarrow \{i \in [0, M - 1] \mid |r2l_i| = 1\}$   
**while**  $|\text{degree\_one}| \geq 1$  **do**  
  `rhs`  $\leftarrow \text{POP } \text{degree\_one}$   
  `lhs`  $\leftarrow \text{POP } r2l_{\text{rhs}}$   
  PUSH (`lhs`, `rhs`) onto `matched`  
  **for all**  $rhs' \in l2r_{\text{lhs}}$  **do**  
    POP  $r2l_{\text{rhs}'}$   
    **if**  $|r2l_{\text{rhs}'}| = 1$  **then**  
      `degree_one`  $\leftarrow \text{degree\_one} \cup \text{rhs}'$   
    **end if**  
  **end for**  
**end while**  
**if**  $|\text{matched}| = |\mathcal{S}|$  **then**  
  **return** `matched`  
**else**  
  **return** `FAIL`  
**end if**

---

On the other hand, querying the model with an  $n$ -gram that was not stored, i.e. with  $x_i \in \mathcal{U} \setminus \mathcal{S}$  we may erroneously return a value  $v \in \mathcal{V}$ .

Since the fingerprint  $f(x_i)$  is assumed to be distributed uniformly at random (u.a.r.) in  $[0, B - 1]$ ,  $g(x_i)$  is also u.a.r. in  $[0, B - 1]$  for  $x_i \in \mathcal{U} \setminus \mathcal{S}$ . Hence with  $|\mathcal{V}|$  values stored in the model, the probability that  $x_i \in \mathcal{U} \setminus \mathcal{S}$  is assigned a value in  $v \in \mathcal{V}$  is

$$\Pr\{g(x_i) \in \mathcal{V} \mid x_i \in \mathcal{U} \setminus \mathcal{S}\} = |\mathcal{V}|/B.$$

We refer to this event as a *false positive*. If  $\mathcal{V}$  is fixed, we can obtain a false positive rate  $\epsilon$  by setting  $B$  as

$$B \equiv |\mathcal{V}|/\epsilon.$$

For example, if  $|\mathcal{V}|$  is 128 then taking  $B = 1024$  gives an error rate of  $\epsilon = 128/1024 = 0.125$  with each entry in  $A$  using  $\lceil \log_2 1024 \rceil = 10$  bits. Clearly  $B$  must be at least  $|\mathcal{V}|$  in order to distinguish each value. We refer to the additional bits allocated to

each location (i.e.  $\lceil \log_2 B \rceil - \log_2 |\mathcal{V}|$  or 3 in our example) as *error bits* in our experiments below.

### 3.7 Constructing the Full Model

When encoding a large set of  $n$ -gram/value pairs  $\mathcal{S}$ , Algorithm 1 will only be practical if the raw data and graph can be held in memory as the perfect hash function is generated. This makes it difficult to encode an extremely large set  $\mathcal{S}$  into a single array  $A$ . The solution we adopt is to split  $\mathcal{S}$  into  $t$  smaller sets  $\mathcal{S}'_i, i \in [t]$  that are arranged in lexicographic order.<sup>4</sup> We can then encode each subset in a separate array  $A'_i, i \in [t]$  in turn in memory. Querying each of these arrays for each  $n$ -gram requested would be inefficient and inflate the error rate since a false positive could occur on each individual array. Instead we store an index of the final  $n$ -gram encoded in each array and given a request for an  $n$ -gram's value, perform a binary search for the appropriate array.

### 3.8 Sanity Checks

Our models are consistent in the following sense

$$(w_1, w_2, \dots, w_n) \in \mathcal{S} \implies (w_2, \dots, w_n) \in \mathcal{S}.$$

Hence we can infer that an  $n$ -gram can *not* be present in the model, if the  $n - 1$ -gram consisting of the final  $n - 1$  words has already tested false. Following (Talbot and Osborne, 2007a) we can avoid unnecessary false positives by not querying for the longer  $n$ -gram in such cases.

Backoff smoothing algorithms typically request the longest  $n$ -gram supported by the model first, requesting shorter  $n$ -grams only if this is not found. In our case, however, if a query is issued for the 5-gram  $(w_1, w_2, w_3, w_4, w_5)$  when only the unigram  $(w_5)$  is present in the model, the probability of a false positive using such a backoff procedure would not be  $\epsilon$  as stated above, but rather the probability that we fail to avoid an error on *any* of the four queries performed prior to requesting the unigram, i.e.  $1 - (1 - \epsilon)^4 \approx 4\epsilon$ . We therefore query the model first with the unigram working up to the full  $n$ -gram requested by the decoder only if the preceding queries test positive. The probability of returning a false positive for any  $n$ -gram requested by the decoder (but not in the model) will then be at most  $\epsilon$ .

<sup>4</sup>In our system we use subsets of 5 million  $n$ -grams which can easily be encoded using less than 2GB of working space.

## 4 Experimental Set-up

### 4.1 Distributed LM Framework

We deploy the randomized LM in a distributed framework which allows it to scale more easily by distributing it across multiple language model servers. We encode the model stored on each language model server using the randomized scheme.

The proposed randomized LM can encode parameters estimated using any smoothing scheme (e.g. Kneser-Ney, Katz etc.). Here we choose to work with *stupid backoff* smoothing (Brants et al., 2007) since this is significantly more efficient to train and deploy in a distributed framework than a *context-dependent* smoothing scheme such as Kneser-Ney. Previous work (Brants et al., 2007) has shown it to be appropriate to large-scale language modeling.

### 4.2 LM Data Sets

The language model is trained on four data sets:

**target:** The English side of Arabic-English parallel data provided by LDC (132 million tokens).

**gigaword:** The English Gigaword dataset provided by LDC (3.7 billion tokens).

**webnews:** Data collected over several years, up to January 2006 (34 billion tokens).

**web:** The Web 1T 5-gram Version 1 corpus provided by LDC (1 trillion tokens).<sup>5</sup>

An initial experiment will use the Web 1T 5-gram corpus only; all other experiments will use a log-linear combination of models trained on each corpus. The combined model is pre-compiled with weights trained on development data by our system.

### 4.3 Machine Translation

The SMT system used is based on the framework proposed in (Och and Ney, 2004) where translation is treated as the following optimization problem

$$\hat{\mathbf{e}} = \arg \max_{\mathbf{e}} \sum_{i=1}^M \lambda_i \Phi_i(\mathbf{e}, \mathbf{f}). \quad (3)$$

Here  $\mathbf{f}$  is the source sentence that we wish to translate,  $\mathbf{e}$  is a translation in the target language,  $\Phi_i, i \in [M]$  are feature functions and  $\lambda_i, i \in [M]$  are weights. (Some features may not depend on  $\mathbf{f}$ .)

<sup>5</sup> $N$ -grams with count  $< 40$  are not included in this data set.

	Full Set	Entropy-Pruned
# 1-grams	13,588,391	13,588,391

Total	3,795,790,711	1,283,522,262

Table 1: Num. of  $n$ -grams in the Web 1T 5-gram corpus.

## 5 Experiments

This section describes three sets of experiments: first, we encode the Web 1T 5-gram corpus as a randomized language model and compare the resulting size with other representations; then we measure false positive rates when requesting  $n$ -grams for a held-out data set; finally we compare translation quality when using conventional (lossless) languages models and our randomized language model.

Note that the standard practice of measuring perplexity is not meaningful here since (1) for efficient computation, the language model is not normalized; and (2) even if this were not the case, quantization and false positives would render it unnormalized.

### 5.1 Encoding the Web 1T 5-gram corpus

We build a language model from the Web 1T 5-gram corpus. Parameters, corresponding to negative logarithms of relative frequencies, are quantized to 8-bits using a uniform quantizer. More sophisticated quantizers (e.g. (S. Lloyd, 1982)) may yield better results but are beyond the scope of this paper.

Table 1 provides some statistics about the corpus. We first encode the full set of  $n$ -grams, and then a version that is reduced to approx. 1/3 of its original size using entropy pruning (Stolcke, 1998).

Table 2 shows the total space and number of bytes required per  $n$ -gram to encode the model under different schemes: “LDC gzip’d” is the size of the files as delivered by LDC; “Trie” uses a compact trie representation (e.g., (Clarkson et al., 1997; Church et al., 2007)) with 3 byte word ids, 1 byte values, and 3 byte indices; “Block encoding” is the encoding used in (Brants et al., 2007); and “randomized” uses our novel randomized scheme with 12 error bits. The latter requires around 60% of the space of the next best representation and less than half of the com-

	size (GB)	bytes/ $n$ -gram
<b>Full Set</b>		
LDC gzip'd	24.68	6.98
Trie	21.46	6.07
Block Encoding	18.00	5.14
Randomized	10.87	3.08
<b>Entropy Pruned</b>		
Trie	7.70	6.44
Block Encoding	6.20	5.08
Randomized	3.68	3.08

Table 2: Web 1T 5-gram language model sizes with different encodings. “Randomized” uses 12 error bits.

monly used trie encoding. Our method is the only one to use the same amount of space per parameter for both full and entropy-pruned models.

## 5.2 False Positive Rates

All  $n$ -grams explicitly inserted into our randomized language model are retrieved without error; however,  $n$ -grams not stored may be incorrectly assigned a value resulting in a false positive. Section (3) analyzed the theoretical error rate; here, we measure error rates in practice when retrieving  $n$ -grams for approx. 11 million tokens of previously unseen text (news articles published after the training data had been collected). We measure this separately for all  $n$ -grams of order 2 to 5 from the same text.

The language model is trained on the four data sources listed above and contains 24 billion  $n$ -grams. With 8-bit parameter values, the model requires 55.2/69.0/82.7 GB storage when using 8/12/16 error bits respectively (this corresponds to 2.46/3.08/3.69 bytes/ $n$ -gram).

Using such a large language model results in a large fraction of known  $n$ -grams in new text. Table 3 shows, e.g., that almost half of all 5-grams from the new text were seen in the training data.

Column (1) in Table 4 shows the number of false positives that occurred for this test data. Column (2) shows this as a fraction of the number of unseen  $n$ -grams in the data. This number should be close to  $2^{-b}$  where  $b$  is the number of error bits (i.e. 0.003906 for 8 bits and 0.000244 for 12 bits). The error rates for bigrams are close to their expected values. The numbers are much lower for higher  $n$ -gram orders due to the use of sanity checks (see Section 3.8).

	total	seen	unseen
2gms	11,093,093	98.98%	1.02%
3gms	10,652,693	91.08%	8.92%
4gms	10,212,293	68.39%	31.61%
5gms	9,781,777	45.51%	54.49%

Table 3: Number of  $n$ -grams in test set and percentages of  $n$ -grams that were seen/unseen in the training data.

	(1) false pos.	(2) $\frac{\text{false pos}}{\text{unseen}}$	(3) $\frac{\text{false pos}}{\text{total}}$
<b>8 error bits</b>			
2gms	376	0.003339	0.000034
3gms	2839	0.002988	0.000267
4gms	6659	0.002063	0.000652
5gms	6356	0.001192	0.000650
total	16230	0.001687	0.000388
<b>12 error bits</b>			
2gms	25	0.000222	0.000002
3gms	182	0.000192	0.000017
4gms	416	0.000129	0.000041
5gms	407	0.000076	0.000042
total	1030	0.000107	0.000025

Table 4: False positive rates with 8 and 12 error bits.

The overall fraction of  $n$ -grams requested for which an error occurs is of most interest in applications. This is shown in Column (3) and is around a factor of 4 smaller than the values in Column (2). On average, we expect to see 1 error in around 2,500 requests when using 8 error bits, and 1 error in 40,000 requests with 12 error bits (see “total” row).

## 5.3 Machine Translation

We run an improved version of our 2006 NIST MT Evaluation entry for the Arabic-English “Unlimited” data track.<sup>6</sup> The language model is the same one as in the previous section.

Table 5 shows baseline translation BLEU scores for a lossless (non-randomized) language model with parameter values quantized into 5 to 8 bits. We use MT04 data for system development, with MT05 data and MT06 (“NIST” subset) data for blind testing. As expected, results improve when using more bits. There seems to be little benefit in going beyond

<sup>6</sup>See <http://www.nist.gov/speech/tests/mt/2006/doc/>

bits	dev	test	test
	MT04	MT05	MT06
5	0.5237	0.5608	0.4636
6	0.5280	0.5671	0.4649
7	0.5299	0.5691	0.4672
8	0.5304	0.5697	0.4663

Table 5: Baseline BLEU scores with lossless  $n$ -gram model and different quantization levels (bits).

Figure 3: BLEU scores on the MT05 data set.

8 bits. Overall, our baseline results compare favorably to those reported on the NIST MT06 web site.

We now replace the language model with a randomized version. Fig. 3 shows BLEU scores for the MT05 evaluation set with parameter values quantized into 5 to 8 bits and 8 to 16 additional ‘error’ bits. Figure 4 shows a similar graph for MT06 data. We again see improvements as quantization uses more bits. There is a large drop in performance when reducing the number of error bits from 10 to 8, while increasing it beyond 12 bits offers almost no further gains with scores that are almost identical to the lossless model. Using 8-bit quantization and 12 error bits results in an overall requirement of  $(8 + 12) \times 1.23 = 24.6$  bits = 3.08 bytes per  $n$ -gram.

All runs use the sanity checks described in Section 3.8. Without sanity checks, scores drop, e.g. by 0.002 for 8-bit quantization and 12 error bits.

Randomization and entropy pruning can be combined to achieve further space savings with minimal loss in quality as shown in Table (6). The BLEU score drops by between 0.0007 to 0.0018 while the

unpruned rand	69	0.5299	0.5692	0.4659
pruned block	42	0.5294	0.5683	0.4665
pruned rand	27	0.5289	0.5679	0.4656

Table 6: Combining randomization and entropy pruning. All models use 8-bit values; “rand” uses 12 error bits.

model is reduced to approx. 1/4 of its original size.

## 6 Conclusions

We have presented a novel randomized language model based on perfect hashing. It can associate arbitrary parameter types with  $n$ -grams. Values explicitly inserted into the model are retrieved without error; false positives may occur but are controlled by the number of bits used per  $n$ -gram. The amount of storage needed is independent of the size of the vocabulary and the  $n$ -gram order. Lookup is very efficient: the values of 3 cells in a large array are combined with the fingerprint of an  $n$ -gram.

Experiments have shown that this randomized language model can be combined with entropy pruning to achieve further memory reductions; that error rates occurring in practice are much lower than those predicted by theoretical analysis due to the use of runtime sanity checks; and that the same translation quality as a lossless language model representation can be achieved when using 12 ‘error’ bits, resulting in approx. 3 bytes per  $n$ -gram (this includes one byte to store parameter values).

## Abstract

We improve the quality of statistical machine translation (SMT) by applying models that predict word forms from their stems using extensive morphological and syntactic information from both the source and target languages. Our inflection generation models are trained independently of the SMT system. We investigate different ways of combining the inflection prediction component with the SMT system by training the base MT system on fully inflected forms or on word stems. We applied our inflection generation models in translating English into two morphologically complex languages, Russian and Arabic, and show that our model improves the quality of SMT over both phrasal and syntax-based SMT systems according to BLEU and human judgments.

## 1 Introduction

One of the outstanding problems for further improving machine translation (MT) systems is the difficulty of dividing the MT problem into sub-problems and tackling each sub-problem in isolation to improve the overall quality of MT. Evidence for this difficulty is the fact that there has been very little work investigating the use of such independent sub-components, though we started to see some successful cases in the literature, for example in word alignment (Fraser and Marcu, 2007), target language capitalization (Wang et al., 2006) and case marker generation (Toutanova and Suzuki, 2007).

This paper describes a successful attempt to integrate a subcomponent for generating word inflections into a statistical machine translation (SMT)

system. Our research is built on previous work in the area of using morpho-syntactic information for improving SMT. Work in this area is motivated by two advantages offered by morphological analysis: (1) it provides linguistically motivated clustering of words and makes the data less sparse; (2) it captures morphological constraints applicable on the target side, such as agreement phenomena. This second problem is very difficult to address with word-based translation systems, when the relevant morphological information in the target language is either non-existent or implicitly encoded in the source language. These two aspects of morphological processing have often been addressed separately: for example, morphological pre-processing of the input data is a common method of addressing the first aspect, e.g. (Goldwater and McClosky, 2005), while the application of a target language model has almost solely been responsible for addressing the second aspect. Minkov et al. (2007) introduced a way to address these problems by using a rich feature-based model, but did not apply the model to MT.

In this paper, we integrate a model that predicts target word inflection in the translations of English into two morphologically complex languages (Russian and Arabic) and show improvements in the MT output. We study several alternative methods for integration and show that it is best to propagate uncertainty among the different components as shown by other research, e.g. (Finkel et al., 2006), and in some cases, to factor the translation problem so that the baseline MT system can take advantage of the reduction in sparsity by being able to work on word stems. We also demonstrate that our independently trained models are portable, showing that they can improve both syntactic and phrasal SMT systems.

## 2 Related work

There has been active research on incorporating morphological knowledge in SMT. Several approaches use pre-processing schemes, including segmentation of clitics (Lee, 2004; Habash and Sadat, 2006), compound splitting (Nießen and Ney, 2004) and stemming (Goldwater and McClosky, 2005). Of these, the segmentation approach is difficult to apply when the target language is morphologically rich as the segmented morphemes must be put together in the output (El-Kahlout and Oflazer, 2006); and in fact, most work using pre-processing focused on translation into English. In recent work, Koehn and Hoang (2007) proposed a general framework for including morphological features in a phrase-based SMT system by factoring the representation of words into a vector of morphological features and allowing a phrase-based MT system to work on any of the factored representations, which is implemented in the Moses system. Though our motivation is similar to that of Koehn and Hoang (2007), we chose to build an independent component for inflection prediction in isolation rather than folding morphological information into the main translation model. While this may lead to search errors due to the fact that the models are not integrated as tightly as possible, it offers some important advantages, due to the very decoupling of the components. First, our approach is not affected by restrictions on the allowable context size or a phrasal segmentation that are imposed by current MT decoders. This also makes the model portable and applicable to different types of MT systems. Second, we avoid the problem of the combinatorial expansion in the search space which currently arises in the factored approach of Moses.

Our inflection prediction model is based on (Minkov et al., 2007), who build models to predict the inflected forms of words in Russian and Arabic, but do not apply their work to MT. In contrast, we focus on methods of integration of an inflection prediction model with an MT system, and on evaluation of the model’s impact on translation. Other work closely related to ours is (Toutanova and Suzuki, 2007), which uses an independently trained case marker prediction model in an English-Japanese translation system, but it focuses on the problem of generating a small set of closed class words rather

than generating inflected forms for each word in translation, and proposes different methods of integration of the components.

## 3 Inflection prediction models

This section describes the task and our model for inflection prediction, following (Minkov et al., 2007).

We define the task of inflection prediction as the task of choosing the correct inflections of given target language stems, given a corresponding source sentence. The stemming and inflection operations we use are defined by lexicons.

### 3.1 Lexicon operations

For each target language we use a lexicon  $L$  which determines the following necessary operations:

*Stemming*: returns the set of possible morphological stems  $S_w = \{s^1, \dots, s^l\}$  for the word  $w$  according to  $L$ .<sup>1</sup>

*Inflection*: returns the set of surface word forms  $I_w = \{i^1, \dots, i^m\}$  for the stems  $S_w$  according to  $L$ .

*Morphological analysis*: returns the set of possible morphological analyses  $A_w = \{a^1, \dots, a^v\}$  for  $w$ . A morphological analysis  $a$  is a vector of categorical values, where each dimension and its possible values are defined by  $L$ .

For the morphological analysis operation, we used the same set of morphological features described in (Minkov et al., 2007), that is, seven features for Russian (POS, Person, Number, Gender, Tense, Mood and Case) and 12 for Arabic (POS, Person, Number, Gender, Tense, Mood, Negation, Determiner, Conjunction, Preposition, Object and Possessive pronouns). Each word is factored into a stem (uninflected form) and a subset of these features, where features can have either binary (as in Determiner in Arabic) or multiple values. Some features are relevant only for a particular (set of) part-of-speech (POS) (e.g., Gender is relevant only in nouns, pronouns, verbs, and adjectives in Russian), while others combine with practically all categories (e.g., Conjunction in Arabic). The number of possible inflected forms per stem is therefore quite large: as we see in Table 1 of Section 3, there are on average 14 word forms per stem in Russian and 24 in

<sup>1</sup>Alternatively, stemming can return a disambiguated stem analysis; in which case the set  $S_w$  consists of one item. The same is true with the operation of morphological analysis.

Arabic for our dataset. This makes the generation of correct forms a challenging problem in MT.

The Russian lexicon was obtained by intersecting a general domain lexicon with our training data (Table 2), and the Arabic lexicon was obtained by running the Buckwalter morphological analyser (Buckwalter, 2004) on the training data. Contextual disambiguation of morphology was not performed in either of these languages. In addition to the forms supposed by our lexicon, we also treated capitalization as an inflectional feature in Russian, and defined all true-case word variants as possible inflections of its stem(s). Arabic does not use capitalization.

### 3.2 Task

More formally, our task is as follows: given a source sentence  $e$ , a sequence of stems in the target language  $S_1, \dots, S_t, \dots, S_n$  forming a translation of  $e$ , and additional morpho-syntactic annotations  $A$  derived from the input, select an inflection  $y_t$  from its inflection set  $I_t$  for every stem set  $S_t$  in the target sentence.

### 3.3 Models

We built a Maximum Entropy Markov model for inflection prediction following (Minkov et al., 2007). The model decomposes the probability of an inflection sequence into a product of local probabilities for the prediction for each word. The local probabilities are conditioned on the previous  $k$  predictions ( $k$  is set to four in Russian and two in Arabic in our experiments). The probability of a predicted inflection sequence, therefore, is given by:

$$p(\bar{y} | \bar{x}) = \prod_{t=1}^n p(y_t | y_{t-1} \dots y_{t-k}, x_t), y_t \in I_t,$$

where  $I_t$  is the set of inflections corresponding to  $S_t$ , and  $x_t$  refers to the *context* at position  $t$ . The context available to the task includes extensive morphological and syntactic information obtained from the aligned source and target sentences. Figure 1 shows an example of an aligned English-Russian sentence pair: on the source (English) side, POS tags and word dependency structure are indicated by solid arcs. The alignments between English and Russian words are indicated by the dotted lines. The dependency structure on the Russian side, indicated by solid arcs, is given by a treelet MT system (see Section 4.1), projected from the word dependency struc-

Figure 1: Aligned English-Russian sentence pair with syntactic and morphological annotation.

ture of English and word alignment information.

The features for our inflection prediction model are binary and pair up predicates on the *context* ( $\bar{x}, y_{t-1} \dots y_{t-k}$ ) and the *target label* ( $y_t$ ). The features at a certain position  $t$  can refer to any word in the source sentence, any word stem in the target language, or any morpho-syntactic information in  $A$ . This is the source of the power of a model used as an independent component – because it does not need to be integrated in the main search of an MT decoder, it is not subject to the decoder’s locality constraints, and can thus make use of more global information.

### 3.4 Performance on reference translations

Table 1 summarizes the results of applying the inflection prediction model on *reference* translations, simulating the ideal case where the translations input to our model contain correct stems in correct order. We stemmed the reference translations, predicted the inflection for each stem, and measured the accuracy of prediction, using a set of sentences that were not part of the training data (1K sentences were used for Arabic and 5K for Russian).<sup>2</sup> Our model performs significantly better than both the random and trigram language model baselines, and achieves an accuracy of over 91%, which suggests that the model is effective when its input is clean in its stem choice and order. Next, we apply our model in the more noisy but realistic scenario of predicting inflections of MT output sentences.

<sup>2</sup>The accuracy is based on the words in our lexicon. We define the stem of an out-of-vocabulary (OOV) word to be itself, so in the MT scenario described below, we will not predict the word forms for an OOV item, and will simply leave it unchanged.

	Russian	Arabic
Random	16.4	8.7
LM	81.0	69.4
Model	91.6	91.0
Avg   <i>I</i>	13.9	24.1

Table 1: Results on reference translations (accuracy, %).

## 4 Machine translation systems and data

We integrated the inflection prediction model with two types of machine translation systems: systems that make use of syntax and surface phrase-based systems.

### 4.1 Treelet translation system

This is a syntactically-informed MT system, designed following (Quirk et al., 2005). In this approach, translation is guided by treelet translation pairs, where a treelet is a connected subgraph of a syntactic dependency tree. Translations are scored according to a linear combination of feature functions. The features are similar to the ones used in phrasal systems, and their weights are trained using max-BLEU training (Och, 2003). There are nine feature functions in the treelet system, including log-probabilities according to inverted and direct channel models estimated by relative frequency, lexical weighting channel models following Vogel et al. (2003), a trigram target language model, two order models, word count, phrase count, and average phrase size functions.

The treelet translation model is estimated using a parallel corpus. First, the corpus is word-aligned using an implementation of lexicalized-HMMs (He, 2007); then the source sentences are parsed into a dependency structure, and the dependency is projected onto the target side following the heuristics described in (Quirk et al., 2005). These aligned sentence pairs form the training data of the inflection models as well. An example was given in Figure 1.

### 4.2 Phrasal translation system

This is a re-implementation of the Pharaoh translation system (Koehn, 2004). It uses the same lexicalized-HMM model for word alignment as the treelet system, and uses the standard extraction heuristics to extract phrase pairs using forward and backward alignments. In decoding, the system uses a linear combination of feature functions whose

weights are trained using max-BLEU training. The features include log-probabilities according to inverted and direct channel models estimated by relative frequency, lexical weighting channel models, a trigram target language model, distortion, word count and phrase count.

### 4.3 Data sets

For our English-Russian and English-Arabic experiments, we used data from a technical (computer) domain. For each language pair, we used a set of parallel sentences (**train**) for training the MT system sub-models (e.g., phrase tables, language model), a set of parallel sentences (**lambda**) for training the combination weights with max-BLEU training, a set of parallel sentences (**dev**) for training a small number of combination parameters for our integration methods (see Section 5), and a set of parallel sentences (**test**) for final evaluation. The details of these sets are shown in Table 2. The training data for the inflection models is always a subset of the training set (**train**). All MT systems for a given language pair used the same datasets.

Dataset	sent pairs	word tokens (avg/sent)	
<b>English-Russian</b>			
		English	Russian
train	1,642K	24,351K (14.8)	22,002K (13.4)
lambda	2K	30K (15.1)	27K (13.7)
dev	1K	14K (13.9)	13K (13.5)
test	4K	61K (15.3)	60K (14.9)
<b>English-Arabic</b>			
		English	Arabic
train	463K	5,223K (11.3)	4,761K (10.3)
lambda	2K	22K (11.1)	20K (10.0)
dev	1K	11K (11.1)	10K (10.0)
test	4K	44K (11.0)	40K (10.1)

Table 2: Data set sizes, rounded up to the nearest 1000.

## 5 Integration of inflection models with MT systems

We describe three main methods of integration we have considered. The methods differ in the extent to which the factoring of the problem into two subproblems — predicting stems and predicting inflections — is reflected in the base MT systems. In the first method, the MT system is trained to produce fully inflected target words and the inflection model can change the inflections. In the other two methods, the

MT system is trained to produce sequences of target language stems  $\mathbf{S}$ , which are then inflected by the inflection component. Before we motivate these methods, we first describe the general framework for integrating our inflection model into the MT system.

For each of these methods, we assume that the output of the base MT system can be viewed as a ranked list of translation hypotheses for each source sentence  $e$ . More specifically, we assume an output  $\{\mathbf{S}_1, \mathbf{S}_2, \dots, \mathbf{S}_m\}$  of  $m$ -best translations which are sequences of target language stems. The translations further have scores  $\{w_1, w_2, \dots, w_m\}$  assigned by the base MT system. We also assume that each translation hypothesis  $\mathbf{S}_i$  together with source sentence  $e$  can be annotated with the annotation  $A$ , as illustrated in Figure 1. We discuss how we convert the output of the base MT systems to this form in the subsections below.

Given such a list of candidate stem sequences, the base MT model together with the inflection model and a language model choose a translation  $\mathbf{Y}^*$  as follows:

$$(1) Y_i = \arg \max_{Y'_i \in \text{Inf}(S_i)} \lambda_1 \log P_{IM}(Y'_i | \mathbf{S}_i) + \lambda_2 \log P_{LM}(Y'_i), i = 1 \dots n$$

$$(2) Y^* = \arg \max_{i=1 \dots n} \lambda_1 \log P_{IM}(Y_i | \mathbf{S}_i) + \lambda_2 \log P_{LM}(Y_i) + \lambda_3 w_i$$

In these formulas, the dependency on  $e$  and  $A$  is omitted for brevity in the expression for the probability according to the inflection model  $P_{IM}$ .  $P_{LM}(Y'_i)$  is the joint probability of the sequence of inflected words according to a trigram language model (LM). The LM used for the integration is the same LM used in the base MT system that is trained on fully inflected word forms (the base MT system trained on stems uses an LM trained on a stem sequence). Equation (1) shows that the model first selects the best sequence of inflected forms for each MT hypothesis  $\mathbf{S}_i$  according to the LM and the inflection model. Equation (2) shows that from these  $n$  fully inflected hypotheses, the model then selects the one which has the best score, combined with the base MT score  $w_i$  for  $S_i$ . We should note that this method does not represent standard  $n$ -best re-ranking because the input from the base MT system contains sequences of stems, and the model is generating fully inflected translations from them. Thus the chosen translation may not be in the provided  $n$ -best list. This method is more similar to the one used

in (Wang et al., 2006), with the difference that they use only 1-best input from a base MT system.

The interpolation weights  $\lambda$  in Equations (1) and (2) as well as the optimal number of translations  $n$  from the base MT system to consider, given a maximum of  $m=100$  hypotheses, are trained using a separate dataset. We performed a grid search on the values of  $\lambda$  and  $n$ , to maximize the BLEU score of the final system on a development set (dev) of 1000 sentences (Table 2).

The three methods of integration differ in the way the base MT engine is applied. Since we always discard the choices of specific inflected forms for the target stems by converting candidate translations to sequences of stems, it is interesting to know whether we need a base MT system that produces fully inflected translations or whether we can do as well or better by training the base MT systems to produce sequences of stems. Stemming the target sentences is expected to be helpful for word alignment, especially when the stemming operation is defined so that the word alignment becomes more one-to-one (Goldwater and McClosky, 2005). In addition, stemming the target sentences reduces the sparsity in the translation tables and language model, and is likely to impact positively the performance of an MT system in terms of its ability to recover correct sequences of stems in the target. Also, machine learning tells us that solving a more complex problem than we are evaluated on (in our case for the base MT, predicting stems together with their inflections instead of just predicting stems) is theoretically unjustified (Vapnik, 1995).

However, for some language pairs, stemming one language can make word alignment worse, if it leads to more violations in the assumptions of current word alignment models, rather than making the source look more like the target. In addition, using a trigram LM on stems may lead to larger violations of the Markov independence assumptions, than using a trigram LM on fully inflected words. Thus, if we apply the exact same base MT system to use stemmed forms in alignment and/or translation, it is not a priori clear whether we would get a better result than if we apply the system to use fully inflected forms.

## 5.1 Method 1

In this method, the base MT system is trained in the usual way, from aligned pairs of source sentences and fully inflected target sentences. The inflection model is then applied to re-inflect the 1-best or  $m$ -best translations and to select an output translation. The hypotheses in the  $m$ -best output from the base MT system are stemmed and the scores of the stemmed hypotheses are assumed to be equal to the scores of the original ones.<sup>3</sup> Thus we obtain input of the needed form, consisting of  $m$  sequences of target language stems along with scores.

For this and other methods, if we are working with an  $m$ -best list from the treelet system, every translation hypothesis contains the annotations  $A$  that our model needs, because the system maintains the alignment, parse trees, etc., as part of its search space. Thus we do not need to do anything further to obtain input of the form necessary for application of the inflection model.

For the phrase-based system, we generated the annotations needed by first parsing the source sentence  $e$ , aligning the source and candidate translations with the word-alignment model used in training, and projected the dependency tree to the target using the algorithm of (Quirk et al., 2005). Note that it may be better to use the word alignment maintained as part of the translation hypotheses during search, but our solution is more suitable to situations where these can not be easily obtained.

For all methods, we study two settings for integration. In the first, we only consider ( $n=1$ ) hypotheses from the base MT system. In the second setting, we allow the model to use up to 100 translations, and to automatically select the best number to use. As seen in Table 3, ( $n=16$ ) translations were chosen for Russian and as seen in Table 5, ( $n=2$ ) were chosen for Arabic for this method.

## 5.2 Method 2

In this method, the base MT system is trained to produce sequences of stems in the target language. The most straightforward way to achieve this is to stem the training parallel data and to train the MT system using this input. This is our Method 3 described

<sup>3</sup>It may be better to take the max of the scores for a stem sequence occurring more than once in the list, or take the log-sum-exp of the scores.

below. We formulated Method 2 as an intermediate step, to decouple the impact of stemming at the alignment and translation stages.

In Method 2, word alignment is performed using fully inflected target language sentences. After alignment, the target language is stemmed and the base MT systems' sub-models are trained using this stemmed input and alignment. In addition to this word-aligned corpus the MT systems use another product of word alignment: the IBM model 1 translation tables. Because the trained translation tables of IBM model 1 use fully inflected target words, we generated stemmed versions of the translation tables by applying the rules of probability.

## 5.3 Method 3

In this method the base MT system produces sequences of target stems. It is trained in the same way as the baseline MT system, except its input parallel training data are preprocessed to stem the target sentences. In this method, stemming can impact word alignment in addition to the translation models.

## 6 MT performance results

Before delving into the results for each method, we discuss our evaluation measures. For automatically measuring performance, we used 4-gram BLEU against a single reference translation. We also report oracle BLEU scores which incorporate two kinds of oracle knowledge. For the methods using  $n=1$  translation from a base MT system, the oracle BLEU score is the BLEU score of the stemmed translation compared to the stemmed reference, which represents the upper bound achievable by changing only the inflected forms (but not stems) of the words in a translation. For models using  $n > 1$  input hypotheses, the oracle also measures the gain from choosing the best possible stem sequence in the provided ( $m=100$ -best) hypothesis list, in addition to choosing the best possible inflected forms for these stems. For the models in the tables, even if, say,  $n=16$  was chosen in parameter fitting, the oracle is measured on the initially provided list of 100-best.

### 6.1 English-Russian treelet system

Table 3 shows the results of the baseline and the model using the different methods for the treelet MT system on English-Russian. The baseline is the

Model	BLEU	Oracle BLEU
Base MT ( $n=1$ )	29.24	-
Method 1 ( $n=1$ )	30.44	36.59
Method 1 ( $n=16$ )	30.61	45.33
Method 2 ( $n=1$ )	30.79	37.38
Method 2 ( $n=16$ )	31.24	48.48
Method 3 ( $n=1$ )	31.42	38.06
Method 3 ( $n=32$ )	31.80	49.19

Table 3: Test set performance for English-to-Russian MT (BLEU) results by model using a treelet MT system.

treelet system described in Section 4.1 and trained on the data in Table 2.

We can see that Method 1 results in a good improvement of 1.2 BLEU points, even when using only the best ( $n = 1$ ) translation from the baseline. The oracle improvement achievable by predicting inflections is quite substantial: more than 7 BLEU points. Propagating the uncertainty of the baseline system by using more input hypotheses consistently improves performance across the different methods, with an additional improvement of between .2 and .4 BLEU points.

From the results of Method 2 we can see that reducing sparsity at translation modeling is advantageous. Both the oracle BLEU of the first hypothesis and the achieved performance of the model improved; the best performance achieved by Method 2 is .63 points higher than the performance of Method 1. We should note that the oracle performance for Method 2,  $n > 1$  is measured using 100-best lists of target stem sequences, whereas the one for Method 1 is measured using 100-best lists of inflected target words. This can be a disadvantage for Method 1, because a 100-best list of inflected translations actually contains about 50 different sequences of stems (the rest are distinctions in inflections). Nevertheless, even if we measure the oracle for Method 2 using 40-best, it is higher than the 100-best oracle of Method 1. In addition, it appears that using a hypothesis list larger than  $n > 1=100$  is not be helpful for our method, as the model chose to use only up to 32 hypotheses.

Finally, we can see that using stemming at the word alignment stage further improved both the oracle and the achieved results. The performance of the best model is 2.56 BLEU points better than the baseline. Since stemming in Russian for the most part removes properties of words which are not ex-

pressed in English at the word level, these results are consistent with previous results using stemming to improve word alignment. From these results, we also see that about half of the gain from using stemming in the base MT system came from improving word alignment, and half came from using translation models operating at the less sparse stem level.

Overall, the improvement achieved by predicting morphological properties of Russian words with a feature-rich component model is substantial, given the relatively large size of the training data (1.6 million sentences), and indicates that these kinds of methods are effective in addressing the problems in translating morphology-poor to morphology-rich languages.

## 6.2 English-Russian phrasal system

For the phrasal system, we performed integration only with Method 1, using the top 1 or 100-best translations. This is the most straightforward method for combining with any system, and we applied it as a proof-of-concept experiment.

Model	BLEU	Oracle BLEU
Base MT ( $n=1$ )	36.00	-
Method 1 ( $n=1$ )	36.43	42.33
Method 1 ( $n=100$ )	36.72	55.00

Table 4: Test set performance for English-to-Russian MT (BLEU) results by model using a phrasal MT system.

The phrasal MT system is trained on the same data as the treelet system. The phrase size and distortion limit were optimized (we used phrase size of 7 and distortion limit of 3). This system achieves a substantially better BLEU score (by 6.76) than the treelet system. The oracle BLEU score achievable by Method 1 using  $n=1$  translation, though, is still 6.3 BLEU point higher than the achieved BLEU.

Our model achieved smaller improvements for the phrasal system (0.43 improvement for  $n=1$  translations and 0.72 for the selected  $n=100$  translations). However, this improvement is encouraging given the large size of the training data. One direction for potentially improving these results is to use word alignments from the MT system, rather than using an alignment model to predict them.

Model	BLEU	Oracle BLEU
Base MT ( $n=1$ )	35.54	-
Method 1 ( $n=1$ )	37.24	42.29
Method 1 ( $n=2$ )	37.41	52.21
Method 2 ( $n=1$ )	36.53	42.46
Method 2 ( $n=4$ )	36.72	54.74
Method 3 ( $n=1$ )	36.87	42.96
Method 3 ( $n=2$ )	36.92	54.90

Table 5: Test set performance for English-to-Arabic MT (BLEU) results by model using a treelet MT system.

### 6.3 English-Arabic treelet system

The Arabic system also improves with the use of our mode: the best system (Method 1,  $n=2$ ) achieves the BLEU score of 37.41, a 1.87 point improvement over the baseline. Unlike the case of Russian, Method 2 and 3 do not achieve better results than Method 1, though the oracle BLEU score improves in these models (54.74 and 54.90 as opposed to 52.21 of Method 1). We do notice, however, that the oracle improvement for the 1-best analysis is much smaller than what we obtained in Russian.

We have been unable to closely diagnose why performance did not improve using Methods 2 and 3 so far due to the absence of expertise in Arabic, but one factor we suspect is affecting performance the most in Arabic is the definition of stemming: the effect of stemming is most beneficial when it is applied specifically to normalize the distinctions not explicitly encoded in the other language; it may hurt performance otherwise. We believe that in the case of Arabic, this latter situation is actually happening: grammatical properties explicitly encoded in English (e.g., definiteness, conjunction, pronominal clitics) are lost when the Arabic words are stemmed. This may be having a detrimental effect on the MT systems that are based on stemmed input. Further investigation is necessary to confirm this hypothesis.

### 6.4 Human evaluation

In this section we briefly report the results of human evaluation on the output of our inflection prediction system, as the correlation between BLEU scores and human evaluation results is not always obvious. We compared the output of our component against the best output of the treelet system without our component. We evaluated the following three scenarios: (1) Arabic Method 1 with  $n=1$ , which corresponds to the best performing system in BLEU according to

Table 5; (2) Russian, Method 1 with  $n=1$ ; (3) Russian, Method 3 with  $n=32$ , which corresponds to the best performing system in BLEU in Table 3. Note that in (1) and (2), the only differences in the compared outputs are the changes in word inflections, while in (3) the outputs may differ in the selection of the stems.

In all scenarios, two human judges (native speakers of these languages) evaluated 100 sentences that had different translations by the baseline system and our model. The judges were given the reference translations but not the source sentences, and were asked to classify each sentence pair into three categories: (1) the baseline system is better (score=-1), (2) the output of our model is better (score=1), or (3) they are of the same quality (score=0).

	human eval score	BLEU diff
Arabic Method 1	0.1	1.9
Russian Method 1	0.255	1.2
Russian Method 3	0.26	2.6

Table 6: Human evaluation results

Table 6 shows the results of the averaged, aggregated score across two judges per evaluation scenario, along with the BLEU score improvements achieved by applying our model. We see that in all cases, the human evaluation scores are positive, indicating that our models produce translations that are better than those produced by the baseline system.<sup>4</sup> We also note that in Russian, the human evaluation scores are similar for Method 1 and 3 (0.255 and 0.26), though the BLEU score gains are quite different (1.2 vs 2.6). This may be attributed to the fact that human evaluation typically favors the scenario where only word inflections are different (Toutanova and Suzuki, 2007).

## 7 Conclusion and future work

We have shown that an independent model of morphology generation can be successfully integrated with an SMT system, making improvements in both phrasal and syntax-based MT. In the future, we would like to include more sophistication in the design of a lexicon for a particular language pair based on error analysis, and extend our pre-processing to include other operations such as word segmentation.

<sup>4</sup>However, the improvement in Arabic is not statistically significant on this 100 sentence set.

## Abstract

People rarely articulate explicitly what a native speaker of a language is already assumed to know. So to acquire the stereotypical knowledge that underpins much of what is said in a given culture, one must look to what is implied by language rather than what is overtly stated. Similes are a convenient vehicle for this kind of knowledge, insofar as they mark out the most salient aspects of the most frequently evoked concepts. In this paper we perform a multilingual exploration of the space of common-place similes, by mining a large body of Chinese similes from the web and comparing these to the English similes harvested by Veale and Hao (2007). We demonstrate that while the simile-frame is inherently leaky in both languages, a multilingual analysis allows us to filter much of the noise that otherwise hinders the knowledge extraction process. In doing so, we can also identify a core set of stereotypical descriptions that exist in both languages and accurately map these descriptions onto a multilingual lexical ontology like HowNet. Finally, we demonstrate that conceptual descriptions that are derived from common-place similes are extremely compact and predictive of ontological structure.

## 1 Introduction

Direct perception of our environment is just one of the ways we can acquire knowledge of the world. Another, more distinctly human approach, is through the comprehension of linguistic descriptions of another person's perceptions and beliefs.

Since computers have limited means of human-like perception, the latter approach is also very much suited to the automatic acquisition of world knowledge by a computer (see Hearst, 1992; Charniak and Berland, 1999; Etzioni *et al.*, 2004; Völker *et al.*, 2005; Almuhareb and Poesio, 2005; Cimiano and Wenderoth, 2007; Veale and Hao, 2007). Thus, by using the web as a distributed text corpus (see Keller *et al.*, 2002), a multitude of facts and beliefs can be extracted, for purposes ranging from question-answering to ontology population.

The possible configurations of different concepts can also be learned from how the words denoting these concepts are distributed; thus, a computer can learn that coffee is a beverage that can be served hot or cold, white or black, strong or weak and sweet or bitter (see Almuhareb and Poesio, 2005). But it is difficult to discern from these facts the idealized or stereotypical states of the world, e.g., that one *expects* coffee to be hot and beer to be cold, so that if one spills coffee, we naturally infer the possibilities of scalding and staining without having to be told that the coffee was hot or black; the assumptions of hotness and blackness are just two stereotypical facts about coffee that we readily take for granted. Lenat and Guha (1990) describe these assumed facts as residing in the *white space* of a text, in the body of common-sense assumptions that are rarely articulated as explicit statements. These culturally-shared common-sense beliefs cannot be harvested directly from a single web resource or document set, but must be gleaned indirectly, from telling phrases that are scattered across the many texts of the web.

Veale and Hao (2007) argue that the most pivotal

reference points of this world-view can be detected in common-place similes like “as lazy as a dog”, “as fat as a hippo” or “as chaste as a nun”. To the extent that this world-view is ingrained in and influenced by how we speak, it can differ from culture to culture and language to language. In English texts, for example, the concept Tortoise is stereotypically associated with the properties *slowness*, *patience* and *wrinkled*, but in Chinese texts, we find that the same animal is a model of *slowness*, *ugliness*, and *nutritional value*. Likewise, because Chinese “wine” has a high alcohol content, the dimension of Strength is much more salient to a Chinese speaker than an English speaker, as reflected in how the word 酒 is used in statements such as 像酒一样浓重, which means “as strong as wine”, or literally, “as wine equally strong”.

In this paper, we compare the same web-based approach to acquiring stereotypical concept descriptions from text using two very different languages, English and Chinese, to determine the extent to which the same cross-cultural knowledge is unearthed for each. In other words, we treat the web as a large parallel corpus (e.g., see Resnick and Smith, 2003), though not of parallel documents in different languages, but of corresponding translation-equivalent phrases. By seeking translation equivalence between different pieces of textually-derived knowledge, this paper addresses the following questions: if a particular syntagmatic pattern is useful for mining knowledge in English, can its translated form be equally useful for Chinese? To what extent does the knowledge acquired using different source languages overlap, and to what extent is this knowledge language- (and culture-) specific? Given that the syntagmatic patterns used in each language are not wholly unambiguous or immune to noise, to what extent should finding the same beliefs expressed in two different languages increase our confidence in the acquired knowledge? Finally, what representational synergies arise from finding these same facts expressed in two different languages?

Given these goals, the rest of the paper assumes the following structure: in section 2, we summarize related work on syntagmatic approaches to knowledge-acquisition; in section 3, we describe our multilingual efforts in English and Chinese to acquire stereotypical or generic-level facts

from the web, by using corresponding translations of the commonplace stereotype-establishing pattern “as ADJ as a NOUN”; and in section 4, we describe how these English and Chinese data-sets can be unified using the bilingual ontology HowNet (Dong and Dong, 2006). This mapping allows us to determine the meaning overlap in both data sets, the amount of noise in each data set, and the degree to which this noise is reduced when parallel translations can be identified. In section 5 we demonstrate the overall usefulness of stereotype-based knowledge-representation by replicating the clustering experiments of Almuhareb and Poesio (2004, 2005) and showing that stereotype-based representations are both compact and predictive of ontological classification. We conclude the paper with some final remarks in section 6.

## 2 Related Work

Text-based approaches to knowledge acquisition range from the ambitiously comprehensive, in which an entire text or resource is fully parsed and analyzed in depth, to the surgically precise, in which highly-specific text patterns are used to eke out correspondingly specific relationships from a large corpus. Endeavors such as that of Harabagiu *et al.* (1999), in which each of the textual glosses in WordNet (Fellbaum, 1998) is linguistically analyzed to yield a sense-tagged logical form, is an example of the former approach. In contrast, foundational efforts such as that of Hearst (1992) typify the latter surgical approach, in which one fishes in a large text for word sequences that strongly suggest a particular semantic relationship, such as hypernymy or, in the case of Charniak and Berland (1999), the part-whole relation. Such efforts offer high precision but low recall, and extract just a tiny (but very useful) subset of the semantic content of a text. The Know-ItAll system of Etzioni *et al.* (2004) employs the same generic patterns as Hearst (e.g., “NPs such as  $NP_1$ ,  $NP_2$ , ...”), and more besides, to extract a whole range of facts that can be exploited for web-based question-answering. Cimiano and Wenderoth (2007) also use a range of Hearst-like patterns to find text sequences in web-text that are indicative of the lexico-semantic properties of words; in particular, these authors use phrases like “to \* a new

NOUN” and “the purpose of NOUN is to \*” to identify the agentive and telic roles of given nouns, thereby fleshing out the noun’s qualia structure as posited by Pustejovsky’s (1990) theory of the generative lexicon.

The basic Hearst approach has even proven useful for identifying the meta-properties of concepts in a formal ontology. Völker *et al.* (2005) show that patterns like “is no longer a|an NOUN” can identify, with reasonable accuracy, those concepts in an ontology that are not rigid, which is to say, concepts like Teacher and Student whose instances may at any point stop being instances of these concepts. Almuhareb and Poesio (2005) use patterns like “a|an|the \* C is|was” and “the \* of the C is|was” to find the actual properties of concepts as they are used in web texts; the former pattern is used to identify value features like *hot*, *red*, *large*, etc., while the latter is used to identify the attribute features that correspond to these values, such as temperature, color and size. Almuhareb and Poesio go on to demonstrate that the values and attributes that are found for word-concepts on the web yield a sufficiently rich representation for these word-concepts to be automatically clustered into a form resembling that assigned by WordNet (see Fellbaum, 1998). Veale and Hao (2007) show that the pattern “as ADJ as a|an NOUN” can also be used to identify the value feature associated with a given concept, and argue that because this pattern corresponds to that of the simile frame in English, the adjectival features that are retrieved are much more likely to be highly salient of the noun-concept (the simile vehicle) that is used. Whereas Almuhareb and Poesio succeed in identifying the range of potential attributes and values that may be possessed by a particular concept, Veale and Hao succeed in identifying the generic properties of a concept as it is conceived in its stereotypical form. As noted by the latter authors, this results in a much smaller yet more diagnostic feature set for each concept. However, because the simile frame is often exploited for ironic purposes in web texts (e.g., “as meaty as a skeleton”), and because irony is so hard to detect, Veale and Hao suggest that the adjective:noun pairings found on the web should be hand-filtered to remove such examples. Given this onerous requirement for hand-filtering, and the unique, culturally-

loaded nature of the noise involved, we use the work of Veale and Hao as the basis for the cross-cultural investigation in this paper.

### 3 Harvesting Knowledge from Similes: English and Chinese

Because similes are containers of culturally-received knowledge, we can reasonably expect the most commonly used similes to vary significantly from language to language, especially when those languages correspond to very different cultures. These similes form part of the linguistic currency of a culture which must be learned by a speaker, and indeed, some remain opaque even to the most educated native speakers. In “A Christmas Carol”, for instance, Dickens (1943/1984) questions the meaning of “as dead as a doornail”, and notes: “I might have been inclined, myself, to regard a coffin-nail as the deadest piece of ironmongery in the trade. But the wisdom of our ancestors is in the simile”.

Notwithstanding the opacity of some instances of the simile form, similes are very revealing about the concepts one most encounters in everyday language. In section 5 we demonstrate that concept descriptions which are harvested from similes are both extremely compact and highly predictive of ontological structure. For now, we turn to the process by which similes can be harvested from the text of the web. In section 3.1 we summarize the efforts of Veale and Hao, whose database of English similes drives part of our current investigation. In section 3.2 we describe how a comparable database of Chinese similes can be harvested from the web.

#### 3.1 Harvesting English Similes

Veale and Hao (2007) use the Google API in conjunction with Princeton WordNet (Fellbaum, 1998) as the basis of their harvesting system. They first extracted a list of antonymous adjectives, such as “hot” or “cold”, from WordNet, the intuition being that explicit similes will tend to exploit properties that occupy an exemplary point on a scale. For every adjective ADJ on this list, they then sent the query “as ADJ as \*” to Google and scanned the first 200 snippets returned for different noun values for the wildcard \*. The complete set of nouns extracted in this way was then used to drive a sec-

ond harvesting phase, in which the query “*as \* as a NOUN*” was used to collect similes that employ different adjectives or which lie beyond the 200-snippet horizon of the original search. Based on this wide-ranging series of core samples (of 200 hits each) from across the web, Veale and Hao report that both phases together yielded 74,704 simile instances (of 42,618 unique types, or unique adjective:noun pairings), relating 3769 different adjectives to 9286 different nouns. As often noted by other authors, such as Völker *et al.* (2005), a pattern-oriented approach to knowledge mining is prone to noise, not least because the patterns used are rarely leak-free (inasmuch as they admit word sequences that do not exhibit the desired relationship), and because these patterns look at small text sequences in isolation from their narrative contexts. Veale and Hao (2007) report that when the above 42,618 simile types are hand-annotated by a native speaker, only 12,259 were judged as non-ironic and meaningful in a null context. In other words, just 29% of the retrieved pairings conform to what one would consider a well-formed and reusable simile that conveys some generic aspect of cultural knowledge. Of those deemed invalid, 2798 unique pairings were tagged as ironic, insofar as they stated precisely the opposite of what is stereotypically believed to be true.

### 3.2 Harvesting Chinese Similes

To harvest a comparable body of Chinese similes from the web, we also use the Google API, in conjunction with both WordNet and HowNet (Dong and Dong, 2006). HowNet is a bilingual lexical ontology that associates English and Chinese word labels with an underlying set of approximately 100,000 lexical concepts. While each lexical concept is defined using a unique numeric identifier, almost all of HowNet’s concepts can be uniquely identified by a pairing of English and Chinese labels. For instance, the word “王八” can mean both Tortoise and Cuckold in Chinese, but the combined label `tortoise|王八` uniquely picks out the first sense while `cuckold|王八` uniquely picks out the second. Though Chinese has a large number of figurative expressions, the yoking of English to Chinese labels still serves to identify the correct sense in almost every case. For instance, “绿帽子” is another word for Cuckold in Chinese, but it can also translate as “green

hat” and “green scarf”. Nonetheless, `green_hat|绿帽子` uniquely identifies the literal sense of “绿帽子” (a green covering) while `green_scarf|绿帽子` and `cuckold|绿帽子` both identify the same human sense, the former being a distinctly culture-specific metaphor for cuckolded males (in English, a dispossessed lover “wears the cuckold’s horns”; in Chinese, one apparently “wears a green scarf”).

We employ the same two-phase design as Veale and Hao: an initial set of Chinese adjectives are extracted from HowNet, with the stipulation that their English translations (as given by HowNet) are also categorized as adjectives in WordNet. We then use the Chinese equivalent of the English simile frame “*像\* 一样ADJ*” (literally, “*as-NOUN-equally-ADJ*”) to retrieve a set of noun values that stereotypically embody these adjectival features. Again, a set of 200 snippets is analyzed for each query, and only those values of the Google *\** wildcard that HowNet categorizes as nouns are accepted. In a second phase, these nouns are used to create new queries of the form “*像Noun一样\**” and the resulting Google snippets are now scanned for adjectival values of *\**.

In all, 25,585 unique Chinese similes (i.e., pairings of an adjective to a noun) are harvested, linking 3080 different Chinese adjectives to 4162 Chinese nouns. When hand-annotated by a native Chinese speaker, the Chinese simile frame reveals itself to be considerably less leaky than the corresponding English frame. Over 58% of these pairings (14,867) are tagged as well-formed and meaningful similes that convey some stereotypical element of world knowledge. The Chinese pattern “*像\*一样\**” is thus almost twice as reliable as the English “*as \* as a \**” pattern. In addition, Chinese speakers exploit the simile frame much less frequently for ironic purposes, since just 185 of the retrieved similes (or 0.7%) are tagged as ironic, compared with ten times as many (or 7%) retrieved English similes. In the next section we consider the extent to which these English and Chinese similes convey the same information.

## 4 Tagging and Mapping of Similes

In each case, the harvesting processes for English and for Chinese allow us to acquire stereotypi-

cal associations between words, not word senses. Nonetheless, the frequent use of synonymous terms introduces a substantial degree of redundancy in these associations, and this redundancy can be used to perform sense discrimination. In the case of English similes, Veale and Hao (2007) describe how two English similes “as A as  $N_1$ ” and “as A as  $N_2$ ” will be mutually disambiguating if  $N_1$  and  $N_2$  are synonyms in WordNet, or if some sense of  $N_1$  is a hypernym or hyponym of some sense of  $N_2$  in WordNet. This heuristic allows Veale and Hao to automatically sense-tag 85%, or 10,378, of the unique similes that are annotated as valid. We apply a similar intuition to the disambiguation of Chinese similes: though HowNet does not support the notion of a synset, different word-senses that have the same meaning will be associated with the same logical definition. Thus, the Chinese word “著名” can translate as “celebrated”, “famous”, “well-known” and “reputable”, but all four of these possible senses, given by celebrated|著名, famous|著名, well-known|著名 and reputable|著名, are associated with the same logical form in HowNet, which defines them as a specialization of ReputationValue|名声值. This allows us to safely identify “著名” with this logical form. Overall, 69% of Chinese similes can have both their adjective and noun assigned to specific HowNet meanings in this way.

#### 4.1 Translation Equivalence Among Similes

Since HowNet represents an integration of English and Chinese lexicons, it can easily be used to connect the English and Chinese data-sets. For while the words used in any given simile are likely to be ambiguous (in the case of one-character Chinese words, highly so), it would seem unlikely that an incorrect translation of a web simile would also be found on the web. This is an intuition that we can now use the annotated data-sets to evaluate.

For every English simile of the form  $\langle A_e \text{ as } N_e \rangle$ , we use HowNet to generate a range of possible Chinese variations  $\langle A_{c0} \text{ as } N_{c0} \rangle$ ,  $\langle A_{c1} \text{ as } N_{c0} \rangle$ ,  $\langle A_{c0} \text{ as } N_{c1} \rangle$ ,  $\langle A_{c1} \text{ as } N_{c1} \rangle$ , ... by using the HowNet lexical entries  $A_e|A_{c0}$ ,  $A_e|A_{c1}$ , ...,  $N_e|N_{c0}$ ,  $N_e|N_{c1}$ , ... as a translation bridge. If the variation  $\langle A_{ci} \text{ as } N_{cj} \rangle$  is found in the Chinese data-set, then translation equivalence is assumed between  $\langle A_e \text{ as}$

<i>Language</i>	<i>Precision</i>	<i>Recall</i>	<i>F1</i>
<i>English</i>	0.76	0.25	0.38
<i>Chinese</i>	0.82	0.27	0.41

Table 1: Automatic filtering of similes using Translation Equivalence.

$N_e \rangle$  and  $\langle A_{ci} \text{ as } N_{cj} \rangle$ ; furthermore,  $A_e|A_{ci}$  is assumed to be the HowNet sense of the adjectives  $A_e$  and  $A_{ci}$  while  $N_{cj}$  is assumed to be the HowNet sense of the nouns  $N_e$  and  $N_{cj}$ . Sense-tagging is thus a useful side-effect of simile-mapping with a bilingual lexicon.

We attempt to find Chinese translation equivalences for all 42,618 of the English adjective:noun pairings harvested by Veale and Hao; this includes both the 12,259 pairings that were hand-annotated as valid stereotypical facts, and the remaining 30,359 that were dismissed as noisy or ironic. Using HowNet, we can establish equivalences from 4177 English similes to 4867 Chinese similes. In those mapped, we find 3194 English similes and 4019 Chinese similes that were hand-annotated as valid by their respective native-speaker judges. In other words, translation equivalence can be used to separate well-formed stereotypical beliefs from ill-formed or ironic beliefs with approximately 80% precision. The precise situation is summarized in Table 1.

As noted in section 3, just 29% of raw English similes and 58% of raw Chinese similes that are harvested from web-text are judged as valid stereotypical statements by a native-speaking judge. For the task of filtering irony and noise from raw data sets, translation equivalence thus offers good precision but poor recall, since most English similes appear not to have a corresponding Chinese variant on the web. Nonetheless, this heuristic allows us to reliably identify a sizeable body of cross-cultural stereotypes that hold in both languages.

##### 4.1.1 Error Analysis

Noisy propositions may add little but empty content to a representation, but ironic propositions will actively undermine a representation from within, leading to inferences that are not just unlikely, but patently false (as is generally the intention of irony). Since Veale and Hao (2007) annotate their data-

set for irony, this allows us to measure the number of egregious mistakes made when using translation equivalence as a simile filter. Overall, we see that 1% of Chinese similes that are accepted via translation equivalence are ironic, accounting for 9% of all errors made when filtering Chinese similes. Likewise, 1% of the English similes that are accepted are ironic, accounting for 5% of all errors made when filtering English similes.

## 4.2 Representational Synergies

By mapping WordNet-tagged English similes onto HowNet-tagged Chinese similes, we effectively obtain two representational viewpoints onto the same shared data set. For instance, though HowNet has a much shallower hierarchical organization than WordNet, it compensates by encapsulating the meaning of different word senses using simple logical formulae of semantic primitives, or sememes, that are derived from the meaning of common Chinese characters. WordNet and HowNet thus offer two complementary levels or granularities of generalization that can be exploited as the context demands.

### 4.2.1 Adjective Organization

Unlike WordNet, HowNet organizes its adjectival senses hierarchically, allowing one to obtain a weaker form of a given description by climbing the hierarchy, or to obtain a stronger form by descending the hierarchy from a particular sense. Thus, one can go up from kaleidoscopic|斑驳陆离 to colored|彩, or down from colored|彩 to any of motley|斑驳, dappled|斑驳, prismatic|斑驳陆离 and even gorgeous|斑斓. Once stereotypical descriptions have been sense-tagged relative to HowNet, they can easily be further enhanced or bleached to suit the context of their use. For example, by allowing a Chinese adjective to denote any of the senses above it or below in the HowNet hierarchy, we can extend the mapping of English to Chinese similes so as to achieve an improved recall of .36 (though we note that this technique reduces the precision of the translation-equivalence heuristic to .75).

As demonstrated by Almuhareb and Poesio (2004), the best conceptual descriptions combine adjectival values with the attributes that they fill.

Because adjectival senses hook into HowNet's upper ontology via a series of abstract taxonyms like TasteValue|美丑值, ReputationValue|名声值 and AmountValue|多少值, a taxonym of the form AttributeValue can be identified for every adjective sense in HowNet. For example, the English adjective "beautiful" can denote either beautiful|美, organized by HowNet under BeautyValue|美丑值, or beautiful|婉, organized by HowNet under gracious|雅 which in turn is organized under GraceValue|典雅值. The adjective "beautiful" can therefore specify either the Grace or Beauty attributes of a concept. Once similes have been sense-tagged, we can build up a picture of most salient attributes of our stereotypical concepts. For instance, "peacock" similes yield the following attributes via HowNet: *Beauty, Appearance, Color, Pride, Behavior, Resplendence, Bearing and Grace*; likewise "demon" similes yield the following: *Morality, Behavior, Temperament, Ability and Competence*.

### 4.2.2 Orthographic Form

The Chinese data-set lacks counterparts to many similes that one would not think of as culturally-determined, such "as red as a ruby", "as cruel as a tyrant" and "as smelly as a skunk". One significant reason for this kind of omission is not cultural difference, but obviousness: many Chinese words are multi-character gestalts of different ideas (see Packard, 2000), so that these ideas form an explicit part of the orthography of a lexical concept. For instance, using HowNet, we can see that skunk|臭鼬 is actually a gestalt of the concepts smelly|臭 and weasel|鼬, so the simile "as smelly as a skunk" is already somewhat redundant in Chinese (somewhat akin to the English similes "as hot as a hotdog" or "as hard as a hardhat").

Such decomposition can allow us to find those English similes that are already orthographically explicit in Chinese word-forms. We simply look for pairs of HowNet senses of the form Noun|XYZ and Adj|X, where X and XYZ are Chinese words and the simile "as Adj as a/an Noun" is found in the English simile set. When we do so, we find that 648 English similes, from "as meaty as a steak" to "as resonant as a cello", are already fossilized in the orthographic realization of the corresponding Chinese concepts. When fossilized similes are uncovered in this way,

the recall of translation equivalence as a noise filter rises to .29, while its precision rises to .84 (see Table 1)

## 5 Empirical Evaluation: Simile-derived Representations

Stereotypes persist in language and culture because they are, more often than not, cognitively useful: by emphasizing the most salient aspects of a concept, a stereotype acts as a dense conceptual description that is easily communicated, widely shared, and which supports rapid inference. To demonstrate the usefulness of stereotype-based concept descriptions, we replicate here the clustering experiments of Almuhareb and Poesio (2004, 2005), who in turn demonstrated that conceptual features that are mined from specific textual patterns can be used to construct WordNet-like ontological structures. These authors used different text patterns for mining feature values (like *hot*) and attributes (like *temperature*), and their experiments evaluated the relative effectiveness of each as a means of ontological clustering. Since our focus in this paper is on the harvesting of feature values, we replicate here only their experiments with values.

Almuhareb and Poesio (2004) used as their experimental basis a sampling of 214 English nouns from 13 of WordNet’s upper-level semantic categories, and proceeded to harvest adjectival features for these noun-concepts from the web using the textual pattern “[a | an | the] \* C [is | was]”. This pattern yielded a combined total of 51,045 value features for these 214 nouns, such as *hot*, *black*, etc., which were then used as the basis of a clustering algorithm in an attempt to reconstruct the WordNet classifications for all 214 nouns. Clustering was performed by the CLUTO-2.1 package (Karypis, 2003), which partitioned the 214 nouns in 13 categories on the basis of their 51,045 web-derived features. Comparing these clusters with the original WordNet-based groupings, Almuhareb and Poesio report a clustering accuracy of 71.96%. In a second, larger experiment, Almuhareb and Poesio (2005) sampled 402 nouns from 21 different semantic classes in WordNet, and harvested 94,989 feature values from the web using the same textual pattern. They then applied the repeated bisections clustering algorithm to

<i>Approach</i>	<i>accuracy</i>	<i>features</i>
<i>Almuhareb + Poesio</i>	71.96%	51,045
<i>Simile-derived stereotypes</i>	70.2%	2,209

Table 2: Results for experiment 1 (214 nouns, 13 WN categories).

<i>Approach</i>	<i>Cluster purity</i>	<i>Cluster entropy</i>	<i>features</i>
<i>Almu. + Poesio</i> (no filtering)	56.7%	38.4%	94,989
<i>Almu. + Poesio</i> (with filtering)	62.7%	33.8%	51345
<i>Simile-derived stereotypes</i> (no filtering)	64.3%	33%	5,547

Table 3: Results for experiment 2 (402 nouns, 21 WN categories).

this larger data set, and report an initial cluster purity measure of 56.7%. Suspecting that a noisy feature set had contributed to the apparent drop in performance, these authors then proceed to apply a variety of noise filters to reduce the set of feature values to 51,345, which in turn leads to an improved cluster purity measure of 62.7%.

We replicated both of Almuhareb and Poesio’s experiments on the same experimental data-sets (of 214 and 402 nouns respectively), using instead the English simile pattern “as \* as a NOUN” to harvest features for these nouns from the web. Note that in keeping with the original experiments, no hand-tagging or filtering of these features is performed, so that every raw match with the simile pattern is used. Overall, we harvest just 2209 feature values for the 214 nouns of experiment 1, and 5547 features for the 402 nouns of experiment 2. A comparison of both sets of results for experiment 1 is shown in Table 2, while a comparison based on experiment 2 is shown in Table 3.

While Almuhareb and Poesio achieve marginally higher clustering on the 214 nouns of experiment 1, they do so by using over 20 times as many features.

In experiment 2, we see a similar ratio of feature quantities before filtering; after some initial filtering, Almuhareb and Poesio reduce their feature set to just under 10 times the size of the simile-derived feature set.

These experiments demonstrate two key points about stereotype-based representations. First, the feature representations do not need to be hand-filtered and noise-free to be effective; we see from the above results that the raw values extracted from the simile pattern prove slightly more effective than filtered feature sets used by Almuhareb and Poesio. Secondly, and perhaps more importantly, stereotype-based representations prove themselves a much more compact means (by factor of 10 to 20 times) of achieving the same clustering goals.

## 6 Conclusions

Knowledge-acquisition from texts can be a process fraught with complexity: such texts - especially web-based texts - are frequently under-determined and vague; highly ambiguous, both lexically and structurally; and dense with figures of speech, hyperbolae and irony. None of the syntagmatic frames surveyed in section 2, from the “NP such as  $NP_1$ ,  $NP_2$  ...” pattern of Hearst (1992) and Etzioni *et al.* (2004) to the “no longer NOUN” pattern of Völker *et al.* (2005), are leak-free and immune to noise. Cimiano and Wenderoth (2007) mitigate this problem somewhat by performing part-of-speech analysis on all extracted text sequences, but the problem remains: the surgical, pattern-based approach offers an efficient and targeted means of knowledge-acquisition from corpora because it largely ignores the context in which these patterns occur; yet one requires this context to determine if a given text sequence really is a good exemplar of the semantic relationship that is sought.

In this paper we have described how stereotypical associations between adjectival properties and noun concepts can be mined from similes in web text. When harvested in both English and Chinese, these associations exhibit two kinds of redundancy that can mitigate the problem of noise. The first kind, *within-language* redundancy, allows us to perform sense-tagging of the adjectives and nouns that are used in similes, by exploiting the

fact that the same stereotypical association can occur in a variety of synonymous forms. By recognizing synonymy between the elements of different similes, we can thus identify the underlying senses (or WordNet synsets) in these similes. The second kind, *between-language* redundancy, exploits the fact that the same associations can occur in different languages, allowing us to exploit translation-equivalence to pin these associations to particular lexical concepts in a multilingual lexical ontology like HowNet. While between-language redundancy is a limited phenomenon, with just 26% of Veale and Hao’s annotated English similes having Chinese translations on the web, this phenomenon does allow us to identify a significant core of shared stereotypical knowledge across these two very different languages.

Overall, our analysis suggests that a comparable number of well-formed Chinese and English similes can be mined from the web (our exploration finds approx. 12,000 unique examples of each). This demonstrates that harvesting stereotypical knowledge from similes is a workable strategy in both languages. Moreover, Chinese simile usage is characterized by two interesting facts that are of some practical import: the simile frame “像NOUN 一样ADJ” is a good deal less leaky and prone to noise than the equivalent English frame, “as ADJ as a NOUN”; and Chinese speakers appear less willing to subvert the stereotypical norms of similes for ironic purposes. Further research is needed to determine whether these observations generalize to other knowledge-mining patterns.

## Abstract

We present a novel semi-supervised training algorithm for learning dependency parsers. By combining a supervised large margin loss with an unsupervised least squares loss, a discriminative, convex, semi-supervised learning algorithm can be obtained that is applicable to large-scale problems. To demonstrate the benefits of this approach, we apply the technique to learning dependency parsers from combined labeled and unlabeled corpora. Using a stochastic gradient descent algorithm, a parsing model can be efficiently learned from semi-supervised data that significantly outperforms corresponding supervised methods.

## 1 Introduction

Supervised learning algorithms still represent the state of the art approach for inferring dependency parsers from data (McDonald et al., 2005a; McDonald and Pereira, 2006; Wang et al., 2007). However, a key drawback of supervised training algorithms is their dependence on labeled data, which is usually very difficult to obtain. Perceiving the limitation of supervised learning—in particular, the

heavy dependence on annotated corpora—many researchers have investigated *semi-supervised* learning techniques that can take both labeled and unlabeled training data as input. Following the common theme of “more data is better data” we also use both a limited labeled corpora and a plentiful unlabeled data resource. Our goal is to obtain better performance than a purely supervised approach without unreasonable computational effort. Unfortunately, although significant recent progress has been made in the area of semi-supervised learning, the performance of semi-supervised learning algorithms still fall far short of expectations, particularly in challenging real-world tasks such as natural language parsing or machine translation.

A large number of distinct approaches to semi-supervised training algorithms have been investigated in the literature (Bennett and Demiriz, 1998; Zhu et al., 2003; Altun et al., 2005; Mann and McCallum, 2007). Among the most prominent approaches are self-training, generative models, semi-supervised support vector machines (S3VM), graph-based algorithms and multi-view algorithms (Zhu, 2005).

Self-training is a commonly used technique for semi-supervised learning that has been ap-

plied to several natural language processing tasks (Yarowsky, 1995; Charniak, 1997; Steedman et al., 2003). The basic idea is to bootstrap a supervised learning algorithm by alternating between inferring the missing label information and retraining. Recently, McClosky et al. (2006a) successfully applied self-training to parsing by exploiting available unlabeled data, and obtained remarkable results when the same technique was applied to parser adaptation (McClosky et al., 2006b). More recently, Haffari and Sarkar (2007) have extended the work of Abney (2004) and given a better mathematical understanding of self-training algorithms. They also show connections between these algorithms and other related machine learning algorithms.

Another approach, generative probabilistic models, are a well-studied framework that can be extremely effective. However, generative models use the EM algorithm for parameter estimation in the presence of missing labels, which is notoriously prone to getting stuck in poor local optima. Moreover, EM optimizes a marginal likelihood score that is not discriminative. Consequently, most previous work that has attempted semi-supervised or unsupervised approaches to parsing have not produced results beyond the state of the art supervised results (Klein and Manning, 2002; Klein and Manning, 2004). Subsequently, alternative estimation strategies for unsupervised learning have been proposed, such as *Contrastive Estimation* (CE) by Smith and Eisner (2005). Contrastive Estimation is a generalization of EM, by defining a notion of learner guidance. It makes use of a set of examples (its *neighborhood*) that are similar in some way to an observed example, requiring the learner to move probability mass to a given example, taking only from the example's neighborhood. Nevertheless, CE still suffers from shortcomings, including local minima.

In recent years, SVMs have demonstrated state of the art results in many supervised learning tasks. As a result, many researchers have put effort on developing algorithms for semi-supervised SVMs (S3VMs) (Bennett and Demiriz, 1998; Altun et al., 2005). However, the standard objective of an S3VM is non-convex on the unlabeled data, thus requiring sophisticated global optimization heuristics to obtain reasonable solutions. A number of researchers have proposed several efficient approx-

imation algorithms for S3VMs (Bennett and Demiriz, 1998; Chapelle and Zien, 2005; Xu and Schuurmans, 2005). For example, Chapelle and Zien (2005) propose an algorithm that smoothes the objective with a Gaussian function, and then performs a gradient descent search in the primal space to achieve a local solution. An alternative approach is proposed by Xu and Schuurmans (2005) who formulate a semi-definite programming (SDP) approach. In particular, they present an algorithm for multi-class unsupervised and semi-supervised SVM learning, which relaxes the original non-convex objective into a close convex approximation, thereby allowing a global solution to be obtained. However, the computational cost of SDP is still quite expensive.

Instead of devising various techniques for coping with non-convex loss functions, we approach the problem from a different perspective. We simply replace the non-convex loss on unlabeled data with an alternative loss that is jointly convex with respect to both the model parameters and (the encoding of) the self-trained prediction targets. More specifically, for the loss on the unlabeled data part, we substitute the original unsupervised structured SVM loss with a least squares loss, but keep constraints on the inferred prediction targets, which avoids trivialization. Although using a least squares loss function for classification appears misguided, there is a precedent for just this approach in the early pattern recognition literature (Duda et al., 2000). This loss function has the advantage that the entire training objective on both the labeled and unlabeled data now becomes convex, since it consists of a convex structured large margin loss on labeled data and a convex least squares loss on unlabeled data. As we will demonstrate below, this approach admits an efficient training procedure that can find a global minimum, and, perhaps surprisingly, can systematically improve the accuracy of supervised training approaches for learning dependency parsers.

Thus, in this paper, we focus on *semi-supervised* language learning, where we can make use of both labeled and unlabeled data. In particular, we investigate a semi-supervised approach for structured large margin training, where the objective is a combination of two convex functions, the structured large margin loss on labeled data and the least squares loss on unlabeled data. We apply the result-

Figure 1: A dependency tree

ing semi-supervised convex objective to dependency parsing, and obtain significant improvement over the corresponding supervised structured SVM. Note that our approach is different from the self-training technique proposed in (McClosky et al., 2006a), although both methods belong to semi-supervised training category.

In the remainder of this paper, we first review the supervised structured large margin training technique. Then we introduce the standard semi-supervised structured large margin objective, which is non-convex and difficult to optimize. Next we present a new semi-supervised training algorithm for structured SVMs which is convex optimization. Finally, we apply this algorithm to dependency parsing and show improved dependency parsing accuracy for both Chinese and English.

## 2 Dependency Parsing Model

Given a sentence  $X = (x_1, \dots, x_n)$  ( $x_i$  denotes each word in the sentence), we are interested in computing a directed dependency tree,  $Y$ , over  $X$ . As shown in Figure 1, in a dependency structure, the basic units of a sentence are the syntactic relationships (aka. head-child or governor-dependent or regent-subordinate relations) between two individual words, where the relationships are expressed by drawing links connecting individual words (Manning and Schütze, 1999). The direction of each link points from a head word to a child word, and each word has one and only one head, except for the head of the sentence. Thus a dependency structure is actually a rooted, directed tree. We assume that a directed dependency tree  $Y$  consists of ordered pairs  $(x_i \rightarrow x_j)$  of words in  $X$  such that each word appears in at least one pair and each word has in-degree at most one. Dependency trees are assumed to be projective here, which means that if there is an arc  $(x_i \rightarrow x_j)$ , then  $x_i$  is an ancestor of all the words

between  $x_i$  and  $x_j$ .<sup>1</sup> Let  $\Phi(X)$  denote the set of all the directed, projective trees that span on  $X$ . The parser’s goal is then to find the most preferred parse; that is, a projective tree,  $Y \in \Phi(X)$ , that obtains the highest “score”. In particular, one would assume that the score of a complete spanning tree  $Y$  for a given sentence, whether probabilistically motivated or not, can be decomposed as a sum of local scores for each link (a word pair) (Eisner, 1996; Eisner and Satta, 1999; McDonald et al., 2005a). Given this assumption, the parsing problem reduces to find

$$\begin{aligned}
 Y^* &= \arg \max_{Y \in \Phi(X)} \text{score}(Y|X) \\
 &= \arg \max_{Y \in \Phi(X)} \sum_{(x_i \rightarrow x_j) \in Y} \text{score}(x_i \rightarrow x_j)
 \end{aligned} \tag{1}$$

where the  $\text{score}(x_i \rightarrow x_j)$  can depend on any measurable property of  $x_i$  and  $x_j$  within the sentence  $X$ . This formulation is sufficiently general to capture most dependency parsing models, including probabilistic dependency models (Eisner, 1996; Wang et al., 2005) as well as non-probabilistic models (McDonald et al., 2005a).

For standard scoring functions, particularly those used in non-generative models, we further assume that the score of each link in (1) can be decomposed into a weighted linear combination of features

$$\text{score}(x_i \rightarrow x_j) = \boldsymbol{\theta} \cdot \mathbf{f}(x_i \rightarrow x_j) \tag{2}$$

where  $\mathbf{f}(x_i \rightarrow x_j)$  is a feature vector for the link  $(x_i \rightarrow x_j)$ , and  $\boldsymbol{\theta}$  are the weight parameters to be estimated during training.

## 3 Supervised Structured Large Margin Training

Supervised structured large margin training approaches have been applied to parsing and produce promising results (Taskar et al., 2004; McDonald et al., 2005a; Wang et al., 2006). In particular, structured large margin training can be expressed as minimizing a regularized loss (Hastie et al., 2004), as shown below:

<sup>1</sup>We assume all the dependency trees are projective in our work (just as some other researchers do), although in the real world, most languages are non-projective.

$$\min_{\boldsymbol{\theta}} \frac{\beta}{2} \boldsymbol{\theta}^\top \boldsymbol{\theta} + \sum_i \max_{L_{i,k}} (\Delta(L_{i,k}, Y_i) - \text{diff}(\boldsymbol{\theta}, Y_i, L_{i,k})) \quad (3)$$

where  $Y_i$  is the target tree for sentence  $X_i$ ;  $L_{i,k}$  ranges over all possible alternative  $k$  trees in  $\Phi(X_i)$ ;  $\text{diff}(\boldsymbol{\theta}, Y_i, L_{i,k}) = \text{score}(\boldsymbol{\theta}, Y_i) - \text{score}(\boldsymbol{\theta}, L_{i,k})$ ;  $\text{score}(\boldsymbol{\theta}, Y_i) = \sum_{(x_m \rightarrow x_n) \in Y_i} \boldsymbol{\theta} \cdot \mathbf{f}(x_m \rightarrow x_n)$ , as shown in Section 2; and  $\Delta(L_{i,k}, Y_i)$  is a measure of distance between the two trees  $L_{i,k}$  and  $Y_i$ . This is an application of the structured large margin training approach first proposed in (Taskar et al., 2003) and (Tsochantaridis et al., 2004).

Using the techniques of Hastie et al. (2004) one can show that minimizing the objective (3) is equivalent to solving the quadratic program

$$\begin{aligned} \min_{\boldsymbol{\theta}, \boldsymbol{\xi}} \quad & \frac{\beta}{2} \boldsymbol{\theta}^\top \boldsymbol{\theta} + \mathbf{e}^\top \boldsymbol{\xi} \quad \text{subject to} \\ & \xi_{i,k} \geq \Delta(L_{i,k}, Y_i) - \text{diff}(\boldsymbol{\theta}, Y_i, L_{i,k}) \\ & \xi_{i,k} \geq 0 \\ & \text{for all } i, L_{i,k} \in \Phi(X_i) \end{aligned} \quad (4)$$

where  $\mathbf{e}$  denotes the vector of all 1's and  $\boldsymbol{\xi}$  represents slack variables. This approach corresponds to the training problem posed in (McDonald et al., 2005a) and has yielded the best published results for English dependency parsing.

To compare with the new semi-supervised approach we will present in Section 5 below, we re-implemented the supervised structured large margin training approach in the experiments in Section 7. More specifically, we solve the following quadratic program, which is based on Equation (3)

$$\min_{\boldsymbol{\theta}} \frac{\alpha}{2} \boldsymbol{\theta}^\top \boldsymbol{\theta} + \sum_i \max_L \sum_{m=1}^k \sum_{n=1}^k \Delta(L_{i,m,n}, Y_{i,m,n}) - \text{diff}(\boldsymbol{\theta}, Y_{i,m,n}, L_{i,m,n}) \quad (5)$$

where  $\text{diff}(\boldsymbol{\theta}, Y_{i,m,n}, L_{i,m,n}) = \text{score}(\boldsymbol{\theta}, Y_{i,m,n}) - \text{score}(\boldsymbol{\theta}, L_{i,m,n})$  and  $k$  is the sentence length. We represent a dependency tree as a  $k \times k$  adjacency matrix. In the adjacency matrix, the value of  $Y_{i,m,n}$  is 1 if the word  $m$  is the head of the word  $n$ , 0 otherwise. Since both the distance function  $\Delta(L_i, Y_i)$  and the score function decompose over links, solving (5) is equivalent to solve the original constrained quadratic program shown in (4).

## 4 Semi-supervised Structured Large Margin Objective

The objective of standard semi-supervised structured SVM is a combination of structured large margin losses on both labeled and unlabeled data. It has the following form:

$$\min_{\boldsymbol{\theta}} \frac{\alpha}{2} \boldsymbol{\theta}^\top \boldsymbol{\theta} + \sum_{i=1}^N \text{structured\_loss}(\boldsymbol{\theta}, X_i, Y_i) + \min_{\mathbf{Y}_j} \sum_{j=1}^U \text{structured\_loss}(\boldsymbol{\theta}, X_j, Y_j) \quad (6)$$

where

$$\begin{aligned} \text{structured\_loss}(\boldsymbol{\theta}, X_i, Y_i) \\ = \max_L \sum_{m=1}^k \sum_{n=1}^k \Delta(L_{i,m,n}, Y_{i,m,n}) - \text{diff}(\boldsymbol{\theta}, Y_{i,m,n}, L_{i,m,n}) \end{aligned} \quad (7)$$

$N$  and  $U$  are the number of labeled and unlabeled training sentences respectively, and  $\mathbf{Y}_j$  ranges over guessed targets on the unsupervised data.

In the second term of the above objective shown in (6), both  $\boldsymbol{\theta}$  and  $\mathbf{Y}_j$  are variables. The resulting loss function has a hat shape (usually called hat-loss), which is non-convex. Therefore the objective as a whole is non-convex, making the search for global optimal difficult. Note that the root of the optimization difficulty for S3VMs is the non-convex property of the second term in the objective function. We will propose a novel approach which can deal with this problem. We introduce an efficient approximation—least squares loss—for the structured large margin loss on unlabeled data below.

## 5 Semi-supervised Convex Training for Structured SVM

Although semi-supervised structured SVM learning has been an active research area, semi-supervised structured SVMs have not been used in many real applications to date. The main reason is that most available semi-supervised large margin learning approaches are non-convex or computationally expensive (e.g. (Xu and Schuurmans, 2005)). These techniques are difficult to implement and extremely hard to scale up. We present a semi-supervised algorithm

for structured large margin training, whose objective is a combination of two convex terms: the supervised structured large margin loss on labeled data and the cheap least squares loss on unlabeled data. The combined objective is still convex, easy to optimize and much cheaper to implement.

### 5.1 Least Squares Convex Objective

Before we introduce the new algorithm, we first introduce a convex loss which we apply it to unlabeled training data for the semi-supervised structured large margin objective which we will introduce in Section 5.2 below. More specifically, we use a *structured* least squares loss to approximate the structured large margin loss on unlabeled data. The corresponding objective is:

$$\min_{\boldsymbol{\theta}, \mathbf{Y}_j} \frac{\alpha}{2} \boldsymbol{\theta}^\top \boldsymbol{\theta} + \frac{\lambda}{2} \sum_{j=1}^U \sum_{m=1}^k \sum_{n=1}^k \left( \boldsymbol{\theta}^\top \mathbf{f}(X_{j,m} \rightarrow X_{j,n}) - Y_{j,m,n} \right)^2 \quad (8)$$

subject to constraints on  $\mathbf{Y}$  (explained below).

The idea behind this objective is that for each possible link ( $X_{j,m} \rightarrow X_{j,n}$ ), we intend to minimize the difference between the link and the corresponding estimated link based on the learned weight vector. Since this is conducted on unlabeled data, we need to estimate both  $\boldsymbol{\theta}$  and  $\mathbf{Y}_j$  to solve the optimization problem. As mentioned in Section 3, a dependency tree  $\mathbf{Y}_j$  is represented as an adjacency matrix. Thus we need to enforce some constraints in the adjacency matrix to make sure that each  $\mathbf{Y}_j$  satisfies the dependency tree constraints. These constraints are critical because they prevent (8) from having a trivial solution in  $\mathbf{Y}$ . More concretely, suppose we use rows to denote heads and columns to denote children. Then we have the following constraints on the adjacency matrix:

- (1) All entries in  $\mathbf{Y}_j$  are between 0 and 1 (convex relaxation of discrete directed edge indicators);
- (2) The sum over all the entries on each column is equal to one (one-head rule);
- (3) All the entries on the diagonal are zeros (no self-link rule);

- (4)  $Y_{j,m,n} + Y_{j,n,m} \leq 1$  (anti-symmetric rule), which enforces directedness.

One final constraint that is sufficient to ensure that a directed tree is obtained, is connectedness (i.e. acyclicity), which can be enforced with an additional semidefinite constraint. Although convex, this constraint is more expensive to enforce, therefore we drop it in our experiments below. (However, adding the semidefinite connectedness constraint appears to be feasible on a sentence by sentence level.)

Critically, the objective (8) is *jointly* convex in both the weights  $\boldsymbol{\theta}$  and the edge indicator variables  $\mathbf{Y}$ . This means, for example, that there are no local minima in (8)—*any* iterative improvement strategy, if it converges at all, must converge to a global minimum.

### 5.2 Semi-supervised Convex Objective

By combining the convex structured SVM loss on labeled data (shown in Equation (5)) and the convex least squares loss on unlabeled data (shown in Equation (8)), we obtain a semi-supervised structured large margin loss

$$\min_{\boldsymbol{\theta}, \mathbf{Y}_j} \frac{\alpha}{2} \boldsymbol{\theta}^\top \boldsymbol{\theta} + \sum_{i=1}^N \text{structured\_loss}(\boldsymbol{\theta}, X_i, Y_i) + \sum_{j=1}^U \text{least\_squares\_loss}(\boldsymbol{\theta}, X_j, Y_j) \quad (9)$$

subject to constraints on  $\mathbf{Y}$  (explained above).

Since the summation of two convex functions is also convex, so is (9). Replacing the two losses with the terms shown in Equation (5) and Equation (8), we obtain the final convex objective as follows:

$$\min_{\boldsymbol{\theta}, \mathbf{Y}_j} \frac{\alpha}{2N} \boldsymbol{\theta}^\top \boldsymbol{\theta} + \sum_{i=1}^N \max_L \sum_{m=1}^k \sum_{n=1}^k \Delta(L_{i,m,n}, Y_{i,m,n}) - \text{diff}(\boldsymbol{\theta}, Y_{i,m,n}, L_{i,m,n}) + \frac{\alpha}{2U} \boldsymbol{\theta}^\top \boldsymbol{\theta} + \frac{\lambda}{2} \sum_{j=1}^U \sum_{m=1}^k \sum_{n=1}^k \left( \boldsymbol{\theta}^\top \mathbf{f}(X_{j,m} \rightarrow X_{j,n}) - Y_{j,m,n} \right)^2 \quad (10)$$

subject to constraints on  $\mathbf{Y}$  (explained above), where  $\text{diff}(\boldsymbol{\theta}, Y_{i,m,n}, L_{i,m,n}) = \text{score}(\boldsymbol{\theta}, Y_{i,m,n}) -$

$score(\theta, L_{i,m,n})$ ,  $N$  and  $U$  are the number of labeled and unlabeled training sentences respectively, as we mentioned before. Note that in (10) we have split the regularizer into two parts; one for the supervised component of the objective, and the other for the unsupervised component. Thus the semi-supervised convex objective is regularized proportionally to the number of labeled and unlabeled training sentences.

## 6 Efficient Optimization Strategy

To solve the convex optimization problem shown in Equation (10), we used a gradient descent approach which simply uses stochastic gradient steps. The procedure is as follows.

- Step 0, initialize the  $\mathbf{Y}_j$  variables of each unlabeled sentence as a right-branching (left-headed) chain model, i.e. the head of each word is its left neighbor.
- Step 1, pass through all the labeled training sentences one by one. The parameters  $\theta$  are updated based on each labeled sentence.
- Step 2, based on the learned parameter weights from the labeled data, update  $\theta$  and  $\mathbf{Y}_j$  on each unlabeled sentence alternatively:
  - treat  $\mathbf{Y}_j$  as a constant, update  $\theta$  on each unlabeled sentence by taking a local gradient step;
  - treat  $\theta$  as a constant, update  $\mathbf{Y}_j$  by calling the optimization software package CPLEX to solve for an optimal local solution.
- Repeat the procedure of step 1 and step 2 until maximum iteration number has reached.

This procedure works efficiently on the task of training a dependency parser. Although  $\theta$  and  $\mathbf{Y}_j$  are updated locally on each sentence, progress in minimizing the total objective shown in Equation (10) is made in each iteration. In our experiments, the objective usually converges within 30 iterations.

## 7 Experimental Results

Given a convex approach to semi-supervised structured large margin training, and an efficient training

algorithm for achieving a global optimum, we now investigate its effectiveness for dependency parsing. In particular, we investigate the accuracy of the results it produces. We applied the resulting algorithm to learn dependency parsers for both English and Chinese.

### 7.1 Experimental Design

#### Data Sets

Since we use a semi-supervised approach, both labeled and unlabeled training data are needed. For experiment on English, we used the English Penn Treebank (PTB) (Marcus et al., 1993) and the constituency structures were converted to dependency trees using the same rules as (Yamada and Matsumoto, 2003). The standard training set of PTB was split into 2 parts: labeled training data—the first 30k sentences in section 2-21, and unlabeled training data—the remaining sentences in section 2-21. For Chinese, we experimented on the Penn Chinese Treebank 4.0 (CTB4) (Palmer et al., 2004) and we used the rules in (Bikel, 2004) for conversion. We also divided the standard training set into 2 parts: sentences in section 400-931 and sentences in section 1-270 are used as labeled and unlabeled data respectively. For both English and Chinese, we adopted the standard development and test sets throughout the literature.

As listed in Table 1 with greater detail, we experimented with sets of data with different sentence length: PTB-10/CTB4-10, PTB-15/CTB4-15, PTB-20/CTB4-20, CTB4-40 and CTB4, which contain sentences with up to 10, 15, 20, 40 and all words respectively.

#### Features

For simplicity, in current work, we only used two sets of features—word-pair and tag-pair indicator features, which are a subset of features used by other researchers on dependency parsing (McDonald et al., 2005a; Wang et al., 2007). Although our algorithms can take arbitrary features, by only using these simple features, we already obtained very promising results on dependency parsing using both the supervised and semi-supervised approaches. Using the full set of features described in (McDonald et al., 2005a; Wang et al., 2007) and comparing the corresponding dependency parsing

English	PTB-10	Training(l/ul) Dev Test	3026/1016 163 270
	PTB-15	Training Dev Test	7303/2370 421 603
	PTB-20	Training Dev Test	12519/4003 725 1034
Chinese	CTB4-10	Training(l/ul) Dev Test	642/347 61 40
	CTB4-15	Training Dev Test	1262/727 112 83
	CTB4-20	Training Dev Test	2038/1150 163 118
	CTB4-40	Training Dev Test	4400/2452 274 240
	CTB4	Training Dev Test	5314/2977 300 289

results with previous work remains a direction for future work.

### Dependency Parsing Algorithms

For simplicity of implementation, we use a standard CKY parser in the experiments, although Eisner’s algorithm (Eisner, 1996) and the Spanning Tree algorithm (McDonald et al., 2005b) are also applicable.

### 7.2 Results

We evaluate parsing accuracy by comparing the directed dependency links in the parser output against the directed links in the treebank. The parameters  $\alpha$  and  $\lambda$  which appear in Equation (10) were tuned on the development set. Note that, during training, we only used the raw sentences of the unlabeled data. As shown in Table 2 and Table 3, for each data set, the semi-supervised approach achieves a significant improvement over the supervised one in dependency parsing accuracy on both Chinese and English. These positive results are somewhat surprising since a very simple loss function was used on

the unlabeled data. A key benefit of the approach is that a straightforward training algorithm can be used to obtain global solutions. Note that the results of our model are not directly comparable with previous parsing results shown in (McClosky et al., 2006a), since the parsing accuracy is measured in terms of dependency relations while their results are  $f$ -score of the bracketings implied in the phrase structure.

## 8 Conclusion and Future Work

In this paper, we have presented a novel algorithm for semi-supervised structured large margin training. Unlike previous proposed approaches, we introduce a convex objective for the semi-supervised learning algorithm by combining a convex structured SVM loss and a convex least square loss. This new semi-supervised algorithm is much more computationally efficient and can easily scale up. We have proved our hypothesis by applying the algorithm to the significant task of dependency parsing. The experimental results show that the proposed semi-supervised large margin training algorithm outperforms the supervised one, without much additional computational cost.

There remain many directions for future work. One obvious direction is to use the whole Penn Treebank as labeled data and use some other unannotated data source as unlabeled data for semi-supervised training. Next, as we mentioned before, a much richer feature set can be used in our model to get better dependency parsing results. Another direction is to apply the semi-supervised algorithm to other natural language problems, such as machine translation, topic segmentation and chunking. In these areas, there are only limited annotated data available. Therefore semi-supervised approaches are necessary to achieve better performance. The proposed semi-supervised convex training approach can be easily applied to these tasks.

## Abstract

In this paper, we present a novel backward transliteration approach which can further assist the existing statistical model by mining monolingual web resources. Firstly, we employ the syllable-based search to revise the transliteration candidates from the statistical model. By mapping all of them into existing words, we can filter or correct some pseudo candidates and improve the overall recall. Secondly, an AdaBoost model is used to re-rank the revised candidates based on the information extracted from monolingual web pages. To get a better precision during the re-ranking process, a variety of web-based information is exploited to adjust the ranking score, so that some candidates which are less possible to be transliteration names will be assigned with lower ranks. The experimental results show that the proposed framework can significantly outperform the baseline transliteration system in both precision and recall.

## 1 Introduction \*

The task of Name Entity (NE) translation is to translate a name entity from source language to target language, which plays an important role in machine translation and cross-language information retrieval (CLIR). Transliteration is a subtask in NE translation, which translates NEs based on the phonetic similarity. In NE translation, most person names are transliterated, and some parts of location names or organization names also need to be transliterated. Transliteration has two directions: forward transliteration which transforms an original name into target language, and backward transliteration which recovers a name back to its original expression. For instance, the original English per-

son name “Clinton” can be forward transliterated to its Chinese expression “克/ke 林/lin 顿/dun” and the backward transliteration is the inverse processing. In this paper, we focus on backward transliteration from Chinese to English.

Many previous researches have tried to build a transliteration model using statistical approach [Knight and Graehl, 1998; Lin and Chen, 2002; Virga and Khudanpur, 2003; Gao, 2004]. There are two main challenges in statistical backward transliteration: First, statistical transliteration approach selects the most probable translations based on the knowledge learned from the training data. This approach, however, does not work well when there are multiple standards [Gao, 2004]. Second, backward transliteration is more challenging than forward transliteration as it is required to disambiguate the noises introduced in the forward transliteration and estimate the original name as close as possible [Lin and Chen, 2002]. One of the most important causes in introducing noises is that: some silent syllables in original names have been missing when they are transliterated to target language. For example, when “Campbell” is transliterated into “坎/kan 贝/bei 尔/er”, the “p” is missing.

In order to make up the disadvantages of statistical approach, some researchers have been seeking for the assistance of web resource. [Wang et al., 2004; Cheng et al., 2004; Nagata et al., 2001; Zhang et al, 2005] used bilingual web pages to extract translation pairs. Other efforts have been made to combine a statistical transliteration model with web mining [Al-Onaizan and Knight, 2002; Long Jiang et al, 2007]. Most of these methods need bilingual resources. However, those kinds of resources are not readily available in many cases. Moreover, to search for bilingual pages, we have to depend on the performance of search engines. We can't get Chinese-English bilingual pages when the input is a Chinese query. Therefore, the existing

\*Contact: Jun ZHAO, [jzhao@nlpr.ia.ac.cn](mailto:jzhao@nlpr.ia.ac.cn).

assistance approaches using web-mining to assist transliteration are not suitable for Chinese to English backward transliteration.

Thus in this paper, we mainly focus on the following two problems to be solved in transliteration.

**Problem I:** Some silent syllables are missing in English-Chinese forward transliteration. How to recover them effectively and efficiently in backward transliteration is still an open problem.

**Problem II:** Statistical transliteration always chooses the translations based on probabilities. However, in some cases, the correct translation may have lower probability. Therefore, more studies are needed on combination with other techniques as supplements.

Aiming at these two problems, we propose a method which mines monolingual web resources to assist backward transliteration. The main ideas are as follows. We assume that for every Chinese entity name which needs to be backward transliterated to an English original name, the correct transliteration exists somewhere in the web. What we need to do is to find out the answers based on the clues given by statistical transliteration results. Different from the traditional methods which extract transliteration pairs from bilingual pages, we only use monolingual web resources. Our method has two advantages. Firstly, there are much more monolingual web resources available to be used. Secondly, our method can revise the transliteration candidates to the existing words before the subsequent re-ranking process, so that we can better mine the correct transliteration from the Web.

Concretely, there are two phases involved in our approach. In the first phase, we split the result of transliteration into syllables, and then a syllable-based searching processing can be employed to revise the result in a word list generated from web pages, with an expectation of higher recall of transliteration. In the second phase, we use a revised word as a search query to get its contexts and hit information, which are integrated into the AdaBoost classifier to determine whether the word is a transliteration name or not with a confidence score. This phase can readjust the candidate's score to a more reasonable point so that precision of transliteration can be improved. Table 1 illustrates how to transliterate the Chinese name “阿/a加/jia西/xi” back to “Agassi”.

Chinese name	Transliteration results	Revised Candidate	Re-rank Results
阿加西	aggasi agahi agacy agacie ...	aggasi agahi agacy agacie ...	aggasi agahi agacy agacie ...

阿加西	aggasi	agasi	<b>agassi</b>
a jia xi	agahi	agathi	agasi
Agassi	agacy	agathe	agache
	agacie	<b>agassi</b>	agga
	...	...	...

Table 1. An example of transliteration flow

The experimental results show that our approach improves the recall from 41.73% to 59.28% in open test when returning the top-100 results, and the top-5 precision is improved from 19.69% to 52.19%.

The remainder of the paper is structured as follows. Section 2 presents the framework of our system. We discuss the details of our statistical transliteration model in Section 3. In Section 4, we introduce the approach of revising and re-ranking the results of transliteration. The experiments are reported in Section 5. The last section gives the conclusion and the prediction of future work.

## 2 System Framework

Our system has three main modules.

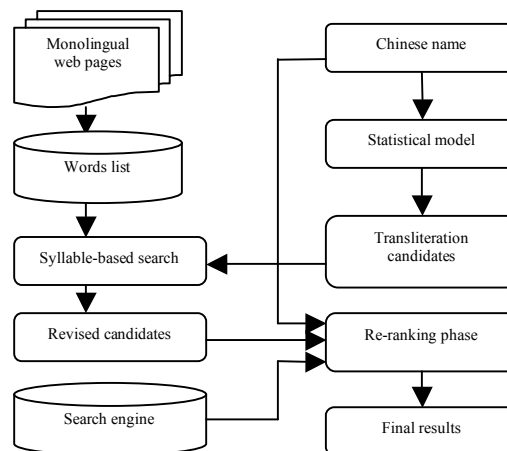

Figure 1. System framework

1) **Statistical transliteration:** This module receives a Chinese Pinyin sequence as its input, and output the  $N$ -best results as the transliteration candidates.

2) **Candidate transliteration revision through syllable-based searching:** In the module, a transliteration candidate is transformed into a syllable query. We use a syllable-based searching strategy to select the revised candidate from a huge word list. Each word in the list is indexed by syllables, and the similarity between the word and the query is calculated. The most similar words are returned as the revision results. This module guar-

antees the transliteration candidates are all existing words.

3) **Revised candidate re-ranking in web pages**: In the module, we search the revised candidates to get their contexts and hit information which we can use to score the probability of being a transliteration name. This phase doesn't generate new candidates, but re-rank the revised candidate set to improve the performance in top-5.

Under this framework, we can solve the two problems of statistical model mentioned above.

(1) The silent syllables will be given lower weights in syllable-based search, so the missing syllables will be recovered through selecting the most similar existing words which can contain some silent syllables.

(2) The query expansion technology can recall more potential transliteration candidates by expanding syllables to their "synonymies". So the mistakes introduced when selecting syllables in statistical transliteration will be corrected through giving suitable weights to synonymies.

Through the revision phase, the results of statistical model which may have illegal spelling will be mapped to its most similar existing words. That can improve the recall. In re-ranking phase, the revised candidate set will be re-ranked to put the right answer on the top using hybrid information got from web resources. So the precision of transliteration will be improved.

### 3 Statistical Transliteration Model

We use syllables as translation units to build a statistical Chinese-English backward transliteration model in our system.

#### 3.1 Traditional Statistical Translation Model

[P. Brown et al., 1993] proposed an IBM source-channel model for statistical machine translation (SMT). When the channel output  $f=f_1, f_2, \dots, f_n$  observed, we use formula (1) to seek for the original sentence  $e=e_1, e_2, \dots, e_n$  with the most likely posteriori.

$$e' = \arg \max_e P(e | f) = \arg \max_e P(f | e)P(e) \quad (1)$$

The translation model  $P(f | e)$  is estimated from a paired corpus of foreign-language sentences and their English translations. The language model  $P(e)$  is trained from English texts.

#### 3.2 Our Transliteration Model

The alignment method is the base of statistical transliteration model. There are mainly two kinds of alignment methods: phoneme-based alignment [Knight and Graehl, 1998; Virga and Khudanpur, 2003] and grapheme-based alignment [Long Jiang, 2007]. In our system, we adopt the syllable-based alignment from Chinese pinyin to English syllables, where the syllabication rules mentioned in [Long Jiang et al., 2007] are used.

For example, Chinese name "希/xi 尔/er 顿/dun" and its backward transliteration "Hilton" can be aligned as follows. "Hilton" is split into syllable sequence as "hi/l/ton", and the alignment pairs are "xi-hi", "er-l", "dun-ton".

Based on the above alignment method, we can get our statistical Chinese-English backward transliteration model as,

$$E = \arg \max_E p(PY | ES)p(ES) \quad (2)$$

Where,  $PY$  is a Chinese Pinyin sequence,  $ES$  is a English syllables sequence,  $p(PY | ES)$  is the probability of translating  $ES$  into  $PY$ ,  $p(ES)$  is the generative probability of a English syllable language model.

#### 3.3 The Difference between Backward Transliteration and Traditional Translation

Chinese-English backward transliteration has some differences from traditional translation.

1) We don't need to adjust the order of syllables when transliteration.

2) The language model in backward transliteration describes the relationship of syllables in words. It can't work as well as the language model describing the word relationship in sentences.

We think that the crucial problem in backward transliteration is selecting the right syllables at every step. It's very hard to obtain the exact answer only based on the statistical transliteration model. We will try to improve the statistical model performance with the assistance of mining web resources.

#### 4 Mining Monolingual Web Pages to Assist Backward Transliteration

In order to get assistance from monolingual Web resource to improve statistical transliteration, our

method contains two main phases: “revision” and “re-ranking”. In the revision phase, transliteration candidates are revised using syllable-based search in the word list, which are generated by collecting the existing words in web pages. Because the process of named entity recognition may lose some NEs, we will reserve all the words in web corpus without any filtering. The revision process can improve the recall through correcting some mistakes in the transliteration results of statistical model.

In the re-ranking phase, we search every revised candidate on English pages, score them according to their contexts and hit information so that the right answer will be given a higher rank.

#### 4.1 Using Syllable-based Retrieval to Revise Transliteration Candidates

In this section, we will propose two methods respectively for the two problems of statistical model mentioned in section 1.

##### 4.1.1 Syllable-based retrieval model

When we search a transliteration candidate  $t_i$  in the word list, we firstly split it into syllables  $\{es_1, es_2, \dots, es_n\}$ . Then this syllable sequence is used as a query for syllable-based searching.

We define some notions here.

- Term set  $T = \{t_1, t_2, \dots, t_k\}$  is an orderly set of all syllables which can be viewed as terms.
- Pinyin set  $P = \{py_1, py_2, \dots, py_k\}$  is an orderly set of all Pinyin.
- An input word can be represented by a vector of syllables  $\{es_1, es_2, \dots, es_n\}$ .

We calculate the similarity between a transliteration result and each word in the list to select the most similar words as the revised candidates. The  $\{es_1, es_2, \dots, es_n\}$  will be transformed into a vector  $V_{query} = \{t_1, t_2, \dots, t_k\}$  where  $t_i$  represents the  $i$ th term in  $T$ . The value of  $t_i$  is equal to 0 if the  $i$ th term doesn't appear in query. In the same way, the word in list can also be transformed into vector representation. So the similarity can be calculated as the inner product between these two vectors.

We don't use *tf* and *idf* conceptions as traditional information retrieval (IR) to calculate the terms' weight. We use the weight of  $t_i$  to express the expectation probability of  $i$ th term having pronunciation. If the term has a lower probability of having pronunciation, its weight is low. So when we searching, the missing silent syllables in the results

of statistical transliteration model can be recovered because such syllables have little impact on similarity measurement. The formula we used is as follows.

$$Sim(query, word) = \frac{V_{query} \times V_{word}}{L_{word} / L_{py}} \quad (3)$$

The numerator is the inner product of two vectors. The denominator is the length of word  $L_{word}$  divided by the length of Chinese pinyin sequence  $L_{py}$ . In this formula, the more syllables in one word, the higher score of inner production it may get, but the word will get a loss for its longer length. The word which has the shortest length and the highest syllable hitting ratio will be the best.

Another difference from traditional IR is how to deal with the order of the words in a query. According to transliteration, the similarity must be calculated under the limitation of keeping order, which can't be satisfied by current methods. We use the algorithm like calculating the edit distance between two words. The syllables are viewed as the units which construct a word. The edit distance calculation finds the best matching with the least operation cost to change one word to another word by using deletion/addition/insertion operations on syllables. But the complexity will be too high to afford if we calculate the edit distance between a query and each word in the list. So, we just calculate the edit distance for the words which get high score without the order limitation. This trade off method can save much time but still keep performance.

##### 4.1.2 Mining the Equivalent through Syllable Expansion

In most collections, the same concept may be referred to using different words. This issue, known as synonymy, has an impact on the recall of most information retrieval systems. In this section, we try to use the expansion technology to solve problem II. There are three kinds of expansions to be explained below.

**Syllable expansion based on phonetic similarity:** The syllables which correspond to the same Chinese pinyin can be viewed as synonymies. For example, the English syllables “din” and “tin” can be aligned to the same Chinese pinyin “ding”.

Given a Chinese pinyin sequence  $\{py_1, py_2, \dots, py_n\}$  as the input of transliteration model, for every  $py_i$ , there are a set of syllables

$\{es_1, es_2, \dots, es_k\}$  which can be selected as its translation. The statistical model will select the most probable one, while others containing the right answer are discarded. To solve this problem, we expand the query to take the synonymies of terms into consideration. We create an expansion set for each Chinese pinyin. A syllable  $es_i$  will be selected into the expansion set of  $py_j$  based on the alignment probability  $P(es_i|py_j)$  which can be extracted from the training corpus. The phonetic similarity expansion is based on the input Chinese Pinyin sequence, so it's same for all candidates.

**Syllable expansion based on syllable similarity:** If two syllables have similar alignment probability with every pinyin, we can view these two syllables as synonymy. Therefore, if a syllable is in the query, its synonymies should be contained too. For example, “fea” and “fe” can replace each other.

To calculate the similarity, we first obtain the alignment probability  $P(py_i|es_k)$  of every syllable. Then the distance between any two syllables will be calculated using formula (4).

$$Sim(es_j, es_k) = \frac{1}{N} \sum_{i=1}^N P(py_i | es_j) P(py_i | es_k) \quad (4)$$

This formula is used to evaluate the similarity of two syllables in alignment. The expansion set of the  $i$ th syllable can be generated by selecting the most similar  $N$  syllables. This kind of expansion is conducted upon the output of statistical transliteration model.

**Syllable expansion based on syllable edit distance:** The disadvantage of last two expansions is that they are entirely dependent on the training set. In other word, if some syllables haven't appeared in the training corpus, they will not be expanded. To solve the problem, we use the method of expansion based on edit distance. We use edit distance to measure the similarity between two syllables, one is in training set and the other is absent. Because the edit distance expansion is not very relevant to pronunciation, we will give this expansion method a low weight in combination. It works when new syllables arise.

**Combine the above three strategies:** We will combine the three kinds of expansion method together. We use the linear interpolation to integrate them. The formulas are follows.

$$S = (1 - \alpha)S_{pre} + \alpha S_{sy} + \beta S_{ed} \quad (5)$$

$$S = (1 - \alpha)S_{pre} + \alpha S_{py} + \beta S_{ed} \quad (6)$$

where  $S_{pre}$  is the score of exact matching,  $S_{sy}$  is the score of expansion based on syllables similarity and  $S_{py}$  based on phonetic similarity. We will adjust these parameters to get the best performance. The experimental results and analysis will be reported in section 5.3.

## 4.2 Re-Ranking the Revised Candidates Set using the Monolingual Web Resource

In the first phase, we have generated the revised candidate set  $\{rc_1, rc_2, \dots, rc_n\}$  from the word list using the transliteration results as clues. The objective is to improve the overall recall. In the second phase, we try to improve the precision, i.e. we wish to re-rank the candidate set so that the correct answer will be put in a higher rank.

[Al-Onaizan et al., 2002] has proposed some methods to re-score the transliteration candidates. The limitation of their approach is that some candidates are propbale not existing words, with which we will not get any information from web. So it can only re-rank the transliteration results to improve the precision of top-5. In our work, we can improve the recall of transliteration through the revising process before re-ranking.

In this section, we employ the AdaBoost framework which integrates several kinds of features to re-rank the revised candidate set. The function of the AdaBoost classifier is to calculate the probability of the candidate being a NE. Then we can re-rank the revised candidate set based on the score. The features used in our system are as follows.

**NE or not:** Using  $rc_i$  as query to search for monolingual English Web Pages, we can get the context set  $\{T_{i1}, T_{i2}, \dots, T_{in}\}$  of  $rc_i$ . Then for every  $T_{ik}$ , we use the named entity recognition (NER) software to determine whether  $rc_i$  is a NE or not. If  $rc_i$  is recognized as a NE in some  $T_{ik}$ ,  $rc_i$  will get a score. If  $rc_i$  can't be recognized as NE in any contexts, it will be pruned.

**The hit of the revised candidate:** We can get the hit information of  $rc_i$  from search engine. It is used to evaluate the importance of  $rc_i$ . Unlike [Al-Onaizan et al., 2002], in which the hit can be used to eliminate the translation results which contain illegal spelling, we just use hit number as a feature.

**The limitation of compound NEs:** When transliterating a compound NE, we always split them into several parts, and then combine their transliteration results together. But in this circumstance,

every part can add a limitation in the selection of the whole NE. For example: “希/xi拉/la里/li·克/ke林/lin顿/dun” is a compound name. “希/xi拉/la里/li” can be transliterate to “Hilary” or “Hilaly” and “克/ke林/lin顿/dun” can be transliterate to “Clinton” or “Klinton”. But the combination of “Hilary·Clinton” will be selected for it is the most common combination. So the hit of combination query will be extracted as a feature in classifier.

**Hint words around the NE:** We can take some hint words around the NE into the query, in order to add some limitations to filter out noisy words. For example: “总统 (president)” can be used as hint word for “克林顿 (Clinton)”. To find the hint words, we first search the Chinese name in Chinese web pages. The frequent words can be extracted as hint words and they will be translated to English using a bilingual dictionary. These hint words are combined with the revised candidates to search English web pages. So, the hit of the query will be extracted as feature.

The formula of AdaBoost is as follow.

$$H(x) = \text{sign}\left(\sum_{t=1}^T \alpha_t h_t(x)\right) \quad (7)$$

Where  $\alpha_t$  is the weight for the  $i$ th weak classifier  $h_t(x)$ .  $\alpha_t$  can be calculated based on the precision of its corresponding classifier.

## 5 Experiments

We carry out experiments to investigate how much the revision process and the re-ranking process can improve the performance compared with the baseline of statistical transliteration model. We will also evaluate to which extents we can solve the two problems mentioned in section 1 with the assistance of Web resources.

### 5.1 Experimental data

The training corpus for statistical transliteration model comes from the corpus of Chinese <-> English Name Entity Lists v 1.0 (LDC2005T34). It contains 565,935 transliteration pairs. Ruling out those pairs which are not suitable for the research on Chinese-English backward transliteration, such as Chinese-Japanese, we select a training set which contains 14,443 pairs of Chinese-European & American person names. In the training set, 1,344

pairs are selected randomly as the close test data. 1,294 pairs out of training set are selected as the open test data. To set up the word list, a 2GB-sized collection of web pages is used. Since 7.42% of the names in the test data don’t appear in the list, we use *Google* to get the web page containing the absent names and add these pages into the collection. The word list contains 672,533 words.

### 5.2 Revision phase vs. statistical approach

Using the results generated from statistical model as baseline, we evaluate the revision module in recall first. The statistical transliteration model works in the following 4 steps: 1) Chinese name are transformed into pinyin representation and the English names are split into syllables. 2) The *GIZA++*<sup>1</sup> tool is invoked to align pinyin to syllables, and the alignment probabilities  $P(py|es)$  are obtained. 3) Those frequent sequences of syllables are combined as phrases. For example, “be/r/g” $\rightarrow$ ”berg”, “s/ky” $\rightarrow$ ”sky”. 4) *Camel*<sup>2</sup> decoder is executed to generate 100-best candidates for every name.

We compare the statistical transliteration results with the revised results in Table 2. From Table 2 we can find that the recall of top-100 after revision is improved by 13.26% in close test set and 17.55% in open test set. It proves that the revision module is effective for correcting the mistakes made in statistical transliteration model.

	Transliteration results		Revised results	
	close	open	close	open
Top1	33.64%	9.41%	27.15%	11.04%
Top5	40.37%	13.38%	42.83%	19.69%
Top10	47.79%	17.56%	56.98%	26.52%
Top20	61.88%	25.44%	71.05%	37.81%
Top50	66.49%	36.19%	82.16%	46.22%
Top100	<b>72.52%</b>	<b>41.73%</b>	<b>85.78%</b>	<b>59.28%</b>

Table 2. Statistical model vs. Revision module

To show the effects of the revision on the two above-mentioned problems in which the statistical model does not solve well: the losing of silent syllables and the selection bias problem, we make a statistics of the improvements with a measurement of “correction time”.

For a Chinese word whose correct transliteration appears in top-100 candidates only if it has been

<sup>1</sup> <http://www.fjoch.com/GIZA++.html>

<sup>2</sup> <http://www.nlp.org.cn>

revised, we count the “correction time”. For example, when “Argahi” is revised to “Agassi” the correction time is “1” for Problem II and “1” for Problem I, because in “hi” $\rightarrow$ “si” the syllable is expanded, and in “si” $\rightarrow$ “ssi” an “s” is added.

	Close test	Open test
Problem I	0.6931	0.7853
Problem II	0.9264	1.1672

Table 3. Average time of correction

This measurement reflects the efficiency of the revision of search strategy, in contrast to those spelling correction techniques in which several operations of “add” and “expand” are inevitable. It has proved that the more an average correction time is, the more efficient our strategy is.

Figure 2. Length influence in recall comparison

The recall of the statistical model relies on the length of English name in some degree. It is more difficult to obtain an absolutely correct answer for longer names, because they may contain more silent and confused syllables. However, through the revision phase, this tendency can be effectively alleviated. In Figure 2, we make a comparison between the results of the statistical model and the revision module with the changing of syllable’s length in open test. The curves demonstrate that the revision indeed prevents the decrease of recall for longer names.

### 5.3 Parameter setting in the revision phase

We will show the experimental results when setting different parameters for query expansion. In the expansion based on phonetic similarity, for every Chinese pinyin, we select at most 20 syllables to create an expansion set. We set  $\beta = 0.1$  in formula (5). The results are shown in the columns labeled “exp1” in Table 4.

From the results we can conclude that, we get the best performance when  $\alpha = 0.4$ . That means the performance is best when the weight of exact

matching is a little larger than the weight of fuzzy matching. We can also see that, higher weight of exact matching will lead to low recall, while higher weight of fuzzy matching will bring noise in.

The expansion method based on syllable similarity is also evaluated. For every syllable, we select at most 15 syllables to create the expansion set. We set  $\beta = 0.1$ . The results are shown in the columns labeled “exp2” in Table 4.

From the results we can conclude that, we get the best performance when  $\alpha = 0.5$ . It means that we can’t put emphasis on any matching methods. Comparison with the expansion based on phonetic similarity, the performance is poorer. It means that the expansion based on phonetic similarity is more suitable for revising transliteration candidates.

### 5.4 Revision phase vs. re-ranking phase

After the phase of revising transliteration candidates, we re-rank the revised candidate set with the assistance of monolingual web resources. In this section, we will show the improvement in precision after re-ranking.

We have selected four kinds of features to integrate in the AdaBoost framework. To determine whether the candidate is NE or not in its context, we use the software tool *Lingpipe*<sup>3</sup>. The queries are sent to *google*, so that we can get the hit of queries and the top-10 snippets will be extracted as context.

The comparison of revision results and re-ranking results is shown as follows.

	Revised results		Re-ranked results	
	close	open	close	open
Top1	27.15%	11.04%	<b>58.08%</b>	<b>38.63%</b>
Top5	42.83%	19.69%	<b>76.35%</b>	<b>52.19%</b>
Top10	56.98%	26.52%	83.92%	54.33%
Top20	71.05%	37.81%	83.92%	57.61%
Top50	82.16%	46.22%	83.92%	57.61%
Top100	<b>85.78%</b>	<b>59.28%</b>	85.78%	59.28%

Table 4. Parameters Experiment

rank. Through the revision module, we get both higher recall and higher precision than statistical transliteration model when at most 5 results are returned.

We also use the average rank and average reciprocal rank (ARR) [Voorhees and Tice, 2000] to evaluate the improvement. ARR is calculated as

$$ARR = \frac{1}{M} \sum_{i=1}^M \frac{1}{R(i)} \quad (8)$$

where  $R(i)$  is the rank of the answer of  $i$ th test word.  $M$  is the size of test set. The higher of ARR, the better the performance is.

The results are shown as Table 6.

	Statistical model		Revision module		Re-rank Module	
	close	open	close	open	close	open
Average rank	37.63	70.94	24.52	58.09	16.71	43.87
ARR	0.3815	0.1206	0.3783	0.1648	0.6519	0.4492

Table 6. ARR and AR evaluation

The ARR after revision phase is lower than the statistical model. Because the goal of revision module is to improve the recall as possible as we can, some noisy words will be introduced in. The noisy words will be pruned in re-ranking module. That is why we get the highest ARR value at last. So we can conclude that the revision module improves recall and re-ranking module improves precision, which help us get a better performance than pure statistical transliteration model

## 6 Conclusion

In this paper, we present a new approach which can revise the results generated from statistical transliteration model with the assistance of monolingual web resource. Through the revision process, the recall of transliteration results has been improved from 72.52% to 85.78% in the close test set and from 41.73% to 59.28% in open test set, respectively. We improve the precision in re-ranking phase, the top-5 precision can be improved to 76.35% in close test and 52.19% in open test. The

promising results show that our approach works pretty well in the task of backward transliteration.

In the future, we will try to improve the similarity measurement in the revision phase. And we also wish to develop a new approach using the transliteration candidates to search for their right answer more directly and effectively.

## Abstract

This paper presents an empirical study on the robustness and generalization of two alternative role sets for semantic role labeling: PropBank numbered roles and VerbNet thematic roles. By testing a state-of-the-art SRL system with the two alternative role annotations, we show that the PropBank role set is more robust to the lack of verb-specific semantic information and generalizes better to infrequent and unseen predicates. Keeping in mind that thematic roles are better for application needs, we also tested the best way to generate VerbNet annotation. We conclude that tagging first PropBank roles and mapping into VerbNet roles is as effective as training and tagging directly on VerbNet, and more robust for domain shifts.

## 1 Introduction

Semantic Role Labeling is the problem of analyzing clause predicates in open text by identifying arguments and tagging them with semantic labels indicating the role they play with respect to the verb. Such sentence-level semantic analysis allows to determine “who” did “what” to “whom”, “when” and “where”, and, thus, characterize the participants and properties of the *events* established by the predicates. This kind of semantic analysis is very interesting for a broad spectrum of NLP applications (information extraction, summarization, question answering, machine translation, etc.), since it opens the door to exploit the semantic relations among linguistic constituents.

The properties of the semantically annotated corpora available have conditioned the type of research

and systems that have been developed so far. PropBank (Palmer et al., 2005) is the most widely used corpus for training SRL systems, probably because it contains running text from the Penn Treebank corpus with annotations on all verbal predicates. Also, a few evaluation exercises on SRL have been conducted on this corpus in the CoNLL-2004 and 2005 conferences. However, a serious criticism to the PropBank corpus refers to the role set it uses, which consists of a set of numbered core arguments, whose semantic translation is verb-dependent. While Arg0 and Arg1 are intended to indicate the general roles of Agent and Theme, other argument numbers do not generalize across verbs and do not correspond to general semantic roles. This fact might compromise generalization and portability of SRL systems, especially when the training corpus is small.

More recently, a mapping from PropBank numbered arguments into VerbNet thematic roles has been developed and a version of the PropBank corpus with thematic roles has been released (Loper et al., 2007). Thematic roles represent a compact set of verb-independent general roles widely used in linguistic theory (e.g., Agent, Theme, Patient, Recipient, Cause, etc.). We foresee two advantages of using such thematic roles. On the one hand, statistical SRL systems trained from them could generalize better and, therefore, be more robust and portable, as suggested in (Yi et al., 2007). On the other hand, roles in a paradigm like VerbNet would allow for inferences over the assigned roles, which is only possible in a more limited way with PropBank.

In a previous paper (Zapirain et al., 2008), we presented a first comparison between the two previous role sets on the SemEval-2007 Task 17 corpus (Pradhan et al., 2007). The SemEval-2007 corpus only

comprised examples about 50 different verbs. The results of that paper were, thus, considered preliminary, as they could depend on the small amount of data (both in training data and number of verbs) or the specific set of verbs being used. Now, we extend those experiments to the entire PropBank corpus, and we include two extra experiments on domain shifts (using the Brown corpus as test set) and on grouping VerbNet labels. More concretely, this paper explores two aspects of the problem. First, having in mind the claim that general thematic roles should be more robust to changing domains and unseen predicates, we study the performance of a state-of-the-art SRL system trained on either codification of roles and some specific settings, i.e. including/excluding verb-specific information, labeling unseen verb predicates, or domain shifts. Second, assuming that application scenarios would prefer dealing with general thematic role labels, we explore the best way to label a text with thematic roles, namely, by training directly on VerbNet roles or by using the PropBank SRL system and perform a posterior mapping into thematic roles.

The results confirm our preliminary findings (Zapirain et al., 2008). We observe that the PropBank roles are more robust in all tested experimental conditions, i.e., the performance decrease is more severe for VerbNet. Besides, tagging first PropBank roles and then mapping into VerbNet roles is as effective as training and tagging directly on VerbNet, and more robust for domain shifts.

The rest of the paper is organized as follows: Section 2 contains some background on PropBank and VerbNet role sets. Section 3 presents the experimental setting and the base SRL system used for the role set comparisons. In Section 4 the main comparative experiments on robustness are described. Section 5 is devoted to analyze the posterior mapping of PropBank outputs into VerbNet thematic roles, and includes results on domain-shift experiments using Brown as test set. Finally, Sections 6 and 7 contain a discussion of the results.

## 2 Corpora and Semantic Role Sets

The PropBank corpus is the result of adding a semantic layer to the syntactic structures of Penn Treebank II (Palmer et al., 2005). Specifically, it pro-

vides information about predicate-argument structures to all verbal predicates of the Wall Street Journal section of the treebank. The role set is theory-neutral and consists of a set of numbered core arguments (Arg0, Arg1, ..., Arg5). Each verb has a *frameset* listing its allowed role labels and mapping each numbered role to an English-language description of its semantics.

Different senses for a polysemous verb have different framesets, but the argument labels are semantically consistent in all syntactic alternations of the same verb-sense. For instance in “Kevin broke [the window]<sub>Arg1</sub>” and in “[The door]<sub>Arg1</sub> broke into a million pieces”, for the verb *broke.01*, both Arg1 arguments have the same semantic meaning, that is “broken entity”. Nevertheless, argument labels are not necessarily consistent across different verbs (or verb senses). For instance, the same Arg2 label is used to identify the Destination argument of a proposition governed by the verb *send* and the Beneficiary argument of the verb *compose*. This fact might compromise generalization of systems trained on PropBank, which might be focusing too much on verb-specific knowledge. It is worth noting that the two most frequent arguments, Arg0 and Arg1, are intended to indicate the general roles of Agent and Theme and are usually consistent across different verbs. However, this correspondence is not total. According to the study by (Yi et al., 2007), Arg0 corresponds to Agent 85.4% of the time, but also to Experiencer (7.2%), Theme (2.1%), and Cause (1.9%). Similarly, Arg1 corresponds to Theme in 47.0% of the occurrences but also to Topic (23.0%), Patient (10.8%), and Product (2.9%), among others. Contrary to core arguments, adjuncts (Temporal and Location markers, etc.) are annotated with a closed set of general and verb-independent labels.

VerbNet (Kipper et al., 2000) is a computational verb lexicon in which verbs are organized hierarchically into classes depending on their syntactic/semantic linking behavior. The classes are based on Levin’s verb classes (Levin, 1993) and each contains a list of member verbs and a correspondence between the shared syntactic frames and the semantic information, such as thematic roles and selectional constraints. There are 23 thematic roles (Agent, Patient, Theme, Experiencer, Source, Beneficiary, Instrument, etc.) which, unlike the Prop-

Bank numbered arguments, are considered as general verb-independent roles.

This level of abstraction makes them, in principle, better suited (compared to PropBank numbered arguments) for being directly exploited by general NLP applications. But, VerbNet by itself is not an appropriate resource to train SRL systems. As opposed to PropBank, the number of tagged examples is far more limited in VerbNet. Fortunately, in the last years a twofold effort has been made in order to generate a large corpus fully annotated with thematic roles. Firstly, the SemLink<sup>1</sup> resource (Loper et al., 2007) established a mapping between PropBank framesets and VerbNet thematic roles. Secondly, the SemLink mapping was applied to a representative portion of the PropBank corpus and manually disambiguated (Loper et al., 2007). The resulting corpus is currently available for the research community and makes possible comparative studies between role sets.

### 3 Experimental Setting

#### 3.1 Datasets

The data used in this work is the benchmark corpus provided by the SRL shared task of CoNLL-2005 (Carreras and Màrquez, 2005). The dataset, of over 1 million tokens, comprises PropBank sections 02–21 for training, and sections 24 and 23 for development and test, respectively. From the input information, we used part of speech tags and full parse trees (generated using Charniak’s parser) and discarded named entities. Also, we used the publicly available SemLink mapping from PropBank into VerbNet roles (Loper et al., 2007) to generate a replicate of the CoNLL-2005 corpus containing also the VerbNet annotation of roles.

Unfortunately, SemLink version 1.0 does not cover all propositions and arguments in the PropBank corpus. In order to have an homogeneous corpus and not to bias experimental evaluation, we decided to discard all incomplete examples and keep only those propositions that were 100% mapped into VerbNet roles. The resulting corpus contains 56% of the original propositions, that is, over 50,000 propositions in the training set. This subcorpus is much larger than the SemEval-2007 Task 17 dataset used

<sup>1</sup><http://verbs.colorado.edu/semLink/>

in our previous experimental work (Zapirain et al., 2008). The difference is especially noticeable in the diversity of predicates represented. In this case, there are 1,709 different verbs (1,505 lemmas) compared to the 50 verbs of the SemEval corpus. We believe that the size and richness of this corpus is enough to test and extract reliable conclusions on the robustness and generalization across verbs of the role sets under study.

In order to study the behavior of both role sets in out-of-domain data, we made use of the PropBanked Brown corpus (Marcus et al., 1994) for testing, as it is also mapped into VerbNet thematic roles in the SemLink resource. Again, we discarded those propositions that were not entirely mapped into thematic roles (45%).

#### 3.2 SRL System

Our basic Semantic Role Labeling system represents the tagging problem as a Maximum Entropy Markov Model (MEMM). The system uses full syntactic information to select a sequence of constituents from the input text and tags these tokens with Begin/Inside/Outside (BIO) labels, using state-of-the-art classifiers and features. The system achieves very good performance in the CoNLL-2005 shared task dataset and in the SRL subtask of the SemEval-2007 English lexical sample task (Zapirain et al., 2007). Check this paper for a complete description of the system.

When searching for the most likely state sequence, the following constraints are observed<sup>2</sup>:

1. No duplicate argument classes for Arg0–Arg5 PropBank (or VerbNet) roles are allowed.
2. If there is a R-X argument (reference), then there has to be a X argument before (referent).
3. If there is a C-X argument (continuation), then there has to be a X argument before.
4. Before a I-X token, there has to be a B-X or I-X token.
5. Given a predicate, only the arguments described in its PropBank (or VerbNet) lexical entry (i.e., the verbal frameset) are allowed.

<sup>2</sup>Note that some of the constraints are dependent of the role set used, i.e., PropBank or VerbNet

Regarding the last constraint, the lexical entries of the verbs were constructed from the training data itself. For instance, the verb *build* appears with four different PropBank core roles (Arg0–3) and five VerbNet roles (Product, Material, Asset, Attribute, Theme), which are the only ones allowed for that verb at test time. Note that in the cases where the verb sense was known we could constraint the possible arguments to those that appear in the lexical entry of that sense, as opposed of using the arguments that appear in all senses.

#### 4 On the Generalization of Role Sets

We first seek a basic reference of the comparative performance of the classifier on each role set. We devised two settings based on our dataset. In the first setting (‘SemEval’) we use all the available information provided in the corpus, including the verb senses in PropBank and VerbNet. This information was available both in the training and test, and was thus used as an additional feature by the classifier and to constrain further the possible arguments when searching for the most probable Viterbi path. We call this setting ‘SemEval’ because the SemEval-2007 competition (Pradhan et al., 2007) was performed using this configuration.

Being aware that, in a real scenario, the sense information will not be available, we devised the second setting (‘CoNLL’), where the hand-annotated verb sense information was discarded. This is the setting used in the CoNLL 2005 shared task (Carreras and Màrquez, 2005).

The results for the first setting are shown in the ‘SemEval setting’ rows of Table 1. The correct, excess, missed, precision, recall and  $F_1$  measures are reported, as customary. The significance intervals for  $F_1$  are also reported. They have been obtained with bootstrap resampling (Noreen, 1989).  $F_1$  scores outside of these intervals are assumed to be significantly different from the related  $F_1$  score ( $p < 0.05$ ). The results for PropBank are slightly better, which is reasonable, as the number of labels that the classifier has to learn in the case of VerbNet should make the task harder. In fact, given the small difference, one could think that VerbNet labels, being more numerous, are easier to learn, perhaps because they are more consistent across verbs.

In the second setting (‘CoNLL setting’ row in the same table) the PropBank classifier degrades slightly, but the difference is not statistically significant. On the contrary, the drop of 1.6 points for VerbNet is significant, and shows greater sensitivity to the absence of the sense information for verbs. One possible reason could be that the VerbNet classifier is more dependant on the argument filter (i.e., the 5th constraint in Section 3.2, which only allows roles that occur in the verbal frameset) used in the Viterbi search, and lacking the sense information makes the filter less useful. In fact, we have attested that the 5th constrain discard more than 60% of the possible candidates for VerbNet, making the task of the classifier easier.

In order to test this hypothesis, we run the CoNLL setting with the 5th constraint disabled (that is, allowing any argument). The results in the ‘CoNLL setting (no 5th)’ rows of Table 1 show that the drop for PropBank is negligible and not significant, while the drop for VerbNet is more important, and statistically significant.

Another view of the data is obtained if we compute the  $F_1$  scores for core arguments and adjuncts separately (last two columns in Table 1). The performance drop for PropBank in the first three rows is equally distributed on both core arguments and adjuncts. On the contrary, the drop for VerbNet roles is more acute in core arguments (3.7 points), while adjuncts with the 5th constraint disabled get results close to the SemEval setting. These results confirm that the information in the verbal frameset is more important in VerbNet than in PropBank, as only core arguments are constrained in the verbal framesets. The explanation could stem from the fact that current SRL systems rely more on syntactic information than pure semantic knowledge. While PropBank arguments Arg0–5 are easier to distinguish on syntactic grounds alone, it seems quite difficult to distinguish among roles like Theme and Topic unless we have access to the specific verbal frameset. This corresponds nicely with the performance drop for VerbNet when there is less information about the verb in the algorithm (i.e., sense or frameset).

We further analyzed the results by looking at each of the individual core arguments and adjuncts. Table 2 shows these results on the CoNLL setting. The performance for the most frequent roles is similar

PropBank								
Experiment	correct	excess	missed	precision	recall	F <sub>1</sub>	F <sub>1</sub> core	F <sub>1</sub> adj.
SemEval setting	6,022	1,378	1,722	81.38	77.76	79.53 ±0.9	82.25	72.48
CoNLL setting	5,977	1,424	1,767	80.76	77.18	78.93 ±0.9	81.64	71.90
CoNLL setting (no 5th)	5,972	1,434	1,772	80.64	77.12	78.84 ±0.9	81.49	71.50
No verbal features	5,557	1,828	2,187	75.25	71.76	73.46 ±1.0	74.87	70.11
Unseen verbs	267	89	106	75.00	71.58	73.25 ±4.0	76.21	64.92

VerbNet								
Experiment	correct	excess	missed	precision	recall	F <sub>1</sub>	F <sub>1</sub> core	F <sub>1</sub> adj.
SemEval setting	5,927	1,409	1,817	80.79	76.54	78.61 ±0.9	81.28	71.83
CoNLL setting	5,816	1,548	1,928	78.98	75.10	76.99 ±0.9	79.44	70.20
CoNLL setting (no 5th)	5,746	1,669	1,998	77.49	74.20	75.81 ±0.9	77.60	71.67
No verbal features	4,679	2,724	3,065	63.20	60.42	61.78 ±0.9	59.19	69.95
Unseen verbs	207	136	166	60.35	55.50	57.82 ±4.3	55.04	63.41

Table 1: Basic results using PropBank (top) and VerbNet (bottom) role sets on different settings.

for both. Arg0 gets 88.49, while Agent and Experiencer get 87.31 and 87.76 respectively. Arg2 gets 79.91, but there is more variation on Theme, Topic and Patient (which get 75.46, 85.70 and 78.64 respectively).

Finally, we grouped the results according to the frequency of the verbs in the training data. Table 3 shows that both PropBank and VerbNet get decreasing results for less frequent verbs. PropBank gets better results in all frequency ranges, except for the most frequent, which contains a single verb (*say*).

Overall, the results on this section point out at the weaknesses of the VerbNet role set regarding robustness and generalization. The next sections examine further its behavior.

#### 4.1 Generalization to Unseen Predicates

In principle, the PropBank core roles (Arg0–4) get a different interpretation depending of the verb, that is, the meaning of each of the roles is described separately for each verb in the PropBank framesets. Still, the annotation criteria used with PropBank tried to make the two main roles (Arg0 and Arg1, which account for most of the occurrences) consistent across verbs. On the contrary, in VerbNet all roles are completely independent of the verb, in the sense that the interpretation of the role does not vary across verbs. But, at the same time, each verbal entry lists the possible roles it accepts, and the combinations allowed.

This experiment tests the sensitivity of the two approaches when the SRL system encounters a verb which does not occur in the training data. In principle, we would expect the VerbNet semantic labels, which are more independent across verbs, to be

more robust at tagging new predicates. It is worth noting that this is a realistic scenario, even for the verb-specific PropBank labels. Predicates which do not occur in the training data, but do have a PropBank lexicon entry, could appear quite often in the text to be analyzed.

For this experiment, we artificially created a test set for unseen verbs. We chose 50 verbs at random, and split them into 40 verbs for training and 10 for testing (yielding 13,146 occurrences for training and 2,723 occurrences for testing; see Table 4).

The results obtained after training and testing the classifier are shown in the last rows in Table 1. Note that they are not directly comparable to the other results mentioned so far, as the train and test sets are smaller. Figures indicate that the performance of the PropBank argument classifier is considerably higher than the VerbNet classifier, with a  $\sim 15$  point gap.

This experiment shows that lacking any information about verbal head, the classifier has a hard time to distinguish among VerbNet roles. In order to confirm this, we performed the following experiment.

#### 4.2 Sensitivity to Verb-dependent Features

In this experiment we want to test the sensitivity of the role sets when the classifier does not have any information of the verb predicate. We removed from the training and testing data all the features which make any reference to the verb, including, among others: the surface form, lemma and POS of the verb, and all the combined features that include the verb form (please, refer to (Zapirain et al., 2007) for a complete description of the feature set).

The results are shown in the ‘No verbal features’

	CoNLL setting				No verb features

Test	<i>allow, approve, buy, find, improve, kill, produce, prove, report, rush</i>

Table 4: Verbs used in the *unseen verb* experiment

rows of Table 1. The performance drops more than 5 points in PropBank, but the drop for VerbNet is dramatic, with more than 15 points.

A closer look at the detailed role-by-role performances can be done if we compare the F<sub>1</sub> rows in the CoNLL setting and in the ‘no verb features’ setting in Table 2. Those results show that both Arg0 and Arg1 are quite robust to the lack of target verb information, while Arg2 and Arg3 get more affected. Given the relatively low number of Arg2 and Arg3 arguments, their performance drop does not affect so much the overall PropBank performance. In the case of VerbNet, the picture is very different. Focusing on the most frequent roles first, while the performance drop for Experiencer, Agent and Topic is of 1, 10 and 12 points respectively, the other roles get very heavy losses (e.g. Theme and Patient drop 23 and 50 points), and the rest of roles are barely found. It is worth noting that the adjunct labels get very similar performances in both PropBank and VerbNet cases. In fact, Table 1 in the last two rows shows very clearly that the performance drop is caused by the core arguments.

The better robustness of the PropBank roles can be explained by the fact that, when creating PropBank, the human PropBank annotators tried to be consistent when tagging Arg0 and Arg1 across verbs. We also think that both Arg0 and Arg1 can be detected quite well relying on unlexicalized syntactic features only, that is, not knowing which are the verbal and nominal heads. On the other hand, distinguishing between Arg2–4 is more dependant on the subcategorization frame of the verb, and thus more sensitive to the lack of verbal information.

In the case of VerbNet, the more fine-grained distinction among roles seems to depend more on the meaning of the predicate. For instance, distinguishing between Agent–Experiencer, or Theme–Topic–Patient. The lack of the verbal head makes it much more difficult to distinguish among those roles. The same phenomena can be observed among the roles not typically realized as Subject or Object such as Recipient, Source, Product, or Stimulus.

## 5 Mapping into VerbNet Thematic Roles

As mentioned in the introduction, the interpretation of PropBank roles depends on the verb, and that

Test on WSJ	all	core	adj.
PropBank to VerbNet (hand)	79.17 ±0.9	81.77	72.50
VerbNet (SemEval setting)	78.61 ±0.9	81.28	71.84
PropBank to VerbNet (MF)	77.15 ±0.9	79.09	71.90
VerbNet (CoNLL setting)	76.99 ±0.9	79.44	70.88
Test on Brown			
PropBank to VerbNet (MF)	64.79 ±1.0	68.93	55.94
VerbNet (CoNLL setting)	62.87 ±1.0	67.07	54.69

Table 5: Results on VerbNet roles using two different strategies. Topmost 4 rows for the usual test set (WSJ), and the 2 rows below for the Brown test set.

makes them less suitable for NLP applications. On the other hand, VerbNet roles have a direct interpretation. In this section, we test the performance of two different approaches to tag input sentences with VerbNet roles: (1) train on corpora tagged with VerbNet, and tag the input directly; (2) train on corpora tagged with PropBank, tag the input with PropBank roles, and use a PropBank to VerbNet mapping to output VerbNet roles.

The results for the first approach are already available (cf. Table 1). For the second approach, we just need to map PropBank roles into VerbNet roles using SemLink (Loper et al., 2007). We devised two experiments. In the first one we use the hand-annotated verb class in the test set. For each predicate we translate PropBank roles into VerbNet roles making use of the SemLink mapping information corresponding to that verb lemma and its verbal class.

For instance, consider an occurrence of *allow* in a test sentence. If the occurrence has been manually annotated with the VerbNet class 29.5, we can use the following entry in SemLink to add the VerbNet role Predicate to the argument labeled with Arg1, and Agent to the Arg0 argument.

```
<predicate lemma="allow">
  <argmap pb-roleset="allow.01" vn-class="29.5">
    <role pb-arg="1" vn-theta="Predicate" />
    <role pb-arg="0" vn-theta="Agent" />
  </argmap>
</predicate>
```

The results obtained using the hand-annotated VerbNet classes (and the SemEval setting for PropBank), are shown in the first row of Table 5. If we compare these results to those obtained by VerbNet in the SemEval setting (second row of Table 5), they are 0.5 points better, but the difference is not statistically significant.

experiment	corr.	F <sub>1</sub>
Grouped (CoNLL Setting)	5,951	78.11±0.9
PropBank to VerbNet to Grouped	5,970	78.21±0.9

Table 6: Results for VerbNet grouping experiments.

In a second experiment, we discarded the sense annotations from the dataset, and tried to predict the VerbNet class of the target verb using the most frequent class for the verb in the training data. Surprisingly, the accuracy of choosing the most frequent class is 97%. In the case of *allow* the most frequent class is 29.5, so we would use the same SemLink entry as above. The third row in Table 5 shows the results using the most frequent VerbNet class (and the CoNLL setting for PropBank). The performance drop compared to the use of the hand-annotated VerbNet class is of 2 points and statistically significant, and 0.2 points above the results obtained using VerbNet directly on the same conditions (fourth row of the same Table).

The last two rows in table 5 show the results when testing on the the Brown Corpus. In this case, the difference is larger, 1.9 points, and statistically significant in favor of the mapping approach. These results show that VerbNet roles are less robust to domain shifts. The performance drop when moving to an out-of-domain corpus is consistent with previously published results (Carreras and Màrquez, 2005).

## 5.1 Grouping experiments

VerbNet roles are more numerous than PropBank roles, and that, in itself, could cause a drop in performance. Motivated by the results in (Yi et al., 2007), we grouped the 23 VerbNet roles in 7 coarser role groups. Note that their groupings are focused on the roles which map to PropBank Arg2. In our case we are interested in a more general grouping which covers all VerbNet roles, so we added two additional groups (Agent-Experiencer and Theme-Topic-Patient). We re-tagged the roles in the datasets with those groups, and then trained and tested our SRL system on those grouped labels. The results are shown in the first row of Table 6. In order to judge if our groupings are easier to learn, we can see that the performance gain with respect to the ungrouped roles (fourth row of Table 5) is small (76.99

vs. 78.11) but significant. But if we compare them to the results of the PropBank to VerbNet mapping, where we simply substitute the fine-grained roles by their corresponding groups, we see that they still lag behind (second row in Table 6).

Although one could argue that better motivated groupings could be proposed, these results indicate that the larger number of VerbNet roles does not explain in itself the performance difference when compared to PropBank.

## 6 Related Work

As far as we know, there are only two other works performing comparisons of alternative role sets on a common test data. Gildea and Jurafsky (2002) mapped FrameNet frame elements into a set of *abstract thematic roles* (i.e., more general roles such as Agent, Theme, Location), and concluded that their system could use these thematic roles without degradation in performance.

(Yi et al., 2007) is a closely related work. They also compare PropBank and VerbNet role sets, but they focus on the performance of Arg2. They show that splitting Arg2 instances into subgroups based on VerbNet thematic roles improves the performance of the PropBank-based classifier. Their claim is that since VerbNet uses argument labels that are more consistent across verbs, they would provide more consistent training instances which would generalize better, especially to new verbs and genres. In fact they get small improvements in PropBank (WSJ) and a large improvement when testing on Brown.

An important remark is that Yi et al. use a combination of grouped VerbNet roles (for Arg2) and PropBank roles (for the rest of arguments). In contrast, our study compares both role sets as they stand, without modifications or mixing. Another difference is that they compare the systems based on the PropBank roles —by mapping the output VerbNet labels back to PropBank Arg2— while in our case we decided to do just the contrary (i.e., mapping PropBank output into VerbNet labels and compare there). As we already said, we think that VerbNet-based labels can be more useful for NLP applications, so our target is to have a SRL system that provides VerbNet annotations. While not in direct contradiction, both studies show different angles of the complex relation

between the two role sets.

## 7 Conclusion and Future work

In this paper we have presented a study of the performance of a state-of-the-art SRL system trained on two alternative codifications of roles (PropBank and VerbNet) and some particular settings, e.g., including/excluding verb-specific information in features, labeling of infrequent and unseen verb predicates, and domain shifts. We observed that PropBank labeling is more robust in all previous experimental conditions, showing less performance drops than VerbNet labels.

Assuming that application-based scenarios would prefer dealing with general thematic role labels, we explore the best way to label a text with VerbNet thematic roles, namely, by training directly on VerbNet roles or by using the PropBank SRL system and performing a posterior mapping into thematic roles. While results are similar and not statistically significant in the WSJ test set, when testing on the Brown out-of-domain test set the difference in favor of PropBank plus mapping step is statistically significant. We also tried to map the fine-grained VerbNet roles into coarser roles, but it did not yield better results than the mapping from PropBank roles. As a side-product, we show that a simple most frequent sense disambiguation strategy for verbs is sufficient to provide excellent results in the PropBank to VerbNet mapping.

Regarding future work, we would like to explore ways to improve the performance on VerbNet roles, perhaps using selectional preferences. We also want to work on the adaptation to new domains of both roles sets.

## Acknowledgements

We are grateful to Martha Palmer and Edward Loper for kindly providing us with the SemLink mappings. This work has been partially funded by the Basque Government (IT-397-07) and by the Ministry of Education (KNOW TIN2006-15049, OpenMT TIN2006-15307-C03-02). ## Abstract

This paper presents a translation model that is based on tree sequence alignment, where a tree sequence refers to a single sequence of sub-trees that covers a phrase. The model leverages on the strengths of both phrase-based and linguistically syntax-based method. It automatically learns aligned tree sequence pairs with mapping probabilities from word-aligned biparsed parallel texts. Compared with previous models, it not only captures non-syntactic phrases and discontinuous phrases with linguistically structured features, but also supports multi-level structure reordering of tree typology with larger span. This gives our model stronger expressive power than other reported models. Experimental results on the NIST MT-2005 Chinese-English translation task show that our method statistically significantly outperforms the baseline systems.

## 1 Introduction

Phrase-based modeling method (Koehn et al., 2003; Och and Ney, 2004a) is a simple, but powerful mechanism to machine translation since it can model local reorderings and translations of multi-word expressions well. However, it cannot handle long-distance reorderings properly and does not exploit discontinuous phrases and linguistically syntactic structure features (Quirk and Menezes, 2006). Recently, many syntax-based models have been proposed to address the above deficiencies (Wu, 1997; Chiang, 2005; Eisner, 2003; Ding and Palmer, 2005; Quirk et al, 2005; Cowan et al., 2006; Zhang et al., 2007; Bod, 2007; Yamada and Knight, 2001; Liu et al., 2006; Liu et al., 2007; Gildea, 2003; Poutsma, 2000; Hearne and Way,

2003). Although good progress has been reported, the fundamental issues in applying linguistic syntax to SMT, such as non-isomorphic tree alignment, structure reordering and non-syntactic phrase modeling, are still worth well studying.

In this paper, we propose a tree-to-tree translation model that is based on tree sequence alignment. It is designed to combine the strengths of phrase-based and syntax-based methods. The proposed model adopts tree sequence<sup>1</sup> as the basic translation unit and utilizes tree sequence alignments to model the translation process. Therefore, it not only describes non-syntactic phrases with syntactic structure information, but also supports multi-level tree structure reordering in larger span. These give our model much more expressive power and flexibility than those previous models. Experiment results on the NIST MT-2005 Chinese-English translation task show that our method significantly outperforms Moses (Koehn et al., 2007), a state-of-the-art phrase-based SMT system, and other linguistically syntax-based methods, such as SCFG-based and STSG-based methods (Zhang et al., 2007). In addition, our study further demonstrates that 1) structure reordering rules in our model are very useful for performance improvement while discontinuous phrase rules have less contribution and 2) tree sequence rules are able to model non-syntactic phrases with syntactic structure information, and thus contribute much to the performance improvement, but those rules consisting of more than three sub-trees have almost no contribution.

The rest of this paper is organized as follows: Section 2 reviews previous work. Section 3 elabo-

---

<sup>1</sup> A tree sequence refers to an ordered sub-tree sequence that covers a phrase or a consecutive tree fragment in a parse tree. It is the same as the concept “forest” used in Liu et al (2007).

rates the modelling process while Sections 4 and 5 discuss the training and decoding algorithms. The experimental results are reported in Section 6. Finally, we conclude our work in Section 7.

## 2 Related Work

Many techniques on linguistically syntax-based SMT have been proposed in literature. Yamada and Knight (2001) use noisy-channel model to transfer a target parse tree into a source sentence. Eisner (2003) studies how to learn non-isomorphic tree-to-tree/string mappings using a STSG. Ding and Palmer (2005) propose a syntax-based translation model based on a probabilistic synchronous dependency insertion grammar. Quirk et al. (2005) propose a dependency treelet-based translation model. Cowan et al. (2006) propose a feature-based discriminative model for target language syntactic structures prediction, given a source parse tree. Huang et al. (2006) study a TSG-based tree-to-string alignment model. Liu et al. (2006) propose a tree-to-string model. Zhang et al. (2007b) present a STSG-based tree-to-tree translation model. Bod (2007) reports that the unsupervised STSG-based translation model performs much better than the supervised one. The motivation behind all these work is to exploit linguistically syntactic structure features to model the translation process. However, most of them fail to utilize non-syntactic phrases well that are proven useful in the phrase-based methods (Koehn et al., 2003).

The formally syntax-based model for SMT was first advocated by Wu (1997). Xiong et al. (2006) propose a MaxEnt-based reordering model for BTG (Wu, 1997) while Setiawan et al. (2007) propose a function word-based reordering model for BTG. Chiang (2005)'s hierarchal phrase-based model achieves significant performance improvement. However, no further significant improvement is achieved when the model is made sensitive to syntactic structures by adding a constituent feature (Chiang, 2005).

In the last two years, many research efforts were devoted to integrating the strengths of phrase-based and syntax-based methods. In the following, we review four representatives of them.

1) Hassan et al. (2007) integrate supertags (a kind of lexicalized syntactic description) into the target side of translation model and language mod-

el under the phrase-based translation framework, resulting in good performance improvement. However, neither source side syntactic knowledge nor reordering model is further explored.

2) Galley et al. (2006) handle non-syntactic phrasal translations by traversing the tree upwards until a node that subsumes the phrase is reached. This solution requires larger applicability contexts (Marcu et al., 2006). However, phrases are utilized independently in the phrase-based method without depending on any contexts.

3) Addressing the issues in Galley et al. (2006), Marcu et al. (2006) create an xRS rule headed by a pseudo, non-syntactic non-terminal symbol that subsumes the phrase and its corresponding multi-headed syntactic structure; and one sibling xRS rule that explains how the pseudo symbol can be combined with other genuine non-terminals for acquiring the genuine parse trees. The name of the pseudo non-terminal is designed to reflect the full realization of the corresponding rule. The problem in this method is that it neglects alignment consistency in creating sibling rules and the naming mechanism faces challenges in describing more complicated phenomena (Liu et al., 2007).

4) Liu et al. (2006) treat all bilingual phrases as lexicalized tree-to-string rules, including those non-syntactic phrases in training corpus. Although the solution shows effective empirically, it only utilizes the source side syntactic phrases of the input parse tree during decoding. Furthermore, the translation probabilities of the bilingual phrases and other tree-to-string rules are not compatible since they are estimated independently, thus having different parameter spaces. To address the above problems, Liu et al. (2007) propose to use forest-to-string rules to enhance the expressive power of their tree-to-string model. As is inherent in a tree-to-string framework, Liu et al.'s method defines a kind of auxiliary rules to integrate forest-to-string rules into tree-to-string models. One problem of this method is that the auxiliary rules are not described by probabilities since they are constructed during decoding, rather than learned from the training corpus. So, to balance the usage of different kinds of rules, they use a very simple feature counting the number of auxiliary rules used in a derivation for penalizing the use of forest-to-string and auxiliary rules.

In this paper, an alternative solution is presented to combine the strengths of phrase-based and syn-

Figure 1: A word-aligned parse tree pairs of a Chinese sentence and its English translation

Figure 2: Two Examples of tree sequences

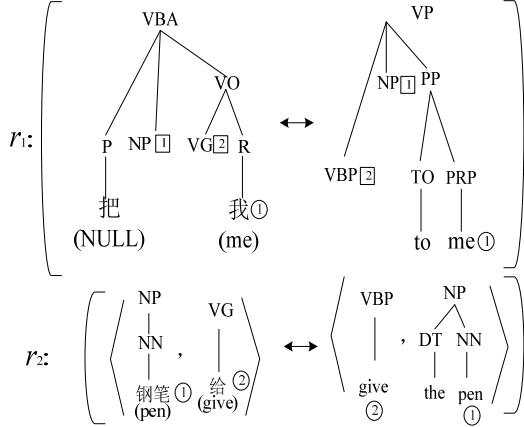

Figure 3: Two examples of translation rules

tax-based methods. Unlike previous work, our solution neither requires larger applicability contexts (Galley et al., 2006), nor depends on pseudo nodes (Marcu et al., 2006) or auxiliary rules (Liu et al., 2007). We go beyond the single sub-tree mapping model to propose a tree sequence alignment-based translation model. To the best of our knowledge, this is the first attempt to empirically explore the tree sequence alignment based model in SMT.

### 3 Tree Sequence Alignment Model

#### 3.1 Tree Sequence Translation Rule

The leaf nodes of a sub-tree in a tree sequence can be either non-terminal symbols (grammar tags) or terminal symbols (lexical words). Given a pair of source and target parse trees  $T(f_1^J)$  and  $T(e_1^I)$  in Fig. 1, Fig. 2 illustrates two examples of tree sequences derived from the two parse trees. A tree sequence translation rule  $r$  is a pair of aligned tree sequences  $r = \langle TS(f_1^{j_2}), TS(e_1^{i_2}), \tilde{A} \rangle$ , where:

- $TS(f_1^{j_2})$  is a source tree sequence, covering the span  $[j_1, j_2]$  in  $T(f_1^J)$ , and
- $TS(e_1^{i_2})$  is a target one, covering the span  $[i_1, i_2]$  in  $T(e_1^I)$ , and
- $\tilde{A}$  are the alignments between leaf nodes of two tree sequences, satisfying the following condition:  $\forall (i, j) \in \tilde{A}: i_1 \leq i \leq i_2 \leftrightarrow j_1 \leq j \leq j_2$ .

Fig. 3 shows two rules extracted from the tree pair shown in Fig. 1, where  $r_1$  is a tree-to-tree rule and  $r_2$  is a tree sequence-to-tree sequence rule. Obviously, tree sequence rules are more powerful than phrases or tree rules as they can capture all phrases (including both syntactic and non-syntactic phrases) with syntactic structure information and allow any tree node operations in a longer span. We expect that these properties can well address the issues of non-isomorphic structure alignments, structure reordering, non-syntactic phrases and discontinuous phrases translations.

#### 3.2 Tree Sequence Translation Model

Given the source and target sentences  $f_1^J$  and  $e_1^I$  and their parse trees  $T(f_1^J)$  and  $T(e_1^I)$ , the tree sequence-to-tree sequence translation model is formulated as:

$$\begin{aligned}
 Pr(e_1^I | f_1^J) &= \sum_{T(f_1^J), T(e_1^I)} Pr(e_1^I, T(e_1^I), T(f_1^J) | f_1^J) \\
 &= \sum_{T(f_1^J), T(e_1^I)} (Pr(T(f_1^J) | f_1^J) \\
 &\quad \cdot Pr(T(e_1^I) | T(f_1^J), f_1^J) \\
 &\quad \cdot Pr(e_1^I | T(e_1^I), T(f_1^J), f_1^J))
 \end{aligned} \tag{1}$$

In our implementation, we have:

- 1)  $Pr(T(f_1^J) | f_1^J) \equiv 1$  since we only use the best source and target parse tree pairs in training.
- 2)  $Pr(e_1^l | T(e_1^l), T(f_1^J), f_1^J) \equiv 1$  since we just output the leaf nodes of  $T(e_1^l)$  to generate  $e_1^l$  regardless of source side information.

Since  $T(f_1^J)$  contains the information of  $f_1^J$ , now we have:

$$\begin{aligned} Pr(e_1^l | f_1^J) &= Pr(T(e_1^l) | T(f_1^J), f_1^J) \\ &= Pr(T(e_1^l) | T(f_1^J)) \end{aligned} \quad (2)$$

By Eq. (2), translation becomes a tree structure mapping issue. We model it using our tree sequence-based translation rules. Given the source parse tree  $T(f_1^J)$ , there are multiple derivations that could lead to the same target tree  $T(e_1^l)$ , the mapping probability  $Pr(T(e_1^l) | T(f_1^J))$  is obtained by summing over the probabilities of all derivations. The probability of each derivation  $\theta$  is given as the product of the probabilities of all the rules  $p(r_i)$  used in the derivation (here we assume that a rule is applied *independently* in a derivation).

$$\begin{aligned} Pr(e_1^l | f_1^J) &= Pr(T(e_1^l) | T(f_1^J)) \\ &= \sum_{\theta} \prod_{r_i \in \theta} p(r_i : \langle TS(e_1^l), TS(f_1^J), \tilde{A} \rangle) \end{aligned} \quad (3)$$

Eq. (3) formulates the tree sequence alignment-based translation model. Figs. 1 and 3 show how the proposed model works. First, the source sentence is parsed into a source parse tree. Next, the source parse tree is detached into two source tree sequences (the left hand side of rules in Fig. 3). Then the two rules in Fig. 3 are used to map the two source tree sequences to two target tree sequences, which are then combined to generate a target parse tree. Finally, a target translation is yielded from the target tree.

Our model is implemented under log-linear framework (Och and Ney, 2002). We use seven basic features that are analogous to the commonly used features in phrase-based systems (Koehn, 2004): 1) bidirectional rule mapping probabilities; 2) bidirectional lexical rule translation probabilities; 3) the target language model; 4) the number of rules used and 5) the number of target words. In addition, we define two new features: 1) the number of lexical words in a rule to control the model's preference for lexicalized rules over un-lexicalized

rules and 2) the average tree depth in a rule to balance the usage of hierarchical rules and flat rules. Note that we do not distinguish between larger (taller) and shorter source side tree sequences, i.e. we let these rules compete directly with each other.

#### 4 Rule Extraction

Rules are extracted from word-aligned, bi-parsed sentence pairs  $\langle T(f_1^J), T(e_1^l), A \rangle$ , which are classified into two categories:

- **initial rule**, if all leaf nodes of the rule are terminals (i.e. lexical word), and
- **abstract rule**, otherwise, i.e. at least one leaf node is a non-terminal (POS or phrase tag).

Given an *initial rule*  $\langle TS(f_{j_1}^{j_2}), TS(e_{i_1}^{i_2}), \tilde{A} \rangle$ , its *sub initial rule* is defined as a triple  $\langle TS(f_{j_3}^{j_4}), TS(e_{i_3}^{i_4}), \hat{A} \rangle$  if and only if:

- $\langle TS(f_{j_3}^{j_4}), TS(e_{i_3}^{i_4}), \hat{A} \rangle$  is an *initial rule*.
- $\forall (i, j) \in \tilde{A} : i_3 \leq i \leq i_4 \leftrightarrow j_3 \leq j \leq j_4$ , i.e.  $\hat{A} \subseteq \tilde{A}$
- $TS(f_{j_3}^{j_4})$  is a sub-graph of  $TS(f_{j_1}^{j_2})$  while  $TS(e_{i_3}^{i_4})$  is a sub-graph of  $TS(e_{i_1}^{i_2})$ .

Rules are extracted in two steps:

- 1) Extracting *initial rules* first.
- 2) Extracting *abstract rules* from extracted *initial rules* with the help of *sub initial rules*.

It is straightforward to extract *initial rules*. We first generate all fully lexicalized source and target tree sequences using a dynamic programming algorithm and then iterate over all generated source and target tree sequence pairs  $\langle TS(f_{j_1}^{j_2}), TS(e_{i_1}^{i_2}) \rangle$ . If the condition " $\forall (i, j) \in A : i_1 \leq i \leq i_2 \leftrightarrow j_1 \leq j \leq j_2$ " is satisfied, the triple  $\langle TS(f_{j_1}^{j_2}), TS(e_{i_1}^{i_2}), \tilde{A} \rangle$  is an *initial rule*, where  $\tilde{A}$  are alignments between leaf nodes of  $TS(f_{j_1}^{j_2})$  and  $TS(e_{i_1}^{i_2})$ . We then derive *abstract rules* from *initial rules* by removing one or more of its *sub initial rules*. The *abstract rule* extraction algorithm presented next is implemented using dynamic programming. Due to space limitation, we skip the details here. In order to control the number of rules, we set three constraints for both finally extracted initial and abstract rules:

- 1) The depth of a tree in a rule is not greater

than  $h$ .

- 2) The number of non-terminals as leaf nodes is not greater than  $c$ .
- 3) The tree number in a rule is not greater than  $d$ .

In addition, we limit *initial rules* to have at most seven lexical words as leaf nodes on either side. However, in order to extract long-distance reordering rules, we also generate those *initial rules* with more than seven lexical words for *abstract rules* extraction only (not used in decoding). This makes our *abstract rules* more powerful in handling global structure reordering. Moreover, by configuring these parameters we can implement other translation models easily: 1) STSG-based model when  $d = 1$ ; 2) SCFG-based model when  $d = 1$  and  $h = 2$ ; 3) phrase-based translation model only (no reordering model) when  $c = 0$  and  $h = 1$ .

---

#### Algorithm 1: *abstract rules* extraction

---

**Input:** *initial rule* set  $r_{ini}$

**Output:** *abstract rule* set  $r_{abs}$

---

- 1: **for each**  $r_i \in r_{ini}$ , **do**
  - 2:   put all *sub initial rules* of  $r_i$  into a set  $r_i^{subini}$
  - 3:   **for each** subset  $\Theta \subseteq r_i^{subini}$  **do**
  - 4:     **if** there are spans overlapping between any two rules in the subset  $\Theta$  **then**
  - 5:       **continue** //go to line 3
  - 6:     **end if**
  - 7:     generate an abstract rule by removing the portions covered by  $\Theta$  from  $r_i$  and co-indexing the pairs of non-terminals that rooting the removed source and target parts
  - 8:     add them into the *abstract rule* set  $r_{abs}$
  - 9:   **end do**
  - 10: **end do**
- 

## 5 Decoding

Given  $T(f_1^J)$ , the decoder is to find the best derivation  $\theta$  that generates  $\langle T(f_1^J), T(e_1^I) \rangle$ .

$$\begin{aligned} \hat{e} &= \arg \max_{e_1^I} Pr(T(e_1^I) | T(f_1^J)) \\ &\approx \arg \max_{e_1^I, \theta} \prod_{r_i \in \theta} p(r_i) \end{aligned} \quad (4)$$

---

#### Algorithm 2: *Tree Sequence-based Decoder*

---

**Input:**  $T(f_1^J)$

**Output:**  $T(e_1^I)$

---

**Data structures:**

$h[J_1, J_2]$  To store translations to a span  $[J_1, J_2]$

- 1: **for**  $s = 0$  to  $J - 1$  **do** //  $s$ : span length
  - 2:   **for**  $j_1 = 1$  to  $J - s$ ,  $j_2 = j_1 + s$  **do**
  - 3:     **for each** rule  $r$  spanning  $[j_1, j_2]$  **do**
  - 4:       **if**  $r$  is an *initial rule* **then**
  - 5:         insert  $r$  into  $h[J_1, J_2]$
  - 6:       **else**
  - 7:         generate new translations from  $r$  by replacing non-terminal leaf nodes of  $r$  with their corresponding spans' translations that are already translated in previous steps
  - 8:         insert them into  $h[j_1, j_2]$
  - 9:       **end if**
  - 10:     **end for**
  - 11:   **end for**
  - 12: **end for**
  - 13: output the hypothesis with the highest score in  $h[1, J]$  as the final best translation
- 

The decoder is a span-based beam search together with a function for mapping the source derivations to the target ones. Algorithm 2 illustrates the decoding algorithm. It translates each span iteratively from small one to large one (lines 1-2). This strategy can guarantee that when translating the current span, all spans smaller than the current one have already been translated before if they are translatable (line 7). When translating a span, if the usable rule is an *initial rule*, then the tree sequence on the target side of the rule is a candidate translation (lines 4-5). Otherwise, we replace the non-terminal leaf nodes of the current *abstract rule* with their corresponding spans' translations that are already translated in previous steps (line 7). To speed up the decoder, we use several thresholds to limit search beams for each span:

- 1)  $\alpha$ , the maximal number of rules used
- 2)  $\beta$ , the minimal log probability of rules
- 3)  $\gamma$ , the maximal number of translations yield

It is worth noting that the decoder does not force a complete target parse tree to be generated. If no rules can be used to generate a complete target parse tree, the decoder just outputs whatever have

been translated so far monotonically as one hypothesis.

## 6 Experiments

### 6.1 Experimental Settings

We conducted Chinese-to-English translation experiments. We trained the translation model on the FBIS corpus (7.2M+9.2M words) and trained a 4-gram language model on the Xinhua portion of the English Gigaword corpus (181M words) using the SRILM Toolkits (Stolcke, 2002) with modified Kneser-Ney smoothing. We used sentences with less than 50 characters from the NIST MT-2002 test set as our development set and the NIST MT-2005 test set as our test set. We used the Stanford parser (Klein and Manning, 2003) to parse bilingual sentences on the training set and Chinese sentences on the development and test sets. The evaluation metric is case-sensitive BLEU-4 (Papineni et al., 2002). We used GIZA++ (Och and Ney, 2004) and the heuristics “grow-diag-final” to generate *m-to-n* word alignments. For the MER training (Och, 2003), we modified Koehn’s MER trainer (Koehn, 2004) for our tree sequence-based system. For significance test, we used Zhang et al’s implementation (Zhang et al, 2004).

We set three baseline systems: Moses (Koehn et al., 2007), and SCFG-based and STSG-based tree-to-tree translation models (Zhang et al., 2007). For Moses, we used its default settings. For the SCFG/STSG and our proposed model, we used the same settings except for the parameters  $d$  and  $h$  ( $d=1$  and  $h=2$  for the SCFG;  $d=1$  and  $h=6$  for the STSG;  $d=4$  and  $h=6$  for our model). We optimized these parameters on the training and development sets:  $c=3$ ,  $\alpha=20$ ,  $\beta=-100$  and  $\gamma=100$ .

### 6.2 Experimental Results

We carried out a number of experiments to examine the proposed tree sequence alignment-based translation model. In this subsection, we first report the rule distributions and compare our model with the three baseline systems. Then we study the model’s expressive ability by comparing the contributions made by different kinds of rules, including *strict* tree sequence rules, non-syntactic phrase rules, structure reordering rules and discontinuous

phrase rules<sup>2</sup>. Finally, we investigate the impact of maximal sub-tree number and sub-tree depth in our model. All of the following discussions are held on the training and test data.

Rule	Initial Rules		Abstract Rules	
	L	P	U	Total
<b>BP</b>	322,965	0	0	322,965
<b>TR</b>	443,010	144,459	24,871	612,340
<b>TSR</b>	225,570	103,932	714	330,216

Table 1: # of rules used in the testing ( $d=4$ ,  $h=6$ ) (**BP**: bilingual phrase (used in Moses), **TR**: tree rule (only 1 tree), **TSR**: tree sequence rule (> 1 tree), **L**: fully lexicalized, **P**: partially lexicalized, **U**: unlexicalized)

Table 1 reports the statistics of rules used in the experiments. It shows that:

1) We verify that the **BPs** are fully covered by the *initial rules* (i.e. lexicalized rules), in which the lexicalized **TSRs** model all non-syntactic phrase pairs with rich syntactic information. In addition, we find that the number of *initial rules* is greater than that of bilingual phrases. This is because one bilingual phrase can be covered by more than one *initial rule* which having different sub-tree structures.

2) *Abstract rules* generalize *initial rules* to unseen data and with structure reordering ability. The number of the *abstract rule* is far less than that of the *initial rules*. This is because leaf nodes of an *abstract rule* can be non-terminals that can represent any sub-trees using the non-terminals as roots.

Fig. 4 compares the performance of different models. It illustrates that:

1) Our tree sequence-based model significantly outperforms ( $p < 0.01$ ) previous phrase-based and linguistically syntax-based methods. This empirical-ly verifies the effect of the proposed method.

2) Both our method and STSG outperform Moses significantly. Our method also clearly outperforms STSG. These results suggest that:

- The linguistically motivated structure features are very useful for SMT, which can be cap-

<sup>2</sup> To be precise, we examine the contributions of *strict* tree sequence rules and single tree rules separately in this section. Therefore, unless specified, the term “tree sequence rules” used in this section only refers to the *strict* tree sequence rules, which must contain at least two sub-trees on the source side.

tured by the two syntax-based models through tree node operations.

- Our model is much more effective in utilizing linguistic structures than STSG since it uses tree sequence as basic translation unit. This allows our model not only to handle structure reordering by tree node operations in a larger span, but also to capture non-syntactic phrases, which circumvents previous syntactic constraints, thus giving our model more expressive power.

3) The linguistically motivated SCFG shows much lower performance. This is largely because SCFG only allows sibling nodes reordering and fails to utilize both non-syntactic phrases and those syntactic phrases that cannot be covered by a single CFG rule. It thereby suggests that SCFG is less effective in modelling parse tree structure transfer between Chinese and English when using Penn Treebank style linguistic grammar and under word-alignment constraints. However, formal SCFG show much better performance in the formally syntax-based translation framework (Chiang, 2005). This is because the formal syntax is learned from phrases directly without relying on any linguistic theory (Chiang, 2005). As a result, it is more robust to the issue of non-syntactic phrase usage and non-isomorphic structure alignment.

Figure 4: Performance comparison of different methods

Rule Type	TR (STSG)	TR +TSR_L	TR+TSR_L +TSR_P	TR +TSR
BLEU(%)	24.71	25.72	25.93	26.07

Table 2: Contributions of **TSRs** (see Table 1 for the definitions of the abbreviations used in this table)

Table 2 measures the contributions of different kinds of tree sequence rules. It suggests that:

1) All the three kinds of **TSRs** contribute to the performance improvement and their combination

further improves the performance. It suggests that they are complementary to each other since the lexicalized **TSRs** are used to model non-syntactic phrases while the other two kinds of **TSRs** can generalize the lexicalized rules to unseen phrases.

2) The lexicalized **TSRs** make the major contribution since they can capture non-syntactic phrases with syntactic structure features.

Rule Type	BLEU (%)
<b>TR+TSR</b>	26.07
( <b>TR+TSR</b> ) w/o <b>SRR</b>	24.62
( <b>TR+TSR</b> ) w/o <b>DPR</b>	25.78

Table 3: Effect of **Structure Reordering Rules (SRR)**: refers to the structure reordering rules that have at least two non-terminal leaf nodes with inverted order in the source and target sides, which are usually not captured by phrase-based models. Note that the reordering between lexical words and non-terminal leaf nodes is not considered here) and **Discontinuous Phrase Rules (DPR)**: refers to these rules having at least one non-terminal leaf node between two lexicalized leaf nodes) in our tree sequence-based model ( $d = 4$  and  $h = 6$ )

Rule Type	# of rules	# of rules overlapped (Intersection)
SRR	68,217	18,379 (26.9%)
DPR	57,244	18,379 (32.1%)

Table 4: numbers of SRR and DPR rules

Table 3 shows the contributions of SRR and DPR. It clearly indicates that SRRs are very effective in reordering structures, which improve performance by 1.45 (26.07-24.62) BLEU score. However, DPRs have less impact on performance in our tree sequence-based model. This seems in contradiction to the previous observations<sup>3</sup> in literature. However, it is not surprising simply because we use tree sequences as the basic translation units. Thereby, our model can capture all phrases. In this sense, our model behaves like a phrase-based model, less sensitive to discontinuous phras-

<sup>3</sup> Wellington et al. (2006) reports that discontinuities are very useful for translational equivalence analysis using binary-branching structures under word alignment and parse tree constraints while they are almost of no use if under word alignment constraints only. Bod (2007) finds that discontinuous phrase rules make significant performance improvement in linguistically STSG-based SMT models.

es (Wellington et al., 2006). Our additional experiments also verify that discontinuous phrase rules are complementary to syntactic phrase rules (Bod, 2007) while non-syntactic phrase rules may compromise the contribution of discontinuous phrase rules. Table 4 reports the numbers of these two kinds of rules. It shows that around 30% rules are shared by the two kinds of rule sets. These overlapped rules contain at least two non-terminal leaf nodes plus two terminal leaf nodes, which implies that longer rules do not affect performance too much.

Figure 5: Accuracy changing with different maximal tree depths ( $h = 1$  to  $6$  when  $d = 4$ )

Figure 6: Accuracy changing with the different maximal number of trees in a tree sequence ( $d = 1$  to  $5$ ), the upper line is for  $h = 6$  while the lower line is for  $h = 2$ .

Fig. 5 studies the impact when setting different maximal tree depth ( $h$ ) in a rule on the performance. It demonstrates that:

1) Significant performance improvement is achieved when the value of  $h$  is increased from 1 to 2. This can be easily explained by the fact that when  $h = 1$ , only monotonic search is conducted, while  $h = 2$  allows non-terminals to be leaf nodes, thus introducing preliminary structure features to the search and allowing non-monotonic search.

2) Internal structures and large span (due to  $h$  increasing) are also useful as attested by the gain

of 0.86 (26.14-25.28) Blue score when the value of  $h$  increases from 2 to 4.

Fig. 6 studies the impact on performance by setting different maximal tree number ( $d$ ) in a rule. It further indicates that:

1) Tree sequence rules ( $d > 1$ ) are useful and even more helpful if we limit the tree depth to no more than two (lower line,  $h=2$ ). However, tree sequence rules consisting of more than three sub-trees have almost no contribution to the performance improvement. This is mainly due to data sparseness issue when  $d > 3$ .

2) Even if only two-layer sub-trees (lower line) are allowed, our method still outperforms STSG and Moses when  $d > 1$ . This further validates the effectiveness of our design philosophy of using multi-sub-trees as basic translation unit in SMT.

## 7 Conclusions and Future Work

In this paper, we present a tree sequence alignment-based translation model to combine the strengths of phrase-based and syntax-based methods. The experimental results on the NIST MT-2005 Chinese-English translation task demonstrate the effectiveness of the proposed model. Our study also finds that in our model the tree sequence rules are very useful since they can model non-syntactic phrases and reorderings with rich linguistic structure features while discontinuous phrases and tree sequence rules with more than three sub-trees have less impact on performance.

There are many interesting research topics on the tree sequence-based translation model worth exploring in the future. The current method extracts large amount of rules. Many of them are redundant, which make decoding very slow. Thus, effective rule optimization and pruning algorithms are highly desirable. Ideally, a linguistically and empirically motivated theory can be worked out, suggesting what kinds of rules should be extracted given an input phrase pair. For example, most function words and headwords can be kept in *abstract rules* as features. In addition, word alignment is a hard constraint in our rule extraction. We will study direct structure alignments to reduce the impact of word alignment errors. We are also interested in comparing our method with the forest-to-string model (Liu et al., 2007). Finally, we would also like to study unsupervised learning-based bilingual parsing for SMT.

## Abstract

We present the first English syllabification system to improve the accuracy of letter-to-phoneme conversion. We propose a novel discriminative approach to automatic syllabification based on structured SVMs. In comparison with a state-of-the-art syllabification system, we reduce the syllabification word error rate for English by 33%. Our approach also performs well on other languages, comparing favorably with published results on German and Dutch.

## 1 Introduction

Pronouncing an unfamiliar word is a task that is often accomplished by breaking the word down into smaller components. Even small children learning to read are taught to pronounce a word by “sounding out” its parts. Thus, it is not surprising that Letter-to-Phoneme (L2P) systems, which convert orthographic forms of words into sequences of phonemes, can benefit from subdividing the input word into smaller parts, such as syllables or morphemes. Marchand and Damer (2007) report that incorporating oracle syllable boundary information improves the accuracy of their L2P system, but they fail to emulate that result with any of their automatic syllabification methods. Demberg et al. (2007), on the other hand, find that morphological segmentation boosts L2P performance in German, but not in English. To our knowledge, no previous English orthographic syllabification system has been able to actually improve performance on the larger L2P problem.

In this paper, we focus on the task of automatic orthographic syllabification, with the explicit goal

of improving L2P accuracy. A syllable is a subdivision of a word, typically consisting of a vowel, called the nucleus, and the consonants preceding and following the vowel, called the onset and the coda, respectively. Although in the strict linguistic sense syllables are phonological rather than orthographic entities, our L2P objective constrains the input to orthographic forms. Syllabification of phonemic representation is in fact an easier task, which we plan to address in a separate publication.

Orthographic syllabification is sometimes referred to as *hyphenation*. Many dictionaries provide hyphenation information for orthographic word forms. These hyphenation schemes are related to, and influenced by, phonemic syllabification. They serve two purposes: to indicate where words may be broken for end-of-line divisions, and to assist the dictionary reader with correct pronunciation (Gove, 1993). Although these purposes are not always consistent with our objective, we show that we can improve L2P conversion by taking advantage of the available hyphenation data. In addition, automatic hyphenation is a legitimate task by itself, which could be utilized in word editors or in synthesizing new trade names from several concepts.

We present a discriminative approach to orthographic syllabification. We formulate syllabification as a tagging problem, and learn a discriminative tagger from labeled data using a structured support vector machine (SVM) (Tsochantaridis et al., 2004). With this approach, we reduce the error rate for English by 33%, relative to the best existing system. Moreover, we are also able to improve a state-of-the-art L2P system by incorporating our syllabification models. Our method is not language specific; when applied to German and Dutch, our performance is

comparable with the best existing systems in those languages, even though our system has been developed and tuned on English only.

The paper is structured as follows. After discussing previous computational approaches to the problem (Section 2), we introduce structured SVMs (Section 3), and outline how we apply them to orthographic syllabification (Section 4). We present our experiments and results for the syllabification task in Section 5. In Section 6, we apply our syllabification models to the L2P task. Section 7 concludes.

## 2 Related Work

Automatic preprocessing of words is desirable because the productive nature of language ensures that no finite lexicon will contain all words. Marchand et al. (2007) show that rule-based methods are relatively ineffective for orthographic syllabification in English. On the other hand, few data-driven syllabification systems currently exist.

Demberg (2006) uses a fourth-order Hidden Markov Model to tackle orthographic syllabification in German. When added to her L2P system, Demberg’s orthographic syllabification model effects a one percent absolute improvement in L2P word accuracy.

Bouma (2002) explores syllabification in Dutch. He begins with finite state transducers, which essentially implement a general preference for onsets. Subsequently, he uses transformation-based learning to automatically extract rules that improve his system. Bouma’s best system, trained on some 250K examples, achieves 98.17% word accuracy. Daelemans and van den Bosch (1992) implement a back-propagation network for Dutch orthography, but find it is outperformed by less complex look-up table approaches.

Marchand and Damper (2007) investigate the impact of syllabification on the L2P problem in English. Their Syllabification by Analogy (SbA) algorithm is a data-driven, lazy learning approach. For each input word, SbA finds the most similar substrings in a lexicon of syllabified words and then applies these dictionary syllabifications to the input word. Marchand and Damper report 78.1% word accuracy on the NETtalk dataset, which is not good enough to improve their L2P system.

Chen (2003) uses an n-gram model and Viterbi decoder as a syllabifier, and then applies it as a pre-processing step in his maximum-entropy-based English L2P system. He finds that the syllabification pre-processing produces no gains over his baseline system.

Marchand et al. (2007) conduct a more systematic study of existing syllabification approaches. They examine syllabification in both the pronunciation and orthographic domains, comparing their own SbA algorithm with several instance-based learning approaches (Daelemans et al., 1997; van den Bosch, 1997) and rule-based implementations. They find that SbA universally outperforms these other approaches by quite a wide margin.

Syllabification of phonemes, rather than letters, has also been investigated (Müller, 2001; Pearson et al., 2000; Schmid et al., 2007). In this paper, our focus is on orthographic forms. However, as with our approach, some previous work in the phonetic domain has formulated syllabification as a tagging problem.

## 3 Structured SVMs

A structured support vector machine (SVM) is a large-margin training method that can learn to predict structured outputs, such as tag sequences or parse trees, instead of performing binary classification (Tsochantaridis et al., 2004). We employ a structured SVM that predicts tag sequences, called an SVM Hidden Markov Model, or SVM-HMM. This approach can be considered an HMM because the Viterbi algorithm is used to find the highest scoring tag sequence for a given observation sequence. The scoring model employs a Markov assumption: each tag’s score is modified only by the tag that came before it. This approach can be considered an SVM because the model parameters are trained discriminatively to separate correct tag sequences from incorrect ones by as large a margin as possible. In contrast to generative HMMs, the learning process requires labeled training data.

There are a number of good reasons to apply the structured SVM formalism to this problem. We get the benefit of discriminative training, not available in a generative HMM. Furthermore, we can use an arbitrary feature representation that does not require

any conditional independence assumptions. Unlike a traditional SVM, the structured SVM considers complete tag sequences during training, instead of breaking each sequence into a number of training instances.

Training a structured SVM can be viewed as a multi-class classification problem. Each training instance  $x_i$  is labeled with a correct tag sequence  $y_i$  drawn from a set of possible tag sequences  $Y_i$ . As is typical of discriminative approaches, we create a feature vector  $\Psi(x, y)$  to represent a candidate  $y$  and its relationship to the input  $x$ . The learner’s task is to weight the features using a vector  $w$  so that the correct tag sequence receives more weight than the competing, incorrect sequences:

$$\forall_i \forall_{y \in Y_i, y \neq y_i} [\Psi(x_i, y_i) \cdot w > \Psi(x_i, y) \cdot w] \quad (1)$$

Given a trained weight vector  $w$ , the SVM tags new instances  $x_i$  according to:

$$\operatorname{argmax}_{y \in Y_i} [\Psi(x_i, y) \cdot w] \quad (2)$$

A structured SVM finds a  $w$  that satisfies Equation 1, and separates the correct taggings by as large a margin as possible. The  $\operatorname{argmax}$  in Equation 2 is conducted using the Viterbi algorithm.

Equation 1 is a simplification. In practice, a structured distance term is added to the inequality in Equation 1 so that the required margin is larger for tag sequences that diverge further from the correct sequence. Also, slack variables are employed to allow a trade-off between training accuracy and the complexity of  $w$ , via a tunable cost parameter.

For most structured problems, the set of negative sequences in  $Y_i$  is exponential in the length of  $x_i$ , and the constraints in Equation 1 cannot be explicitly enumerated. The structured SVM solves this problem with an iterative online approach:

1. Collect the most damaging incorrect sequence  $y$  according to the current  $w$ .
2. Add  $y$  to a growing set  $\bar{Y}_i$  of incorrect sequences.
3. Find a  $w$  that satisfies Equation 1, using the partial  $\bar{Y}_i$  sets in place of  $Y_i$ .
4. Go to next training example, loop to step 1.

This iterative process is explained in far more detail in (Tsochantaridis et al., 2004).

## 4 Syllabification with Structured SVMs

In this paper we apply structured SVMs to the syllabification problem. Specifically, we formulate syllabification as a tagging problem and apply the SVM-HMM software package<sup>1</sup> (Altun et al., 2003). We use a linear kernel, and tune the SVM’s cost parameter on a development set. The feature representation  $\Psi$  consists of emission features, which pair an aspect of  $x$  with a single tag from  $y$ , and transition features, which count tag pairs occurring in  $y$ . With SVM-HMM, the crux of the task is to create a tag scheme and feature set that produce good results. In this section, we discuss several different approaches to tagging for the syllabification task. Subsequently, we outline our emission feature representation. While developing our tagging schemes and feature representation, we used a development set of 5K words held out from our CELEX training data. All results reported in this section are on that set.

### 4.1 Annotation Methods

We have employed two different approaches to tagging in this research. **Positional tags** capture where a letter occurs within a syllable; **Structural tags** express the role each letter is playing within the syllable.

#### Positional Tags

The **NB tag** scheme simply labels every letter as either being at a syllable boundary (B), or not (N). Thus, the word *im-mor-al-ly* is tagged  $\langle N B N N B N B N N \rangle$ , indicating a syllable boundary after each *B* tag. This binary classification approach to tagging is implicit in several previous implementations (Daelemans and van den Bosch, 1992; Bouma, 2002), and has been done explicitly in both the orthographic (Demberg, 2006) and phoneme domains (van den Bosch, 1997).

A weakness of NB tags is that they encode no knowledge about the length of a syllable. Intuitively, we expect the length of a syllable to be valuable information — most syllables in English contain fewer than four characters. We introduce a tagging scheme that sequentially numbers the *N* tags to impart information about syllable length. Under the **Numbered**

<sup>1</sup>[http://svmlight.joachims.org/svm\\_struct.html](http://svmlight.joachims.org/svm_struct.html)

**NB tag** scheme, *im-mor-al-ly* is annotated as  $\langle N1 B N1 N2 B N1 B N1 N2 \rangle$ . With this tag set, we have effectively introduced a bias in favor of shorter syllables: tags like *N6*, *N7*... are comparatively rare, so the learner will postulate them only when the evidence is particularly compelling.

### Structural Tags

Numbered NB tags are more informative than standard NB tags. However, neither annotation system can represent the internal structure of the syllable. This has advantages: tags can be automatically generated from a list of syllabified words without even a passing familiarity with the language. However, a more informative annotation, tied to phonotactics, ought to improve accuracy. Krenn (1997) proposes the **ONC tag** scheme, in which phonemes of a syllable are tagged as an onset, nucleus, or coda. Given these ONC tags, syllable boundaries can easily be generated by applying simple regular expressions.

Unfortunately, it is not as straightforward to generate ONC-tagged training data in the orthographic domain, even with syllabified training data. Silent letters are problematic, and some letters can behave differently depending on their context (in English, consonants such as *m*, *y*, and *l* can act as vowels in certain situations). Thus, it is difficult to generate ONC tags for orthographic forms without at least a cursory knowledge of the language and its principles.

For English, tagging the syllabified training set with ONC tags is performed by the following simple algorithm. In the first stage, all letters from the set  $\{a, e, i, o, u\}$  are marked as vowels, while the remaining letters are marked as consonants. Next, we examine all the instances of the letter *y*. If a *y* is both preceded and followed by a consonant, we mark that instance as a vowel rather than a consonant. In the second stage, the first group of consecutive vowels in each syllable is tagged as nucleus. All letters preceding the nucleus are then tagged as onset, while all letters following the nucleus are tagged as coda.

Our development set experiments suggested that numbering ONC tags increases their performance. Under the **Numbered ONC tag** scheme, the single-syllable word *stealth* is labeled  $\langle O1 O2 N1 N2 C1 C2 C3 \rangle$ .

A disadvantage of Numbered ONC tags is that, unlike positional tags, they do not represent syllable breaks explicitly. Within the ONC framework, we need the conjunction of two tags (such as an *N1* tag followed by an *O1* tag) to represent the division between syllables. This drawback can be overcome by combining ONC tags and NB tags in a hybrid **Break ONC tag** scheme. Using Break ONC tags, the word *lev-i-ty* is annotated as  $\langle O N C B N B O N \rangle$ . The  $\langle NB \rangle$  tag indicates a letter is both part of the nucleus and before a syllable break, while the  $\langle N \rangle$  tag represents a letter that is part of a nucleus but in the middle of a syllable. In this way, we get the best of both worlds: tags that encapsulate information about syllable structure, while also representing syllable breaks explicitly with a single tag.

### 4.2 Emission Features

SVM-HMM predicts a tag for each letter in a word, so emission features use aspects of the input to help predict the correct tag for a specific letter. Consider the tag for the letter *o* in the word *immorally*. With a traditional HMM, we consider only that it is an *o* being emitted, and assess potential tags based on that single letter. The SVM framework is less restrictive: we can include *o* as an emission feature, but we can also include features indicating that the preceding and following letters are *m* and *r* respectively. In fact, there is no reason to confine ourselves to only one character on either side of the focus letter.

After experimenting with the development set, we decided to include in our feature set a window of eleven characters around the focus character, five on either side. Figure 1 shows that performance gains level off at this point. Special beginning- and end-of-word characters are appended to words so that every letter has five characters before and after. We also experimented with asymmetric context windows, representing more characters after the focus letter than before, but we found that symmetric context windows perform better.

Because our learner is effectively a linear classifier, we need to explicitly represent any important conjunctions of features. For example, the bigram *bl* frequently occurs within a single English syllable, while the bigram *lb* generally straddles two syllables. Similarly, a fourgram like *tion* very often

Figure 1: Word accuracy as a function of the window size around the focus character, using unigram features on the development set.

forms a syllable in and of itself. Thus, in addition to the single-letter features outlined above, we also include in our representation any bigrams, trigrams, four-grams, and five-grams that fit inside our context window. As is apparent from Figure 2, we see a substantial improvement by adding bigrams to our feature set. Higher-order n-grams produce increasingly smaller gains.

Figure 2: Word accuracy as a function of maximum n-gram size on the development set.

In addition to these primary n-gram features, we experimented with linguistically-derived features. Intuitively, basic linguistic knowledge, such as whether a letter is a consonant or a vowel, should be helpful in determining syllabification. However, our experiments suggested that including features like these has no significant effect on performance. We believe that this is caused by the ability of the SVM to learn such generalizations from the n-gram features alone.

## 5 Syllabification Experiments

In this section, we will discuss the results of our best emission feature set (five-gram features with a context window of eleven letters) on held-out unseen test sets. We explore several different languages and datasets, and perform a brief error analysis.

### 5.1 Datasets

Datasets are especially important in syllabification tasks. Dictionaries sometimes disagree on the syllabification of certain words, which makes a gold standard difficult to obtain. Thus, any reported accuracy is only with respect to a given set of data.

In this paper, we report the results of experiments on two datasets: CELEX and NETtalk. We focus mainly on CELEX, which has been developed over a period of years by linguists in the Netherlands. CELEX contains English, German, and Dutch words, and their orthographic syllabifications. We removed all duplicates and multiple-word entries for our experiments. The NETtalk dictionary was originally developed with the L2P task in mind. The syllabification data in NETtalk was created manually in the phoneme domain, and then mapped directly to the letter domain.

NETtalk and CELEX do not provide the same syllabification for every word. There are numerous instances where the two datasets differ in a perfectly reasonable manner (*e.g. for-ging* in NETtalk vs. *forg-ing* in CELEX). However, we argue that NETtalk is a vastly inferior dataset. On a sample of 50 words, NETtalk agrees with Merriam-Webster's syllabifications in only 54% of instances, while CELEX agrees in 94% of cases. Moreover, NETtalk is riddled with truly bizarre syllabifications, such as *be-aver*, *dis-hcloth* and *som-ething*. These syllabifications make generalization very hard, and are likely to complicate the L2P task we ultimately want to accomplish. Because previous work in English primarily used NETtalk, we report our results on both datasets. Nevertheless, we believe NETtalk is unsuitable for building a syllabification model, and that results on CELEX are much more indicative of the efficacy of our (or any other) approach.

At 20K words, NETtalk is much smaller than CELEX. For NETtalk, we randomly divide the data into 13K training examples and 7K test words. We

randomly select a comparably-sized training set for our CELEX experiments (14K), but test on a much larger, 25K set. Recall that 5K training examples were held out as a development set.

## 5.2 Results

We report the results using two metrics. Word accuracy (WA) measures how many words match the gold standard. Syllable break error rate (SBER) captures the incorrect tags that cause an error in syllabification. Word accuracy is the more demanding metric. We compare our system to Syllabification by Analogy (SbA), the best existing system for English (Marchand and Damper, 2007). For both CELEX and NETtalk, SbA was trained and tested with the same data as our structured SVM approach.

Data Set	Method	WA	SBER
CELEX	NB tags	86.66	2.69
	Numbered NB	89.45	2.51
	Numbered ONC	89.86	2.50
	Break ONC	89.99	2.42
	SbA	84.97	3.96
NETtalk	Numbered NB	81.75	5.01
	SbA	75.56	7.73

Table 1: Syllabification performance in terms of word accuracy and syllable break error percentage.

Table 1 presents the word accuracy and syllable break error rate achieved by each of our tag sets on both the CELEX and NETtalk datasets. Of our four tag sets, NB tags perform noticeably worse. This is an important result because it demonstrates that it is not sufficient to simply model a syllable’s boundaries; we must also model a syllable’s length or structure to achieve the best results. Given the similarity in word accuracy scores, it is difficult to draw definitive conclusions about the remaining three tags sets, but it does appear that there is an advantage to modeling syllable structure, as both ONC tag sets score better than the best NB set.

All variations of our system outperform SbA on both datasets. Overall, our best tag set lowers the error rate by one-third, relative to SbA’s performance. Note that we employ only numbered NB tags for the NETtalk test; we could not apply structural tag schemes to the NETtalk training data because of its

bizarre syllabification choices.

Our higher level of accuracy is also achieved more efficiently. Once a model is learned, our system can syllabify 25K words in about a minute, while SbA requires several hours (Marchand, 2007). SVM training times vary depending on the tag set and dataset used, and the number of training examples. On 14K CELEX examples with the ONC tag set, our model trained in about an hour, on a single-processor P4 3.4GHz processor. Training time is, of course, a one-time cost. This makes our approach much more attractive for inclusion in an actual L2P system.

Figure 3 shows our method’s learning curve. Even small amounts of data produce adequate performance — with only 2K training examples, word accuracy is already over 75%. Using a 60K training set and testing on a held-out 5K set, we see word accuracies climb to 95.65%.

Figure 3: Word accuracy as function of the size of the training data.

## 5.3 Error Analysis

We believe that the reason for the relatively low performance of unnumbered NB tags is the weakness of the signal coming from NB emission features. With the exception of *q* and *x*, every letter can take on either an N tag or a B tag with almost equal probability. This is not the case with Numbered NB tags. Vowels are much more likely to have N2 or N3 tags (because they so often appear in the middle of a syllable), while consonants take on N1 labels with greater probability.

The numbered NB and ONC systems make many of the same errors, on words that we might expect to

cause difficulty. In particular, both suffer from being unaware of compound nouns and morphological phenomena. All three systems, for example, incorrectly syllabify *hold-o-ver* as *hol-dov-er*. This kind of error is caused by a lack of knowledge of the component words. The three systems also display trouble handling consecutive vowels, as when *co-ad-ju-tors* is syllabified incorrectly as *coad-ju-tors*. Vowel pairs such as *oa* are not handled consistently in English, and the SVM has trouble predicting the exceptions.

## 5.4 Other Languages

We take advantage of the language-independence of Numbered NB tags to apply our method to other languages. Without even a cursory knowledge of German or Dutch, we have applied our approach to these two languages.

# Data Points	Dutch	German
~ 50K	98.20	98.81
~ 250K	99.45	99.78

Table 2: Syllabification performance in terms of word accuracy percentage.

We have randomly selected two training sets from the German and Dutch portions of CELEX. Our smaller model is trained on ~ 50K words, while our larger model is trained on ~ 250K. Table 2 shows our performance on a 30K test set held out from both training sets. Results from both the small and large models are very good indeed.

Our performance on these language sets is clearly better than our best score for English (compare at 95% with a comparable amount of training data). Syllabification is a more regular process in German and Dutch than it is in English, which allows our system to score higher on those languages.

Our method’s word accuracy compares favorably with other methods. Bouma’s finite state approach for Dutch achieves 96.49% word accuracy using 50K training points, while we achieve 98.20%. With a larger model, trained on about 250K words, Bouma achieves 98.17% word accuracy, against our 99.45%. Demberg (2006) reports that her HMM approach for German scores 97.87% word accuracy, using a 90/10 training/test split on the CELEX

dataset. On the same set, Demberg et al. (2007) obtain 99.28% word accuracy by applying the system of Schmid et al. (2007). Our score using a similar split is 99.78%.

Note that none of these scores are directly comparable, because we did not use the same train-test splits as our competitors, just similar amounts of training and test data. Furthermore, when assembling random train-test splits, it is quite possible that words sharing the same lemma will appear in both the training and test sets. This makes the problem much easier with large training sets, where the chance of this sort of overlap becomes high. Therefore, any large data results may be slightly inflated as a prediction of actual out-of-dictionary performance.

## 6 L2P Performance

As we stated from the outset, one of our primary motivations for exploring orthographic syllabification is the improvements it can produce in L2P systems. To explore this, we tested our model in conjunction with a recent L2P system that has been shown to predict phonemes with state-of-the-art word accuracy (Jiampojarn et al., 2007). Using a model derived from training data, this L2P system first divides a word into letter chunks, each containing one or two letters. A local classifier then predicts a number of likely phonemes for each chunk, with confidence values. A phoneme-sequence Markov model is then used to select the most likely sequence from the phonemes proposed by the local classifier.

Syllabification	English	Dutch	German
None	84.67	91.56	90.18
Numbered NB	85.55	92.60	90.59
Break ONC	85.59	N/A	N/A
Dictionary	86.29	93.03	90.57

Table 3: Word accuracy percentage on the letter-to-phoneme task with and without the syllabification information.

To measure the improvement syllabification can effect on the L2P task, the L2P system was trained with syllabified, rather than unsyllabified words. Otherwise, the execution of the L2P system remains unchanged. Data for this experiment is again drawn

from the CELEX dictionary. In Table 3, we report the average word accuracy achieved by the L2P system using 10-fold cross-validation. We report L2P performance without any syllabification information, with perfect dictionary syllabification, and with our small learned models of syllabification. L2P performance with dictionary syllabification represents an approximate upper bound on the contributions of our system.

Our syllabification model improves L2P performance. In English, perfect syllabification produces a relative error reduction of 10.6%, and our model captures over half of the possible improvement, reducing the error rate by 6.0%. To our knowledge, this is the first time a syllabification model has improved L2P performance in English. Previous work includes Marchand and Damper (2007)’s experiments with SbA and the L2P problem on NETalk. Although perfect syllabification reduces their L2P relative error rate by 18%, they find that their learned model actually increases the error rate. Chen (2003) achieved word accuracy of 91.7% for his L2P system, testing on a different dictionary (Pronlex) with a much larger training set. He does not report word accuracy for his syllabification model. However, his baseline L2P system is not improved by adding a syllabification model.

For Dutch, perfect syllabification reduces the relative L2P error rate by 17.5%; we realize over 70% of the available improvement with our syllabification model, reducing the relative error rate by 12.4%.

In German, perfect syllabification produces only a small reduction of 3.9% in the relative error rate. Experiments show that our learned model actually produces a slightly higher reduction in the relative error rate. This anomaly may be due to errors or inconsistencies in the dictionary syllabifications that are not replicated in the model output. Previously, Demberg (2006) generated statistically significant L2P improvements in German by adding syllabification pre-processing. However, our improvements are coming at a much higher baseline level of word accuracy – 90% versus only 75%.

Our results also provide some evidence that syllabification preprocessing may be more beneficial to L2P than morphological preprocessing. Demberg et al. (2007) report that oracle morphological annotation produces a relative error rate reduction

of 3.6%. We achieve a larger decrease at a higher level of accuracy, using an automatic pre-processing technique. This may be because orthographic syllabifications already capture important facts about a word’s morphology.

## 7 Conclusion

We have applied structured SVMs to the syllabification problem, clearly outperforming existing systems. In English, we have demonstrated a 33% relative reduction in error rate with respect to the state of the art. We used this improved syllabification to increase the letter-to-phoneme accuracy of an existing L2P system, producing a system with 85.5% word accuracy, and recovering more than half of the potential improvement available from perfect syllabification. This is the first time automatic syllabification has been shown to improve English L2P. Furthermore, we have demonstrated the language-independence of our system by producing competitive orthographic syllabification solutions for both Dutch and German, achieving word syllabification accuracies of 98% and 99% respectively. These learned syllabification models also improve accuracy for German and Dutch letter-to-phoneme conversion.

In future work on this task, we plan to explore adding morphological features to the SVM, in an effort to overcome errors in compound words and inflectional forms. We would like to experiment with performing L2P and syllabification jointly, rather than using syllabification as a pre-processing step for L2P. We are also working on applying our method to phonetic syllabification.

## Acknowledgements

Many thanks to Sittichai Jiampoamarn for his help with the L2P experiments, and to Yannick Marchand for providing the SbA results.

## Abstract

In this paper, we propose a novel string-to-dependency algorithm for statistical machine translation. With this new framework, we employ a target dependency language model during decoding to exploit long distance word relations, which are unavailable with a traditional n-gram language model. Our experiments show that the string-to-dependency decoder achieves 1.48 point improvement in BLEU and 2.53 point improvement in TER compared to a standard hierarchical string-to-string system on the NIST 04 Chinese-English evaluation set.

## 1 Introduction

In recent years, hierarchical methods have been successfully applied to Statistical Machine Translation (Graehl and Knight, 2004; Chiang, 2005; Ding and Palmer, 2005; Quirk et al., 2005). In some language pairs, i.e. Chinese-to-English translation, state-of-the-art hierarchical systems show significant advantage over phrasal systems in MT accuracy. For example, Chiang (2007) showed that the Hiero system achieved about 1 to 3 point improvement in BLEU on the NIST 03/04/05 Chinese-English evaluation sets compared to a start-of-the-art phrasal system.

Our work extends the hierarchical MT approach. We propose a string-to-dependency model for MT, which employs rules that represent the source side as strings and the target side as dependency structures. We restrict the target side to the so called *well-formed* dependency structures, in order to cover a large set of non-constituent transfer rules (Marcu et al., 2006), and enable efficient decoding through dynamic programming. We incorporate a dependency

language model during decoding, in order to exploit long-distance word relations which are unavailable with a traditional n-gram language model on target strings.

For comparison purposes, we replicated the Hiero decoder (Chiang, 2005) as our baseline. Our string-to-dependency decoder shows 1.48 point improvement in BLEU and 2.53 point improvement in TER on the NIST 04 Chinese-English MT evaluation set.

In the rest of this section, we will briefly discuss previous work on hierarchical MT and dependency representations, which motivated our research. In section 2, we introduce the model of string-to-dependency decoding. Section 3 illustrates of the use of dependency language models. In section 4, we describe the implementation details of our MT system. We discuss experimental results in section 5, compare to related work in section 6, and draw conclusions in section 7.

### 1.1 Hierarchical Machine Translation

Graehl and Knight (2004) proposed the use of target-tree-to-source-string transducers ( $xRS$ ) to model translation. In  $xRS$  rules, the right-hand-side( $rhs$ ) of the target side is a tree with non-terminals(NTs), while the  $rhs$  of the source side is a string with NTs. Galley et al. (2006) extended this string-to-tree model by using Context-Free parse trees to represent the target side. A tree could represent multi-level transfer rules.

The Hiero decoder (Chiang, 2007) does not require explicit syntactic representation on either side of the rules. Both source and target are strings with NTs. Decoding is solved as chart parsing. Hiero can be viewed as a hierarchical string-to-string model.

Ding and Palmer (2005) and Quirk et al. (2005)

Figure 1: The dependency tree for sentence *the boy will find it interesting*

followed the tree-to-tree approach (Shieber and Schabes, 1990) for translation. In their models, dependency treelets are used to represent both the source and the target sides. Decoding is implemented as tree transduction preceded by source side dependency parsing. While tree-to-tree models can represent richer structural information, existing tree-to-tree models did not show advantage over string-to-tree models on translation accuracy due to a much larger search space.

One of the motivations of our work is to achieve desirable trade-off between model capability and search space through the use of the so called *well-formed* dependency structures in rule representation.

## 1.2 Dependency Trees

Dependency trees reveal long-distance relations between words. For a given sentence, each word has a parent word which it depends on, except for the *root* word.

Figure 1 shows an example of a dependency tree. Arrows point from the child to the parent. In this example, the word *find* is the root.

Dependency trees are simpler in form than CFG trees since there are no constituent labels. However, dependency relations directly model semantic structure of a sentence. As such, dependency trees are a desirable prior model of the target sentence.

## 1.3 Motivations for Well-Formed Dependency Structures

We restrict ourselves to the so-called *well-formed* target dependency structures based on the following considerations.

### Dynamic Programming

In (Ding and Palmer, 2005; Quirk et al., 2005), there is no restriction on dependency treelets used in transfer rules except for the size limit. This may result in a high dimensionality in hypothesis represen-

tation and make it hard to employ shared structures for efficient dynamic programming.

In (Galley et al., 2004), rules contain NT slots and combination is only allowed at those slots. Therefore, the search space becomes much smaller. Furthermore, shared structures can be easily defined based on the labels of the slots.

In order to take advantage of dynamic programming, we fixed the positions onto which another another tree could be attached by specifying NTs in dependency trees.

### Rule Coverage

Marcu et al. (2006) showed that many useful phrasal rules cannot be represented as hierarchical rules with the existing representation methods, even with composed transfer rules (Galley et al., 2006). For example, the following rule

- $\langle (\text{hong})_{\text{Chinese}}, (\text{DT}(\text{the}) \text{JJ}(\text{red}))_{\text{English}} \rangle$

is not a valid string-to-tree transfer rule since *the red* is a partial constituent.

A number of techniques have been proposed to improve rule coverage. (Marcu et al., 2006) and (Galley et al., 2006) introduced artificial constituent nodes dominating the phrase of interest. The binarization method used by Wang et al. (2007) can cover many non-constituent rules also, but not all of them. For example, it cannot handle the above example. DeNeefe et al. (2007) showed that the best results were obtained by combing these methods.

In this paper, we use *well-formed* dependency structures to handle the coverage of non-constituent rules. The use of dependency structures is due to the flexibility of dependency trees as a representation method which does not rely on constituents (Fox, 2002; Ding and Palmer, 2005; Quirk et al., 2005). The *well-formedness* of the dependency structures enables efficient decoding through dynamic programming.

## 2 String-to-Dependency Translation

### 2.1 Transfer Rules with Well-Formed Dependency Structures

A string-to-dependency grammar  $G$  is a 4-tuple  $G = \langle \mathcal{R}, X, T_f, T_e \rangle$ , where  $\mathcal{R}$  is a set of transfer rules.  $X$  is the only non-terminal, which is similar to the Hiero system (Chiang, 2007).  $T_f$  is a set of

terminals in the source language, and  $T_e$  is a set of terminals in the target language<sup>1</sup>.

A string-to-dependency transfer rule  $R \in \mathcal{R}$  is a 4-tuple  $R = \langle S_f, S_e, D, A \rangle$ , where  $S_f \in (T_f \cup \{X\})^+$  is a source string,  $S_e \in (T_e \cup \{X\})^+$  is a target string,  $D$  represents the dependency structure for  $S_e$ , and  $A$  is the alignment between  $S_f$  and  $S_e$ . Non-terminal alignments in  $A$  must be one-to-one.

In order to exclude undesirable structures, we only allow  $S_e$  whose dependency structure  $D$  is *well-formed*, which we will define below. In addition, the same well-formedness requirement will be applied to partial decoding results. Thus, we will be able to employ shared structures to merge multiple partial results.

Based on the results in previous work (DeNeeffe et al., 2007), we want to keep two kinds of dependency structures. In one kind, we keep dependency trees with a sub-root, where all the children of the sub-root are complete. We call them **fixed** dependency structures because the head is known or fixed. In the other, we keep dependency structures of sibling nodes of a common head, but the head itself is unspecified or floating. Each of the siblings must be a complete constituent. We call them **floating** dependency structures. Floating structures can represent many linguistically meaningful non-constituent structures: for example, like *the red*, a modifier of a noun. Only those two kinds of dependency structures are **well-formed** structures in our system.

Furthermore, we operate over *well-formed* structures in a bottom-up style in decoding. However, the description given above does not provide a clear definition on how to combine those two types of structures. In the rest of this section, we will provide formal definitions of *well-formed* structures and combinatory operations over them, so that we can easily manipulate *well-formed* structures in decoding. Formal definitions also allow us to easily extend the framework to incorporate a dependency language model in decoding. Examples will be provided along with the formal definitions.

Consider a sentence  $S = w_1 w_2 \dots w_n$ . Let  $d_1 d_2 \dots d_n$  represent the parent word IDs for each word. For example,  $d_4 = 2$  means that  $w_4$  depends

<sup>1</sup>We ignore the left hand side here because there is only one non-terminal  $X$ . Of course, this formalism can be extended to have multiple NTs.

Figure 2: Fixed dependency structures

Figure 3: Floating dependency structures

on  $w_2$ . If  $w_i$  is a root, we define  $d_i = 0$ .

**Definition 1** A dependency structure  $d_{i..j}$  is **fixed on head  $h$** , where  $h \in [i, j]$ , or **fixed for short**, if and only if it meets the following conditions

- $d_h \notin [i, j]$
- $\forall k \in [i, j]$  and  $k \neq h$ ,  $d_k \in [i, j]$
- $\forall k \notin [i, j]$ ,  $d_k = h$  or  $d_k \notin [i, j]$

In addition, we say the category of  $d_{i..j}$  is  $(-, h, -)$ , where  $-$  means this field is undefined.

**Definition 2** A dependency structure  $d_{i..j}$  is **floating with children  $C$** , for a non-empty set  $C \subseteq \{i, \dots, j\}$ , or **floating for short**, if and only if it meets the following conditions

- $\exists h \notin [i, j]$ , s.t.  $\forall k \in C$ ,  $d_k = h$
- $\forall k \in [i, j]$  and  $k \notin C$ ,  $d_k \in [i, j]$
- $\forall k \notin [i, j]$ ,  $d_k \notin [i, j]$

We say the category of  $d_{i..j}$  is  $(C, -, -)$  if  $j < h$ , or  $(-, -, C)$  otherwise. A category is composed of the three fields  $(A, h, B)$ , where  $h$  is used to represent the head, and  $A$  and  $B$  are designed to model left and right dependents of the head respectively.

A dependency structure is **well-formed** if and only if it is either *fixed* or *floating*.

### Examples

We can represent dependency structures with graphs. Figure 2 shows examples of fixed structures, Figure 3 shows examples of floating structures, and Figure 4 shows ill-formed dependency structures.

It is easy to verify that the structures in Figures 2 and 3 are well-formed. 4(a) is ill-formed because

Figure 4: Ill-formed dependency structures

*boy* does not have its child word *the* in the tree. 4(b) is ill-formed because it is not a continuous segment.

As for the example *the red* mentioned above, it is a *well-formed* floating dependency structure.

## 2.2 Operations on Well-Formed Dependency Structures and Categories

One of the purposes of introducing *floating* dependency structures is that siblings having a common parent will become a well-defined entity, although they are not considered a constituent. We always build well-formed partial structures on the target side in decoding. Furthermore, we combine partial dependency structures in a way such that we can obtain all possible well-formed but no ill-formed dependency structures during bottom-up decoding.

The solution is to employ *categories* introduced above. Each well-formed dependency structure has a category. We can apply four combinatory operations over the categories. If we can combine two categories with a certain *category operation*, we can use a corresponding *tree operation* to combine two dependency structures. The category of the combined dependency structure is the result of the combinatory *category operations*.

We first introduce three meta category operations. Two of them are unary operations, *left raising* (LR) and *right raising* (RR), and one is the binary operation *unification* (UF).

First, the raising operations are used to turn a completed fixed structure into a floating structure. It is easy to verify the following theorem according to the definitions.

**Theorem 1** *A fixed structure with category  $(-, h, -)$  for span  $[i, j]$  is also a floating structure with children  $\{h\}$  if there are no outside words depending on word  $h$ .*

$$\forall k \notin [i, j], d_k \neq h. \quad (1)$$

Therefore we can always *raise* a fixed structure if we assume it is complete, i.e. (1) holds.

Figure 5: A dependency tree with flexible combination

### Definition 3 Meta Category Operations

- $LR((-, h, -)) = (\{h\}, -, -)$
- $RR((-, h, -)) = (-, -, \{h\})$
- $UF((A_1, h_1, B_1), (A_2, h_2, B_2)) = \text{NORM}((A_1 \sqcup A_2, h_1 \sqcup h_2, B_1 \sqcup B_2))$

Unification is well-defined if and only if we can unify all three elements and the result is a valid fixed or floating category. For example, we can unify a fixed structure with a floating structure or two floating structures in the same direction, but we cannot unify two fixed structures.

$$h_1 \sqcup h_2 = \begin{cases} h_1 & \text{if } h_2 = - \\ h_2 & \text{if } h_1 = - \\ \text{undefined} & \text{otherwise} \end{cases}$$

$$A_1 \sqcup A_2 = \begin{cases} A_1 & \text{if } A_2 = - \\ A_2 & \text{if } A_1 = - \\ A_1 \cup A_2 & \text{otherwise} \end{cases}$$

$$\text{NORM}((A, h, B)) = \begin{cases} (-, h, -) & \text{if } h \neq - \\ (A, -, -) & \text{if } h = -, B = - \\ (-, -, B) & \text{if } h = -, A = - \\ \text{undefined} & \text{otherwise} \end{cases}$$

Next we introduce the four tree operations on *dependency structures*. Instead of providing the formal definition, we use figures to illustrate these operations to make it easy to understand. Figure 1 shows a traditional dependency tree. Figure 5 shows the four operations to combine partial dependency structures, which are *left adjoining* (LA), *right adjoining* (RA), *left concatenation* (LC) and *right concatenation* (RC).

Child and parent subtrees can be combined with *adjoining* which is similar to the traditional dependency formalism. We can either adjoin a fixed structure or a floating structure to the head of a fixed structure.

Complete siblings can be combined via *concatenation*. We can concatenate two fixed structures, one fixed structure with one floating structure, or two floating structures in the same direction. The flexibility of the order of operation allows us to take ad-

Figure 6: Operations over well-formed structures

vantage of various translation fragments encoded in transfer rules.

Figure 6 shows alternative ways of applying operations on *well-formed* structures to build larger structures in a bottom-up style. Numbers represent the order of operation.

We use the same names for the operations on categories for the sake of convenience. We can easily use the meta category operations to define the four combinatory operations. The definition of the operations in the left direction is as follows. Those in the right direction are similar.

**Definition 4** *Combinatory category operations*

$$\begin{aligned}
& \text{LA}((A_1, -, -), (-, h_2, -)) \\
= & \text{UF}((A_1, -, -), (-, h_2, -)) \\
& \text{LA}((-, h_1, -), (-, h_2, -)) \\
= & \text{UF}(\text{LR}((-, h_1, -)), (-, h_2, -)) \\
& \text{LC}((A_1, -, -), (A_2, -, -)) \\
= & \text{UF}((A_1, -, -), (A_2, -, -)) \\
& \text{LC}((A_1, -, -), (-, h_2, -)) \\
= & \text{UF}((A_1, -, -), \text{LR}((-, h_2, -))) \\
& \text{LC}((-, h_1, -), (A_2, -, -)) \\
= & \text{UF}(\text{LR}((-, h_1, -)), (A_2, -, -)) \\
& \text{LC}((-, h_1, -), (-, h_2, -)) \\
= & \text{UF}(\text{LR}((-, h_1, -)), \text{LR}((-, h_2, -)))
\end{aligned}$$

It is easy to verify the *soundness* and *completeness* of category operations based on one-to-one mapping of the conditions in the definitions of corresponding operations on dependency structures and on categories.

**Theorem 2 (soundness and completeness)**

Suppose  $X$  and  $Y$  are well-formed dependency structures.  $OP(\text{cat}(X), \text{cat}(Y))$  is well-defined for a given operation  $OP$  if and only if  $OP(X, Y)$  is well-defined. Furthermore,

$$\text{cat}(OP(X, Y)) = OP(\text{cat}(X), \text{cat}(Y))$$

Suppose we have a dependency tree for *a red apple*, where both  $a$  and  $red$  depend on  $apple$ . There are two ways to compute the category of this string from the bottom up.

$$\begin{aligned}
& \text{cat}(D_{a\_red\_apple}) \\
= & \text{LA}(\text{cat}(D_a), \text{LA}(\text{cat}(D_{red}), \text{cat}(D_{apple}))) \\
= & \text{LA}(\text{LC}(\text{cat}(D_a), \text{cat}(D_{red})), \text{cat}(D_{apple}))
\end{aligned}$$

Based on Theorem 2, it follows that combinatory operation of categories has the *confluence* property, since the result dependency structure is determined.

**Corollary 1 (confluence)** *The category of a well-formed dependency tree does not depend on the order of category calculation.*

With categories, we can easily track the types of dependency structures and constrain operations in decoding. For example, we have a rule with dependency structure  $find \leftarrow X$ , where  $X$  right adjoins to  $find$ . Suppose we have two floating structures<sup>2</sup>,

$$\begin{aligned}
\text{cat}(X_1) &= (\{he, will\}, -, -) \\
\text{cat}(X_2) &= (-, -, \{it, interesting\})
\end{aligned}$$

We can replace  $X$  by  $X_2$ , but not by  $X_1$  based on the definition of category operations.

**2.3 Rule Extraction**

Now we explain how we get the string-to-dependency rules from training data. The procedure is similar to (Chiang, 2007) except that we maintain tree structures on the target side, instead of strings.

Given sentence-aligned bi-lingual training data, we first use GIZA++ (Och and Ney, 2003) to generate word level alignment. We use a statistical CFG parser to parse the English side of the training data, and extract dependency trees with Magerman’s rules (1995). Then we use heuristic rules to extract transfer rules recursively based on the GIZA alignment and the target dependency trees. The rule extraction procedure is as follows.

1. Initialization:

All the 4-tuples  $(P_f^{i,j}, P_e^{m,n}, D, A)$  are valid phrase alignments, where source phrase  $P_f^{i,j}$  is

<sup>2</sup>Here we use words instead of word indexes in categories to make the example easy to understand.

Figure 7: Replacing *it* with *X* in  $D_1$

aligned to target phrase  $P_e^{m,n}$  under alignment<sup>3</sup>  $A$ , and  $D$ , the dependency structure for  $P_e^{m,n}$ , is *well-formed*. All *valid phrase templates* are *valid rules templates*.

## 2. Inference:

Let  $(P_f^{i,j}, P_e^{m,n}, D_1, A)$  be a *valid rule template*, and  $(P_f^{p,q}, P_e^{s,t}, D_2, A)$  a *valid phrase alignment*, where  $[p, q] \subset [i, j]$ ,  $[s, t] \subset [m, n]$ ,  $D_2$  is a sub-structure of  $D_1$ , and at least one word in  $P_f^{i,j}$  but not in  $P_f^{p,q}$  is aligned.

We create a new *valid rule template*  $(P'_f, P'_e, D', A)$ , where we obtain  $P'_f$  by replacing  $P_f^{p,q}$  with label  $X$  in  $P_f^{i,j}$ , and obtain  $P'_e$  by replacing  $P_e^{s,t}$  with  $X$  in  $P_e^{m,n}$ . Furthermore, We obtain  $D'$  by replacing sub-structure  $D_2$  with  $X$  in  $D_1$ <sup>4</sup>. An example is shown in Figure 7.

Among all valid rule templates, we collect those that contain at most two NTs and at most seven elements in the source as transfer rules in our system.

## 2.4 Decoding

Following previous work on hierarchical MT (Chiang, 2005; Galley et al., 2006), we solve decoding as chart parsing. We view target dependency as the hidden structure of source fragments.

The parser scans all source cells in a bottom-up style, and checks matched transfer rules according to the source side. Once there is a completed rule, we build a larger dependency structure by substituting component dependency structures for corresponding NTs in the target dependency structure of rules.

Hypothesis dependency structures are organized in a shared forest, or AND-OR structures. An AND-

<sup>3</sup>By  $P_f^{i,j}$  aligned to  $P_e^{m,n}$ , we mean all words in  $P_f^{i,j}$  are either aligned to words in  $P_e^{m,n}$  or unaligned, and vice versa. Furthermore, at least one word in  $P_f^{i,j}$  is aligned to a word in  $P_e^{m,n}$ .

<sup>4</sup>If  $D_2$  is a *floating* structure, we need to merge several dependency links into one.

structure represents an application of a rule over component OR-structures, and an OR-structure represents a set of alternative AND-structures with the same *state*. A **state** means a  $n$ -tuple that characterizes the information that will be inquired by up-level AND-structures.

Supposing we use a traditional tri-gram language model in decoding, we need to specify the leftmost two words and the rightmost two words in a state. Since we only have a single NT  $X$  in the formalism described above, we do not need to add the NT label in states. However, we need to specify one of the three types of the dependency structure: fixed, floating on the left side, or floating on the right side. This information is encoded in the category of the dependency structure.

In the next section, we will explain how to extend categories and states to exploit a dependency language model during decoding.

## 3 Dependency Language Model

For the dependency tree in Figure 1, we calculate the probability of the tree as follows

$$\begin{aligned}
 Prob &= P_T(find) \\
 &\times P_L(will|find-as-head) \\
 &\times P_L(boy|will, find-as-head) \\
 &\times P_L(the|boy-as-head) \\
 &\times P_R(it|find-as-head) \\
 &\times P_R(interesting|it, find-as-head)
 \end{aligned}$$

Here  $P_T(x)$  is the probability that word  $x$  is the root of a dependency tree.  $P_L$  and  $P_R$  are left and right side generative probabilities respectively. Let  $w_h$  be the head, and  $w_{L_1}w_{L_2}\dots w_{L_n}$  be the children on the left side from the nearest to the farthest. Suppose we use a tri-gram dependency LM,

$$\begin{aligned}
 &P_L(w_{L_1}w_{L_2}\dots w_{L_n}|w_h-as-head) \\
 = &P_L(w_{L_1}|w_h-as-head) \\
 &\times P_L(w_{L_2}|w_{L_1}, w_h-as-head) \\
 &\times \dots \times P_L(w_{L_n}|w_{L_{n-1}}, w_{L_{n-2}}) \quad (2)
 \end{aligned}$$

$w_h$ -as-head represents  $w_h$  used as the head, and it is different from  $w_h$  in the dependency language model. The right side probability is similar.

In order to calculate the dependency language model score, or depLM score for short, on the fly for

partial hypotheses in a bottom-up decoding, we need to save more information in categories and states.

We use a 5-tuple  $(LF, LN, h, RN, RF)$  to represent the category of a dependency structure.  $h$  represents the head.  $LF$  and  $RF$  represent the farthest two children on the left and right sides respectively. Similarly,  $LN$  and  $RN$  represent the nearest two children on the left and right sides respectively. The three types of categories are as follows.

- fixed:  $(LF, -, h, -, RF)$
- floating left:  $(LF, LN, -, -, -)$
- floating right:  $(-, -, -, RN, RF)$

Similar operations as described in Section 2.2 are used to keep track of the head and boundary child nodes which are then used to compute depLM scores in decoding. Due to the limit of space, we skip the details here.

## 4 Implementation Details

### Features

1. Probability of the source side given the target side of a rule
2. Probability of the target side given the source side of a rule
3. Word alignment probability
4. Number of target words
5. Number of concatenation rules used
6. Language model score
7. Dependency language model score
8. Discount on ill-formed dependency structures

We have eight features in our system. The values of the first four features are accumulated on the rules used in a translation. Following (Chiang, 2005), we also use concatenation rules like  $X \rightarrow XX$  for backup. The 5th feature counts the number of concatenation rules used in a translation. In our system, we allow substitutions of dependency structures with unmatched categories, but there is a discount for such substitutions.

### Weight Optimization

We tune the weights with several rounds of decoding-optimization. Following (Och, 2003), the k-best results are accumulated as the input of the optimizer. Powell’s method is used for optimization with 20 random starting points around the weight vector of the last iteration.

## Rescoring

We rescore 1000-best translations (Huang and Chiang, 2005) by replacing the 3-gram LM score with the 5-gram LM score computed offline.

## 5 Experiments

We carried out experiments on three models.

- baseline: replication of the Hiero system.
- filtered: a string-to-string MT system as in baseline. However, we only keep the transfer rules whose target side can be generated by a well-formed dependency structure.
- str-dep: a string-to-dependency system with a dependency LM.

We take the replicated Hiero system as our baseline because it is the closest to our string-to-dependency model. They have similar rule extraction and decoding algorithms. Both systems use only one non-terminal label in rules. The major difference is in the representation of target structures. We use dependency structures instead of strings; thus, the comparison will show the contribution of using dependency information in decoding.

All models are tuned on BLEU (Papineni et al., 2001), and evaluated on both BLEU and Translation Error Rate (TER) (Snover et al., 2006) so that we could detect over-tuning on one metric.

We used part of the NIST 2006 Chinese-English large track data as well as some LDC corpora collected for the DARPA GALE program (LDC2005E83, LDC2006E34 and LDC2006G05) as our bilingual training data. It contains about 178M/191M words in source/target. Hierarchical rules were extracted from a subset which has about 35M/41M words<sup>5</sup>, and the rest of the training data were used to extract phrasal rules as in (Och, 2003; Chiang, 2005). The English side of this subset was also used to train a 3-gram dependency LM. Traditional 3-gram and 5-gram LMs were trained on a corpus of 6G words composed of the LDC Gigaword corpus and text downloaded from Web (Bulyko et al., 2007). We tuned the weights on NIST MT05 and tested on MT04.

<sup>5</sup>It includes eight corpora: LDC2002E18, LDC2003E07, LDC2004T08\_HK\_News, LDC2005E83, LDC2005T06, LDC2005T10, LDC2006E34, and LDC2006G05

Model	#Rules
baseline	140M
filtered	26M
str-dep	27M

Table 1: Number of transfer rules

Model	BLEU%		TER%	
	lower	mixed	lower	mixed
Decoding (3-gram LM)				
baseline	38.18	35.77	58.91	56.60
filtered	37.92	35.48	57.80	55.43
str-dep	39.52	37.25	56.27	54.07
Rescoring (5-gram LM)				
baseline	40.53	38.26	56.35	54.15
filtered	40.49	38.26	55.57	53.47
str-dep	41.60	39.47	55.06	52.96

Table 2: BLEU and TER scores on the test set.

Table 1 shows the number of transfer rules extracted from the training data for the tuning and test sets. The constraint of well-formed dependency structures greatly reduced the size of the rule set. Although the rule size increased a little bit after incorporating dependency structures in rules, the size of string-to-dependency rule set is less than 20% of the baseline rule set size.

Table 2 shows the BLEU and TER scores on MT04. On decoding output, the string-to-dependency system achieved 1.48 point improvement in BLEU and 2.53 point improvement in TER compared to the baseline hierarchical string-to-string system. After 5-gram rescoring, it achieved 1.21 point improvement in BLEU and 1.19 improvement in TER. The *filtered* model does not show improvement on BLEU. The filtered string-to-string rules can be viewed the string projection of string-to-dependency rules. It means that just using dependency structure does not provide an improvement on performance. However, dependency structures allow the use of a dependency LM which gives rise to significant improvement.

## 6 Discussion

The *well-formed* dependency structures defined here are similar to the data structures in previous work on mono-lingual parsing (Eisner and Satta, 1999; McDonald et al., 2005). However, here we have *fixed* structures growing on both sides to exploit various translation fragments learned in the training data,

while the operations in mono-lingual parsing were designed to avoid artificial ambiguity of derivation.

Charniak et al. (2003) described a two-step string-to-CFG-tree translation model which employed a syntax-based language model to select the best translation from a target parse forest built in the first step. Only translation probability  $P(F|E)$  was employed in the construction of the target forest due to the complexity of the syntax-based LM. Since our dependency LM models structures over target words directly based on dependency trees, we can build a single-step system. This dependency LM can also be used in hierarchical MT systems using lexicalized CFG trees.

The use of a dependency LM in MT is similar to the use of a structured LM in ASR (Xu et al., 2002), which was also designed to exploit long-distance relations. The depLM is used in a bottom-up style, while SLM is employed in a left-to-right style.

## 7 Conclusions and Future Work

In this paper, we propose a novel string-to-dependency algorithm for statistical machine translation. For comparison purposes, we replicated the Hiero system as described in (Chiang, 2005). Our string-to-dependency system generates 80% fewer rules, and achieves 1.48 point improvement in BLEU and 2.53 point improvement in TER on the decoding output on the NIST 04 Chinese-English evaluation set.

Dependency structures provide a desirable platform to employ linguistic knowledge in MT. In the future, we will continue our research in this direction to carry out translation with deeper features, for example, propositional structures (Palmer et al., 2005). We believe that the *fixed* and *floating* structures proposed in this paper can be extended to model predicates and arguments.

# Forest Reranking: Discriminative Parsing with Non-Local Features\*

Liang Huang

Philadelphia, PA 19104  
lh Huang3@cis.upenn.edu

## Abstract

Conventional  $n$ -best reranking techniques often suffer from the limited scope of the  $n$ -best list, which rules out many potentially good alternatives. We instead propose *forest reranking*, a method that reranks a packed forest of exponentially many parses. Since exact inference is intractable with non-local features, we present an approximate algorithm inspired by forest rescoring that makes discriminative training practical over the whole Treebank. Our final result, an F-score of 91.7, outperforms both 50-best and 100-best reranking baselines, and is better than any previously reported systems trained on the Treebank.

## 1 Introduction

Discriminative reranking has become a popular technique for many NLP problems, in particular, parsing (Collins, 2000) and machine translation (Shen et al., 2005). Typically, this method first generates a list of top- $n$  candidates from a baseline system, and then reranks this  $n$ -best list with arbitrary features that are not computable or intractable to compute within the baseline system. But despite its apparent success, there remains a major drawback: this method suffers from the limited scope of the  $n$ -best list, which rules out many potentially good alternatives. For example 41% of the correct parses were not in the candidates of  $\sim 30$ -best parses in (Collins, 2000). This situation becomes worse with longer sentences because the number of possible interpretations usually grows exponentially with the

sentence length. As a result, we often see very few variations among the  $n$ -best trees, for example, 50-best trees typically just represent a combination of 5 to 6 binary ambiguities (since  $2^5 < 50 < 2^6$ ).

Alternatively, discriminative parsing is tractable with exact and efficient search based on dynamic programming (DP) if all features are restricted to be *local*, that is, only looking at a local window within the factored search space (Taskar et al., 2004; McDonald et al., 2005). However, we miss the benefits of non-local features that are not representable here.

Ideally, we would wish to combine the merits of both approaches, where an efficient inference algorithm could integrate both local and non-local features. Unfortunately, exact search is intractable (at least in theory) for features with unbounded scope. So we propose *forest reranking*, a technique inspired by forest rescoring (Huang and Chiang, 2007) that approximately reranks the packed forest of exponentially many parses. The key idea is to compute non-local features incrementally from bottom up, so that we can rerank the  $n$ -best subtrees at all internal nodes, instead of only at the root node as in conventional reranking (see Table 1). This method can thus be viewed as a step towards the integration of discriminative reranking with traditional chart parsing.

Although previous work on discriminative parsing has mainly focused on short sentences ( $\leq 15$  words) (Taskar et al., 2004; Turian and Melamed, 2007), our work scales to the whole Treebank, where

Figure 1: A partial forest of the example sentence.

we achieved an F-score of 91.7, which is a 19% error reduction from the 1-best baseline, and outperforms both 50-best and 100-best reranking. This result is also better than any previously reported systems trained on the Treebank.

## 2 Packed Forests as Hypergraphs

Informally, a packed parse forest, or *forest* in short, is a compact representation of all the derivations (i.e., parse trees) for a given sentence under a context-free grammar (Billot and Lang, 1989). For example, consider the following sentence

<sub>0</sub> I <sub>1</sub> saw <sub>2</sub> him <sub>3</sub> with <sub>4</sub> a <sub>5</sub> mirror <sub>6</sub>

where the numbers between words denote string positions. Shown in Figure 1, this sentence has (at least) two derivations depending on the attachment of the prep. phrase  $PP_{3,6}$  “with a mirror”: it can either be attached to the verb “saw”,

$$\frac{VBD_{1,2} \quad NP_{2,3} \quad PP_{3,6}}{VP_{1,6}}, \quad (*)$$

or be attached to “him”, which will be further combined with the verb to form the same VP as above. These two derivations can be represented as a single forest by sharing common sub-derivations. Such a forest has a structure of a hypergraph (Klein and Manning, 2001; Huang and Chiang, 2005), where items like  $PP_{3,6}$  are called *nodes*, and deductive steps like (\*) correspond to *hyperedges*.

More formally, a **forest** is a pair  $\langle V, E \rangle$ , where  $V$  is the set of **nodes**, and  $E$  the set of **hyperedges**. For a given sentence  $w_{1:l} = w_1 \dots w_l$ , each node  $v \in V$  is in the form of  $X_{i,j}$ , which denotes the recognition of nonterminal  $X$  spanning the substring from positions  $i$  through  $j$  (that is,  $w_{i+1} \dots w_j$ ). Each hyperedge  $e \in E$  is a pair  $\langle tails(e), head(e) \rangle$ , where

$head(e) \in V$  is the consequent node in the deductive step, and  $tails(e) \in V^*$  is the list of antecedent nodes. For example, the hyperedge for deduction (\*) is notated:

$$e_1 = \langle (VBD_{1,2}, NP_{2,3}, PP_{3,6}), VP_{1,6} \rangle$$

We also denote  $IN(v)$  to be the set of **incoming hyperedges** of node  $v$ , which represent the different ways of deriving  $v$ . For example, in the forest in Figure 1,  $IN(VP_{1,6})$  is  $\{e_1, e_2\}$ , with  $e_2 = \langle (VBD_{1,2}, NP_{2,6}), VP_{1,6} \rangle$ . We call  $|e|$  the **arity** of hyperedge  $e$ , which counts the number of tail nodes in  $e$ . The arity of a hypergraph is the maximum arity over all hyperedges. A CKY forest has an arity of 2, since the input grammar is required to be binary branching (cf. Chomsky Normal Form) to ensure cubic time parsing complexity. However, in this work, we use forests from a Treebank parser (Charniak, 2000) whose grammar is often flat in many productions. For example, the arity of the forest in Figure 1 is 3. Such a Treebank-style forest is easier to work with for reranking, since many features can be directly expressed in it. There is also a distinguished **root node** TOP in each forest, denoting the goal item in parsing, which is simply  $S_{0,l}$  where  $S$  is the start symbol and  $l$  is the sentence length.

## 3 Forest Reranking

### 3.1 Generic Reranking with the Perceptron

We first establish a unified framework for parse reranking with both  $n$ -best lists and packed forests.

For a given sentence  $s$ , a generic reranker selects the best parse  $\hat{y}$  among the set of candidates  $cand(s)$  according to some scoring function:

$$\hat{y} = \operatorname{argmax}_{y \in cand(s)} score(y) \quad (1)$$

In  $n$ -best reranking,  $cand(s)$  is simply a set of  $n$ -best parses from the baseline parser, that is,  $cand(s) = \{y_1, y_2, \dots, y_n\}$ . Whereas in forest reranking,  $cand(s)$  is a forest implicitly representing the set of exponentially many parses.

As usual, we define the score of a parse  $y$  to be the dot product between a high dimensional feature representation and a weight vector  $\mathbf{w}$ :

$$score(y) = \mathbf{w} \cdot \mathbf{f}(y) \quad (2)$$

where the feature extractor  $\mathbf{f}$  is a vector of  $d$  functions  $\mathbf{f} = (f_1, \dots, f_d)$ , and each feature  $f_j$  maps a parse  $y$  to a real number  $f_j(y)$ . Following (Charniak and Johnson, 2005), the first feature  $f_1(y) = \log \Pr(y)$  is the log probability of a parse from the baseline generative parser, while the remaining features are all integer valued, and each of them counts the number of times that a particular configuration occurs in parse  $y$ . For example, one such feature  $f_{2000}$  might be a question

“how many times is a VP of length 5 surrounded by the word ‘has’ and the period?”

which is an instance of the **WordEdges** feature (see Figure 2(c) and Section 3.2 for details).

Using a machine learning algorithm, the weight vector  $\mathbf{w}$  can be estimated from the training data where each sentence  $s_i$  is labelled with its correct (“**gold-standard**”) parse  $y_i^*$ . As for the learner, Collins (2000) uses the boosting algorithm and Charniak and Johnson (2005) use the maximum entropy estimator. In this work we use the averaged perceptron algorithm (Collins, 2002) since it is an online algorithm much simpler and orders of magnitude faster than Boosting and MaxEnt methods.

Shown in Pseudocode 1, the perceptron algorithm makes several passes over the whole training data, and in each iteration, for each sentence  $s_i$ , it tries to predict a best parse  $\hat{y}_i$  among the candidates  $\text{cand}(s_i)$  using the current weight setting. Intuitively, we want the gold parse  $y_i^*$  to be picked, but in general it is *not* guaranteed to be within  $\text{cand}(s_i)$ , because the grammar may fail to cover the gold parse, and because the gold parse may be pruned away due to the limited scope of  $\text{cand}(s_i)$ . So we define an **oracle parse**  $y_i^+$  to be the candidate that has the highest Parseval F-score with respect to the gold tree  $y_i^*$ :<sup>1</sup>

$$y_i^+ \triangleq \operatorname{argmax}_{y \in \text{cand}(s_i)} F(y, y_i^*) \quad (3)$$

where function  $F$  returns the F-score. Now we train the reranker to pick the oracle parses as often as possible, and in case an error is made (line 6), perform an update on the weight vector (line 7), by adding the difference between two feature representations.

<sup>1</sup>If one uses the gold  $y_i^*$  for oracle  $y_i^+$ , the perceptron will continue to make updates towards something unreachable even when the decoder has picked the best possible candidate.

---

### Pseudocode 1 Perceptron for Generic Reranking

---

```

1: Input: Training examples  $\{\text{cand}(s_i), y_i^+\}_{i=1}^N$   $\triangleright y_i^+$  is the
   oracle tree for  $s_i$  among  $\text{cand}(s_i)$ 
2:  $\mathbf{w} \leftarrow \mathbf{0}$   $\triangleright$  initial weights
3: for  $t \leftarrow 1 \dots T$  do  $\triangleright T$  iterations
4:   for  $i \leftarrow 1 \dots N$  do
5:      $\hat{y} = \operatorname{argmax}_{y \in \text{cand}(s_i)} \mathbf{w} \cdot \mathbf{f}(y)$ 
6:     if  $\hat{y} \neq y_i^+$  then
7:        $\mathbf{w} \leftarrow \mathbf{w} + \mathbf{f}(y_i^+) - \mathbf{f}(\hat{y})$ 
8: return  $\mathbf{w}$ 

```

---

In  $n$ -best reranking, since all parses are explicitly enumerated, it is trivial to compute the oracle tree.<sup>2</sup> However, it remains widely open how to identify the *forest oracle*. We will present a dynamic programming algorithm for this problem in Sec. 4.1.

We also use a refinement called “averaged parameters” where the final weight vector is the average of weight vectors after each sentence in each iteration over the training data. This averaging effect has been shown to reduce overfitting and produce much more stable results (Collins, 2002).

### 3.2 Factorizing Local and Non-Local Features

A key difference between  $n$ -best and forest reranking is the handling of features. In  $n$ -best reranking, all features are treated equivalently by the decoder, which simply computes the value of each one on each candidate parse. However, for forest reranking, since the trees are not explicitly enumerated, many features can not be directly computed. So we first classify features into local and non-local, which the decoder will process in very different fashions.

We define a feature  $f$  to be **local** if and only if it can be factored among the local productions in a tree, and **non-local** if otherwise. For example, the **Rule** feature in Fig. 2(a) is local, while the **ParentRule** feature in Fig. 2(b) is non-local. It is worth noting that some features which seem complicated at the first sight are indeed local. For example, the **WordEdges** feature in Fig. 2(c), which classifies a node by its label, span length, and surrounding words, is still local since all these information are encoded either in the node itself or in the input sentence. In contrast, it would become non-local if we replace the surrounding words by surrounding POS

<sup>2</sup>In case multiple candidates get the same highest F-score, we choose the parse with the highest log probability from the baseline parser to be the oracle parse (Collins, 2000).

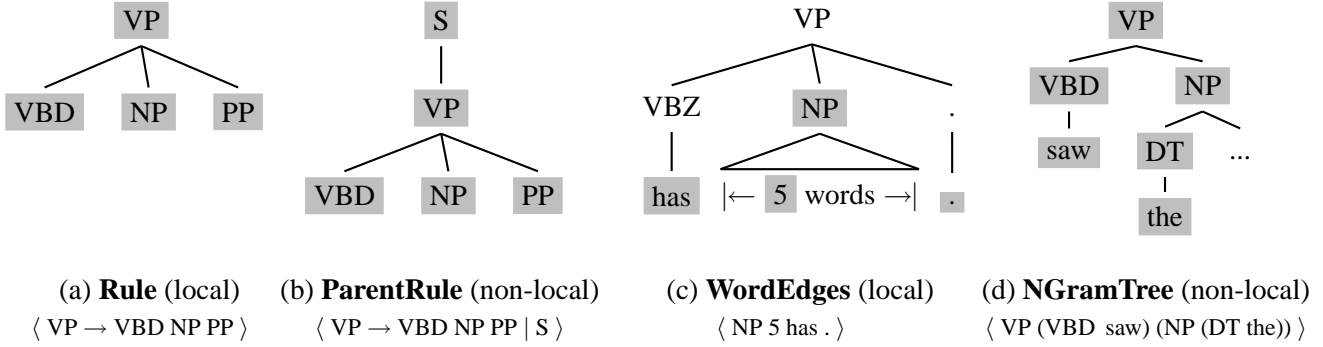

Figure 2: Illustration of some example features. Shaded nodes denote information included in the feature.

tags, which are generated dynamically.

More formally, we split the feature extractor  $\mathbf{f} = (f_1, \dots, f_d)$  into  $\mathbf{f} = (\mathbf{f}_L; \mathbf{f}_N)$  where  $\mathbf{f}_L$  and  $\mathbf{f}_N$  are the local and non-local features, respectively. For the former, we extend their domains from parses to hyperedges, where  $f(e)$  returns the value of a local feature  $f \in \mathbf{f}_L$  on hyperedge  $e$ , and its value on a parse  $y$  factors across the hyperedges (local productions),

$$\mathbf{f}_L(y) = \sum_{e \in y} \mathbf{f}_L(e) \quad (4)$$

and we can pre-compute  $\mathbf{f}_L(e)$  for each  $e$  in a forest.

Non-local features, however, can not be pre-computed, but we still prefer to compute them *early as possible*, which we call “on-the-fly” computation, so that our decoder can be sensitive to them at internal nodes. For instance, the **NGramTree** feature in Fig. 2 (d) returns the minimum tree fragmentation spanning a bigram, in this case “saw” and “the”, and should thus be computed at the *smallest common ancestor* of the two, which is the VP node in this example. Similarly, the **ParentRule** feature in Fig. 2 (b) can be computed when the S subtree is formed. In doing so, we essentially factor non-local features across *subtrees*, where for each subtree  $y'$  in a parse  $y$ , we define a **unit feature**  $\hat{f}(y')$  to be the part of  $f(y)$  that are computable within  $y'$ , but not computable in any (proper) subtree of  $y'$ . Then we have:

$$\mathbf{f}_N(y) = \sum_{y' \in y} \hat{\mathbf{f}}_N(y') \quad (5)$$

Intuitively, we compute the unit non-local features at each subtree from bottom-up. For example, for the binary-branching node  $A_{i,k}$  in Fig. 3, the

Figure 3: Example of the unit **NGramTree** feature at node  $A_{i,k}$ :  $\langle A (B \dots w_{j-1}) (C \dots w_j) \rangle$ .

unit **NGramTree** instance is for the pair  $\langle w_{j-1}, w_j \rangle$  on the boundary between the two subtrees, whose smallest common ancestor is the current node. Other unit **NGramTree** instances within this span have already been computed in the subtrees, except those for the boundary words of the whole node,  $w_i$  and  $w_{k-1}$ , which will be computed when this node is further combined with other nodes in the future.

### 3.3 Approximate Decoding via Cube Pruning

Before moving on to approximate decoding with non-local features, we first describe the algorithm for exact decoding when only local features are present, where many concepts and notations will be re-used later. We will use  $\mathbf{D}(v)$  to denote the top derivations of node  $v$ , where  $D_1(v)$  is its 1-best derivation. We also use the notation  $\langle e, \mathbf{j} \rangle$  to denote the derivation along hyperedge  $e$ , using the  $j_i$ th sub-derivation for tail  $u_i$ , so  $\langle e, \mathbf{1} \rangle$  is the best derivation along  $e$ . The exact decoding algorithm, shown in Pseudocode 2, is an instance of the bottom-up Viterbi algorithm, which traverses the hypergraph in a topological order, and at each node  $v$ , calculates its 1-best derivation using each incoming hyperedge  $e \in \text{IN}(v)$ . The cost of  $e$ ,  $c(e)$ , is the score of its

```

---

(pre-computed) local features  $\mathbf{w} \cdot \mathbf{f}_L(e)$ . This algorithm has a time complexity of  $O(E)$ , and is almost identical to traditional chart parsing, except that the forest might be more than binary-branching.

For non-local features, we adapt cube pruning from forest rescoring (Chiang, 2007; Huang and Chiang, 2007), since the situation here is analogous to machine translation decoding with integrated language models: we can view the scores of unit non-local features as the language model cost, computed on-the-fly when combining sub-constituents.

Shown in Pseudocode 3, cube pruning works bottom-up on the forest, keeping a beam of at most  $k$  derivations at each node, and uses the  $k$ -best parsing Algorithm 2 of Huang and Chiang (2005) to speed up the computation. When combining the sub-

derivations along a hyperedge  $e$  to form a new subtree  $y' = \langle e, \mathbf{j} \rangle$ , we also compute its unit non-local feature values  $\mathbf{f}_N(\langle e, \mathbf{j} \rangle)$  (line 25). A priority queue (*heap* in Pseudocode 3) is used to hold the candidates for the next-best derivation, which is initialized to the set of best derivations along each hyperedge (lines 7 to 9). Then at each iteration, we pop the best derivation (lines 12), and push its successors back into the priority queue (line 14). Analogous to the language model cost in forest rescoring, the unit feature cost here is a non-monotonic score in the dynamic programming backbone, and the derivations may thus be extracted *out-of-order*. So a buffer *buf* is used to hold extracted derivations, which is sorted at the end (line 15) to form the list of top- $k$  derivations  $\mathbf{D}(v)$  of node  $v$ . The complexity of this algorithm is  $O(E + Vk \log k\mathcal{N})$  (Huang and Chiang, 2005), where  $O(\mathcal{N})$  is the time for on-the-fly feature extraction for each subtree, which becomes the bottleneck in practice.

## 4 Supporting Forest Algorithms

### 4.1 Forest Oracle

Recall that the Parseval F-score is the harmonic mean of labelled precision  $P$  and labelled recall  $R$ :

$$F(y, y^*) \triangleq \frac{2PR}{P+R} = \frac{2|y \cap y^*|}{|y| + |y^*|} \quad (6)$$

where  $|y|$  and  $|y^*|$  are the numbers of brackets in the test parse and gold parse, respectively, and  $|y \cap y^*|$  is the number of matched brackets. Since the harmonic mean is a non-linear combination, we can not optimize the F-scores on sub-forests independently with a greedy algorithm. In other words, the optimal F-score tree in a forest is *not* guaranteed to be composed of two optimal F-score subtrees.

We instead propose a dynamic programming algorithm which optimizes the number of matched brackets for a given number of test brackets. For example, our algorithm will ask questions like,

“when a test parse has 5 brackets, what is the maximum number of matched brackets?”

More formally, at each node  $v$ , we compute an *oracle function*  $ora[v] : \mathbb{N} \mapsto \mathbb{N}$ , which maps an integer  $t$  to  $ora[v](t)$ , the max. number of matched brackets

---

**Pseudocode 4** Forest Oracle Algorithm
 

---

```

1: function ORACLE( $\langle V, E \rangle, y^*$ )
2:   for  $v \in V$  in topological order do
3:     for  $e \in BS(v)$  do
4:        $e$  is  $v \rightarrow u_1 u_2 \dots u_{|e|}$ 
5:        $ora[v] \leftarrow ora[v] \oplus (\otimes_i ora[u_i])$ 
6:        $ora[v] \leftarrow ora[v] \uparrow (1, \mathbf{1}_{v \in y^*})$ 
7:   return  $F(y^+, y^*) = \max_t \frac{2 \cdot ora[\text{TOP}](t)}{t + |y^*|} \triangleright \text{oracle } F_1$ 

```

---

for all parses  $y_v$  of node  $v$  with exactly  $t$  brackets:

$$ora[v](t) \triangleq \max_{y_v: |y_v|=t} |y_v \cap y^*| \quad (7)$$

When node  $v$  is combined with another node  $u$  along a hyperedge  $e = \langle (v, u), w \rangle$ , we need to combine the two oracle functions  $ora[v]$  and  $ora[u]$  by distributing the test brackets of  $w$  between  $v$  and  $u$ , and optimize the number of matched brackets. To do this we define a *convolution operator*  $\otimes$  between two functions  $f$  and  $g$ :

$$(f \otimes g)(t) \triangleq \max_{t_1+t_2=t} f(t_1) + g(t_2) \quad (8)$$

For instance:

$$\begin{array}{c|c} t & f(t) \\ \hline 2 & 1 \\ 3 & 2 \end{array} \otimes \begin{array}{c|c} t & g(t) \\ \hline 4 & 4 \\ 5 & 4 \end{array} = \begin{array}{c|c} t & (f \otimes g)(t) \\ \hline 6 & 5 \\ 7 & 6 \\ 8 & 6 \end{array}$$

The oracle function for the head node  $w$  is then

$$ora[w](t) = (ora[v] \otimes ora[u])(t-1) + \mathbf{1}_{w \in y^*} \quad (9)$$

where  $\mathbf{1}$  is the indicator function, returning 1 if node  $w$  is found in the gold tree  $y^*$ , in which case we increment the number of matched brackets. We can also express Eq. 9 in a purely functional form

$$ora[w] = (ora[v] \otimes ora[u]) \uparrow (1, \mathbf{1}_{w \in y^*}) \quad (10)$$

where  $\uparrow$  is a *translation operator* which shifts a function along the axes:

$$(f \uparrow (a, b))(t) \triangleq f(t-a) + b \quad (11)$$

Above we discussed the case of one hyperedge. If there is another hyperedge  $e'$  deriving node  $w$ , we also need to combine the resulting oracle functions from both hyperedges, for which we define a *pointwise addition operator*  $\oplus$ :

$$(f \oplus g)(t) \triangleq \max\{f(t), g(t)\} \quad (12)$$

Shown in Pseudocode 4, we perform these computations in a bottom-up topological order, and finally at the root node TOP, we can compute the best global F-score by maximizing over different numbers of test brackets (line 7). The oracle tree  $y^+$  can be recursively restored by keeping backpointers for each  $ora[v](t)$ , which we omit in the pseudocode.

The time complexity of this algorithm for a sentence of  $l$  words is  $O(|E| \cdot l^{2(a-1)})$  where  $a$  is the arity of the forest. For a CKY forest, this amounts to  $O(l^3 \cdot l^2) = O(l^5)$ , but for general forests like those in our experiments the complexities are much higher. In practice it takes on average 0.05 seconds for forests pruned by  $p = 10$  (see Section 4.2), but we can pre-compute and store the oracle for each forest before training starts.

## 4.2 Forest Pruning

Our forest pruning algorithm (Jonathan Graehl, p.c.) is very similar to the method based on marginal probability (Charniak and Johnson, 2005), except that ours prunes hyperedges as well as nodes. Basically, we use an Inside-Outside algorithm to compute the Viterbi inside cost  $\beta(v)$  and the Viterbi outside cost  $\alpha(v)$  for each node  $v$ , and then compute the **merit**  $\alpha\beta(e)$  for each hyperedge:

$$\alpha\beta(e) = \alpha(\text{head}(e)) + \sum_{u_i \in \text{tails}(e)} \beta(u_i) \quad (13)$$

Intuitively, this merit is the cost of the best derivation that traverses  $e$ , and the difference  $\delta(e) = \alpha\beta(e) - \beta(\text{TOP})$  can be seen as the distance away from the globally best derivation. We prune away all hyperedges that have  $\delta(e) > p$  for a threshold  $p$ . Nodes with all incoming hyperedges pruned are also pruned. The key difference from (Charniak and Johnson, 2005) is that in this algorithm, a node can “partially” survive the beam, with a subset of its hyperedges pruned. In practice, this method prunes on average 15% more hyperedges than their method.

## 5 Experiments

We compare the performance of our forest reranker against  $n$ -best reranking on the Penn English Treebank (Marcus et al., 1993). The baseline parser is the Charniak parser, which we modified to output a

packed forest for each sentence.<sup>3</sup>

## 5.1 Data Preparation

We use the standard split of the Treebank: sections 02-21 as the training data (39832 sentences), section 22 as the development set (1700 sentences), and section 23 as the test set (2416 sentences). Following (Charniak and Johnson, 2005), the training set is split into 20 folds, each containing about 1992 sentences, and is parsed by the Charniak parser with a model trained on sentences from the remaining 19 folds. The development set and the test set are parsed with a model trained on all 39832 training sentences.

We implemented both  $n$ -best and forest reranking systems in Python and ran our experiments on a 64-bit Dual-Core Intel Xeon with 3.0GHz CPUs. Our feature set is summarized in Table 2, which closely follows Charniak and Johnson (2005), except that we excluded the non-local features **Edges**, **NGram**, and **CoPar**, and simplified **Rule** and **NGramTree** features, since they were too complicated to compute.<sup>4</sup> We also added four *unlexicalized* local features from Collins (2000) to cope with data-sparsity.

Following Charniak and Johnson (2005), we extracted the features from the 50-best parses on the training set (sec. 02-21), and used a cut-off of 5 to prune away low-count features. There are 0.8M features in our final set, considerably fewer than that of Charniak and Johnson which has about 1.3M fea-

<sup>3</sup>This is a relatively minor change to the Charniak parser, since it implements Algorithm 3 of Huang and Chiang (2005) for efficient enumeration of  $n$ -best parses, which requires storing the forest. The modified parser and related scripts for handling forests (e.g. oracles) will be available on my homepage.

<sup>4</sup>In fact, our **Rule** and **ParentRule** features are two special cases of the original **Rule** feature in (Charniak and Johnson, 2005). We also restricted **NGramTree** to be on bigrams only.

Figure 4: Forests (shown with various pruning thresholds) enjoy higher oracle scores and more compact sizes than  $n$ -best lists (on sec 23).

tures in the updated version.<sup>5</sup> However, our initial experiments show that, even with this much simpler feature set, our 50-best reranker performed equally well as theirs (both with an F-score of 91.4, see Tables 3 and 4). This result confirms that our feature set design is appropriate, and the averaged perceptron learner is a reasonable candidate for reranking.

The forests dumped from the Charniak parser are huge in size, so we use the forest pruning algorithm in Section 4.2 to prune them down to a reasonable size. In the following experiments we use a threshold of  $p = 10$ , which results in forests with an average number of 123.1 hyperedges per forest. Then for each forest, we annotate its forest oracle, and on each hyperedge, pre-compute its local features.<sup>6</sup> Shown in Figure 4, these forests have a forest oracle of 97.8, which is 1.1% higher than the 50-best oracle (96.7), and are 8 times smaller in size.

## 5.2 Results and Analysis

Table 3 compares the performance of forest reranking against standard  $n$ -best reranking. For both systems, we first use only the local features, and then all the features. We use the development set to determine the optimal number of iterations for averaged perceptron, and report the  $F_1$  score on the test set. With only local features, our forest reranker achieves an F-score of 91.25, and with the addition of non-

<sup>5</sup><http://www.cog.brown.edu/~mj/software.htm>. We follow this version as it corrects some bugs from their 2005 paper which leads to a 0.4% increase in performance (see Table 4).

<sup>6</sup>A subset of local features, e.g. **WordEdges**, is independent of which hyperedge the node takes in a derivation, and can thus be annotated on nodes rather than hyperedges. We call these features *node-local*, which also include part of **Word** features.

local features, the accuracy rises to 91.69 (with beam size  $k = 15$ ), which is a 0.26% absolute improvement over 50-best reranking.<sup>7</sup>

This improvement might look relatively small, but it is much harder to make a similar progress with *n*-best reranking. For example, even if we double the size of the *n*-best list to 100, the performance only goes up by 0.06% (Table 3). In fact, the 100-best oracle is only 0.5% higher than the 50-best one (see Fig. 4). In addition, the feature extraction step in 100-best reranking produces huge data files and takes 44 hours in total, though this part can be parallelized.<sup>8</sup> On two CPUs, 100-best reranking takes 25 hours, while our forest-reranker can also finish in 26 hours, with a much smaller disk space. Indeed, this demonstrates the severe redundancies as another disadvantage of *n*-best lists, where many subtrees are repeated across different parses, while the packed forest reduces space dramatically by sharing common sub-derivations (see Fig. 4).

To put our results in perspective, we also compare them with other best-performing systems in Table 4. Our final result (91.7) is better than any previously reported system trained on the Treebank, although

<sup>7</sup>It is surprising that 50-best reranking with local features achieves an even higher F-score of 91.28, and we suspect this is due to the aggressive updates and instability of the perceptron, as we do observe the learning curves to be non-monotonic. We leave the use of more stable learning algorithms to future work.

<sup>8</sup>The *n*-best feature extraction already uses *relative counts* (Johnson, 2006), which reduced file sizes by at least a factor 4.

type	system	F <sub>1</sub> %

	<b>this work</b>	<b>91.7</b>
G	Bod (2003)	90.7
	Petrov and Klein (2007)	90.1
S	McClosky et al. (2006)	<b>92.1</b>

Table 4: Comparison of our final results with other best-performing systems on the whole Section 23. Types D, G, and S denote discriminative, generative, and semi-supervised approaches, respectively.

McClosky et al. (2006) achieved an even higher accuracy (92.1) by leveraging on much larger unlabelled data. Moreover, their technique is orthogonal to ours, and we suspect that replacing their *n*-best reranker by our forest reranker might get an even better performance. Plus, except for *n*-best reranking, most discriminative methods require repeated parsing of the training set, which is generally impractical (Petrov and Klein, 2008). Therefore, previous work often resorts to extremely short sentences ( $\leq 15$  words) or only looked at local features (Taskar et al., 2004; Henderson, 2004; Turian and Melamed, 2007). In comparison, thanks to the efficient decoding, our work not only scaled to the whole Treebank, but also successfully incorporated non-local features, which showed an absolute improvement of 0.44% over that of local features alone.

## 6 Conclusion

We have presented a framework for reranking on packed forests which compactly encodes many more candidates than *n*-best lists. With efficient approximate decoding, perceptron training on the whole Treebank becomes practical, which can be done in about a day even with a Python implementation. Our final result outperforms both 50-best and 100-best reranking baselines, and is better than any previously reported systems trained on the Treebank. We also devised a dynamic programming algorithm for forest oracles, an interesting problem by itself. We believe this general framework could also be applied to other problems involving forests or lattices, such as sequence labeling and machine translation.

# Simple Semi-supervised Dependency Parsing

Terry Koo, Xavier Carreras, and Michael Collins

MIT CSAIL, Cambridge, MA 02139, USA

{maestro, carreras, mcollins}@csail.mit.edu

## Abstract

We present a simple and effective semi-supervised method for training dependency parsers. We focus on the problem of lexical representation, introducing features that incorporate word clusters derived from a large unannotated corpus. We demonstrate the effectiveness of the approach in a series of dependency parsing experiments on the Penn Treebank and Prague Dependency Treebank, and we show that the cluster-based features yield substantial gains in performance across a wide range of conditions. For example, in the case of English unlabeled second-order parsing, we improve from a baseline accuracy of 92.02% to 93.16%, and in the case of Czech unlabeled second-order parsing, we improve from a baseline accuracy of 86.13% to 87.13%. In addition, we demonstrate that our method also improves performance when small amounts of training data are available, and can roughly halve the amount of supervised data required to reach a desired level of performance.

## 1 Introduction

In natural language parsing, lexical information is seen as crucial to resolving ambiguous relationships, yet lexicalized statistics are sparse and difficult to estimate directly. It is therefore attractive to consider intermediate entities which exist at a coarser level than the words themselves, yet capture the information necessary to resolve the relevant ambiguities.

In this paper, we introduce lexical intermediaries via a simple two-stage semi-supervised approach. First, we use a large unannotated corpus to define word clusters, and then we use that clustering to construct a new cluster-based feature mapping for a discriminative learner. We are thus relying on the ability of discriminative learning methods to identify

and exploit informative features while remaining agnostic as to the origin of such features. To demonstrate the effectiveness of our approach, we conduct experiments in dependency parsing, which has been the focus of much recent research—e.g., see work in the CoNLL shared tasks on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007).

The idea of combining word clusters with discriminative learning has been previously explored by Miller et al. (2004), in the context of named-entity recognition, and their work directly inspired our research. However, our target task of dependency parsing involves more complex structured relationships than named-entity tagging; moreover, it is not at all clear that word clusters should have any relevance to syntactic structure. Nevertheless, our experiments demonstrate that word clusters can be quite effective in dependency parsing applications.

In general, semi-supervised learning can be motivated by two concerns: first, given a fixed amount of supervised data, we might wish to leverage additional unlabeled data to facilitate the utilization of the supervised corpus, increasing the performance of the model in absolute terms. Second, given a fixed target performance level, we might wish to use unlabeled data to reduce the amount of annotated data necessary to reach this target.

We show that our semi-supervised approach yields improvements for fixed datasets by performing parsing experiments on the Penn Treebank (Marcus et al., 1993) and Prague Dependency Treebank (Hajič, 1998; Hajič et al., 2001) (see Sections 4.1 and 4.3). By conducting experiments on datasets of varying sizes, we demonstrate that for fixed levels of performance, the cluster-based approach can reduce the need for supervised data by roughly half, which is a substantial savings in data-annotation costs (see Sections 4.2 and 4.4).

The remainder of this paper is divided as follows:

Figure 1: An example of a labeled dependency tree. The tree contains a special token “\*” which is always the root of the tree. Each arc is directed from head to modifier and has a label describing the function of the attachment.

Section 2 gives background on dependency parsing and clustering, Section 3 describes the cluster-based features, Section 4 presents our experimental results, Section 5 discusses related work, and Section 6 concludes with ideas for future research.

## 2 Background

### 2.1 Dependency parsing

Recent work (Buchholz and Marsi, 2006; Nivre et al., 2007) has focused on dependency parsing. Dependency syntax represents syntactic information as a network of head-modifier dependency arcs, typically restricted to be a directed tree (see Figure 1 for an example). Dependency parsing depends critically on predicting head-modifier relationships, which can be difficult due to the statistical sparsity of these word-to-word interactions. Bilexical dependencies are thus ideal candidates for the application of coarse word proxies such as word clusters.

In this paper, we take a part-factored structured classification approach to dependency parsing. For a given sentence  $\mathbf{x}$ , let  $\mathcal{Y}(\mathbf{x})$  denote the set of possible dependency structures spanning  $\mathbf{x}$ , where each  $y \in \mathcal{Y}(\mathbf{x})$  decomposes into a set of “parts”  $r \in y$ . In the simplest case, these parts are the dependency arcs themselves, yielding a first-order or “edge-factored” dependency parsing model. In higher-order parsing models, the parts can consist of interactions between more than two words. For example, the parser of McDonald and Pereira (2006) defines parts for sibling interactions, such as the trio “plays”, “Elianti”, and “.” in Figure 1. The Carreras (2007) parser has parts for both sibling interactions and grandparent interactions, such as the trio “\*”, “plays”, and “Haag” in Figure 1. These kinds of higher-order factorizations allow dependency parsers to obtain a limited form of context-sensitivity.

Given a factorization of dependency structures into parts, we restate dependency parsing as the fol-

Figure 2: An example of a Brown word-cluster hierarchy. Each node in the tree is labeled with a bit-string indicating the path from the root node to that node, where 0 indicates a left branch and 1 indicates a right branch.

lowing maximization:

$$\text{PARSE}(\mathbf{x}; \mathbf{w}) = \operatorname{argmax}_{y \in \mathcal{Y}(\mathbf{x})} \sum_{r \in y} \mathbf{w} \cdot \mathbf{f}(\mathbf{x}, r)$$

Above, we have assumed that each part is scored by a linear model with parameters  $\mathbf{w}$  and feature-mapping  $\mathbf{f}(\cdot)$ . For many different part factorizations and structure domains  $\mathcal{Y}(\cdot)$ , it is possible to solve the above maximization efficiently, and several recent efforts have concentrated on designing new maximization algorithms with increased context-sensitivity (Eisner, 2000; McDonald et al., 2005b; McDonald and Pereira, 2006; Carreras, 2007).

### 2.2 Brown clustering algorithm

In order to provide word clusters for our experiments, we used the Brown clustering algorithm (Brown et al., 1992). We chose to work with the Brown algorithm due to its simplicity and prior success in other NLP applications (Miller et al., 2004; Liang, 2005). However, we expect that our approach can function with other clustering algorithms (as in, e.g., Li and McCallum (2005)). We briefly describe the Brown algorithm below.

The input to the algorithm is a vocabulary of words to be clustered and a corpus of text containing these words. Initially, each word in the vocabulary is considered to be in its own distinct cluster. The algorithm then repeatedly merges the pair of clusters which causes the smallest decrease in the likelihood of the text corpus, according to a class-based bigram language model defined on the word clusters. By tracing the pairwise merge operations, one obtains a hierarchical clustering of the words, which can be represented as a binary tree as in Figure 2.

Within this tree, each word is uniquely identified by its path from the root, and this path can be compactly represented with a bit string, as in Figure 2. In order to obtain a clustering of the words, we select all nodes at a certain depth from the root of the

hierarchy. For example, in Figure 2 we might select the four nodes at depth 2 from the root, yielding the clusters {apple,pear}, {Apple,IBM}, {bought,run}, and {of,in}. Note that the same clustering can be obtained by truncating each word’s bit-string to a 2-bit prefix. By using prefixes of various lengths, we can produce clusterings of different granularities (Miller et al., 2004).

For all of the experiments in this paper, we used the Liang (2005) implementation of the Brown algorithm to obtain the necessary word clusters.

### 3 Feature design

Key to the success of our approach is the use of features which allow word-cluster-based information to assist the parser. The feature sets we used are similar to other feature sets in the literature (McDonald et al., 2005a; Carreras, 2007), so we will not attempt to give a exhaustive description of the features in this section. Rather, we describe our features at a high level and concentrate on our methodology and motivations. In our experiments, we employed two different feature sets: a baseline feature set which draws upon “normal” information sources such as word forms and parts of speech, and a cluster-based feature set that also uses information derived from the Brown cluster hierarchy.

#### 3.1 Baseline features

Our first-order baseline feature set is similar to the feature set of McDonald et al. (2005a), and consists of indicator functions for combinations of words and parts of speech for the head and modifier of each dependency, as well as certain contextual tokens.<sup>1</sup> Our second-order baseline features are the same as those of Carreras (2007) and include indicators for triples of part of speech tags for sibling interactions and grandparent interactions, as well as additional bigram features based on pairs of words involved these higher-order interactions. Examples of baseline features are provided in Table 1.

<sup>1</sup>We augment the McDonald et al. (2005a) feature set with backed-off versions of the “Surrounding Word POS Features” that include only one neighboring POS tag. We also add binned distance features which indicate whether the number of tokens between the head and modifier of a dependency is greater than 2, 5, 10, 20, 30, or 40 tokens.

Baseline	Cluster-based
ht, mt	hc4, mc4
hw, mw	hc6, mc6
hw, ht, mt	hc*, mc*
hw, ht, mw	hc4, mt
ht, mw, mt	ht, mc4
hw, mw, mt	hc6, mt
hw, ht, mw, mt	ht, mc6
...	hc4, mw
	hw, mc4
	...
ht, mt, st	hc4, mc4, sc4
ht, mt, gt	hc6, mc6, sc6
...	ht, mc4, sc4
	hc4, mc4, gc4
	...

Table 1: Examples of baseline and cluster-based feature templates. Each entry represents a class of indicators for tuples of information. For example, “ht, mt” represents a class of indicator features with one feature for each possible combination of head POS-tag and modifier POS-tag. Abbreviations: ht = head POS, hw = head word, hc4 = 4-bit prefix of head, hc6 = 6-bit prefix of head, hc\* = full bit string of head; mt, mw, mc4, mc6, mc\* = likewise for modifier; st, gt, sc4, gc4, ... = likewise for sibling and grandchild.

#### 3.2 Cluster-based features

The first- and second-order cluster-based feature sets are supersets of the baseline feature sets: they include all of the baseline feature templates, and add an additional layer of features that incorporate word clusters. Following Miller et al. (2004), we use prefixes of the Brown cluster hierarchy to produce clusterings of varying granularity. We found that it was nontrivial to select the proper prefix lengths for the dependency parsing task; in particular, the prefix lengths used in the Miller et al. (2004) work (between 12 and 20 bits) performed poorly in dependency parsing.<sup>2</sup> After experimenting with many different feature configurations, we eventually settled on a simple but effective methodology.

First, we found that it was helpful to employ two different types of word clusters:

1. Short bit-string prefixes (e.g., 4–6 bits), which we used as replacements for parts of speech.

<sup>2</sup>One possible explanation is that the kinds of distinctions required in a named-entity recognition task (e.g., “Alice” versus “Intel”) are much finer-grained than the kinds of distinctions relevant to syntax (e.g., “apple” versus “eat”).

2. Full bit strings,<sup>3</sup> which we used as substitutes for word forms.

Using these two types of clusters, we generated new features by mimicking the template structure of the original baseline features. For example, the baseline feature set includes indicators for word-to-word and tag-to-tag interactions between the head and modifier of a dependency. In the cluster-based feature set, we correspondingly introduce new indicators for interactions between pairs of short bit-string prefixes and pairs of full bit strings. Some examples of cluster-based features are given in Table 1.

Second, we found it useful to concentrate on “hybrid” features involving, e.g., one bit-string and one part of speech. In our initial attempts, we focused on features that used cluster information exclusively. While these cluster-only features provided some benefit, we found that adding hybrid features resulted in even greater improvements. One possible explanation is that the clusterings generated by the Brown algorithm can be noisy or only weakly relevant to syntax; thus, the clusters are best exploited when “anchored” to words or parts of speech.

Finally, we found it useful to impose a form of vocabulary restriction on the cluster-based features. Specifically, for any feature that is predicated on a word form, we eliminate this feature if the word in question is *not* one of the top- $N$  most frequent words in the corpus. When  $N$  is between roughly 100 and 1,000, there is little effect on the performance of the cluster-based feature sets.<sup>4</sup> In addition, the vocabulary restriction reduces the size of the feature sets to manageable proportions.

## 4 Experiments

In order to evaluate the effectiveness of the cluster-based feature sets, we conducted dependency parsing experiments in English and Czech. We test the features in a wide range of parsing configurations, including first-order and second-order parsers, and labeled and unlabeled parsers.<sup>5</sup>

<sup>3</sup>As in Brown et al. (1992), we limit the clustering algorithm so that it recovers at most 1,000 distinct bit-strings; thus full bit strings are not equivalent to word forms.

<sup>4</sup>We used  $N = 800$  for all experiments in this paper.

<sup>5</sup>In an “unlabeled” parser, we simply ignore dependency label information, which is a common simplification.

The English experiments were performed on the Penn Treebank (Marcus et al., 1993), using a standard set of head-selection rules (Yamada and Matsumoto, 2003) to convert the phrase structure syntax of the Treebank to a dependency tree representation.<sup>6</sup> We split the Treebank into a training set (Sections 2–21), a development set (Section 22), and several test sets (Sections 0,<sup>7</sup> 1, 23, and 24). The data partition and head rules were chosen to match previous work (Yamada and Matsumoto, 2003; McDonald et al., 2005a; McDonald and Pereira, 2006). The part of speech tags for the development and test data were automatically assigned by MXPOST (Ratnaparkhi, 1996), where the tagger was trained on the entire training corpus; to generate part of speech tags for the training data, we used 10-way jackknifing.<sup>8</sup> English word clusters were derived from the BLLIP corpus (Charniak et al., 2000), which contains roughly 43 million words of Wall Street Journal text.<sup>9</sup>

The Czech experiments were performed on the Prague Dependency Treebank 1.0 (Hajič, 1998; Hajič et al., 2001), which is directly annotated with dependency structures. To facilitate comparisons with previous work (McDonald et al., 2005b; McDonald and Pereira, 2006), we used the training/development/test partition defined in the corpus and we also used the automatically-assigned part of speech tags provided in the corpus.<sup>10</sup> Czech word clusters were derived from the raw text section of the PDT 1.0, which contains about 39 million words of newswire text.<sup>11</sup>

We trained the parsers using the averaged perceptron (Freund and Schapire, 1999; Collins, 2002), which represents a balance between strong performance and fast training times. To select the number

<sup>6</sup>We used Joakim Nivre’s “Penn2Malt” conversion tool (<http://w3.msi.vxu.se/nivre/research/Penn2Malt.html>). Dependency labels were obtained via the “Malt” hard-coded setting.

<sup>7</sup>For computational reasons, we removed a single 249-word sentence from Section 0.

<sup>8</sup>That is, we tagged each fold with the tagger trained on the other 9 folds.

<sup>9</sup>We ensured that the sentences of the Penn Treebank were excluded from the text used for the clustering.

<sup>10</sup>Following Collins et al. (1999), we used a coarsened version of the Czech part of speech tags; this choice also matches the conditions of previous work (McDonald et al., 2005b; McDonald and Pereira, 2006).

<sup>11</sup>This text was disjoint from the training and test corpora.

Table 2: Parent-prediction accuracies on Sections 0, 1, 23, and 24. Abbreviations: dep1/dep1c = first-order parser with baseline/cluster-based features; dep2/dep2c = second-order parser with baseline/cluster-based features; MD1 = McDonald et al. (2005a); MD2 = McDonald and Pereira (2006); suffix -L = labeled parser. Unlabeled parsers are scored using unlabeled parent predictions, and labeled parsers are scored using labeled parent predictions. Improvements of cluster-based features over baseline features are shown in parentheses.

of iterations of perceptron training, we performed up to 30 iterations and chose the iteration which optimized accuracy on the development set. Our feature mappings are quite high-dimensional, so we eliminated all features which occur only once in the training data. The resulting models still had very high dimensionality, ranging from tens of millions to as many as a billion features.<sup>12</sup>

All results presented in this section are given in terms of parent-prediction accuracy, which measures the percentage of tokens that are attached to the correct head token. For labeled dependency structures, both the head token and dependency label must be correctly predicted. In addition, in English parsing we ignore the parent-predictions of punctuation tokens,<sup>13</sup> and in Czech parsing we retain the punctuation tokens; this matches previous work (Yamada and Matsumoto, 2003; McDonald et al., 2005a; McDonald and Pereira, 2006).

#### 4.1 English main results

In our English experiments, we tested eight different parsing configurations, representing all possible choices between baseline or cluster-based feature sets, first-order (Eisner, 2000) or second-order (Carreras, 2007) factorizations, and labeled or unlabeled parsing.

Table 2 compiles our final test results and also includes two results from previous work by McDonald et al. (2005a) and McDonald and Pereira (2006), for the purposes of comparison. We note a few small differences between our parsers and the

parsers evaluated in this previous work. First, the MD1 and MD2 parsers were trained via the MIRA algorithm (Crammer and Singer, 2003; Crammer et al., 2004), while we use the averaged perceptron. In addition, the MD2 model uses only sibling interactions, whereas the dep2/dep2c parsers include both sibling and grandparent interactions.

There are some clear trends in the results of Table 2. First, performance increases with the order of the parser: edge-factored models (dep1 and MD1) have the lowest performance, adding sibling relationships (MD2) increases performance, and adding grandparent relationships (dep2) yields even better accuracies. Similar observations regarding the effect of model order have also been made by Carreras (2007).

Second, note that the parsers using cluster-based feature sets consistently outperform the models using the baseline features, regardless of model order or label usage. Some of these improvements can be quite large; for example, a first-order model using cluster-based features generally performs as well as a second-order model using baseline features. Moreover, the benefits of cluster-based feature sets combine additively with the gains of increasing model order. For example, consider the unlabeled parsers in Table 2: on Section 23, increasing the model order from dep1 to dep2 results in a relative reduction in error of roughly 13%, while introducing cluster-based features from dep2 to dep2c yields an additional relative error reduction of roughly 14%. As a final note, all 16 comparisons between cluster-based features and baseline features shown in Table 2 are statistically significant.<sup>14</sup>

<sup>12</sup>Due to the sparsity of the perceptron updates, however, only a small fraction of the possible features were active in our trained models.

<sup>13</sup>A punctuation token is any token whose gold-standard part of speech tag is one of { ` ` ' ' : , . }.

<sup>14</sup>We used the sign test at the sentence level. The comparison between dep1-L and dep1c-L is significant at  $p < 0.05$ , and all other comparisons are significant at  $p < 0.0005$ .

## 4.2 English learning curves

We performed additional experiments to evaluate the effect of the cluster-based features as the amount of training data is varied. Note that the dependency parsers we use require the input to be tagged with parts of speech; thus the quality of the part-of-speech tagger can have a strong effect on the performance of the parser. In these experiments, we consider two possible scenarios:

1. The tagger has a large training corpus, while the parser has a smaller training corpus. This scenario can arise when tagged data is cheaper to obtain than syntactically-annotated data.
2. The same amount of labeled data is available for training both tagger and parser.

Table 3 displays the accuracy of first- and second-order models when trained on smaller portions of the Treebank, in both scenarios described above. Note that the cluster-based features obtain consistent gains regardless of the size of the training set. When the tagger is trained on the reduced-size datasets, the gains of cluster-based features are more pronounced, but substantial improvements are obtained even when the tagger is accurate.

It is interesting to consider the amount by which cluster-based features reduce the need for supervised data, given a desired level of accuracy. Based on Table 3, we can extrapolate that cluster-based features reduce the need for supervised data by roughly a factor of 2. For example, the performance of the dep1c and dep2c models trained on 1k sentences is roughly the same as the performance of the dep1 and dep2 models, respectively, trained on 2k sentences. This approximate data-halving effect can be

observed throughout the results in Table 3.

When combining the effects of model order and cluster-based features, the reductions in the amount of supervised data required are even larger. For example, in scenario 1 the dep2c model trained on 1k sentences is close in performance to the dep1 model trained on 4k sentences, and the dep2c model trained on 4k sentences is close to the dep1 model trained on the entire training set (roughly 40k sentences).

## 4.3 Czech main results

In our Czech experiments, we considered only unlabeled parsing,<sup>15</sup> leaving four different parsing configurations: baseline or cluster-based features and first-order or second-order parsing. Note that our feature sets were originally tuned for English parsing, and except for the use of Czech clusters, we made no attempt to retune our features for Czech.

Czech dependency structures may contain non-projective edges, so we employ a maximum directed spanning tree algorithm (Chu and Liu, 1965; Edmonds, 1967; McDonald et al., 2005b) as our first-order parser for Czech. For the second-order parsing experiments, we used the Carreras (2007) parser. Since this parser only considers projective dependency structures, we “projectivized” the PDT 1.0 training set by finding, for each sentence, the projective tree which retains the most correct dependencies; our second-order parsers were then trained with respect to these projective trees. The development and test sets were *not* projectivized, so our second-order parser is guaranteed to make errors in test sentences containing non-projective dependencies. To overcome this, McDonald and Pereira (2006) use a

<sup>15</sup>We leave labeled parsing experiments to future work.

two-stage approximate decoding process in which the output of their second-order parser is “deprojectivized” via greedy search. For simplicity, we did not implement a deprojectivization stage on top of our second-order parser, but we conjecture that such techniques may yield some additional performance gains; we leave this to future work.

Table 4 gives accuracy results on the PDT 1.0 test set for our unlabeled parsers. As in the English experiments, there are clear trends in the results: parsers using cluster-based features outperform parsers using baseline features, and second-order parsers outperform first-order parsers. Both of the comparisons between cluster-based and baseline features in Table 4 are statistically significant.<sup>16</sup> Table 5 compares accuracy results on the PDT 1.0 test set for our parsers and several other recent papers.

<sup>16</sup>We used the sign test at the sentence level; both comparisons are significant at  $p < 0.0005$ .

Table 8: Parent-prediction accuracies of unlabeled English parsers on Section 22. Abbreviations: suffix -P = model without POS; other abbreviations are as in Table 2.

#### 4.4 Czech learning curves

As in our English experiments, we performed additional experiments on reduced sections of the PDT; the results are shown in Table 6. For simplicity, we did not retrain a tagger for each reduced dataset, so we always use the (automatically-assigned) part of speech tags provided in the corpus. Note that the cluster-based features obtain improvements at all training set sizes, with data-reduction factors similar to those observed in English. For example, the dep1c model trained on 4k sentences is roughly as good as the dep1 model trained on 8k sentences.

#### 4.5 Additional results

Here, we present two additional results which further explore the behavior of the cluster-based feature sets. In Table 7, we show the development-set performance of second-order parsers as the threshold for lexical feature elimination (see Section 3.2) is varied. Note that the performance of cluster-based features is fairly insensitive to the threshold value, whereas the performance of baseline features clearly degrades as the vocabulary size is reduced.

In Table 8, we show the development-set performance of the first- and second-order parsers when features containing part-of-speech-based information are eliminated. Note that the performance obtained by using clusters *without* parts of speech is close to the performance of the baseline features.

## 5 Related Work

As mentioned earlier, our approach was inspired by the success of Miller et al. (2004), who demonstrated the effectiveness of using word clusters as features in a discriminative learning approach. Our research, however, applies this technique to dependency parsing rather than named-entity recognition.

In this paper, we have focused on developing new representations for lexical information. Previous research in this area includes several models which incorporate hidden variables (Matsuzaki et al., 2005; Koo and Collins, 2005; Petrov et al., 2006; Titov and Henderson, 2007). These approaches have the advantage that the model is able to learn different usages for the hidden variables, depending on the target problem at hand. Crucially, however, these methods do not exploit unlabeled data when learning their representations.

Wang et al. (2005) used distributional similarity scores to smooth a generative probability model for dependency parsing and obtained improvements in a Chinese parsing task. Our approach is similar to theirs in that the Brown algorithm produces clusters based on distributional similarity, and the cluster-based features can be viewed as being a kind of “backed-off” version of the baseline features. However, our work is focused on discriminative learning as opposed to generative models.

Semi-supervised phrase structure parsing has been previously explored by McClosky et al. (2006), who applied a reranked parser to a large unsupervised corpus in order to obtain additional training data for the parser; this self-training approach was shown to be quite effective in practice. However, their approach depends on the usage of a high-quality parse reranker, whereas the method described here simply augments the features of an existing parser. Note that our two approaches are compatible in that we could also design a reranker and apply self-training techniques on top of the cluster-based features.

## 6 Conclusions

In this paper, we have presented a simple but effective semi-supervised learning approach and demonstrated that it achieves substantial improvement over a competitive baseline in two broad-coverage depen-

ency parsing tasks. Despite this success, there are several ways in which our approach might be improved.

To begin, recall that the Brown clustering algorithm is based on a bigram language model. Intuitively, there is a “mismatch” between the kind of lexical information that is captured by the Brown clusters and the kind of lexical information that is modeled in dependency parsing. A natural avenue for further research would be the development of clustering algorithms that reflect the syntactic behavior of words; e.g., an algorithm that attempts to maximize the likelihood of a treebank, according to a probabilistic dependency model. Alternately, one could design clustering algorithms that cluster entire head-modifier arcs rather than individual words.

Another idea would be to integrate the clustering algorithm into the training algorithm in a limited fashion. For example, after training an initial parser, one could parse a large amount of unlabeled text and use those parses to improve the quality of the clusters. These improved clusters can then be used to retrain an improved parser, resulting in an overall algorithm similar to that of McClosky et al. (2006).

Setting aside the development of new clustering algorithms, a final area for future work is the extension of our method to new domains, such as conversational text or other languages, and new NLP problems, such as machine translation.

## Acknowledgments

The authors thank the anonymous reviewers for their insightful comments. Many thanks also to Percy Liang for providing his implementation of the Brown algorithm, and Ryan McDonald for his assistance with the experimental setup. The authors gratefully acknowledge the following sources of support. Terry Koo was funded by NSF grant DMS-0434222 and a grant from NTT, Agmt. Dtd. 6/21/1998. Xavier Carreras was supported by the Catalan Ministry of Innovation, Universities and Enterprise, and a grant from NTT, Agmt. Dtd. 6/21/1998. Michael Collins was funded by NSF grants 0347631 and DMS-0434222.

## Abstract

Synchronous Tree-Adjoining Grammar (STAG) is a promising formalism for syntax-aware machine translation and simultaneous computation of natural-language syntax and semantics. Current research in both of these areas is actively pursuing its incorporation. However, STAG parsing is known to be NP-hard due to the potential for intertwined correspondences between the linked nonterminal symbols in the elementary structures. Given a particular grammar, the polynomial degree of efficient STAG parsing algorithms depends directly on the *rank* of the grammar: the maximum number of correspondences that appear within a single elementary structure. In this paper we present a compile-time algorithm for transforming a STAG into a strongly-equivalent STAG that optimally minimizes the rank,  $k$ , across the grammar. The algorithm performs in  $\mathcal{O}(|G| + |Y| \cdot L_G^3)$  time where  $L_G$  is the maximum number of links in any single synchronous tree pair in the grammar and  $Y$  is the set of synchronous tree pairs of  $G$ .

## 1 Introduction

Tree-adjoining grammar is a widely used formalism in natural-language processing due to its mildly-context-sensitive expressivity, its ability to naturally capture natural-language argument substitution (via its substitution operation) and optional modification (via its adjunction operation), and the existence of efficient algorithms for processing it. Recently, the desire to incorporate syntax-awareness into machine translation systems has generated interest in

the application of synchronous tree-adjoining grammar (STAG) to this problem (Nesson, Shieber, and Rush, 2006; Chiang and Rambow, 2006). In a parallel development, interest in incorporating semantic computation into the TAG framework has led to the use of STAG for this purpose (Nesson and Shieber, 2007; Han, 2006b; Han, 2006a; Nesson and Shieber, 2006). Although STAG does not increase the expressivity of the underlying formalisms (Shieber, 1994), STAG parsing is known to be NP-hard due to the potential for intertwined correspondences between the linked nonterminal symbols in the elementary structures (Satta, 1992; Weir, 1988). Without efficient algorithms for processing it, its potential for use in machine translation and TAG semantics systems is limited.

Given a particular grammar, the polynomial degree of efficient STAG parsing algorithms depends directly on the *rank* of the grammar: the maximum number of correspondences that appear within a single elementary structure. This is illustrated by the tree pairs given in Figure 1 in which no two numbered links may be isolated. (By “isolated”, we mean that the links can be contained in a fragment of the tree that contains no other links and dominates only one branch not contained in the fragment. A precise definition is given in section 3.)

An analogous problem has long been known to exist for synchronous context-free grammars (SCFG) (Aho and Ullman, 1969). The task of producing efficient parsers for SCFG has recently been addressed by binarization or  $k$ -arization of SCFG grammars that produce equivalent grammars in which the rank,  $k$ , has been minimized (Zhang

Figure 1: Example of intertwined links that cannot be binarized. No two links can be isolated in both trees in a tree pair. Note that in tree pair  $\gamma_1$ , any set of three links may be isolated while in tree pair  $\gamma_2$ , no group of fewer than four links may be isolated. In  $\gamma_3$  no group of links smaller than four may be isolated.

Figure 2: An example STAG derivation of the English/French sentence pair “John likes red candies”/“Jean aime les bonbons rouges”. The figure is divided as follows: (a) the STAG grammar, (b) the derivation tree for the sentence pair, and (c) the derived tree pair for the sentences.

and Gildea, 2007; Zhang et al., 2006; Gildea, Satta, and Zhang, 2006). The methods for  $k$ -arization of SCFG cannot be directly applied to STAG because of the additional complexity introduced by the expressivity-increasing adjunction operation of TAG. In SCFG, where substitution is the only available operation and the depth of elementary structures is limited to one, the  $k$ -arization problem reduces to analysis of permutations of strings of non-terminal symbols. In STAG, however, the arbitrary depth of the elementary structures and the lack of restriction to contiguous strings of nonterminals introduced by adjunction substantially complicate the task.

In this paper we offer the first algorithm addressing this problem for the STAG case. We present a compile-time algorithm for transforming a STAG into a strongly-equivalent STAG that optimally minimizes  $k$  across the grammar. This is a critical minimization because  $k$  is the feature of the grammar that appears in the exponent of the complexity of parsing algorithms for STAG. Following the method of Seki

et al. (1991), an STAG parser can be implemented with complexity  $\mathcal{O}(n^{4 \cdot (k+1)} \cdot |G|)$ . By minimizing  $k$ , the worst-case complexity of a parser instantiated for a particular grammar is optimized. The  $k$ -arization algorithm performs in  $\mathcal{O}(|G| + |Y| \cdot L_G^3)$  time where  $L_G$  is the maximum number of links in any single synchronous tree pair in the grammar and  $Y$  is the set of synchronous tree pairs of  $G$ . By comparison, a baseline algorithm performing exhaustive search requires  $\mathcal{O}(|G| + |Y| \cdot L_G^6)$  time.<sup>1</sup>

The remainder of the paper proceeds as follows. In section 2 we provide a brief introduction to the STAG formalism. We present the  $k$ -arization algorithm in section 3 and an analysis of its complexity in section 4. We prove the correctness of the algorithm in section 5.

<sup>1</sup>In a synchronous tree pair with  $L$  links, there are  $\mathcal{O}(L^4)$  pairs of valid fragments. It takes  $\mathcal{O}(L)$  time to check if the two components in a pair have the same set of links. Once the synchronous fragment with the smallest number of links is excised, this process iterates at most  $L$  times, resulting in time  $\mathcal{O}(L_G^6)$ .

Figure 3: A synchronous tree pair containing fragments  $\alpha_L = \gamma_L(n_1, n_2)$  and  $\alpha_R = \gamma_R(n_3)$ . Since  $\text{links}(n_1, n_2) = \text{links}(n_3) = \{\underline{2}, \underline{4}, \underline{5}\}$ , we can define synchronous fragment  $\alpha = \langle \alpha_L, \alpha_R \rangle$ . Note also that node  $n_3$  is a maximal node and node  $n_5$  is not.  $\sigma(n_1) = \underline{2}\underline{5}\underline{5}\underline{3}\underline{3}\underline{2}\underline{4}\underline{4}$ ;  $\sigma(n_3) = \underline{2}\underline{5}\underline{5}\underline{4}\underline{4}\underline{2}$ .

## 2 Synchronous Tree-Adjoining Grammar

A tree-adjoining grammar (TAG) consists of a set of elementary tree structures of arbitrary depth, which are combined by substitution, familiar from context-free grammars, or an operation of adjunction that is particular to the TAG formalism. **Auxiliary trees** are elementary trees in which the root and a frontier node, called the **foot node** and distinguished by the diacritic \*, are labeled with the same nonterminal  $A$ . The adjunction operation involves splicing an auxiliary tree in at an internal node in an elementary tree also labeled with nonterminal  $A$ . Trees without a foot node, which serve as a base for derivations, are called **initial trees**. For further background, refer to the survey by Joshi and Schabes (1997).

We depart from the traditional definition in notation only by specifying adjunction and substitution sites explicitly with numbered links. Each link may be used only once in a derivation. Operations may only occur at nodes marked with a link. For simplicity of presentation we provisionally assume that only one link is permitted at a node. We later drop this assumption.

In a synchronous TAG (STAG) the elementary structures are ordered pairs of TAG trees, with a linking relation specified over pairs of nonterminal nodes. Each link has two locations, one in the left tree in a pair and the other in the right tree. An example of an STAG derivation including both substitution and adjunction is given in Figure 2. For further background, refer to the work of Shieber and Schabes (1990) and Shieber (1994).

## 3 $k$ -arization Algorithm

For a synchronous tree pair  $\gamma = \langle \gamma_L, \gamma_R \rangle$ , a **fragment** of  $\gamma_L$  (or  $\gamma_R$ ) is a complete subtree rooted at some node  $n$  of  $\gamma_L$ , written  $\gamma_L(n)$ , or else a subtree rooted at  $n$  with a gap at node  $n'$ , written  $\gamma_L(n, n')$ ; see Figure 3 for an example. We write  $\text{links}(n)$  and  $\text{links}(n, n')$  to denote the set of links of  $\gamma_L(n)$  and  $\gamma_L(n, n')$ , respectively. When we do not know the root or gap nodes of some fragment  $\alpha_L$ , we also write  $\text{links}(\alpha_L)$ .

We say that a set of links  $\Lambda$  from  $\gamma$  can be **isolated** if there exist fragments  $\alpha_L$  and  $\alpha_R$  of  $\gamma_L$  and  $\gamma_R$ , respectively, both with links  $\Lambda$ . If this is the case, we can construct a synchronous fragment  $\alpha = \langle \alpha_L, \alpha_R \rangle$ . The goal of our algorithm is to decompose  $\gamma$  into synchronous fragments such that the maximum number of links of a synchronous fragment is kept to a minimum, and  $\gamma$  can be obtained from the synchronous fragments by means of the usual substitution and adjunction operations. In order to simplify the presentation of our algorithm we assume, without any loss of generality, that all elementary trees of the source STAG have nodes with at most two children.

### 3.1 Maximal Nodes

A node  $n$  of  $\gamma_L$  (or  $\gamma_R$ ) is called **maximal** if (i)  $\text{links}(n) \neq \emptyset$ , and (ii) it is either the root node of  $\gamma_L$  or, for its parent node  $n'$ , we have  $\text{links}(n') \neq \text{links}(n)$ . Note that for every node  $n'$  of  $\gamma_L$  such that  $\text{links}(n') \neq \emptyset$  there is always a unique maximal node  $n$  such that  $\text{links}(n') = \text{links}(n)$ . Thus, for the purpose of our algorithm, we need only look at maximal nodes as places for excising tree fragments. We can show that the number of maximal nodes  $M_n$  in a subtree  $\gamma_L(n)$  always satisfies  $|\text{links}(n)| \leq M_n \leq 2 \times |\text{links}(n)| - 1$ .

Let  $n$  be some node of  $\gamma_L$ , and let  $l(n)$  be the (unique) link impinging on  $n$  if such a link exists, and  $l(n) = \varepsilon$  otherwise. We associate  $n$  with a string  $\sigma(n)$ , defined by a pre- and post-order traversal of fragment  $\gamma_L(n)$ . The symbols of  $\sigma(n)$  are the links in  $\text{links}(n)$ , viewed as atomic symbols. Given a node  $n$  with  $p$  children  $n_1, \dots, n_p$ ,  $0 \leq p \leq 2$ , we define  $\sigma(n) = l(n) \sigma(n_1) \cdots \sigma(n_p) l(n)$ . See again Figure 3 for an example. Note that  $|\sigma(n)| = 2 \times |\text{links}(n)|$ .

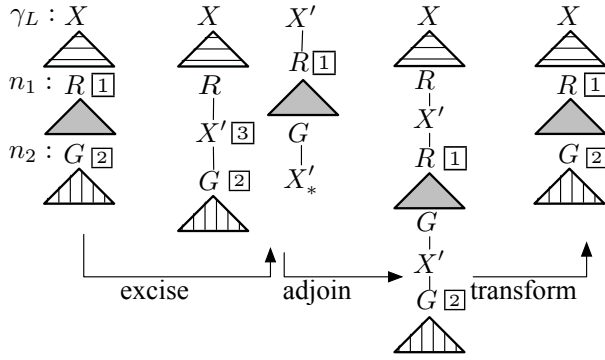

Figure 4: A diagram of the tree transformation performed when fragment  $\gamma_L(n_1, n_2)$  is removed. In this and the diagrams that follow, patterned or shaded triangles represent segments of the tree that contain multiple nodes and at least one link. Where the pattern or shading corresponds across trees in a tree pair, the set of links contained within those triangles are equivalent.

### 3.2 Excision of Synchronous Fragments

Although it would be possible to excise synchronous fragments without creating new nonterminal nodes, for clarity we present a simple tree transformation when a fragment is excised that leaves existing nodes intact. A schematic depiction is given in Figure 4. In the figure, we demonstrate the excision process on one half of a synchronous fragment:  $\gamma_L(n_1, n_2)$  is excised to form two new trees. The excised tree is not processed further. In the excision process the root and gap nodes of the original tree are not altered. The material between them is replaced with a single new node with a fresh nonterminal symbol and a fresh link number. This nonterminal node and link form the adjunction or substitution site for the excised tree. Note that any link impinging on the root node of the excised fragment is by our convention included in the fragment and any link impinging on the gap node is not.

To regenerate the original tree, the excised fragment can be adjoined or substituted back into the tree from which it was excised. The new nodes that were generated in the excision may be removed and the original root and gap nodes may be merged back together retaining any impinging links, respectively. Note that if there was a link on either the root or gap node in the original tree, it is not lost or duplicated

in the process.

### 3.3 Method

Let  $n_L$  and  $n_R$  be the root nodes of trees  $\gamma_L$  and  $\gamma_R$ , respectively. We know that  $\text{links}(n_L) = \text{links}(n_R)$ , and  $|\sigma(n_L)| = |\sigma(n_R)|$ , the second string being a rearrangement of the occurrences of symbols in the first one. The main data structure of our algorithm is a Boolean matrix  $\pi$  of size  $|\sigma(n_L)| \times |\sigma(n_L)|$ , whose rows are addressed by the occurrences of symbols in  $\sigma(n_L)$ , in the given order, and whose columns are similarly addressed by  $\sigma(n_R)$ . For occurrences of links  $\overline{x_1}, \overline{x_2}$ , the element of  $\pi$  at a row addressed by  $x_1$  and a column addressed by  $x_2$  is 1 if  $x_1 = x_2$ , and 0 otherwise. Thus, each row and column of  $\pi$  has exactly two non-zero entries. See Figure 5 for an example.

For a maximal node  $n_1$  of  $\gamma_L$ , we let  $\pi(n_1)$  denote the stripe of adjacent rows of  $\pi$  addressed by substring  $\sigma(n_1)$  of  $\sigma(n_L)$ . If  $n_1$  dominates  $n_2$  in  $\gamma_L$ , we let  $\pi(n_1, n_2)$  denote the rows of  $\pi$  addressed by  $\sigma(n_1)$  but not by  $\sigma(n_2)$ . This forms a pair of horizontal stripes in  $\pi$ . For nodes  $n_3, n_4$  of  $\gamma_R$ , we similarly define  $\pi(n_3)$  and  $\pi(n_3, n_4)$  as vertical stripes of adjacent columns. See again Figure 5.

Our algorithm is reported in Figure 6. For each synchronous tree pair  $\gamma = \langle \gamma_L, \gamma_R \rangle$  from the input grammar, we maintain an agenda  $B$  with all candidate fragments  $\alpha_L$  from  $\gamma_L$  having at least two links. These fragments are processed greedily in order of increasing number of links. The function ISOLATE(), described in more detail be-

```

1: Function KARIZE( $G$ ) { $G$  a binary STAG}
2:  $G' \leftarrow$  STAG with empty set of synch trees;
3: for all  $\gamma = \langle \gamma_L, \gamma_R \rangle$  in  $G$  do
4:   init  $\pi$  and  $B$ ;
5:   while  $B \neq \emptyset$  do
6:      $\alpha_L \leftarrow$  next fragment from  $B$ ;
7:      $\alpha_R \leftarrow$  ISOLATE( $\alpha_L, \pi, \gamma_R$ );
8:     if  $\alpha_R \neq \text{null}$  then
9:       add  $\langle \alpha_L, \alpha_R \rangle$  to  $G'$ ;
10:       $\gamma \leftarrow$  excise  $\langle \alpha_L, \alpha_R \rangle$  from  $\gamma$ ;
11:      update  $\pi$  and  $B$ ;
12:   add  $\gamma$  to  $G'$ ;
13: return  $G'$ 

```

Figure 6: Main algorithm.

low, looks for a right fragment  $\alpha_R$  with the same links as  $\alpha_L$ . Upon success, the synchronous fragment  $\alpha = \langle \alpha_L, \alpha_R \rangle$  is added to the output grammar. Furthermore, we excise  $\alpha$  from  $\gamma$  and update data structures  $\pi$  and  $B$ . The above process is iterated until  $B$  becomes empty. We show in section 5 that this greedy strategy is sound and complete.

The function ISOLATE() is specified in Figure 7. We take as input a left fragment  $\alpha_L$ , which is associated with one or two horizontal stripes in  $\pi$ , depending on whether  $\alpha_L$  has a gap node or not. The left boundary of  $\alpha_L$  in  $\pi$  is the index  $x_1$  of the column containing the leftmost occurrence of a 1 in the horizontal stripes associated with  $\alpha_L$ . Similarly, the right boundary of  $\alpha_L$  in  $\pi$  is the index  $x_2$  of the column containing the rightmost occurrence of a 1 in these stripes. We retrieve the shortest substring  $\sigma(n)$  of  $\sigma(n_R)$  that spans over indices  $x_1$  and  $x_2$ . This means that  $n$  is the lowest node from  $\gamma_R$  such that the links of  $\alpha_L$  are a subset of the links of  $\gamma_R(n)$ .

If the condition at line 3 is satisfied, all of the matrix entries of value 1 that are found from column  $x_1$  to column  $x_2$  fall within the horizontal stripes associated with  $\alpha_L$ . In this case we can report the right fragment  $\alpha_R = \gamma_R(n)$ . Otherwise, we check whether the entries of value 1 that fall outside of the two horizontal stripes in between columns  $x_1$  and  $x_2$  occur within adjacent columns, say from column  $x_3 \geq x_1$  to column  $x_4 \leq x_2$ . In this case, we check whether there exists some node  $n'$  such that the substring of  $\sigma(n)$  from position  $x_3$  to  $x_4$  is

```

1: Function ISOLATE( $\alpha_L, \pi, \gamma_R$ )
2: select  $n \in \gamma_R$  such that  $\sigma(n)$  is the shortest
   string within  $\sigma(n_R)$  including left/right bound-
   aries of  $\alpha_L$  in  $\pi$ ;
3: if  $|\sigma(n)| = 2 \times |\text{links}(\alpha_L)|$  then
4:   return  $\gamma_R(n)$ ;
5: select  $n' \in \gamma_R$  such that  $\sigma(n')$  is the gap string
   within  $\sigma(n)$  for which  $\text{links}(n) - \text{links}(n') =$ 
    $\text{links}(\alpha_L)$ ;
6: if  $n'$  is not defined then
7:   return null; {more than one gap}
8: return  $\gamma_R(n, n')$ ;

```

Figure 7: Find synchronous fragment.

an occurrence of string  $\sigma(n')$ . This means that  $n'$  is the gap node, and we report the right fragment  $\alpha_R = \gamma_R(n, n')$ . See again Figure 5.

We now drop the assumption that only one link may impinge on a node. When multiple links impinge on a single node  $n$ ,  $l(n)$  is an arbitrary order over those links. In the execution of the algorithm, any stripe that contains one link in  $l(n)$  it must include every link in  $l(n)$ . This prevents the excision of a proper subset of the links at any node. This preserves correctness because excising any proper subset would impose an order over the links at  $n$  that is not enforced in the input grammar. Because the links at a node are treated as a unit, the complexity of the algorithm is not affected.

## 4 Complexity

We discuss here an implementation of the algorithm of section 3 resulting in time complexity  $\mathcal{O}(|G| + |Y| \cdot L_G^3)$ , where  $Y$  is the set of synchronous tree pairs of  $G$  and  $L_G$  is the maximum number of links in a synchronous tree pair in  $Y$ .

Consider a synchronous tree pair  $\gamma = \langle \gamma_L, \gamma_R \rangle$  with  $L$  links. If  $M$  is the number of maximal nodes in  $\gamma_L$  or  $\gamma_R$ , we have  $M = \Theta(L)$  (Section 3.1). We implement the sparse table  $\pi$  in  $\mathcal{O}(L)$  space, recording for each row and column the indices of its two non-zero entries. We also assume that we can go back and forth between maximal nodes  $n$  and strings  $\sigma(n)$  in constant time. Here each  $\sigma(n)$  is represented by its boundary positions within  $\sigma(n_L)$  or  $\sigma(n_R)$ ,  $n_L$  and  $n_R$  the root nodes of  $\gamma_L$  and  $\gamma_R$ , respectively.

At line 2 of the function ISOLATE() (Figure 7) we retrieve the left and right boundaries by scanning the rows of  $\pi$  associated with input fragment  $\alpha_L$ . We then retrieve node  $n$  by visiting all maximal nodes of  $\gamma_L$  spanning these boundaries. Under the above assumptions, this can be done in time  $\mathcal{O}(L)$ . In a similar way we can implement line 5, resulting in overall run time  $\mathcal{O}(L)$  for function ISOLATE().

In the function KARIZE() (Figure 6) we use buckets  $B_i$ ,  $1 \leq i \leq L$ , where each  $B_i$  stores the candidate fragments  $\alpha_L$  with  $|\text{links}(\alpha_L)| = i$ . To populate these buckets, we first process fragments  $\gamma_L(n)$  by visiting bottom up the maximal nodes of  $\gamma_L$ . The quantity  $|\text{links}(n)|$  is computed from the quantities  $|\text{links}(n_i)|$ , where  $n_i$  are the highest maximal nodes dominated by  $n$ . (There are at most two such nodes.) Fragments  $\gamma_L(n, n')$  can then be processed using the relation  $|\text{links}(n, n')| = |\text{links}(n)| - |\text{links}(n')|$ . In this way each fragment is processed in constant time, and population of all the buckets takes  $\mathcal{O}(L^2)$  time.

We now consider the while loop at lines 5 to 11 in function KARIZE(). For a synchronous tree pair  $\gamma$ , the loop iterates once for each candidate fragment  $\alpha_L$  in some bucket. We have a total of  $\mathcal{O}(L^2)$  iterations, since the initial number of candidates in the buckets is  $\mathcal{O}(L^2)$ , and the possible updating of the buckets after a synchronous fragment is removed does not increase the total size of all the buckets. If the links in  $\alpha_L$  cannot be isolated, one iteration takes time  $\mathcal{O}(L)$  (the call to function ISOLATE()). If the links in  $\alpha_L$  can be isolated, then we need to restructure  $\pi$  and to repopulate the buckets. The former can be done in time  $\mathcal{O}(L)$  and the latter takes time  $\mathcal{O}(L^2)$ , as already discussed. Crucially, the updating of  $\pi$  and the buckets takes place no more than  $L - 1$  times. This is because each time we excise a synchronous fragment, the number of links in  $\gamma$  is reduced by at least one.

We conclude that function KARIZE() takes time  $\mathcal{O}(L^3)$  for each synchronous tree  $\gamma$ , and the total running time is  $\mathcal{O}(|G| + |Y| \cdot L_G^3)$ , where  $Y$  is the set of synchronous tree pairs of  $G$ . The term  $|G|$  accounts for the reading of the input, and dominates the complexity of the algorithm only in case there are very few links in each synchronous tree pair.

Figure 8: In  $\gamma$  links  $\boxed{3}$  and  $\boxed{5}$  cannot be isolated because the fragment would have to contain two gaps. However, after the removal of fragment  $\gamma(n_1, n_2)$ , an analogous fragment  $\gamma'(n_3, n_4)$  may be removed.

## 5 Proof of Correctness

The algorithm presented in the previous sections produces an optimal  $k$ -arization for the input grammar. In this section we sketch a proof of correctness of the strategy employed by the algorithm.<sup>2</sup>

The  $k$ -arization strategy presented above is greedy in that it always chooses the excisable fragment with the smallest number of links at each step and does not perform any backtracking. We must therefore show that this process cannot result in a non-optimal solution. If fragments could not overlap each other, this would be trivial to show because the excision process would be confluent. If all overlapping fragments were cases of complete containment of one fragment within another, the proof would also be trivial because the smallest-to-largest excision order would guarantee optimality. However, it is possible for fragments to partially overlap each other, meaning that the intersection of the set of links contained in the two fragments is non-empty and the difference between the set of links in one fragment and the other is also non-empty. Overlapping fragment configurations are given in Figure 9 and discussed in detail below.

The existence of partially overlapping fragments complicates the proof of optimality for two reasons. First, the excision of a fragment  $\alpha$  that is partially overlapped with another fragment  $\beta$  necessarily precludes the excision of  $\beta$  at a later stage in the ex-

<sup>2</sup>Note that the soundness of the algorithm can be easily verified from the fact that the removal of fragments can be reversed by performing standard STAG adjunction and substitution operations until a single STAG tree pair is produced. This tree pair is trivially homomorphic to the original tree pair and can easily be mapped to the original tree pair.

Figure 9: The four possible configurations of overlapped fragments within a single tree. For type 1, let  $\alpha = \gamma(n_1, n_3)$  and  $\beta = \gamma(n_2, n_4)$ . The roots and gaps of the fragments are interleaved. For type 1', let  $\alpha = \gamma(n_1, n_3)$  and  $\beta = \gamma(n_2)$ . The root of  $\beta$  dominates the gap of  $\alpha$ . For type 2, let  $\alpha = \gamma(n_5, n_6)$  and  $\beta = \gamma(n_5, n_7)$ . The fragments share a root and have gap nodes that do not dominate each other. For type 3 let  $\alpha = \gamma(n_8, n_{10})$  and  $\beta = \gamma(n_9, n_{11})$ . The root of  $\alpha$  dominates the root of  $\beta$ , both roots dominate both gaps, but neither gap dominates the other.

cision process. Second, the removal of a fragment may cause a previously non-isolatable set of links to become isolatable, effectively creating a new fragment that may be advantageous to remove. This is demonstrated in Figure 8. These possibilities raise the question of whether the choice between removing fragments  $\alpha$  and  $\beta$  may have consequences at a later stage in the excision process. We demonstrate that this choice cannot affect the  $k$  found for a given grammar.

We begin by sketching the proof of a lemma that shows that removal of a fragment  $\beta$  that partially overlaps another fragment  $\alpha$  always leaves an analogous fragment that may be removed.

### 5.1 Validity Preservation

Consider a STAG tree pair  $\gamma$  containing the set of links  $\Lambda$  and two synchronous fragments  $\alpha$  and  $\beta$  with  $\alpha$  containing links  $\text{links}(\alpha)$  and  $\beta$  containing  $\text{links}(\beta)$  ( $\text{links}(\alpha), \text{links}(\beta) \subseteq \Lambda$ ).

If  $\alpha$  and  $\beta$  do not overlap, the removal of  $\beta$  is defined as validity preserving with respect to  $\alpha$ .

If  $\alpha$  and  $\beta$  overlap, removal of  $\beta$  from  $\gamma$  is **validity preserving** with respect to  $\alpha$  if after the removal there exists a valid synchronous fragment (containing at most one gap on each side) that contains all and only the links  $(\text{links}(\alpha) - \text{links}(\beta)) \cup \{\boxed{\alpha}\}$  where  $\boxed{\alpha}$  is the new link added to  $\gamma$ .

Figure 10: Removal from a tree pair  $\gamma$  containing type 1–type 2 fragment overlap. The fragment  $\alpha$  is represented by the horizontal-lined pieces of the tree pair. The fragment  $\beta$  is represented by the vertical-lined pieces of the tree pair. Cross-hatching indicates the overlapping portion of the two fragments.

We prove a lemma that removal of any synchronous fragment from an STAG tree pair is validity preserving with respect to all of the other synchronous fragments in the tree pair.

It suffices to show that for two arbitrary synchronous fragments  $\alpha$  and  $\beta$ , the removal of  $\beta$  is validity preserving with respect to  $\alpha$ . We show this by examination of the possible configurations of  $\alpha$  and  $\beta$ .

Consider the case in which  $\beta$  is fully contained within  $\alpha$ . In this case  $\text{links}(\beta) \subsetneq \text{links}(\alpha)$ . The removal of  $\beta$  leaves the root and gap of  $\alpha$  intact in both trees in the pair, so it remains a valid fragment. The new link is added at the new node inserted where  $\beta$  was removed. Since  $\beta$  is fully contained within  $\alpha$ , this node is below the root of  $\alpha$  but not below its gap. Thus, the removal process leaves  $\alpha$  with the links  $(\text{links}(\alpha) - \text{links}(\beta)) \cup \{\boxed{\alpha}\}$ , where  $\boxed{\alpha}$  is the link added in the removal process; the removal is validity preserving.

Synchronous fragments may partially overlap in several different ways. There are four possible configurations for an overlapped fragment within a single tree, depicted in Figure 9. These different single-tree overlap types can be combined in any way to form valid synchronous fragments. Due to space constraints, we consider two illustrative cases and leave the remainder as an exercise to the reader.

An example of removing fragments from a tree set containing type 1–type 2 overlapped fragments is given in Figure 10. Let  $\alpha = \langle \gamma_L(n_1, n_3), \gamma_R(n_5, n_6) \rangle$ . Let

$\beta = \langle \gamma_L(n_2, n_4), \gamma_R(n_5, n_7) \rangle$ . If  $\alpha$  is removed, the validity preserving fragment for  $\beta$  is  $\langle \gamma'_L(n_1, n_4), \gamma'_R(n_5) \rangle$ . It contains the links in the vertical-lined part of the tree and the new link  $\boxed{x}$ . This forms a valid fragment because both sides contain at most one gap and both contain the same set of links. In addition, it is validity preserving for  $\beta$  because it contains exactly the set of links that were in  $\text{links}(\beta)$  and not in  $\text{links}(\alpha)$  plus the new link  $\boxed{x}$ . If we instead choose to remove  $\beta$ , the validity preserving fragment for  $\alpha$  is  $\langle \gamma'_L(n_1, n_4), \gamma'_R(n_5) \rangle$ . The links in each side of this fragment are the same, each side contains at most one gap, and the set of links is exactly the set left over from  $\text{links}(\alpha)$  once  $\text{links}(\beta)$  is removed plus the newly generated link  $\boxed{x}$ .

An example of removing fragments from a tree set containing type 1'–type 3 (reversed) overlapped fragments is given in Figure 11. If  $\alpha$  is removed, the validity preserving fragment for  $\beta$  is  $\langle \gamma'_L(n_1), \gamma'_R(n_4) \rangle$ . If  $\beta$  is removed, the validity preserving fragment for  $\alpha$  is  $\langle \gamma'_L(n_1, n_8), \gamma'_R(n_4) \rangle$ .

Similar reasoning follows for all remaining types of overlapped fragments.

## 5.2 Proof Sketch

We show that smallest-first removal of fragments is optimal. Consider a decision point at which a choice is made about which fragment to remove. Call the size of the smallest fragments at this point  $m$ , and let the set of fragments of size  $m$  be  $X$  with  $\alpha, \beta \in X$ .

There are two cases to consider. First, consider two partially overlapped fragments  $\alpha \in X$  and  $\delta \notin X$ . Note that  $|\text{links}(\alpha)| < |\text{links}(\delta)|$ . Validity preservation of  $\alpha$  with respect to  $\delta$  guarantees that  $\delta$  or its validity preserving analog will still be available for excision after  $\alpha$  is removed. Excising  $\delta$  increases  $k$  more than excising  $\alpha$  or any fragment that removal of  $\alpha$  will lead to before  $\delta$  is considered. Thus, removal of  $\delta$  cannot result in a smaller value for  $k$  if it is removed before  $\alpha$  rather than after  $\alpha$ .

Second, consider two partially overlapped fragments  $\alpha, \beta \in X$ . Due to the validity preservation lemma, we may choose arbitrarily between the fragments in  $X$  without jeopardizing our ability to later remove other fragments (or their validity preserving analogs) in that set. Removal of fragment  $\alpha$  cannot increase the size of any remaining fragment.

Removal of  $\alpha$  or  $\beta$  may generate new fragments

Figure 11: Removal from a tree pair  $\gamma$  containing a type 1'–type 3 (reversed) fragment overlap. The fragment  $\alpha$  is represented by the horizontal lined pieces of the tree pair. The fragment  $\beta$  is represented by the vertical-lined pieces of the tree pair. Cross-hatching indicates the overlapping portion of the two fragments.

that were not previously valid and may reduce the size of existing fragments that it overlaps. In addition, removal of  $\alpha$  may lead to availability of smaller fragments at the next removal step than removal of  $\beta$  (and vice versa). However, since removal of either  $\alpha$  or  $\beta$  produces a  $k$  of size at least  $m$ , the later removal of fragments of size less than  $m$  cannot affect the  $k$  found by the algorithm. Due to validity preservation, removal of any of these smaller fragments will still permit removal of all currently existing fragments or their analogs at a later step in the removal process.

If the removal of  $\alpha$  generates a new fragment  $\delta$  of size larger than  $m$  all remaining fragments in  $X$  (and all others smaller than  $\delta$ ) will be removed before  $\delta$  is considered. Therefore, if removal of  $\beta$  generates a new fragment smaller than  $\delta$ , the smallest-first strategy will properly guarantee its removal before  $\delta$ .

## 6 Conclusion

In order for STAG to be used in machine translation and other natural-language processing tasks it must be possible to process it efficiently. The difficulty in parsing STAG stems directly from the factor  $k$  that indicates the degree to which the correspondences are intertwined within the elementary structures of the grammar. The algorithm presented in this paper is the first method available for  $k$ -arizing a synchronous TAG grammar into an equivalent grammar with an optimal value for  $k$ . The algorithm operates offline and requires only  $\mathcal{O}(|G| + |Y| \cdot L_G^3)$  time. Both the derivation trees and derived trees produced are trivially homomorphic to those that are produced by the original grammar.

## Abstract

This paper describes how external resources can be used to improve parser performance for heavily lexicalised grammars, looking at both robustness and efficiency. In terms of robustness, we try using different types of external data to increase lexical coverage, and find that simple POS tags have the most effect, increasing coverage on unseen data by up to 45%. We also show that filtering lexical items in a supertagging manner is very effective in increasing efficiency. Even using vanilla POS tags we achieve some efficiency gains, but when using detailed lexical types as supertags we manage to halve parsing time with minimal loss of coverage or precision.

## 1 Introduction

Heavily lexicalised grammars have been used in applications such as machine translation and information extraction because they can produce semantic structures which provide more information than less informed parsers. In particular, because of the structural and semantic information attached to lexicon items, these grammars do well at describing complex relationships, like non-projectivity and center embedding. However, the cost of this additional information sometimes makes deep parsers that use these grammars impractical. Firstly because, if the information is not available, the parsers may fail to produce an analysis, a failure of robustness. Secondly, the effect of analysing the extra information can slow the parser down, causing efficiency problems. This paper describes experiments aimed at

improving parser performance in these two areas, by annotating the input given to one such deep parser, the PET parser (Callmeier, 2000), which uses lexicalised grammars developed under the HPSG formalism (Pollard and Sag, 1994).

## 2 Background

In all heavily lexicalised formalisms, such as LTAG, CCG, LFG and HPSG, the lexicon plays a key role in parsing. But a lexicon can never hope to contain all words in open domain text, and so lexical coverage is a central issue in boosting parser robustness. Some systems use heuristics based on numbers, capitalisation and perhaps morphology to guess the category of the unknown word (van Noord and Malouf, 2004), while others have focused on automatically expanding the lexicon (Baldwin, 2005; Hockenmaier et al., 2002; O'Donovan et al., 2005). Another method, described in Section 4, uses external resources such as part-of-speech (POS) tags to select generic lexical entries for out-of-vocabulary words. In all cases, we lose some of the depth of information the hand-crafted lexicon would provide, but an analysis is still produced, though possibly less than fully specified.

The central position of these detailed lexicons causes problems, not only of robustness, but also of efficiency and ambiguity. Many words may have five, six or more lexicon entries associated with them, and this can lead to an enormous search space for the parser. Various means of filtering this search space have been attempted. Kiefer et al. (1999) describes a method of filtering lexical items by specifying and checking for required prefixes and particles

which is particularly effective for German, but also applicable to English. Other research has looked at using dependencies to restrict the parsing process (Sagae et al., 2007), but the most well known filtering method is supertagging. Originally described by Bangalore and Joshi (1994) for use in LTAG parsing, it has also been used very successfully for CCG (Clark, 2002). Supertagging is the process of assigning probable ‘supertags’ to words before parsing to restrict parser ambiguity, where a supertag is a tag that includes more specific information than the typical POS tags. The supertags used in each formalism differ, being elementary trees in LTAG and CCG categories for CCG. Section 3.2 describes an experiment akin to supertagging for HPSG, where the supertags are HPSG lexical types. Unlike elementary trees and CCG categories, which are predominantly syntactic categories, the HPSG lexical types contain a lot of semantic information, as well as syntactic.

In the case study we describe here, the tools, grammars and treebanks we use are taken from work carried out in the DELPH-IN<sup>1</sup> collaboration. This research is based on using HPSG along with Minimal Recursion Semantics (MRS: Copestake et al. (2001)) as a platform to develop deep natural language processing tools, with a focus on multilinguality. The grammars are designed to be bidirectional (used for generation as well as parsing) and so contain very specific linguistic information. In this work, we focus on techniques to improve parsing, not generation, but, as all the methods involve pre-processing and do not change the grammar itself, we do not affect the generation capabilities of the grammars. We use two of the DELPH-IN wide-coverage grammars: the English Resource Grammar (ERG: Copestake and Flickinger (2000)) and a German grammar, GG (Müller and Kasper, 2000; Crysmann, 2003). We also use the PET parser, and the [incr tsdb()] system profiler and treebanking tool (Oepen, 2001) for evaluation.

### 3 Parser Restriction

An exhaustive parser, such as PET, by default produces every parse licensed by the grammar. However, in many application scenarios, this is unnecessary and time consuming. The benefits of us-

<sup>1</sup><http://wiki.delph-in.net/>

ing a deep parser with a lexicalised grammar are the precision and depth of the analysis produced, but this depth comes from making many fine distinctions which greatly increases the parser search space, making parsing slow. By restricting the lexical items considered during parsing, we improve the efficiency of a parser with a possible trade-off of losing correct parses. For example, the noun phrase reading of *The dog barks* is a correct parse, although unlikely. By blocking the use of *barks* as a noun in this case, we lose this reading. This may be an acceptable trade-off in some applications that can make use of the detailed information, but only if it can be delivered in reasonable time. An example of such an application is the real-time speech translation system developed in the Verbmobil project (Wahlster, 2000), which integrated deep parsing results, where available, into its appointment scheduling and travel planning dialogues. In these experiments we look at two methods of restricting the parser, first by using POS tags and then using lexical types. To control the trade-off between efficiency and precision, we vary which lexical items are restricted according to a likelihood threshold from the respective taggers. Only open class words are restricted, since it is the gross distinctions between, for instance, noun and verb that we would like to utilise. Any differences between categories for closed class words are more subtle and we feel the parser is best left to make these distinctions without restriction. The data set used for these experiments is the *jh5* section of the treebank released with the ERG. This text consists of edited written English in the domain of Norwegian hiking instructions from the LOGON project (Oepen et al., 2004).

#### 3.1 Part of Speech Tags

We use TreeTagger (Schmid, 1994) to produce POS tags and then open class words are restricted if the POS tagger assigned a tag with a probability over a certain threshold. A lower threshold will lead to faster parsing, but at the expense of losing more correct parses. We experiment with various thresholds, and results are shown in Table 1. Since a gold standard treebank for our data set was available, it was possible to evaluate the accuracy of the parser. Evaluation of deep parsing results is often reported only in terms of coverage (number of sentences which re-

Threshold	Coverage	Precision	Time
gold	93.5%	92.2%	N/A
unrestricted	93.3%	92.4%	0.67s
1.00	90.7%	91.9%	0.59s
0.98	88.8%	89.3%	0.49s
0.95	88.4%	89.5%	0.48s
0.90	86.4%	88.5%	0.44s
0.80	84.3%	87.0%	0.43s
0.60	81.5%	87.3%	0.39s

Table 1: Results obtained when restricting the parser lexicon according to the POS tag, where words are restricted according to a threshold of POS probabilities.

ceive an analysis), because, since the hand-crafted grammars are optimised for precision over coverage, the analyses are assumed to be correct. However, in this experiment, we are potentially ‘diluting’ the precision of the grammar by using external resources to remove parses and so it is important that we have some idea of how the accuracy is affected. In the table, precision is the percentage of sentences that, having produced at least one parse, produced a correct parse. A parse was judged to be correct if it exactly matched the gold standard tree in all aspects, syntactic and semantic.

The results show quite clearly how the coverage drops as the average parse time per sentence drops. In hybrid applications that can back-off to less informative analyses, this may be a reasonable trade-off, enabling detailed analyses in shorter times where possible, and using the shallower analyses otherwise.

### 3.2 Lexical Types

Another option for restricting the parser is to use the lexical types used by the grammar itself, in a similar method to that described by Prins and van Noord (2003). This could be considered a form of supertagging as used in LTAG and CCG. Restricting by lexical types should have the effect of reducing ambiguity further than POS tags can do, since one POS tag could still allow the use of multiple lexical items with compatible lexical types. On the other hand, it could be considered more difficult to tag accurately, since there are many more lexical types than POS tags (almost 900 in the ERG) and less training data is available.

Configuration	Coverage	Precision	Time
gold	93.5%	92.2%	N/A
unrestricted	93.3%	92.4%	0.67s
0.98 with POS	93.5%	91.9%	0.63s
0.95 with POS	93.1%	92.4%	0.48s
0.90 with POS	92.9%	92.3%	0.37s
0.80 with POS	91.8%	91.8%	0.31s
0.60 with POS	86.2%	93.5%	0.21s
0.98 no POS	92.9%	92.3%	0.62s
0.95 no POS	90.9%	91.0%	0.48s
0.90 no POS	87.7%	89.2%	0.42s
0.80 no POS	79.7%	84.6%	0.33s
0.60 no POS	67.0%	84.2%	0.23s

Table 2: Results obtained when restricting the parser lexicon according to the predicted lexical type, where words are restricted according to a threshold of tag probabilities. Two models, with and without POS tags as features, were used.

While POS taggers such as TreeTagger are common, and there some supertaggers are available, notably that of Clark and Curran (2007) for CCG, no standard supertagger exists for HPSG. Consequently, we developed a Maximum Entropy model for supertagging using the OpenNLP implementation.<sup>2</sup> Similarly to Zhang and Kordoni (2006), we took training data from the gold-standard lexical types in the treebank associated with ERG (in our case, the July-07 version). For each token, we extracted features in two ways. One used features only from the input string itself: four characters from the beginning and end of the target word token, and two words of context (where available) either side of the target. The second used the features from the first, along with POS tags given by TreeTagger for the context tokens.

We held back the *jh5* section of the treebank for testing the Maximum Entropy model. Again, the lexical items that were to be restricted were controlled by a threshold, in this case the probability given by the maximum entropy model. Table 2 shows the results achieved by these two models, with the unrestricted results and the gold standard provided for comparison.

Here we see the same trends of falling coverage

<sup>2</sup><http://maxent.sourceforge.net/>

with falling time for both models, with the POS tagged model consistently outperforming the word-form model. To give a clearer picture of the comparative performance of all three experiments, Figure 1 shows how the results vary with time for both models, and for the POS tag restricted experiment. Here we can see that the coverage and precision of the lexical type restriction experiment that uses the word-form model is just above that of the POS restricted one. However the POS tagged model clearly outperforms both, showing minimal loss of coverage or precision at a threshold which halved the average parsing time. At the lowest parsing time, we see that precision of the POS tagged model even goes up. This can be explained by noting that coverage here goes down, and obviously we are losing more incorrect parses than correct parses.

This echoes the main result from Prins and van Noord (2003), that filtering the lexical categories used by the parser can significantly reduce parsing time, while maintaining, or even improving, precision. The main differences between our method and that of Prins and van Noord are the training data and the tagging model. The key feature of their experiment was the use of ‘unsupervised’ training data, that is, the uncorrected output of their parser. In this experiment, we used gold standard training data, but much less of it (just under 200 000 words) and still achieved a very good precision. It would be interesting to see what amount of unsupervised parser output we would require to achieve the same level of precision. The other difference was the tagging model, maximum entropy versus Hidden Markov Model (HMM). We selected maximum entropy because Zhang and Kordoni (2006) had shown that they got better results using a maximum entropy tagger instead of a HMM one when predicting lexical types, albeit for a slightly different purpose. It is not possible to directly compare results between our experiments and those in Prins and van Noord, because of different languages, data sets and hardware, but it is worth noting that parsing times are much lower in our setup, perhaps more so than can be attributed to 4 years hardware improvement. While the range of sentence lengths appears to be very similar between the data sets, one possible reason for this could be the very large number of lexical categories used in their ALPINO system.

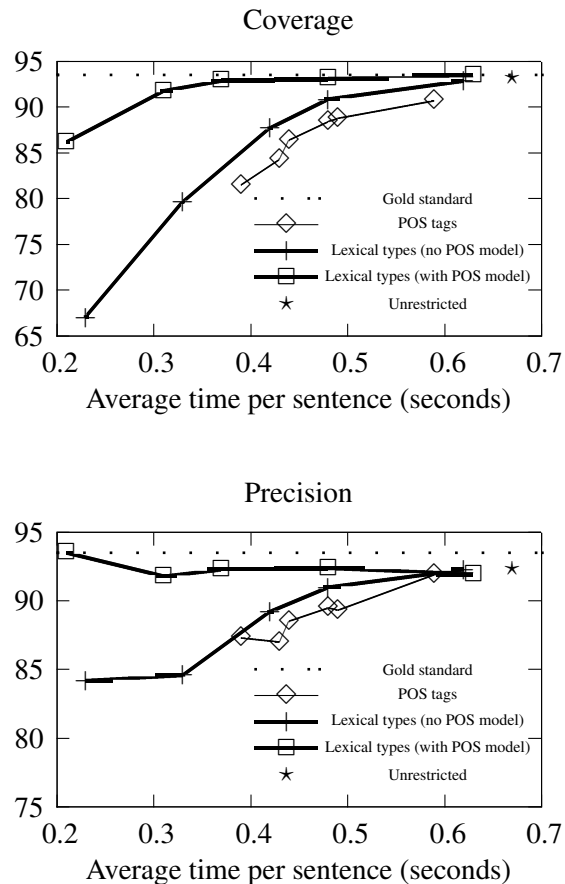

Figure 1: Coverage and precision varying with time for the three restriction experiments. Gold standard and unrestricted results shown for comparison.

While this experiment is similar to that of Clark and Curran (2007), it differs in that their supertagger assign categories to every word, while we look up every word in the lexicon and the tagger is used to filter what the lexicon returns, only if the tagger confidence is sufficiently high. As Table 2 shows, when we use the tags for which the tagger had a low confidence, we lose significant coverage. In order to run as a supertagger rather than a filter, the tagger would need to be much more accurate. While we can look at multi-tagging as an option, we believe much more training data would be needed to achieve a sufficient level of tag accuracy.

Increasing efficiency is important for enabling these heavily lexicalised grammars to bring the benefits of their deep analyses to applications, but simi-

larly important is robustness. The following section is aimed at addressing this issue of robustness, again by using external information.

#### 4 Unknown Word Handling

The lexical information available to the parser is what makes the depth of the analysis possible, and the default configuration of the parser uses an all-or-nothing approach, where a parse is not produced if all the lexical information is not available. However, in order to increase robustness, it is possible to use underspecified lexical information where a fully specified lexical item is not available. One method of doing this, built in to the PET parser, is to use POS tags to select generic lexical items, and hence allow a (less than fully specified) parse to be built.

The six data sets used for these experiments were chosen to give a range of languages and genres. Four sets are English text: *jh5* described in Section 3; *trec* consisting of questions from TREC and included in the treebanks released with the ERG; *a00* which is taken from the BNC and consists of factsheets and newsletters; and *depbank*, the 700 sentences of the Briscoe and Carroll version of DepBank (Briscoe and Carroll, 2006) taken from the Wall Street Journal. The last two data sets are German text: *clef700* consisting of German questions taken from the CLEF competition and *eiche564* a sample of sentences taken from a treebank parsed with the German HPSG grammar, GG and consisting of transcribed German speech data concerning appointment scheduling from the Verbmobil project. Vital statistics of these data sets are described in Table 3.

We used TreeTagger to POS tag the six data sets, with the tagger configured to assign multiple tags, where the probability of the less likely tags was at least half that of the most likely tag. The data was input using a PET input chart (PIC), which allows POS tags to be assigned to each token, and then parsed each with the PET parser.<sup>3</sup> All English data sets used the July-07 CVS version of the ERG and the German sets used the September\_2007 version of GG. Unlike the experiments described in Section 3, adding POS tags in this way will have no effect on sentences which the parser is already able

	Language	Number of Sentences	Ave. Sentence Length
<i>jh5</i>	English	464	14.2
<i>trec</i>	English	693	6.9
<i>a00</i>	English	423	17.2
<i>depbank</i>	English	700	21.5
<i>clef</i>	German	700	7.5
<i>eiche564</i>	German	564	11.5

Table 3: Data sets used in input annotation experiments.

to parse. The POS tags will only be considered when the parser has no lexicon entry for a given word, and hence can only increase coverage. Results are shown in Table 4, comparing the coverage over each set to that obtained without using POS tags to handle unknown words. Coverage here is defined as the percentage of sentences with at least one parse.

These results show very clearly one of the potential drawbacks of using a highly lexicalised grammar formalism like HPSG: unknown words are one of the main causes of parse failure, as quantified in Baldwin et al. (2004) and Nicholson et al. (2008). In the results here, we see that for *jh5*, *trec* and *eiche564*, adding unknown word handling made almost no difference, since the grammars (specifically the lexicons) have been tuned for these data sets. On the other hand, over unseen texts, adding unknown word handling made a dramatic difference to the coverage. This motivates strategies like the POS tag annotation used here, as well as the work on deep lexical acquisition (DLA) described in Zhang and Kordoni (2006) and Baldwin (2005), since no grammar could ever hope to cover all words used within a language.

As mentioned in Section 3, coverage is not the only evaluation metric that should be considered, particularly when adding potentially less precise information to the parsing process (in this case POS tags). Since the primary effect of adding POS tags is shown with those data sets for which we do not have gold standard treebanks, evaluating accuracy in this case is more difficult. However, in order to give some idea of the effects on precision, a sample of 100 sentences from the *a00* data set was evaluated for accuracy, for this and the following experiments.

<sup>3</sup>Subversion revision 384

In this instance, we found there was only a slight drop in precision, where the original analyses had a precision of 82% and the precision of the analyses when POS tags were used was 80%.

Since the parser has the means to accept named entity (NE) information in the input, we also experimented with using generic lexical items generated from NE data. We used SProUT (Becker et al., 2002) to tag the data sets and used PET’s inbuilt NE handling mechanism to add NE items to the input, associated with the appropriate word tokens. This works slightly differently from the POS annotation mechanism, in that NE items are considered by the parser, even when the associated words are in the lexicon. This has the effect of increasing the number of analyses produced for sentences that already have a full lexical span, but could also increase coverage by enabling parses to be produced where there is no lexical span, or where no parse was possible because a token was not recognised as part of a name. In order to isolate the effect of the NE data, we ran one experiment where the input was annotated only with the SProUT data, and another where the POS tags were also added. These results are also in Table 4.

Again, we see coverage increases in the three unseen data sets, *a00*, *depbank* and *clef*, but not to the same extent as the POS tags. Examining the results in more detail, we find that the increases come almost exclusively from sentences without lexical span, rather than in sentences where a token was previously not recognised as part of a name. This means that the NE tagger is operating almost like a POS tagger that only tags proper nouns, and as the POS tagger tags proper nouns quite accurately, we find the NE tagger gives no benefit here. When examining the precision over our sample evaluation set from *a00*, we find that using the NE data alone adds no correct parses, while using NE data with POS tags actually removes correct parses when compared with POS alone, since the (in these cases, incorrect) NE data is preferred over the POS tags. It is possible that another named entity tagger would give better results, and this may be looked at in future experiments.

Other forms of external information might also be used to increase lexical coverage. Zhang and Kordoni (2006) reported a 20% coverage increase over baseline using a lexical type predictor for unknown

words, and so we explored this avenue. The same maximum entropy tagger used in Section 3 was used and each open class word was tagged with its most likely lexical type, as predicted by the maximum entropy model. Table 5 shows the results, with the baseline and POS annotated results for comparison. As with the previous experiments, we see a coverage increase in those data sets which are considered unseen text for these grammars. Again it is clear that the use of POS tags as features obviously improves the maximum entropy model, since this second model has almost 10% better coverage on our unseen texts. However, lexical types do not appear to be as effective for increasing lexical coverage as the POS tags. One difference between the POS and lexical type taggers is that the POS tagger could produce multiple tags per word. Therefore, for the next experiment, we altered the lexical type tagger so it could also produce multiple tags. As with the Tree-Tagger configuration we used for POS annotation, extra lexical type tags were produced if they were at least half as probable as the most likely tag. A lower probability threshold of 0.01 was set, so that hundreds of tags of equal likelihood were not produced in the case where the tagger was unable to make an informed prediction. The results with multiple tagging are also shown in Table 5.

The multiple tagging version gives a coverage increase of between 2 and 10% over the single tag version of the tagger, but, at least for the English data sets, it is still less effective than straight-forward POS tagging. For the German unseen data set, *clef*, we do start getting above what the POS tagger can achieve. This may be in part because of the features used by the lexical type tagger — German, being a more morphologically rich language, may benefit more from the prefix and suffix features used in the tagger.

In terms of precision measured on our sample evaluation set, the single tag version of the lexical type tagger which used POS tag features achieved a very good precision of 87% where, of all the extra sentences that could now be parsed, only one did not have a correct parse. In an application where precision is considered much more important than coverage, this would be a good method of increasing coverage without loss of accuracy. The single tag version that did not use POS tags in the model achieved

	Baseline	with POS	NE only	NE+POS
jh5	93.1%	93.3%	93.1%	93.3%
trec	97.1%	97.5%	97.4%	97.7%
a00	50.1%	83.9%	53.0%	85.8%
depbank	36.3%	76.9%	51.1%	80.4%
clef	22.0%	67.7%	42.3%	75.3%
eiche564	63.8%	63.8%	64.0%	64.0%

Table 4: Parser coverage with baseline using no unknown word handling and unknown word handling using POS tags, SProUT named entity data as the only annotation, or SProUT tags in addition to POS annotation.

	Baseline	Single Lexical Types			Multiple Lexical Types	
		POS	-POS	+POS	-POS	+POS
jh5	93.1%	93.3%	93.3%	93.3%	93.5%	93.5%
trec	97.1%	97.5%	97.3%	97.4%	97.3%	97.4%
a00	50.1%	83.9%	63.8%	72.6%	65.7%	78.5%
depbank	36.3%	76.9%	51.7%	64.4%	53.9%	69.7%
clef	22.0%	67.7%	59.9%	66.8%	69.7%	76.9%
eiche564	63.8%	63.8%	63.8%	63.8%	63.8%	63.8%

Table 5: Parser coverage using a lexical type predictor for unknown word handling. The predictor was run in single tag mode, and then in multi-tag mode. Two different tagging models were used, with and without POS tags as features.

the same precision as with using only POS tags, but without the same increase in coverage. On the other hand, the multiple tagging versions, which at least started approaching the coverage of the POS tag experiment, dropped to a precision of around 76%.

From the results of Section 3, one might expect that at least the lexical type method of handling unknown words might at least lead to quicker parsing than when using POS tags, however POS tags are used differently in this situation. When POS tags are used to restrict the parser, any lexicon entry that unifies with the generic part-of-speech lexical category can be used by the parser. That is, when the word is restricted to, for example, a *verb*, any lexical item with one of the numerous more specific verb categories can be used. In contrast, in these experiments, the lexicon plays no part. The POS tag causes one underspecified lexical item (per POS tag) to be considered in parsing. While these underspecified items may allow more analyses to be built than if the exact category was used, the main contribution to parsing time turned out to be the number of tags assigned to each word, whether that was a POS tag or a lexical type. The POS tagger assigned multiple tags much less frequently than the multiple tagging

lexical type tagger and so had a faster average parsing time. The single tagging lexical type tagger had only slightly fewer tags assigned overall, and hence was slightly faster, but at the expense of a significantly lower coverage.

## 5 Conclusion

The work reported here shows the benefits that can be gained by utilising external resources to annotate parser input in highly lexicalised grammar formalisms. Even something as simple and readily available (for languages likely to have lexicalised grammars) as a POS tagger can massively increase the parser coverage on unseen text. While annotating with named entity data or a lexical type supertagger were also found to increase coverage, the POS tagger had the greatest effect with up to 45% coverage increase on unseen text.

In terms of efficiency, POS tags were also shown to speed up parsing by filtering unlikely lexicon items, but better results were achieved in this case by using a lexical type supertagger. Again encouraging the use of external resources, the supertagging was found to be much more effective when POS tags

were used to train the tagging model, and in this configuration, managed to halve the parsing time with minimal effect on coverage or precision.

## 6 Further Work

A number of avenues of future research were suggested by the observations made during this work. In terms of robustness and increasing lexical coverage, more work into using lexical types for unknown words could be explored. In light of the encouraging results for German, one area to look at is the effect of different features for different languages. Use of back-off models might also be worth considering when the tagger probabilities are low.

Different methods of using the supertagger could also be explored. The experiment reported here used the single most probable type for restricting the lexicon entries used by the parser. Two extensions of this are obvious. The first is to use multiple tags over a certain threshold, by either inputting multiple types as was done for the unknown word handling, or by using a generic type that is compatible with all the predicted types over a certain threshold. The other possible direction to try is to not check the predicted type against the lexicon, but to simply construct a lexical item from the most likely type, given a (high) threshold probability. This would be similar to the CCG supertagging mechanism and is likely to give generous speedups at the possible expense of precision, but it would be illuminating to discover how this trade-off plays out in our setup.

## Abstract

Previous studies evaluate simulated dialog corpora using evaluation measures which can be automatically extracted from the dialog systems' logs. However, the validity of these automatic measures has not been fully proven. In this study, we first recruit human judges to assess the quality of three simulated dialog corpora and then use human judgments as the gold standard to validate the conclusions drawn from the automatic measures. We observe that it is hard for the human judges to reach good agreement when asked to rate the quality of the dialogs from given perspectives. However, the human ratings give consistent ranking of the quality of simulated corpora generated by different simulation models. When building prediction models of human judgments using previously proposed automatic measures, we find that we cannot reliably predict human ratings using a regression model, but we can predict human rankings by a ranking model.

## 1 Introduction

User simulation has been widely used in different phases in spoken dialog system development. In the system development phase, user simulation is used in training different system components. For example, (Levin et al., 2000) and (Scheffler, 2002) exploit user simulations to generate large corpora for using Reinforcement Learning to develop dialog strategies, while (Chung, 2004) implement user simulation to train the speech recognizer and understanding components.

While user simulation is considered to be more low-cost and time-efficient than experiments with human subjects, one major concern is how well the state-of-the-art user simulations can mimic human user behaviors and how well they can substitute for human users in a variety of tasks. (Schatzmann et al., 2005) propose a set of evaluation measures to assess the quality of simulated corpora. They find that these evaluation measures are sufficient to discern simulated from real dialogs. Since this multiple-measure approach does not offer a easily reportable statistic indicating the quality of a user simulation, (Williams, 2007) proposes a single measure for evaluating and rank-ordering user simulations based on the divergence between the simulated and real users' performance. This new approach also offers a lookup table that helps to judge whether an observed ordering of two user simulations is statistically significant.

In this study, we also strive to develop a prediction model of the rankings of the simulated users' performance. However, our approach use human judgments as the gold standard. Although to date there are few studies that use human judges to directly assess the quality of user simulation, we believe that this is a reliable approach to assess the simulated corpora as well as an important step towards developing a comprehensive set of user simulation evaluation measures. First, we can estimate the difficulty of the task of distinguishing real and simulated corpora by knowing how hard it is for human judges to reach an agreement. Second, human judgments can be used as the gold standard of the automatic evaluation measures. Third, we can validate the automatic

measures by correlating the conclusions drawn from the automatic measures with the human judgments.

In this study, we recruit human judges to assess the quality of three user simulation models. Judges are asked to read the transcripts of the dialogs between a computer tutoring system and the simulation models and to rate the dialogs on a 5-point scale from different perspectives. Judges are also given the transcripts between human users and the computer tutor. We first assess human judges' abilities in distinguishing real from simulated users. We find that it is hard for human judges to reach good agreement on the ratings. However, these ratings give consistent ranking on the quality of the real and the simulated user models. Similarly, when we use previously proposed automatic measures to predict human judgments, we cannot reliably predict human ratings using a regression model, but we can consistently mimic human judges' rankings using a ranking model. We suggest that this ranking model can be used to quickly assess the quality of a new simulation model without manual efforts by ranking the new model against the old models.

## 2 Related Work

A lot of research has been done in evaluating different components of Spoken Dialog Systems as well as overall system performance. Different evaluation approaches are proposed for different tasks. Some studies (e.g., (Walker et al., 1997)) build regression models to predict user satisfaction scores from the system log as well as the user survey. There are also studies that evaluate different systems/system components by ranking the quality of their outputs. For example, (Walker et al., 2001) train a ranking model that ranks the outputs of different language generation strategies based on human judges' rankings. In this study, we build both a regression model and a ranking model to evaluate user simulation.

(Schatzmann et al., 2005) summarize some broadly used automatic evaluation measures for user simulation and integrate several new automatic measures to form a comprehensive set of statistical evaluation measures. The first group of measures investigates how much information is transmitted in the dialog and how active the dialog participants are. The second group of measures analyzes the style of

the dialog and the last group of measures examines the efficiency of the dialogs. While these automatic measures are handy to use, these measures have not been validated by humans.

There are well-known practices which validate automatic measures using human judgments. For example, in machine translation, BLEU score (Papineni et al., 2002) is developed to assess the quality of machine translated sentences. Statistical analysis is used to validate this score by showing that BLEU score is highly correlated with the human judgment. In this study, we validate a subset of the automatic measures proposed by (Schatzmann et al., 2005) by correlating the measures with human judgments. We follow the design of (Linguistic Data Consortium, 2005) in obtaining human judgments. We call our study an assessment study.

## 3 System and User Simulation Models

In this section, we describe our dialog system (IT-SPOKE) and the user simulation models which we use in the assessment study. IT-SPOKE is a speech-enabled Intelligent Tutoring System that helps students understand qualitative physics questions. In the system, the computer tutor first presents a physics question and the student types an essay as the answer. Then, the tutor analyzes the essay and initiates a tutoring dialog to correct misconceptions and to elicit further explanations. A corpus of 100 tutoring dialogs was collected between 20 college students (solving 5 physics problems each) and the computer tutor, yielding 1388 student turns. The correctness of student answers is automatically judged by the system and kept in the system's logs. Our previous study manually clustered tutor questions into 20 clusters based on the knowledge (e.g., acceleration, Newton's 3rd Law) that is required to answer each question (Ai and Litman, 2007).

We train three simulation models from the real corpus: the random model, the correctness model, and the cluster model. All simulation models generate student utterances on the word level by picking out the recognized student answers (with potential speech recognition errors) from the human subject experiments with different policies. The **random model (ran)** is a simple unigram model which randomly picks a student's utterance from the real cor-

pus as the answer to a tutor’s question, neglecting which question it is. The **correctness model (cor)** is designed to give a correct/incorrect answer with the same probability as the average of real students. For each tutor’s question, we automatically compute the average correctness rate of real student answers from the system logs. Then, a correct/incorrect answer is randomly chosen from the correct/incorrect answer sets for this question. The **cluster model (clu)** tries to model student learning by assuming that a student will have a higher chance to give a correct answer to the question of a cluster in which he/she mostly answers correctly before. It computes the conditional probability of whether a student answer is correct/incorrect given the content of the tutor’s question and the correctness of the student’s answer to the last previous question that belongs to the same question cluster. We also refer to the real student as the **real student model (real)** in the paper. We hypothesize that the ranking of the four student models (from the most realistic to the least) is: *real*, *clu*, *cor*, and *ran*.

## 4 Assessment Study Design

### 4.1 Data

We decided to conduct a middle-scale assessment study that involved 30 human judges. We conducted a small pilot study to estimate how long it took a judge to answer all survey questions (described in Section 4.2) in one dialog because we wanted to control the length of the study so that judges would not have too much cognitive load and would be consistent and accurate on their answers. Based on the pilot study, we decided to assign each judge 12 dialogs which took about an hour to complete. Each dialog was assigned to two judges. We used three out of the five physics problems from the original real corpus to ensure the variety of dialog contents while keeping the corpus size small. Therefore, the evaluation corpus consisted of 180 dialogs, in which 15 dialogs were generated by each of the 4 student models on each of the 3 problems.

## 4.2 Survey Design

### 4.2.1 Survey questions

We designed a web survey to collect human judgments on a 5-point scale on both utterance and di-

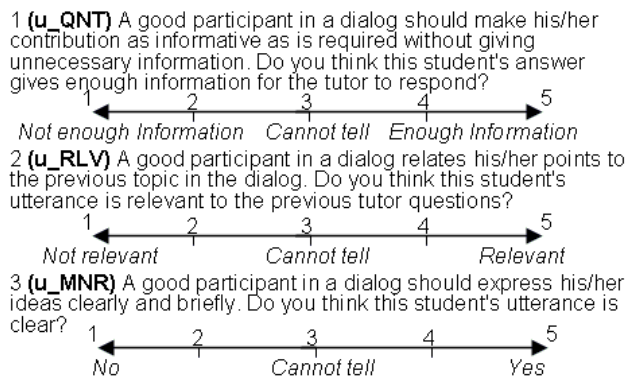

Figure 1: Utterance level questions.

alog levels. Each dialog is separated into pairs of a tutor question and the corresponding student answer. Figure 1 shows the three questions which are asked for each tutor-student utterance pair. The three questions assess the quality of the student answers from three aspects of Grice’s Maxim (Grice, 1975): Maxim of Quantity (**u\_QNT**), Maxim of Relevance (**u\_RLV**), and Maxim of Manner (**u\_MNR**). We do not include the Maxim of Quality because in our task domain the correctness of the student answers depends largely on students’ physics knowledge, which is not a factor we would like to consider when evaluating the realness of the students’ dialog behaviors.

In Figure 2, we show the three dialog level questions which are asked at the end of each dialog. The first question (**d\_TUR**) is a Turing test type of question which aims to obtain an impression of the student’s overall performance. The second question (**d\_QLT**) assesses the dialog quality from a tutoring perspective. The third question (**d\_PAT**) sets a higher standard on the student’s performance. Unlike the first two questions which ask whether the student “looks” good, this question further asks whether the judges would like to partner with the particular student.

### 4.2.2 Survey Website

We display one tutor-student utterance pair and the three utterance level questions on each web page. After the judges answer the three questions, he/she will be led to the next page which displays the next pair of tutor-student utterances in the dialog with the same three utterance level questions. The judge

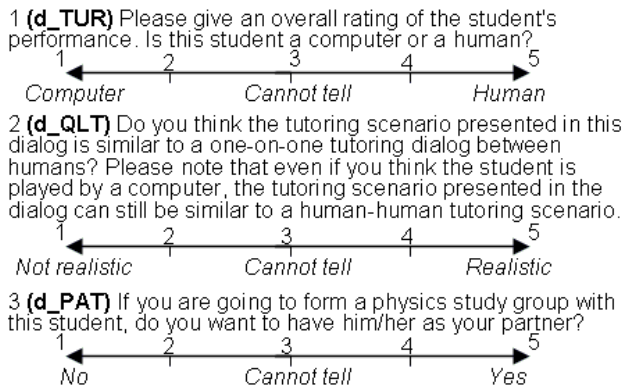

Figure 2: Dialog level questions.

reads through the dialog in this manner and answers all utterance level questions. At the end of the dialog, three dialog level questions are displayed on one webpage. We provide a textbox under each dialog level question for the judge to type in a brief explanation on his/her answer. After the judge completes the three dialog level questions, he/she will be led to a new dialog. This procedure repeats until the judge completes all of the 12 assigned dialogs.

### 4.3 Assessment Study

30 college students are recruited as human judges via flyers. Judges are required to be native speakers of American English to make correct judgments on the language use and fluency of the dialog. They are also required to have taken at least one course on Newtonian physics to ensure that they can understand the physics tutoring dialogs and make judgments about the content of the dialogs. We follow the same task assigning procedure that is used in (Linguistic Data Consortium, 2005) to ensure a uniform distribution of judges across student models and dialogs while maintaining a random choice of judges, models, and dialogs. Judges are instructed to work as quickly as comfortably possible. They are encouraged to provide their intuitive reactions and not to ponder their decisions.

## 5 Assessment Study Results

In the initial analysis, we observe that it is a difficult task for human judges to rate on the 5-point scale and the agreements among the judges are fairly low. Table 1 shows for each question, the percentages of

d_TUR	d_QLT	d_PAT	u_QNT	u_RLV	u_MNR
22.8%	27.8%	35.6%	39.2%	38.4%	38.7%

Table 1: Percent agreements on 5-point scale

pairs of judges who gave the same ratings on the 5-point scale. For the rest of the paper, we collapse the “definitely” types of answers with its adjacent “probably” types of answers (more specifically, answer 1 with 2, and 4 with 5). We substitute scores 1 and 2 with a score of 1.5, and scores 4 and 5 with a score of 4.5. A score of 3 remains the same.

### 5.1 Inter-annotator agreement

Table 2 shows the inter-annotator agreements on the collapsed 3-point scale. The first column presents the question types. In the first row, “diff” stands for the differences between human judges’ ratings. The column “diff=0” shows the percent agreements on the 3-point scale. We can see the improvements from the original 5-point scale when comparing with Table 1. The column “diff=1” shows the percentages of pairs of judges who agree with each other on a weaker basis in that one of the judges chooses “cannot tell”. The column “diff=2” shows the percentages of pairs of judges who disagree with each other. The column “Kappa” shows the un-weighted kappa agreements and the column “Kappa\*” shows the linear weighted kappa. We construct the confusion matrix for each question to compute kappa agreements. Table 3 shows the confusion matrix for d\_TUR. The first three rows of the first three columns show the counts of judges’ ratings on the 3-point scale. For example, the first cell shows that there are 20 cases where both judges give 1.5 to the same dialog. When calculating the linear weighted kappa, we define the distances between the adjacent categories to be one<sup>1</sup>. Note that we randomly picked two judges to rate each dialog so that different dialogs are rated by different pairs of judges and one pair of judges only worked on one dialog together. Thus, the kappa agreements here do not reflect the agreement of one pair of judges. Instead, the kappa agreements show the overall observed agreement among every pair of

<sup>1</sup>We also calculated the quadratic weighted kappa in which the distances are squared and the kappa results are similar to the linear weighted ones. For calculating the two weighted kappas, see <http://faculty.vassar.edu/lowry/kappa.html> for details.

Q	diff=0	diff=1	diff=2	Kappa	Kappa*
d_TUR	35.0%	45.6%	19.4%	0.022	0.079
d_QLT	46.1%	28.9%	25.0%	0.115	0.162
d_PAT	47.2%	30.6%	22.2%	0.155	0.207
u_QNT	66.8%	13.9%	19.3%	0.377	0.430
u_RLV	66.6%	17.2%	16.2%	0.369	0.433
u_MNR	67.5%	15.4%	17.1%	0.405	0.470

Table 2: Agreements on 3-point scale

	score=1.5	score=3	score=4.5	sum
score=1.5	20	26	20	66
score=3	17	11	19	47
score=4.5	15	20	32	67
sum	52	57	71	180

Table 3: Confusion Matrix on d\_TUR

judges controlling for the chance agreement.

We observe that human judges have low agreement on all types of questions, although the agreements on the utterance level questions are better than the dialog level questions. This observation indicates that assessing the overall quality of simulated/real dialogs on the dialog level is a difficult task. The lowest agreement appears on d\_TUR. We investigate the low agreements by looking into judges' explanations on the dialog level questions. 21% of the judges find it hard to rate a particular dialog because that dialog is too short or the student utterances mostly consist of one or two words. There are also some common false beliefs among the judges. For example, 16% of the judges think that humans will say longer utterances while 9% of the judges think that only humans will admit the ignorance of an answer.

## 5.2 Rankings of the models

In Table 4, the first column shows the name of the questions; the second column shows the name of the models; the third to the fifth column present the percentages of judges who choose answer 1 and 2, can't tell, and answer 4 and 5. For example, when looking at the column "1 and 2" for d\_TUR, we see that 22.2% of the judges think a dialog by a real student is generated probably or definitely by a computer; more judges (25.6%) think a dialog by the cluster model is generated by a computer; even more judges (32.2%) think a dialog by the correctness model is generated by a computer; and even

Question	model	1 and 2	can't tell	4 and 5
d_TUR	real	22.2%	28.9%	48.9%
	clu	25.6%	31.1%	43.3%
	cor	32.2%	26.7%	41.1%
	ran	51.1%	28.9%	20.0%
d_QLT	real	20.0%	10.0%	70.0%
	clu	21.1%	20.0%	58.9%
	cor	24.4%	15.6%	60.0%
	ran	60.0%	18.9%	21.1%
d_PAT	real	28.9%	21.1%	50.0%
	clu	41.1%	17.8%	41.1%
	cor	43.3%	18.9%	37.8%
	ran	82.2%	14.4%	3.4%

Table 4: Rankings on Dialog Level Questions

more judges (51.1%) think a dialog by the random model is generated by a computer. When looking at the column "4 and 5" for d\_TUR, we find that most of the judges think a dialog by the real student is generated by a human while the fewest number of judges think a dialog by the random model is generated by a human. Given that more human-like is better, both rankings support our hypothesis that the quality of the models from the best to the worst is: *real*, *clu*, *cor*, and *ran*. In other words, although it is hard to obtain well-agreed ratings among judges, we can combine the judges' ratings to produce the ranking of the models. We see consistent ranking orders on d\_QLT and d\_PAT as well, except for a disorder of cluster and correctness model on d\_QLT indicated by the underlines.

When comparing two models, we can tell which model is better from the above rankings. Nevertheless, we also want to know how significant the difference is. We use t-tests to examine the significance of differences between every two models. We average the two human judges' ratings to get an averaged score for each dialog. For each pair of models, we compare the two groups of the averaged scores for the dialogs generated by the two models using 2-tail t-tests at the significance level of  $p < 0.05$ . In Table 5, the first row presents the names of the models in each pair of comparison. **Sig** means that the t-test is significant after Bonferroni correction; question mark (?) means that the t-test is significant before the correction, but not significant afterwards, we treat this situation as a trend; **not** means that the t-test is not significant at all. The table shows

	real-ran	real-cor	real-clu	ran-cor	ran-clu	cor-clu
d_TUR	sig	not	not	sig	sig	not
d_QLT	sig	not	not	sig	sig	not
d_PAT	sig	?	?	sig	sig	not
u_QNT	sig	not	not	sig	sig	not
u_RLV	sig	not	not	sig	sig	not
u_MNR	sig	not	not	sig	sig	not

Table 5: T-Tests Results

that only the random model is significantly different from all other models. The correctness model and the cluster model are not significantly different from the real student given the human judges’ ratings, neither are the two models significantly different from each other.

### 5.3 Human judgment accuracy on d\_TUR

We look further into d\_TUR in Table 4 because it is the only question that we know the ground truth. We compute the accuracy of human judgment as (number of ratings 4&5 on real dialogs + number of ratings of 1&2 on simulated dialogs)/(2\*total number of dialogs). The accuracy is 39.44%, which serves as further evidence that it is difficult to discern human from simulated users directly. A weaker accuracy is calculated to be 68.35% when we treat “cannot tell” as a correct answer as well.

## 6 Validating Automatic Measures

Since it is expensive to use human judges to rate simulated dialogs, we are interested in building prediction models of human judgments using automatic measures. If the prediction model can reliably mimic human judgments, it can be used to rate new simulation models without collecting human ratings. In this section, we use a subset of the automatic measures proposed in (Schatzmann et al., 2005) that are applicable to our data to predict human judgments. Here, the human judgment on each dialog is calculated as the average of the two judges’ ratings. We focus on predicting human judgments on the dialog level because these ratings represent the overall performance of the student models. We use six high-level dialog feature measures including the number of student turns (**Sturn**), the number of tutor turns (**Tturn**), the number of words per stu-

dent turn (**Swordrate**), the number of words per tutor turn (**Twordrate**), the ratio of system/user words per dialog (**WordRatio**), and the percentage of correct answers (**cRate**).

### 6.1 The Regression Model

We use stepwise multiple linear regression to model the human judgments using the set of automatic features we listed above. The stepwise procedure automatically selects measures to be included in the model. For example, d\_TUR is predicted as  $3.65 - 0.08 * WordRatio - 3.21 * Swordrate$ , with an R-square of 0.12. The prediction models for d\_QLT and d\_PAT have similar low R-square values of 0.08 and 0.17, respectively. This result is not surprising because we only include the surface level automatic measures here. Also, these measures are designed for comparison between models instead of prediction. Thus, in Section 6.2, we build a ranking model to utilize the measures in their comparative manner.

### 6.2 The Ranking Model

We train three ranking models to mimic human judges’ rankings of the real and the simulated student models on the three dialog level questions using RankBoost, a boosting algorithm for ranking ((Freund et al., 2003), (Mairesse et al., 2007)). We briefly explain the algorithm using the same terminologies and equations as in (Mairesse et al., 2007), by building the ranking model for d\_TUR as an example. In the training phase, the algorithm takes as input a group of dialogs that are represented by values of the automatic measures and the human judges’ ratings on d\_TUR. The RankBoost algorithm treats the group of dialogs as ordered pairs:

$$\mathcal{T} = \{(x, y) \mid \begin{array}{l} x, y \text{ are two dialog samples,} \\ x \text{ has a higher human rated score than } y \end{array}\}$$

Each dialog  $x$  is represented by a set of  $m$  indicator functions  $h_s(x)$  ( $1 \leq s \leq m$ ). For example:

$$h_s(x) = \begin{cases} 1 & \text{if WordRatio}(x) \geq 0.47 \\ 0 & \text{otherwise} \end{cases}$$

Here, the threshold of 0.47 is calculated by RankBoost.  $\alpha$  is a parameter associated with each indicator function. For each dialog, a ranking score is

calculated as:

$$F(x) = \sum_s \alpha_s h_s(x) \quad (1)$$

In the training phase, the human ratings are used to set  $\alpha$  by minimizing the loss function:

$$LOSS = \frac{1}{|T|} \sum_{(x,y) \in T} eval(F(x) \leq F(y)) \quad (2)$$

The *eval* function returns 0 if  $(x, y)$  pair is ranked correctly, and 1 otherwise. In other words, **LOSS** score is the percentage of misordered pairs where the order of the predicted scores disagree with the order indicated by human judges. In the testing phase, the ranking score for every dialog is calculated by Equation 1. A baseline model which ranks dialog pairs randomly produces a LOSS of 0.5 (lower is better).

While LOSS indicates how many pairs of dialogs are ranked correctly, our main focus here is to rank the performance of the four student models instead of individual dialogs. Therefore, we propose another Averaged Model Ranking (**AMR**) score. AMR is computed as the sum of the ratings of all the dialogs generated by one model averaged by the number of the dialogs. The four student models are then ranked based on their AMR scores. The chance to get the right ranking order of the four student models by random guess is  $1/(4!)$ .

Table 6 shows a made-up example to illustrate the two measures. *real\_1* and *real\_2* are two dialogs generated by the real student model; *ran\_1* and *ran\_2* are two dialogs by the random model. The second and third column shows the human-rated score as the gold standard and the machine-predicted score in the testing phase respectively. The LOSS in this example is  $1/6$ , because only the pair of *real\_2* and *ran\_1* is misordered out of all the 6 possible pair combinations. We then compute the AMR of the two models. According to human-rated scores, the real model is scored  $0.75 (= (0.9+0.6)/2)$  while the random model is scored  $0.3$ . When looking at the predicted scores, the real model is scored  $0.65$ , which is also higher than the random model with a score of  $0.4$ . We thus conclude that the ranking model ranks the two student models correctly according to the overall rating measure. We use both LOSS and AMR to evaluate the ranking models.

Dialog	Human-rated Score	Predicted Score
real_1	0.9	0.9
real_2	0.6	0.4
ran_1	0.4	0.6
ran_2	0.2	0.2

Table 6: A Made-up Example of the Ranking Model

Cross Validation	d_TUR	d_QLT	d_PAT
Regular	0.176	0.155	0.151
Minus-one-model	0.224	0.180	0.178

Table 7: LOSS scores for Regular and Minus-one-model (during training) Cross Validations

First, we use regular 4-fold cross validation where we randomly hold out 25% of the data for testing and train on the remaining 75% of the data for 4 rounds. Both the training and the testing data consist of dialogs equally distributed among the four student models. However, since the practical usage of the ranking model is to rank a new model against several old models without collecting additional human ratings, we further test the algorithm by repeating the 4 rounds of testing while taking turns to hold out the dialogs from one model in the training data, assuming that model is the new model that we do not have human ratings to train on. The testing corpus still consists of dialogs from all four models. We call this approach the minus-one-model cross validation.

Table 7 shows the LOSS scores for both cross validations. Using 2-tailed t-tests, we observe that the ranking models significantly outperforms the random baseline in all cases after Bonferroni correction ( $p < 0.05$ ). When comparing the two cross validation results for the same question, we see more LOSS in the more difficult minus-one-model case. However, the LOSS scores do not offer a direct conclusion on whether the ranking model ranks the four student models correctly or not. To address this question, we use AMR scores to re-evaluate all cross validation results. Table 8 shows the human-rated and predicted AMR scores averaged over four rounds of testing on the regular cross validation results. We see that the ranking model gives the same rankings of the student models as the human judges on all questions. When applying AMR on the minus-one-model cross validation results, we see similar results that the ranking model reproduces hu-

	real		clu		cor		ran	
	human	predicted	human	predicted	human	predicted	human	predicted
d_TUR	0.68	0.62	0.65	0.59	0.63	0.52	0.51	0.49
d_QLT	0.75	0.71	0.71	0.63	0.69	0.61	0.48	0.50
d_PAR	0.66	0.65	0.60	0.60	0.58	0.57	0.31	0.32

Table 8: AMR Scores for Regular Cross Validation

man judges' rankings. Therefore, we suggest that the ranking model can be used to evaluate a new simulation model by ranking it against several old models. Since our testing corpus is relatively small, we would like to confirm this result on a large corpus and on other dialog systems in the future.

## 7 Conclusion and Future Work

Automatic evaluation measures are used in evaluating simulated dialog corpora. In this study, we investigate a set of previously proposed automatic measures by comparing the conclusions drawn by these measures with human judgments. These measures are considered as valid if the conclusions drawn by these measures agree with human judgments. We use a tutoring dialog corpus with real students, and three simulated dialog corpora generated by three different simulation models trained from the real corpus. Human judges are recruited to read the dialog transcripts and rate the dialogs by answering different utterance and dialog level questions. We observe low agreements among human judges' ratings. However, the overall human ratings give consistent rankings on the quality of the real and simulated user models. Therefore, we build a ranking model which successfully mimics human judgments using previously proposed automatic measures. We suggest that the ranking model can be used to rank new simulation models against the old models in order to assess the quality of the new model.

In the future, we would like to test the ranking model on larger dialog corpora generated by more simulation models. We would also want to include more automatic measures that may be available in the richer corpora to improve the ranking and the regression models.

## Abstract

This work presents an agenda-based approach to improve the robustness of the dialog manager by using dialog examples and n-best recognition hypotheses. This approach supports n-best hypotheses in the dialog manager and keeps track of the dialog state using a discourse interpretation algorithm with the agenda graph and focus stack. Given the agenda graph and n-best hypotheses, the system can predict the next system actions to maximize multi-level score functions. To evaluate the proposed method, a spoken dialog system for a building guidance robot was developed. Preliminary evaluation shows this approach would be effective to improve the robustness of example-based dialog modeling.

## 1 Introduction

Development of spoken dialog systems involves human language technologies which must cooperate to answer user queries. Since the performance in human language technologies such as Automatic Speech Recognition (ASR) and Natural Language Understanding (NLU)<sup>1</sup> have been improved, this advance has made it possible to develop spoken dialog systems for many different application domains.

Nevertheless, there are major problems for practical spoken dialog systems. One of them which must be considered by the Dialog Manager (DM) is the error propagation from ASR and NLU modules. In

<sup>1</sup>Through this paper, we will use the term *natural language* to include both *spoken language* and *written language*

general, errors in spoken dialog systems are prevalent due to errors in speech recognition or language understanding. These errors can cause the dialog system to misunderstand a user and in turn lead to an inappropriate response. To avoid these errors, a basic solution is to improve the accuracy and robustness of the recognition and understanding processes. However, it has been impossible to develop perfect ASR and NLU modules because of noisy environments and unexpected input. Therefore, the development of robust dialog management has also been one of the most important goals in research on practical spoken dialog systems.

In the dialog manager, a popular method to deal with these errors is to adopt dialog mechanisms for detecting and repairing potential errors at the conversational level (McTear et al., 2005; Torres et al., 2005; Lee et al., 2007). In human-computer communication, the goal of error recovery strategy is to maximize the user's satisfaction of using the system by guiding for the repair of the wrong information by human-computer interaction. On the other hand, there are different approaches to improve the robustness of dialog management using n-best hypotheses. Rather than Markov Decision Processes (MDPs), partially observable MDPs (POMDPs) potentially provide a much more powerful framework for robust dialog modeling since they consider n-best hypotheses to estimate the distribution of the belief state (Williams and Young, 2007).

In recent, we proposed another data-driven approach for the dialog modeling called Example-based Dialog Modeling (EBDM) (Lee et al., 2006a). However, difficulties occur when attempting to de-

ploy EBDM in practical spoken dialog systems in which ASR and NLU errors are frequent. Thus, this paper proposes a new method to improve the robustness of the EBDM framework using an agenda-based approach and n-best recognition hypotheses. We consider a domain-specific agenda to estimate the best dialog state and example because, in task-oriented systems, a current dialog state is highly correlated to the previous dialog state. We have also used the example-based error recovery approach to handle exceptional cases due to noisy input or unexpected focus shift.

This paper is organized as follows. Previous related work is described in Section 2, followed by the methodology and problems of the example-based dialog modeling in Section 3. An agenda-based approach for heuristics is presented in Section 4. Following that, we explain greedy selection with n-best hypotheses in Section 5. Section 6 describes the error recovery strategy to handle unexpected cases. Then, Section 7 provides the experimental results of a real user evaluation to verify our approach. Finally, we draw conclusions and make suggestions for future work in Section 8.

## 2 Related Work

In many spoken dialog systems that have been developed recently, various knowledge sources are used. One of the knowledge sources, which are usually application-dependent, is an agenda or task model. These are powerful representations for segmenting large tasks into more reasonable subtasks (Rich and Sidner, 1998; Bohus and Rudnicky, 2003; Young et al., 2007). These are manually designed for various purposes including dialog modeling, search space reduction, domain knowledge, and user simulation.

In Collagen (Rich and Sidner, 1998), a plan tree, which is an approximate representation of a partial SharedPlan, is composed of alternating act and plan recipe nodes for internal discourse state representation and discourse interpretation.

In addition, Bohus and Rudnicky (2003) have presented a RavenClaw dialog management which is an agenda-based architecture using hierarchical task decomposition and an expectation agenda. For modeling dialog, the domain-specific dialog control is represented in the *Dialog Task Specification* layer

using a tree of dialog agents, with each agent handling a certain subtask of the dialog task.

Recently, the problem of a large state space in POMDP framework has been solved by grouping states into partitions using user goal trees and ontology rules as heuristics (Young et al., 2007).

In this paper, we are interested in exploring algorithms that would integrate this knowledge source for users to achieve domain-specific goals. We used an agenda graph whose hierarchy reflects the natural order of dialog control. This graph is used to both keep track of the dialog state and to select the best example using multiple recognition hypotheses for augmenting previous EBDM framework.

## 3 Example-based Dialog Modeling

Our approach is implemented based on Example-Based Dialog Modeling (EBDM) which is one of generic dialog modelings. We begin with a brief overview of the EBDM framework in this section. EBDM was inspired by Example-Based Machine Translation (EBMT) (Nagao, 1984), a translation system in which the source sentence can be translated using similar example fragments within a large parallel corpus, without knowledge of the language's structure. The idea of EBMT can be extended to determine the next system actions by finding similar dialog examples within the dialog corpus. The system action can be predicted by finding semantically similar user utterances with the dialog state. The dialog state is defined as the set of relevant internal variables that affect the next system action. EBDM needs to automatically construct an example database from the dialog corpus. Dialog Example DataBase (DEDDB) is semantically indexed to generalize the data in which the indexing keys can be determined according to state variables chosen by a system designer for domain-specific applications (Figure 1). Each turn pair (user turn, system turn) in the dialog corpus is mapped to semantic instances in the DEDDB. The index constraints represent the state variables which are domain-independent attributes. To determine the next system action, there are three processes in the EBDM framework as follows:

- **Query Generation:** The dialog manager makes Structured Query Language (SQL)

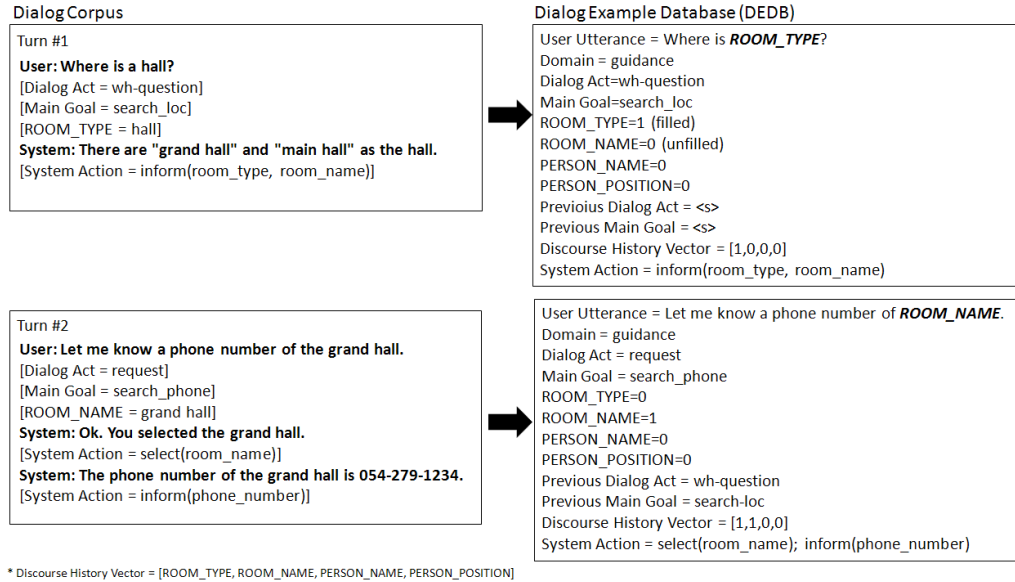

Figure 1: Indexing scheme for dialog example database on building guidance domain

statement using discourse history and NLU results.

- **Example Search:** The dialog manager searches for semantically similar dialog examples in the DEDB given the current dialog state. If no example is retrieved, some state variables can be ignored by relaxing particular variables according to the level of importance given the dialog's genre and domain.
- **Example Selection:** The dialog manager selects the best example to maximize the utterance similarity measure based on lexico-semantic similarity and discourse history similarity.

Figure 2 illustrates the overall strategy of EBDM framework for spoken dialog systems. The EBDM framework is a simple and powerful approach to rapidly develop natural language interfaces for multi-domain dialog processing (Lee et al., 2006b). However, in the context of spoken dialog system for domain-specific tasks, this framework must solve two problems: (1) Keeping track of the dialog state with a view to ensuring steady progress towards task completion, (2) Supporting n-best recognition hypotheses to improve the robustness of dialog manager. Consequently, we sought to solve these prob-

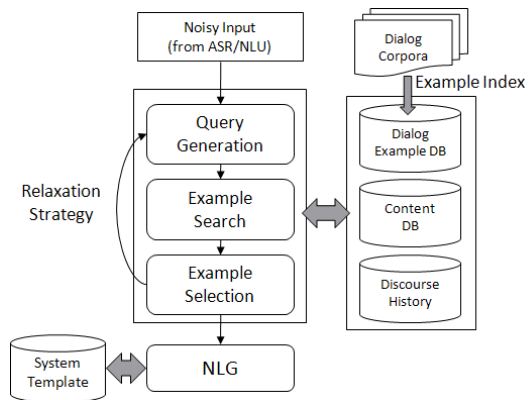

Figure 2: Strategy of the Example-Based Dialog Modeling (EBDM) framework.

lems by integrating the agenda graph as a heuristic which reflects the natural hierarchy and order of subtasks needed to complete the task.

## 4 Agenda Graph

In this paper, agenda graph  $G$  is simply a way of encoding the domain-specific dialog control to complete the task. An agenda is one of the subtask flows, which are possible paths from root node to terminal node.  $G$  is composed of nodes ( $v$ ) which correspond to possible intermediate steps in the process of completing the specified task, and edges ( $e$ ) which con-

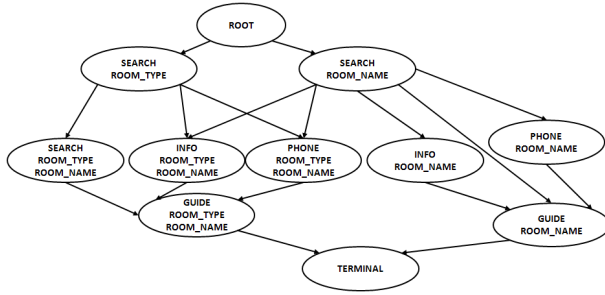

Figure 3: Example of an agenda graph for a building guidance.

nect nodes. In other words,  $v$  corresponds to user goal state to achieve domain-specific subtask in its expected agenda. Each node includes three different components: (1) A precondition that must be true before the subtask is executed; (2) A description of the node that includes its label and identifier; and (3) Links to nodes that will be executed at the subsequent turn. For every edge  $e_{ij} = (v_i, v_j)$ , we defined a transition probability based on prior knowledge of dialog flows. This probability can be assigned based on empirical analysis of human-computer conversations, assuming that the users behave in consistent, goal-directed ways. Alternatively, it can be assigned manually at the discretion of the system developer to control the dialog flow. This heuristic has advantages for practical spoken dialog system because a key condition for successful task-oriented dialog system is that the user and system know which task or subtask is currently being executed. To exemplify, Figure 3 illustrates part of the agenda graph for *PHOPE*, a building guidance robot using the spoken dialog system. In Figure 3,  $G$  is represented by a Directed Acyclic Graph (DAG), where each link in the graph reflects a transition between one user goal state and the next. The set of paths in  $G$  represent an agenda designed by the system developer. We adapted DAG representation because it is more intuitive and flexible than hierarchical tree representation. The syntax for graph representation in our system is described by an XML schema (Figure 4).

#### 4.1 Mapping Examples to Nodes

In the agenda graph  $G$ , each node  $v$  should hold relevant dialog examples corresponding to user goal states. Therefore, the dialog examples in DEDB are

```

<agenda_graph domain="guidance">
  <node node_id="2">
    <property>
      <label>Search Location with Room Type and Room Name</label>
    </property>
    <precondition>
      <main_goal>SEARCH_LOC</main_goal>
      <slot_status name="LOC_ROOM_NAME">1</slot_status>
      <slot_status name="LOC_ROOM_TYPE">1</slot_status>
      <slot_status name="LOC_ROOM_NUMBER">0</slot_status>
    </precondition>
    <next>
      <node_id prob="0.15">4</node_id>
      <node_id prob="0.25">5</node_id>
      <node_id prob="0.60">6</node_id>
    </next>
  </node>
</agenda_graph>
  
```

Figure 4: XML description for the agenda graph

mapped to a user goal state when a precondition of the node is true. Initially, the root node of the DAG is the starting state, where there is no dialog example. Then, the attributes of each dialog example are examined via the preconditions of each user goal node by breadth-first traversal. If the precondition is true, the node holds relevant that may appear in the user's goal state. The method of selecting the best of these examples will be described in 5.

#### 4.2 Discourse Interpretation

Inspired by Collagen (Rich and Sidner, 1998; Lesh et al., 2001), we investigated a discourse interpretation algorithm to consider how the current user's goal can contribute to the current agenda in a focus stack according to Lochbaum's discourse interpretation algorithm (Lochbaum, 1998). The focus stack takes into account the discourse structure by keeping track of discourse states. In our system, the focus stack is a set of user goal nodes which lead to completion of the subtask. The top on the focus stack is the previous node in this set. The focus stack is updated after every utterance. To interpret the type of the discourse state, this breaks down into five main cases of possible current node for an observed user's goal:

- *NEW\_TASK*: Starting a new task to complete a new agenda (Child of the root).
- *NEW\_SUB\_TASK*: Starting a new subtask to partially shift focus (A different child of the parent).

- *NEXT\_TASK*: Working on the next subtask contributing to current agenda (Its child node).
- *CURRENT\_TASK*: Repeating or modifying the observed goal on the current subtask (Current node).
- *PARENT\_TASK*: Modifying the observation on the previous subtask (Parent node).

Nodes in parentheses denote the topological position of the current node relative to the top node on the focus stack. If *NEXT\_TASK* is selected, the current node is pushed to the focus stack. *NEXT\_TASK* covers totally focused behavior, i.e., when there are no unexpected focus shifts. This occurs when the current user utterance is highly correlated to the previous system utterance. The remaining four cases cover various types of discourse state. For example, *NEW\_SUB\_TASK* involves starting a new subtask to partially shift focus, thereby popping the previous goal off the focus stack and pushing a new user goal for the new subtask. *NEW\_TASK*, which is placed on the node linked to root node, involves starting a new task to complete a new agenda. Therefore, a dialog is re-started and the current node is pushed onto the focus stack with the current user goal as its first element.

If none of the above cases holds, the discourse interpretation concludes that the current input should be rejected because we expect user utterances to be correlated to the previous turn in a task-oriented domain. Therefore, this interpretation does not contribute to the current agenda on the focus stack due to ASR and NLU errors that are due to noisy environments and unexpected input. These cases can be handled by using an error recovery strategy in Section 6.

Figure 5 shows some examples of pseudo-codes used in the discourse interpretation algorithm to select the best node among possible next nodes.  $S, H,$  and  $G$  denote the focus stack, hypothesis, and agenda graph, respectively. The **INTERPRET** algorithm is initially called to interpret the current discourse state. Furthermore, the essence of a discourse interpretation algorithm is to find candidate nodes of possible next subtask for an observed user goal, expressed in the definition of **GENERATE**. The **SELECT** algorithm selects the best node to maximize

<pre> INTERPRET(&lt;S,H&gt;,G) ≡ C ← GENERATE(&lt;S,H&gt;,G) if  C  = 1   then return discourse state in C else   c* ← SELECT(&lt;S,H&gt;,C)   return selected discourse state in c* </pre>	<pre> GENERATE(&lt;S,H&gt;,G) ≡ return a union set of : i) NEW_TASK(&lt;S,H&gt;,G) ii) NEW_SUB_TASK(&lt;S,H&gt;,G) iii) NEXT_TASK (&lt;S,H&gt;,G) iv) CURRENT_TASK(&lt;S,H&gt;,G) v) PARENT_TASK(&lt;S,H&gt;,G) </pre>
<pre> NEXT_TASK(&lt;S,H&gt;,G) ≡ C ← ∅ E ← retrieved examples of H foreach e ∈ E   foreach c<sub>s</sub> ∈ {children of top(S) G}     if e is an example of c<sub>s</sub>       then C ← C ∪ {c<sub>s</sub>} return C </pre>	<pre> SELECT(&lt;S,H&gt;,C) ≡ c* = argmax<sub>c</sub> ωS<sub>H</sub>(H)+(1-ω) S<sub>D</sub>(c ∈ C S) return c* </pre>

Figure 5: Pseudo-codes for the discourse interpretation algorithm

the score function based on current input and discourse structure given the focus stack. The details of how the score of candidate nodes are calculated are explained in Section 5.

## 5 Greedy Selection with n-best Hypotheses

Many speech recognizers can generate a list of plausible hypotheses (n-best list) but output only the most probable one. Examination of the n-best list reveals that the best hypothesis, the one with the lowest word error rate, is not always in top-1 position but sometimes in the lower rank of the n-best list. Therefore, we need to select the hypothesis that maximizes the scoring function among a set of n-best hypotheses of each utterance. The role of agenda graph is for a heuristic to score the discourse state to successfully complete the task given the focus stack.

The current system depends on a greedy policy which is based on immediate transitions rather than full transitions from the initial state. The greedy selection with n-best hypotheses is implemented as follows. Firstly, every hypothesis  $h_i$  is scanned and all possible nodes are generated using the discourse interpretation. Secondly, the multi-level score functions are computed for each candidate node  $c_i$  given a hypothesis  $h_i$ . Using the greedy algorithm, the node with the highest score is selected as the user goal state. Finally, the system actions are predicted by the dialog example to maximize the example score in the best node.

The generation of candidate nodes is based on multiple hypotheses from the previous EBDM

framework. This previous EBDM framework chose a dialog example to maximize the utterance similarity measure. However, our system generates a set of multiple dialog examples with each utterance similarity over a threshold given a specific hypothesis. Then, the candidate nodes are generated by matching to each dialog example bound to the node. If the number of matching nodes is exactly one, that node is selected. Otherwise, the best node which would be pushed onto the focus stack must be selected using multi-level score functions.

### 5.1 Node Selection

The node selection is determined by calculating some score functions. We defined multi-level score functions that combine the scores of ASR, SLU, and DM modules, which range from 0.00 to 1.00. The best node is selected by greedy search with multiple hypotheses  $H$  and candidate nodes  $C$  as follows:

$$c^* = \arg \max_{h_i \in H, c_i \in C} \omega S_H(h_i) + (1 - \omega) S_D(c_i|S)$$

where  $H$  is a list of n-best hypotheses and  $C$  is a set of nodes to be generated by the discourse interpretation. For the node selection, we divided the score function into two functions  $S_H(h_i)$ , hypothesis score, and  $S_D(c_i|S)$ , discourse score, where  $c_i$  is the focus node to be generated by single hypothesis  $h_i$ .

We defined the hypothesis score at the utterance level as

$$S_H(h_i) = \alpha S_{rec}(h_i) + \beta S_{cont}(h_i)$$

where  $S_{rec}(h_i)$  denotes the recognition score which is a generalized confidence score over the confidence score of the top-rank hypothesis.  $S_{cont}(h_i)$  is the content score in the view of content management to access domain-specific contents. For example, in the building guidance domain, these contents would be a building knowledge database including room name, room number, and room type. The score is defined as:

$$S_{cont}(h_i) = \begin{cases} \frac{N(C_{h_i})}{N(C_{prev})} & \text{if } C_{h_i} \subseteq C_{prev} \\ \frac{N(C_{h_i})}{N(C_{total})} & \text{if } C_{h_i} \not\subseteq C_{prev} \end{cases}$$

where  $C_{prev}$  is a set of contents at the previous turn and  $C_{total}$  is a set of total contents in the content

database.  $C_{h_i}$  denotes a set of focused contents by hypothesis  $h_i$  at the current turn.  $N(C)$  represents the number of contents  $C$ . This score reflects the degree of content coherence because the number of contents of interest has been gradually reduced without any unexpected focus shift. In the hypothesis score,  $\alpha$  and  $\beta$  denote weights which depend on the accuracy of speech recognition and language understanding, respectively.

In addition to the hypothesis score, we defined the discourse score  $S_D$  at the discourse level to consider the discourse structure between the previous node and current node given the focus stack  $S$ . This score is the degree to which candidate node  $c_i$  is in focus with respect to the previous user goal and system utterance. In the agenda graph  $G$ , each transition has its own probability as prior knowledge. Therefore, when  $c_i$  is *NEXT\_TASK*, the discourse score is computed as

$$S_D(c_i|S) = P(c_i|c = top(S))$$

where  $P(c_i|c = top(S))$  is a transition probability from the top node  $c$  on the focus stack  $S$  to the candidate node  $c_i$ . However, there is a problem for cases other than *NEXT\_TASK* because the graph has no backward probability. To solve this problem, we assume that the transition probability may be lower than that of the *NEXT\_TASK* case because a user utterance is likely to be influenced by the previous turn. Actually, when using the task-oriented dialog system, typical users stay focused most of the time during imperfect communication (Lesh et al., 2001). To assign the backward transition probability, we obtain the minimum transition probability  $P_{min}(S)$  among from the top node on the focus stack  $S$  to its children. Then, the discourse score  $S_D$  can be formalized when the candidate node  $c_i$  does not correspond to *NEXT\_TASK* as follows:

$$S_D(c_i|S) = \max\{P_{min}(S) - \lambda Dist(c_i, c), 0\}$$

where  $\lambda$  is a penalty of distance between candidate node and previous node,  $Dist(c_i, c)$ , according to type of candidate node such as *NEW\_TASK* and *NEW\_SUB\_TASK*. The simplest case is to uniformly assign  $\lambda$  to a specific value.

To select the best node using the node score, we use  $\omega$  ( $0 \leq \omega \leq 1$ ) as an interpolation weight

between the hypothesis score  $S_h$  and the discourse score  $S_D$ . This weight is empirically assigned according to the characteristics of the dialog genre and task. For example,  $\omega$  can set lower to manage the transactional dialog in which the user utterance is highly correlated to the previous system utterance, i.e., a travel reservation task, because this task usually has preference orders to fill slots.

## 5.2 Example Selection

After selecting the best node, we use the example score to select the best dialog example mapped into this node.

$$e^* = \arg \max_{e_j \in E(c^*)} \omega S_{utter}(h^*, e_j) + (1 - \omega) S_{sem}(h^*, e_j)$$

where  $h^*$  is the best hypothesis to maximize the node score and  $e_j$  is a dialog example in the best node  $c^*$ .  $S_{utter}(h, e_j)$  denotes the value of the utterance similarity of the user's utterances between the hypothesis  $h$  and dialog example  $e_j$  in the best node  $c^*$  (Lee et al., 2006a).

To augment the utterance similarity used in the EBDM framework, we also defined the semantic score for example selection,  $S_{sem}(h, e_j)$ :

$$S_{sem}(h, e_j) = \frac{\# \text{ of matching index keys}}{\# \text{ of total index keys}}$$

The semantic score is the ratio of matching index keys to the number of total index keys between hypothesis  $h$  and example record  $e_j$ . This score reflects that a dialog example is semantically closer to the current utterance if the example is selected with more index keys. After processing of the node and example selection, the best example is used to predict the system actions. Therefore, the dialog manager can predict the next actions with the agenda graph and n-best recognition hypotheses.

## 6 Error Recovery Strategy

As noted in Section 4.2, the discourse interpretation sometimes fails to generate candidate nodes. In addition, the dialog manager should confirm the current information when the score falls below some threshold. For these cases, we adapt an example-based error recovery strategy (Lee et al., 2007). In this approach, the system detects that something is

wrong in the user's utterance and takes immediate steps to address the problem using some help messages such as *UtterHelp*, *InfoHelp*, and *UsageHelp* in the example-based error recovery strategies. We also added a new help message, *AgendaHelp*, that uses the agenda graph and the label of each node to tell the user which subtask to perform next such as "SYSTEM: Next, you can do the subtask 1)Search Location with Room Name or 2)Search Location with Room Type".

## 7 Experiment & Result

First we developed the spoken dialog system for *PHOPE* in which an intelligent robot can provide information about buildings (i.e., room number, room location, room name, room type) and people (i.e., name, phone number, e-mail address, cellular phone number). If the user selects a specific room to visit, then the robot takes the user to the desired room. For this system, ten people used the WOZ method to collect a dialog corpus of about 500 utterances from 100 dialogs which were based on a set of pre-defined 10 subjects relating to domain-specific tasks. Then, we designed an agenda graph and integrated it into the EBDM framework.

In an attempt to quantify the impact of our approach, five Korean users participated in a preliminary evaluation. We provided them with pre-defined scenarios and asked them to collect test data from 50 dialogs, including about 150 utterances. After processing each dialog, the participants completed a questionnaire to assess their satisfaction with aspects of the performance evaluation. The speech recognition hypotheses are obtained by using the Hidden Markov model Toolkit (HTK) speech recognizer adapted to our application domain in which the word error rate (WER) is 21.03%. The results of the *Task Completion Rate* (TCR) are shown in Table 1. We explored the effects of our agenda-based approach with n-best hypotheses compared to the previous EBDM framework which has no agenda graph and supports only 1-best hypothesis.

Note that using 10-best hypotheses and the agenda graph increases the TCR from 84.0% to 90.0%, that is, 45 out of 50 dialogs were completed successfully. The average number of turns ( $\#AvgTurn$ ) to completion was also shorter, which

shows 4.35 turns per a dialog using the agenda graph and 10-best hypotheses. From these results, we conclude that the use of the n-best hypotheses with the agenda graph is helpful to improve the robustness of the EBDM framework against noisy inputs.

System	#AvgTurn	TCR (%)
1-best(-AG)	4.65	84.0
10-best(+AG)	4.35	90.0

Table 1: Task completion rate according to using the AG (Agenda Graph) and n-best hypotheses for n=1 and n=10.

## 8 Conclusion & Discussion

This paper has proposed a new agenda-based approach with n-best recognition hypotheses to improve the robustness of the Example-based Dialog Modeling (EBDM) framework. The agenda graph can be thought of as a hidden cost of applying our methodology. However, an explicit agenda is necessary to successfully achieve the purpose of using spoken dialog system. Our preliminary results indicate this fact that the use of agenda graph as heuristics can increase the TCR. In addition, our approach is robust to recognition errors because it maintains multiple hypotheses for each user utterance.

There are several possible subjects for further research on our approach. First, the optimal interpolation weights should be determined. This task will require larger dialog corpora by using user simulation. Second, the cost of designing the agenda graph should be reduced. We have focused on developing a system to construct this graph semi-automatically by applying dialog state clustering and utterance clustering to achieve hierarchical clustering of dialog examples. Finally, future work will include expanding our system to other applications, such as navigation systems for automobiles.

## Abstract

We address two problems in the field of automatic optimization of dialogue strategies: learning effective dialogue strategies when no initial data or system exists, and evaluating the result with real users. We use Reinforcement Learning (RL) to learn multimodal dialogue strategies by interaction with a simulated environment which is “bootstrapped” from small amounts of Wizard-of-Oz (WOZ) data. This use of WOZ data allows development of optimal strategies for domains where no working prototype is available. We compare the RL-based strategy against a supervised strategy which mimics the wizards’ policies. This comparison allows us to measure relative improvement over the training data. Our results show that RL significantly outperforms Supervised Learning when interacting in simulation as well as for interactions with real users. The RL-based policy gains on average 50-times more reward when tested in simulation, and almost 18-times more reward when interacting with real users. Users also subjectively rate the RL-based policy on average 10% higher.

## 1 Introduction

Designing a spoken dialogue system is a time-consuming and challenging task. A developer may spend a lot of time and effort anticipating the potential needs of a specific application environment and then deciding on the most appropriate system action (e.g. confirm, present items, . . .). One of the key advantages of statistical optimisation methods, such as Reinforcement Learning (RL), for dialogue

strategy design is that the problem can be formulated as a principled mathematical model which can be automatically trained on real data (Lemon and Pietquin, 2007; Frampton and Lemon, to appear). In cases where a system is designed from scratch, however, there is often no suitable in-domain data. Collecting dialogue data without a working prototype is problematic, leaving the developer with a classic chicken-and-egg problem.

We propose to learn dialogue strategies by simulation-based RL (Sutton and Barto, 1998), where the simulated environment is learned from small amounts of Wizard-of-Oz (WOZ) data. Using WOZ data rather than data from real Human-Computer Interaction (HCI) allows us to learn optimal strategies for domains where no working dialogue system already exists. To date, automatic strategy learning has been applied to dialogue systems which have already been deployed using hand-crafted strategies. In such work, strategy learning was performed based on already present extensive online operation experience, e.g. (Singh et al., 2002; Henderson et al., 2005). In contrast to this preceding work, our approach enables strategy learning in domains where no prior system is available. Optimised learned strategies are then available from the first moment of online-operation, and tedious hand-crafting of dialogue strategies is omitted. This independence from large amounts of in-domain dialogue data allows researchers to apply RL to new application areas beyond the scope of existing dialogue systems. We call this method ‘bootstrapping’.

In a WOZ experiment, a hidden human operator, the so called “wizard”, simulates (partly or com-

pletely) the behaviour of the application, while subjects are left in the belief that they are interacting with a real system (Fraser and Gilbert, 1991). That is, WOZ experiments only *simulate* HCI. We therefore need to show that a strategy bootstrapped from WOZ data indeed transfers to real HCI. Furthermore, we also need to introduce methods to learn useful user simulations (for training RL) from such limited data.

The use of WOZ data has earlier been proposed in the context of RL. (Williams and Young, 2004) utilise WOZ data to discover the state and action space for MDP design. (Prommer et al., 2006) use WOZ data to build a simulated user and noise model for simulation-based RL. While both studies show promising first results, their simulated environment still contains many hand-crafted aspects, which makes it hard to evaluate whether the success of the learned strategy indeed originates from the WOZ data. (Schatzmann et al., 2007) propose to ‘bootstrap’ with a simulated user which is entirely hand-crafted. In the following we propose an entirely data-driven approach, where all components of the simulated learning environment are learned from WOZ data. We also show that the resulting policy performs well for real users.

## 2 Wizard-of-Oz data collection

Our domains of interest are information-seeking dialogues, for example a multimodal in-car interface to a large database of music (MP3) files. The corpus we use for learning was collected in a multimodal study of German task-oriented dialogues for an in-car music player application by (Rieser et al., 2005). This study provides insights into natural methods of information presentation as performed by human wizards. 6 people played the role of an intelligent interface (the “wizards”). The wizards were able to speak freely and display search results on the screen by clicking on pre-computed templates. Wizards’ outputs were not restricted, in order to explore the different ways they intuitively chose to present search results. Wizard’s utterances were immediately transcribed and played back to the user with Text-To-Speech. 21 subjects (11 female, 10 male) were given a set of predefined tasks to perform, as well as a primary driving task, using a driving simu-

lator. The users were able to speak, as well as make selections on the screen. We also introduced artificial noise in the setup, in order to closer resemble the conditions of real HCI. Please see (Rieser et al., 2005) for further detail.

The corpus gathered with this setup comprises 21 sessions and over 1600 turns. Example 1 shows a typical multimodal presentation sub-dialogue from the corpus (translated from German). Note that the wizard displays quite a long list of possible candidates on an (average sized) computer screen, while the user is driving. This example illustrates that even for humans it is difficult to find an “optimal” solution to the problem we are trying to solve.

- (1) **User:** Please search for music by Madonna .  
**Wizard:** I found seventeen hundred and eleven items. The items are displayed on the screen.  
*[displays list]*  
**User:** Please select ‘Secret’.

For each session information was logged, e.g. the transcriptions of the spoken utterances, the wizard’s database query and the number of results, the screen option chosen by the wizard, and a rich set of contextual dialogue features was also annotated, see (Rieser et al., 2005).

Of the 793 wizard turns 22.3% were annotated as presentation strategies, resulting in 177 instances for learning, where the six wizards contributed about equal proportions.

Information about user preferences was obtained, using a questionnaire containing similar questions to the PARADISE study (Walker et al., 2000). In general, users report that they get distracted from driving if too much information is presented. On the other hand, users prefer shorter dialogues (most of the user ratings are negatively correlated with dialogue length). These results indicate that we need to find a strategy given the competing trade-offs between the number of results (large lists are difficult for users to process), the length of the dialogue (long dialogues are tiring, but collecting more information can result in more precise results), and the noise in the speech recognition environment (in high noise conditions accurate information is difficult to obtain). In the following we utilise the ratings from the user questionnaires to optimise a presentation strategy using simulation-based RL.

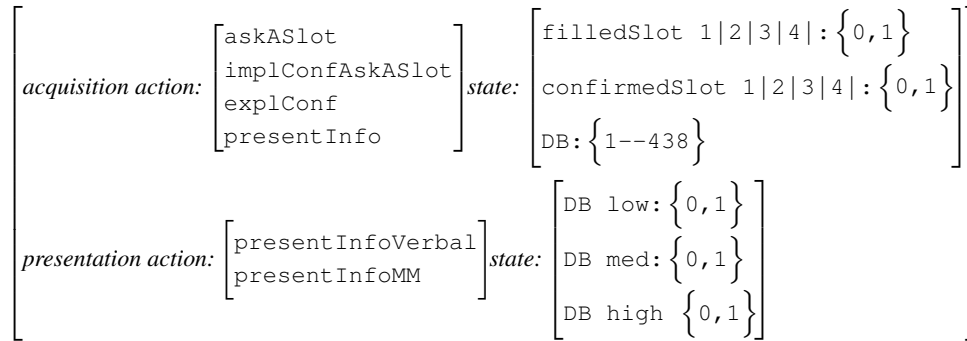

Figure 1: State-Action space for hierarchical Reinforcement Learning

### 3 Simulated Learning Environment

Simulation-based RL (also known as “model-free” RL) learns by interaction with a simulated environment. We obtain the simulated components from the WOZ corpus using data-driven methods. The employed database contains 438 items and is similar in retrieval ambiguity and structure to the one used in the WOZ experiment. The dialogue system used for learning comprises some obvious constraints reflecting the system logic (e.g. that only filled slots can be confirmed), implemented as Information State Update (ISU) rules. All other actions are left for optimisation.

#### 3.1 MDP and problem representation

The structure of an information seeking dialogue system consists of an information acquisition phase, and an information presentation phase. For information acquisition the task of the dialogue manager is to gather ‘enough’ search constraints from the user, and then, ‘at the right time’, to start the information presentation phase, where the presentation task is to present ‘the right amount’ of information in the right way— either on the screen or listing the items verbally. What ‘the right amount’ actually means depends on the application, the dialogue context, and the preferences of users. For optimising dialogue strategies information acquisition and presentation are two closely interrelated problems and need to be optimised simultaneously: *when* to present information depends on the available options for *how* to present them, and vice versa. We therefore formulate the problem as a Markov Decision Process (MDP), relating states to actions in a hierarchical manner (see Figure 1): 4 actions are available for

the information acquisition phase; once the action `presentInfo` is chosen, the information presentation phase is entered, where 2 different actions for output realisation are available. The state-space comprises 8 binary features representing the task for a 4 slot problem: `filledSlot` indicates whether a slot is filled, `confirmedSlot` indicates whether a slot is confirmed. We also add features that human wizards pay attention to, using the feature selection techniques of (Rieser and Lemon, 2006b). Our results indicate that wizards only pay attention to the number of retrieved items (DB). We therefore add the feature DB to the state space, which takes integer values between 1 and 438, resulting in  $2^8 \times 438 = 112,128$  distinct dialogue states. In total there are  $4^{112,128}$  theoretically possible policies for information acquisition.<sup>1</sup> For the presentation phase the DB feature is discretised, as we will further discuss in Section 3.6. For the information presentation phase there are  $2^{2^3} = 256$  theoretically possible policies.

#### 3.2 Supervised Baseline

We create a baseline by applying Supervised Learning (SL). This baseline mimics the average wizard behaviour and allows us to measure the relative improvements over the training data (cf. (Henderson et al., 2005)). For these experiments we use the WEKA toolkit (Witten and Frank, 2005). We learn with the decision tree J4.8 classifier, WEKA’s implementation of the C4.5 system (Quinlan, 1993), and rule induc-

<sup>1</sup>In practise, the policy space is smaller, as some of combinations are not possible, e.g. a slot cannot be confirmed before being filled. Furthermore, some incoherent action choices are excluded by the basic system logic.

	baseline	JRip	J48
timing	52.0( $\pm$ 2.2)	50.2( $\pm$ 9.7)	53.5( $\pm$ 11.7)
modality	51.0( $\pm$ 7.0)	93.5( $\pm$ 11.5)*	94.6( $\pm$ 10.0)*

Table 1: Predicted accuracy for presentation timing and modality (with standard deviation  $\pm$ ), \* denotes statistically significant improvement at  $p < .05$

tion JRIP, the WEKA implementation of RIPPER (Cohen, 1995). In particular, we learn models which predict the following wizard actions:

- Presentation timing: *when* the ‘average’ wizard starts the presentation phase
- Presentation modality: in *which modality* the list is presented.

As input features we use annotated dialogue context features, see (Rieser and Lemon, 2006b). Both models are trained using 10-fold cross validation. Table 1 presents the results for comparing the accuracy of the learned classifiers against the majority baseline. For presentation timing, none of the classifiers produces significantly improved results. Hence, we conclude that there is no distinctive pattern the wizards follow for *when* to present information. For strategy implementation we therefore use a frequency-based approach following the distribution in the WOZ data: in 0.48 of cases the baseline policy decides to present the retrieved items; for the rest of the time the system follows a hand-coded strategy. For learning presentation modality, both classifiers significantly outperform the baseline. The learned models can be rewritten as in Algorithm 1. Note that this rather simple algorithm is meant to represent the average strategy as present in the initial data (which then allows us to measure the relative improvements of the RL-based strategy).

### 3.3 Noise simulation

One of the fundamental characteristics of HCI is an error prone communication channel. Therefore, the simulation of channel noise is an important aspect of the learning environment. Previous work uses data-intensive simulations of ASR errors, e.g. (Pietquin and Dutoit, 2006). We use a simple model simulating the effects of non- and misunderstanding on the interaction, rather than the noise itself. This method is especially suited to learning from small data sets. From our data we estimate a 30% chance of user utterances to be misunderstood, and 4% to be complete non-understandings. We simulate the effects noise has on the user behaviour, as well as for the task accuracy. For the user side, the noise model defines the likelihood of the user accepting or rejecting the system’s hypothesis (for example when the system utters a confirmation), i.e. in 30% of the cases the user rejects, in 70% the user agrees. These probabilities are combined with the probabilities for user actions from the user simulation, as described in the next section. For non-understandings we have the user simulation generating Out-of-Vocabulary utterances with a chance of 4%. Furthermore, the noise model determines the likelihood of task accuracy as calculated in the reward function for learning. A filled slot which is not confirmed by the user has a 30% chance of having been mis-recognised.

### 3.4 User simulation

A user simulation is a predictive model of real user behaviour used for automatic dialogue strategy development and testing. For our domain, the user can either add information (`add`), repeat or paraphrase information which was already provided at an earlier stage (`repeat`), give a simple yes-no answer (`y/n`), or change to a different topic by providing a different slot value than the one asked for (`change`). These actions are annotated manually ( $\kappa = .7$ ). We build two different types of user simulations, one is used for strategy training, and one for testing. Both are simple bi-gram models which predict the next user action based on the previous system action ( $P(a_{user}|a_{system})$ ). We face the problem of learning such models when training data is sparse. For training, we therefore use a cluster-based user simulation method, see (Rieser

and Lemon, 2006a). For testing, we apply smoothing to the bi-gram model. The simulations are evaluated using the SUPER metric proposed earlier (Rieser and Lemon, 2006a), which measures variance and consistency of the simulated behaviour with respect to the observed behaviour in the original data set. This technique is used because for training we need more variance to facilitate the exploration of large state-action spaces, whereas for testing we need simulations which are more realistic. Both user simulations significantly outperform random and majority class baselines. See (Rieser, 2008) for further details.

### 3.5 Reward modelling

The reward function defines the goal of the overall dialogue. For example, if it is most important for the dialogue to be efficient, the reward penalises dialogue length, while rewarding task success. In most previous work the reward function is manually set, which makes it “the most hand-crafted aspect” of RL (Paek, 2006). In contrast, we learn the reward model from data, using a modified version of the PARADISE framework (Walker et al., 2000), following pioneering work by (Walker et al., 1998). In PARADISE multiple linear regression is used to build a predictive model of subjective user ratings (from questionnaires) from objective dialogue performance measures (such as dialogue length). We use PARADISE to predict Task Ease (a variable obtained by taking the average of two questions in the questionnaire)<sup>2</sup> from various input variables, via stepwise regression. The chosen model comprises dialogue length in turns, task completion (as manually annotated in the WOZ data), and the multimodal user score from the user questionnaire, as shown in Equation 2.

$$TaskEase = -20.2 * dialogueLength + 11.8 * taskCompletion + 8.7 * multimodalScore; \quad (2)$$

This equation is used to calculate the overall reward for the information acquisition phase. During learning, Task Completion is calculated online according to the noise model, penalising all slots which are filled but not confirmed.

<sup>2</sup>“The task was easy to solve.”, “I had *no* problems finding the information I wanted.”

For the information presentation phase, we compute a local reward. We relate the multimodal score (a variable obtained by taking the average of 4 questions)<sup>3</sup> to the number of items presented (DB) for each modality, using curve fitting. In contrast to linear regression, curve fitting does not assume a linear inductive bias, but it selects the most likely model (given the data points) by function interpolation. The resulting models are shown in Figure 3.5. The reward for multimodal presentation is a quadratic function that assigns a maximal score to a strategy displaying 14.8 items (curve inflection point). The reward for verbal presentation is a linear function assigning negative scores to all presented items  $\leq 4$ . The reward functions for information presentation intersect at no. items=3. A comprehensive evaluation of this reward function can be found in (Rieser and Lemon, 2008a).

Figure 2: Evaluation functions relating number of items presented in different modalities to multimodal score

### 3.6 State space discretisation

We use linear function approximation in order to learn with large state-action spaces. Linear function approximation learns linear estimates for expected reward values of actions in states represented as feature vectors. This is inconsistent with the idea

<sup>3</sup>“I liked the combination of information being displayed on the screen and presented verbally.”, “Switching between modes did *not* distract me.”, “The displayed lists and tables contained on average the right amount of information.”, “The information presented verbally was easy to remember.”

of non-linear reward functions (as introduced in the previous section). We therefore quantise the state space for information presentation. We partition the database feature into 3 bins, taking the first intersection point between verbal and multimodal reward and the turning point of the multimodal function as discretisation boundaries. Previous work on learning with large databases commonly quantises the database feature in order to learn with large state spaces using manual heuristics, e.g. (Levin et al., 2000; Heeman, 2007). Our quantisation technique is more principled as it reflects user preferences for multi-modal output. Furthermore, in previous work database items were not only quantised in the state-space, but also in the reward function, resulting in a direct mapping between quantised retrieved items and discrete reward values, whereas our reward function still operates on the continuous values. In addition, the decision *when* to present a list (information acquisition phase) is still based on continuous DB values. In future work we plan to engineer new state features in order to learn with non-linear rewards while the state space is still continuous. A continuous representation of the state space allows learning of more fine-grained local trade-offs between the parameters, as demonstrated by (Rieser and Lemon, 2008b).

### 3.7 Testing the Learned Policies in Simulation

We now train and test the multimodal presentation strategies by interacting with the simulated learning environment. For the following RL experiments we used the REALL-DUDE toolkit of (Lemon et al., 2006b). The SHARSHA algorithm is employed for training, which adds hierarchical structure to the well known SARSA algorithm (Shapiro and Langley, 2002). The policy is trained with the cluster-based user simulation over 180k system cycles, which results in about 20k simulated dialogues. In total, the learned strategy has 371 distinct state-action pairs (see (Rieser, 2008) for details).

We test the RL-based and supervised baseline policies by running 500 test dialogues with a smoothed user simulation (so that we are not training and testing on the same simulation). We then compare quantitative dialogue measures performing a paired t-test. In particular, we compare mean values of the final rewards, number of filled and con-

firmed slots, dialog length, and items presented multimodally (`MM items`) and items presented verbally (`verbal items`). RL performs significantly better ( $p < .001$ ) than the baseline strategy. The only non-significant difference is the number of items presented verbally, where both RL and SL strategy settled on a threshold of less than 4 items. The mean performance measures for simulation-based testing are shown in Table 2 and Figure 3.

The major strength of the learned policy is that it learns to keep the dialogues reasonably short (on average 5.9 system turns for RL versus 8.4 turns for SL) by presenting lists as soon as the number of retrieved items is within tolerance range for the respective modality (as reflected in the reward function). The SL strategy in contrast has not learned the right timing nor an upper bound for displaying items on the screen. The results show that simulation-based RL with an environment bootstrapped from WOZ data allows learning of robust strategies which significantly outperform the strategies contained in the initial data set.

One major advantage of RL is that it allows us to provide additional information about user preferences in the reward function, whereas SL simply mimics the data. In addition, RL is based on delayed rewards, i.e. the optimisation of a final goal. For dialogue systems we often have measures indicating how successful and/or satisfying the overall performance of a strategy was, but it is hard to tell how things should have been exactly done in a specific situation. This is what makes RL specifically attractive for dialogue strategy learning. In the next section we test the learned strategy with real users.

## 4 User Tests

### 4.1 Experimental design

For the user tests the RL policy is ported to a working ISU-based dialogue system via table look-up, which indicates the action with the highest expected reward for each state (cf. (Singh et al., 2002)). The supervised baseline is implemented using standard threshold-based update rules. The experimental conditions are similar to the WOZ study, i.e. we ask the users to solve similar tasks, and use similar questionnaires. Furthermore, we decided to use typed user input rather than ASR. The use of text input

Measure	SL baseline		RL Strategy	
	SIM	REAL	SIM	REAL
av. turns	8.42( $\pm$ 3.04)	5.86( $\pm$ 3.2)	5.9( $\pm$ 2.4)***	5.07( $\pm$ 2.9)***
av. speech items	1.04( $\pm$ .2)	1.29( $\pm$ .4)	1.1( $\pm$ .3)	1.2( $\pm$ .4)
av. MM items	61.37( $\pm$ 82.5)	52.2( $\pm$ 68.5)	11.2( $\pm$ 2.4)***	8.73( $\pm$ 4.4)***
av. reward	-1741.3( $\pm$ 566.2)	-628.2( $\pm$ 178.6)	44.06( $\pm$ 51.5)***	37.62( $\pm$ 60.7)***

Table 2: Comparison of results obtained in simulation (SIM) and with real users (REAL) for SL and RL-based strategies; \*\*\* denotes significant difference between SL and RL at  $p < .001$

Figure 3: Graph comparison of objective measures: SLs = SL policy in simulation; SLr = SL policy with real users; RLs = RL policy in simulation; RLr = RL policy with real users.

allows us to target the experiments to the dialogue management decisions, and block ASR quality from interfering with the experimental results (Hajdinjak and Mihelic, 2006). 17 subjects (8 female, 9 male) are given a set of  $6 \times 2$  predefined tasks, which they solve by interaction with the RL-based and the SL-based system in controlled order. As a secondary task users are asked to count certain objects in a driving simulation. In total, 204 dialogues with 1,115 turns are gathered in this setup.

## 4.2 Results

In general, the users rate the RL-based significantly higher ( $p < .001$ ) than the SL-based policy. The results from a paired t-test on the user questionnaire

data show significantly improved Task Ease, better presentation timing, more agreeable verbal and multimodal presentation, and that more users would use the RL-based system in the future (Future Use). All the observed differences have a medium effects size ( $r \geq |.3|$ ).

We also observe that female participants clearly favour the RL-based strategy, whereas the ratings by male participants are more indifferent. Similar gender effects are also reported by other studies on multimodal output presentation, e.g. (Foster and Oberlander, 2006).

Furthermore, we compare objective dialogue performance measures. The dialogues of the RL strategy are significantly shorter ( $p < .005$ ), while fewer items are displayed ( $p < .001$ ), and the help function is used significantly less ( $p < .003$ ). The mean performance measures for testing with real users are shown in Table 2 and Figure 3. However, there is no significant difference for the performance of the secondary driving task.

## 5 Comparison of Results

We finally test whether the results obtained in simulation transfer to tests with real users, following (Lemon et al., 2006a). We evaluate the quality of the simulated learning environment by directly comparing the dialogue performance measures between simulated and real interaction. This comparison enables us to make claims regarding whether a policy which is ‘bootstrapped’ from WOZ data is transferable to real HCI. We first evaluate whether objective dialogue measures are transferable, using a paired t-test. For the RL policy there is no statistical difference in overall performance (reward), dialogue length (turns), and the number of presented items (verbal and multimodal items) between simulated

Measure	WOZ	SL	RL
av. Task Ease	.53±.14	.63±.26	.79±.21***
av. Future Use	.56±.16	.55±.21	.67±.20***

Table 3: Improved user ratings over the WOZ study where \*\*\* denotes  $p < .001$

and real interaction (see Table 2, Figure 3). This indicates that the learned strategy transfers well to real settings. For the SL policy the dialogue length for real users is significantly shorter than in simulation. From an error analysis we conclude that real users intelligently adapt to poor policies, e.g. by changing topic, whereas the simulated users do not react in this way.

Furthermore, we want to know whether the subjective user ratings for the RL strategy improved over the WOZ study. We therefore compare the user ratings from the WOZ questionnaire to the user ratings of the final user tests using a independent t-test and a Wilcoxon Signed Ranks Test. Users rate the RL-policy on average 10% higher. We are especially interested in the ratings for Task Ease (as this was the ultimate measure optimised with PARADISE) and Future Use, as we believe this measure to be an important indicator of acceptance of the technology. The results show that only the RL strategy leads to significantly improved user ratings (increasing average Task Ease by 49% and Future Use by 19%), whereas the ratings for the SL policy are not significantly better than those for the WOZ data, see Table 3.<sup>4</sup> This indicates that the observed difference is indeed due to the improved strategy (and not to other factors like the different user population or the embedded dialogue system).

## 6 Conclusion

We addressed two problems in the field of automatic optimization of dialogue strategies: learning effective dialogue strategies when no initial data or system exists, and evaluating the result with real users. We learned optimal strategies by interaction with a simulated environment which is bootstrapped from

<sup>4</sup>The ratings are normalised as some of the questions were on different scales.

a small amount of Wizard-of-Oz data, and we evaluated the result with real users. The use of WOZ data allows us to develop optimal strategies for domains where no working prototype is available. The developed simulations are entirely data driven and the reward function reflects real user preferences. We compare the Reinforcement Learning-based strategy against a supervised strategy which mimics the (human) wizards’ policies from the original data. This comparison allows us to measure relative improvement over the training data. Our results show that RL significantly outperforms SL in simulation as well as in interactions with real users. The RL-based policy gains on average 50-times more reward when tested in simulation, and almost 18-times more reward when interacting with real users. The human users also subjectively rate the RL-based policy on average 10% higher, and 49% higher for Task Ease. We also show that results obtained in simulation are comparable to results for real users. We conclude that a strategy trained from WOZ data via bootstrapping is transferable to real Human-Computer-Interaction.

In future work will apply similar techniques to statistical planning for Natural Language Generation in spoken dialogue (Lemon, 2008; Janarthanam and Lemon, 2008), (see the EC FP7 CLASSIC project: [www.classic-project.org](http://www.classic-project.org)).

## Abstract

Entropy Guided Transformation Learning (ETL) is a new machine learning strategy that combines the advantages of decision trees (DT) and Transformation Based Learning (TBL). In this work, we apply the ETL framework to four phrase chunking tasks: Portuguese noun phrase chunking, English base noun phrase chunking, English text chunking and Hindi text chunking. In all four tasks, ETL shows better results than Decision Trees and also than TBL with hand-crafted templates. ETL provides a new training strategy that accelerates transformation learning. For the English text chunking task this corresponds to a factor of five speedup. For Portuguese noun phrase chunking, ETL shows the best reported results for the task. For the other three linguistic tasks, ETL shows state-of-the-art competitive results and maintains the advantages of using a rule based system.

## 1 Introduction

Phrase Chunking is a Natural Language Processing (NLP) task that consists in dividing a text into syntactically correlated parts of words. These phrases are non-overlapping, i.e., a word can only be a member of one chunk (Sang and Buchholz, 2000). It provides a key feature that helps on more elaborated NLP tasks such as parsing and information extraction.

Since the last decade, many high-performance chunking systems were proposed, such as, SVM-based (Kudo and Matsumoto, 2001; Wu et al.,

2006), Winnow (Zhang et al., 2002), voted-perceptrons (Carreras and Màrquez, 2003), Transformation-Based Learning (TBL) (Ramshaw and Marcus, 1999; Megyesi, 2002) and Hidden Markov Model (HMM) (Molina and Pla, 2002), Memory-based (Sang, 2002). State-of-the-art systems for English base noun phrase chunking and text chunking are based in statistical techniques (Kudo and Matsumoto, 2001; Wu et al., 2006; Zhang et al., 2002).

TBL is one of the most accurate rule-based techniques for phrase chunking tasks (Ramshaw and Marcus, 1999; Ngai and Florian, 2001; Megyesi, 2002). On the other hand, TBL rules must follow patterns, called templates, that are meant to capture the relevant feature combinations. The process of generating good templates is highly expensive. It strongly depends on the problem expert skills to build them. Even when a template set is available for a given task, it may not be effective when we change from a language to another (dos Santos and Oliveira, 2005).

In this work, we apply Entropy Guided Transformation Learning (ETL) for phrase chunking. ETL is a new machine learning strategy that combines the advantages of Decision Trees (DT) and TBL (dos Santos and Milidiú, 2007a). The ETL key idea is to use decision tree induction to obtain feature combinations (templates) and then use the TBL algorithm to generate transformation rules. ETL produces transformation rules that are more effective than decision trees and also eliminates the need of a problem domain expert to build TBL templates.

We evaluate the performance of ETL over four

phrase chunking tasks: (1) English Base Noun Phrase (NP) chunking; (2) Portuguese NP chunking; (3) English Text Chunking; and (4) Hindi Text Chunking. Base NP chunking consists in recognizing non-overlapping text segments that contain NPs. Text chunking consists in dividing a text into syntactically correlated parts of words. For these four tasks, ETL shows state-of-the-art competitive results and maintains the advantages of using a rule based system.

The remainder of the paper is organized as follows. In section 2, the ETL strategy is described. In section 3, the experimental design and the corresponding results are reported. Finally, in section 4, we present our concluding remarks.

## 2 Entropy Guided Transformation Learning

Entropy Guided Transformation Learning (ETL) is a new machine learning strategy that combines the advantages of Decision Trees (DT) and Transformation-Based Learning (TBL) (dos Santos and Milidiú, 2007a). The key idea of ETL is to use decision tree induction to obtain templates. Next, the TBL strategy is used to generate transformation rules. The proposed method is illustrated in the Fig. 1.

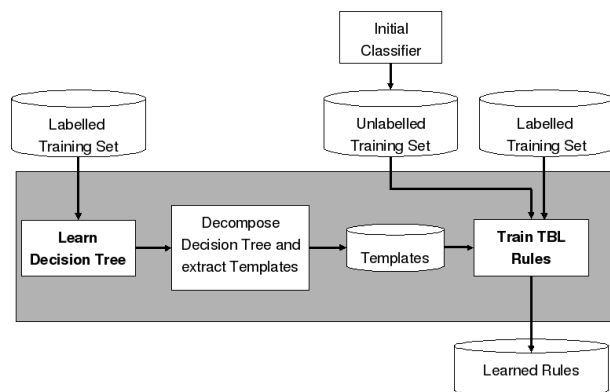

Figure 1: ETL - Entropy Guided Transformation Learning.

A combination of DT and TBL is presented in (Corston-Oliver and Gamon, 2003). The main difference between Corston-Oliver & Gamon work and the ETL strategy is that they extract candidate rules directly from the DT, and then use the TBL strategy

to select the appropriate rules. Another difference is that they use a binary DT, whereas ETL uses a DT that is not necessarily binary.

An evolutionary approach based on Genetic Algorithms (GA) to automatically generate TBL templates is presented in (Milidiú et al., 2007). Using a simple genetic coding, the generated template sets have efficacy near to the handcrafted templates for the tasks: English Base Noun Phrase Identification, Text Chunking and Portuguese Named Entities Recognition. The main drawback of this strategy is that the GA step is computationally expensive. If we need to consider a large context window or a large number of features, it can be infeasible.

The remainder of this section is organized as follows. In section 2.1, we describe the DT learning algorithm. In section 2.2, the TBL algorithm is depicted. In section 2.3, we depict the process of obtaining templates from a decision tree decomposition. Finally, in section 2.4, we present a *template evolution scheme* that speeds up the TBL step.

### 2.1 Decision Trees

Decision tree learning is one of the most widely used machine learning algorithms. It performs a partitioning of the training set using principles of Information Theory. The learning algorithm executes a general to specific search of a feature space. The most informative feature is added to a tree structure at each step of the search. Information Gain Ratio, which is based on the data Entropy, is normally used as the informativeness measure. The objective is to construct a tree, using a minimal set of features, that efficiently partitions the training set into classes of observations. After the tree is grown, a pruning step is carried out in order to avoid overfitting.

One of the most used algorithms for induction of a DT is the C4.5 (Quinlan, 1993). We use Quinlan's C4.5 system throughout this work.

### 2.2 Transformation-Based Learning

Transformation Based error-driven Learning (TBL) is a successful machine learning algorithm introduced by Eric Brill (Brill, 1995). It has since been used for several Natural Language Processing tasks, such as part-of-speech (POS) tagging (Brill, 1995), English text chunking (Ramshaw and Marcus, 1999; dos Santos and Milidiú, 2007b), spelling correc-

tion (Mangu and Brill, 1997), Portuguese appositive extraction (Freitas et al., 2006), Portuguese named entity extraction (Milidiú et al., 2006) and Portuguese noun-phrase chunking (dos Santos and Oliveira, 2005), achieving state-of-the-art performance in many of them.

TBL uses an error correcting strategy. Its main scheme is to generate an ordered list of rules that correct classification mistakes in the training set, which have been produced by an initial classifier.

The requirements of the algorithm are:

- two instances of the training set, one that has been correctly labeled, and another that remains unlabeled;
- an initial classifier, the *baseline system*, which classifies the unlabeled training set by trying to apply the correct class for each sample. In general, the baseline system is based on simple statistics of the labeled training set; and
- a set of rule templates, which are meant to capture the relevant feature combinations that would determine the sample's classification. Concrete rules are acquired by instantiation of this predefined set of rule templates.
- a threshold value, that is used as a stopping criteria for the algorithm and is needed to avoid overfitting to the training data.

The learning method is a mistake-driven greedy procedure that iteratively acquires a set of transformation rules. The TBL algorithm can be depicted as follows:

1. Starts applying the baseline system, in order to guess an initial classification for the unlabeled version of the training set;
2. Compares the resulting classification with the correct one and, whenever a classification error is found, all the rules that can correct it are generated by instantiating the templates. This template instantiation is done by capturing some contextual data of the sample being corrected. Usually, a new rule will correct some errors, but will also generate some other errors by changing correctly classified samples;

3. Computes the rules' scores (errors repaired - errors created). If there is not a rule with a score above an arbitrary threshold, the learning process is stopped;
4. Selects the best scoring rule, stores it in the set of learned rules and applies it to the training set;
5. Returns to step 2.

When classifying a new sample item, the resulting sequence of rules is applied according to its generation order.

### 2.3 DT Template Extraction

There are many ways to extract feature combinations from decision trees. In an path from the root to the leaves, more informative features appear first. Since we want to generate the most promising templates only, we just combine the more informative ones.

The process we use to extract templates from a DT includes a depth-first traversal of the DT. For each visited node, we create a new template that combines its parent node template with the feature used to split the data at that node. This is a very simple decomposition scheme. Nevertheless, it results into extremely effective templates. We also use pruned trees in all experiments shown in section 3.

Fig. 2 shows an excerpt of a DT generated for the English text chunking task<sup>1</sup>. Using the described method to extract templates from the DT shown in Fig. 2, we obtain the template set listed in the left side of Table 1. In order to generate more feature combinations, without largely increasing the number of templates, we extend the template set by including templates that do not have the root node feature. The extended template set for the DT shown in Fig. 2 is listed in the right side of the Table 1.

We have also tried some other strategies that extract a larger number of templates from a DT. However, the efficacy of the learned rules is quite similar to the one generated by the first method. This reinforces the conjecture that a DT generates informative feature combinations.

<sup>1</sup>CK[0] = Chunk tag of the current word (initial classifier result); CK[-1] = previous word Chunk tag; CK[1] = next word Chunk tag; POS[0] = current word POS tag; WRD[0] = current word.

Table 1: Text chunking DT Template set example

Template set	Extended template set	
CK[0]	CK[0]	
CK[0] CK[1]	CK[0] CK[1]	CK[1]
CK[0] CK[1] WRD[0]	CK[0] CK[1] WRD[0]	CK[1] WRD[0]
CK[0] CK[1] WRD[0] CK[-1]	CK[0] CK[1] WRD[0] CK[-1]	CK[1] WRD[0] CK[-1]
CK[0] CK[1] POS[0]	CK[0] CK[1] POS[0]	CK[1] POS[0]
CK[0] CK[-1]	CK[0] CK[-1]	CK[-1]

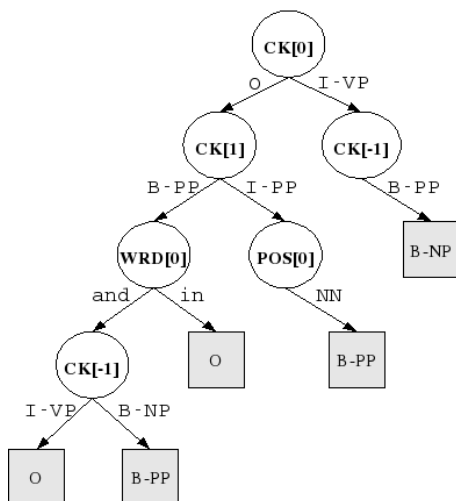

Figure 2: Text chunking decision tree excerpt.

## 2.4 Template Evolution Speedup

TBL training time is highly sensitive to the number and complexity of the applied templates. In (Curran and Wong, 2000), it is argued that we can better tune the *training time vs. templates complexity* trade-off by using an evolutionary template approach. The main idea is to apply only a small number of templates that evolve throughout the training. When training starts, templates are short, consisting of few feature combinations. As training proceeds, templates evolve to more complex ones that contain more feature combinations. In this way, only a few templates are considered at any point in time. Nevertheless, the descriptive power is not significantly reduced.

The template evolution approach can be easily implemented by using template sets extracted from a DT. We implement this idea by successively training TBL models. Each model uses only the templates

that contain feature combinations up to a given tree level. For instance, using the tree shown in Fig. 2, we have the following template sets for the three first training rounds<sup>2</sup>:

1. CK[0] CK[1];  
CK[0] CK[-1]
2. CK[0] CK[1] WRD[0];  
CK[0] CK[1] POS[0]
3. CK[0] CK[1] WRD[0] CK[-1]

Using the template evolution strategy, the training time is decreased by a factor of five for the English text chunking task. This is a remarkable reduction, since we use an implementation of the *fastTBL* algorithm (Ngai and Florian, 2001) that is already a very fast TBL version. The efficacy of the rules generated by the sequential training is quite similar to the one obtained by training with all the templates at the same time.

## 3 Experiments

This section presents the experimental setup and results of the application of ETL to four phrase chunking tasks. ETL results are compared with the results of DT and TBL using hand-crafted templates.

In the TBL step, for each one of the four chunking tasks, the initial classifier assigns to each word the chunk tag that was most frequently associated with the part-of-speech of that word in the training set.

The DT learning works as a feature selector and is not affected by irrelevant features. We have tried several context window sizes when training the classifiers. Some of the tested window sizes would be very hard to be explored by a domain expert using

<sup>2</sup>We ignore templates composed of only one feature test.

TBL alone. The corresponding huge number of possible templates would be very difficult to be managed by a template designer.

For the four tasks, the following experimental setup provided us our best results.

ETL in the ETL learning, we use the features *word*, *POS* and *chunk*. In order to overcome the sparsity problem, we only use the 200 most frequent words to induce the DT. In the DT learning, the chunk tag of the word is the one applied by the initial classifier. On the other hand, the chunk tag of neighbor words are the true ones. We report results for ETL trained with all the templates at the same time as well as using template evolution.

TBL the results for the TBL approach refers to TBL trained with the set of templates proposed in (Ramshaw and Marcus, 1999).

DT the best result for the DT classifier is shown. The features *word*, *POS* and *chunk* are used to generate the DT classifier. The chunk tag of a word and its neighbors are the ones guessed by the initial classifier. Using only the 100 most frequent words gives our best results.

In all experiments, the term  $WS=X$  subscript means that a window of size  $X$  was used for the given model. For instance,  $ETL_{WS=3}$  corresponds to ETL trained with window of size three, that is, the current token, the previous and the next one.

### 3.1 Portuguese noun phrase chunking

For this task, we use the SNR-CLIC corpus described in (Freitas et al., 2005). This corpus is tagged with both POS and NP tags. The NP tags are: I, for in NP; O, for out of NP; and B for the leftmost word of an NP beginning immediately after another NP. We divided the corpus into 3514-sentence (83346 tokens) training set and a 878-sentence (20798 tokens) test set.

In Table 2 we compare the results<sup>3</sup> of ETL with DT and TBL. We can see that ETL, even with a small window size, produces better results than DT and TBL. The  $F_{\beta=1}$  of the  $ETL_{WS=7}$  classifier is 1.8% higher than the one of TBL and 2.6% higher than the one of the DT classifier.

<sup>3</sup>#T = Number of templates.

Table 2: Portuguese noun phrase chunking.

	Acc. (%)	Prec. (%)	Rec. (%)	$F_{\beta=1}$ (%)	# T
BLS	96.57	62.69	74.45	68.06	–
$DT_{WS=13}$	97.35	83.96	87.27	85.58	–
TBL	97.45	85.48	87.32	86.39	100
$ETL_{WS=3}$	97.61	86.12	87.24	86.67	21
$ETL_{WS=5}$	97.68	86.85	87.49	87.17	35
$ETL_{WS=7}$	<b>97.82</b>	<b>88.15</b>	88.20	<b>88.18</b>	34
$ETL_{WS=9}$	<b>97.82</b>	88.02	<b>88.34</b>	<b>88.18</b>	40

Table 3 shows the results<sup>4</sup> of ETL using template evolution. As we can see, for the task of Portuguese noun phrase chunking, the template evolution strategy reduces the average training time in approximately 35%. On the other hand, there is a decrease of the classifier efficacy in some cases.

Table 3: Portuguese noun phrase chunking using ETL with template evolution.

	Acc. (%)	Prec. (%)	Rec. (%)	$F_{\beta=1}$ (%)	TTR (%)
$ETL_{WS=3}$	97.61	86.22	87.27	86.74	20.7
$ETL_{WS=5}$	97.56	86.39	87.10	86.74	38.2
$ETL_{WS=7}$	97.69	87.35	87.89	87.62	37.0
$ETL_{WS=9}$	<b>97.76</b>	<b>87.55</b>	<b>88.14</b>	<b>87.85</b>	41.9

In (dos Santos and Oliveira, 2005), a special set of six templates is shown. These templates are designed to reduce classification errors of preposition within the task of Portuguese noun phrase chunking. These templates use very specific domain knowledge and are difficult to DT and TBL to extract. Table 4 shows the results of an experiment where we include these six templates into the Ramshaw&Marcus template set and also into the template sets generated by ETL. Again, ETL produces better results than TBL.

Table 5 shows the results of using a committee composed by the three best ETL classifiers. The classification is done by selecting the most popular tag among all the three committee members. The achieved  $F_{\beta=1}$ , 89.14% is the best one ever reported for the SNR-CLIC corpus.

<sup>4</sup>TTR = Training time reduction.

Table 4: Portuguese noun phrase chunking using six additional hand-crafted templates.

	Acc. (%)	Prec. (%)	Rec. (%)	$F_{\beta=1}$ (%)	# T
BLS	96.57	62.69	74.45	68.06	–

### 3.2 English base noun phrase chunking

The data used in the base NP chunking experiments is the one by Ramshaw & Marcus (Ramshaw and Marcus, 1999). This corpus contains sections 15-18 and section 20 of the Penn Treebank, and is predivided into 8936-sentence (211727 tokens) training set and a 2012-sentence (47377 tokens) test. This corpus is tagged with both POS and chunk tags.

Table 6 compares the results of ETL with DT and TBL for the base NP chunking. We can see that ETL, even using a small window size, produces better results than DT and TBL. The  $F_{\beta=1}$  of the ETL<sub>WS=9</sub> classifier is 0.87% higher than the one of TBL and 2.31% higher than the one of the DT classifier.

Table 7 shows the results of ETL using template evolution. The template evolution strategy reduces the average training time in approximately 62%. Differently from the Portuguese NP chunking, we observe an increase of the classifier efficacy in almost all the cases.

Table 8 shows the results of using a committee composed by the eight ETL classifiers reported in this section. Table 8 also shows the results for a committee of SVM models presented in (Kudo and Matsumoto, 2001). SVM’s results are the state-of-

Table 6: Base NP chunking.

### 3.3 English text chunking

The data used in the English text chunking experiments is the CoNLL-2000 corpus, which is described in (Sang and Buchholz, 2000). It is composed by the same texts as the Ramshaw & Marcus (Ramshaw and Marcus, 1999) corpus.

Table 9 compares the results of ETL with DTs and TBL for English text chunking. ETL, even using a small window size, produces better results than DTs and TBL. The  $F_{\beta=1}$  of the ETL<sub>WS=3</sub> classifier is 0.28% higher than the one of TBL and 2.17% higher than the one of the DT classifier. It is an interesting linguistic finding that the use of a window of size 3

(the current token, the previous token and the next token) provides the current best results for this task.

Table 9: English text Chunking.

	Acc. (%)	Prec. (%)	Rec. (%)	$F_{\beta=1}$ (%)	# T
BLS	77.29	72.58	82.14	77.07	–
DT <sub>WS=9</sub>	94.29	89.55	91.00	90.27	–
TBL	95.12	92.05	92.28	92.16	100
ETL <sub>WS=3</sub>	<b>95.24</b>	<b>92.32</b>	<b>92.56</b>	<b>92.44</b>	105
ETL <sub>WS=5</sub>	95.12	92.19	92.27	92.23	167
ETL <sub>WS=7</sub>	95.13	92.24	92.32	92.28	183
ETL <sub>WS=9</sub>	95.07	92.10	92.27	92.19	205

Table 10 shows the results of ETL using template evolution. The template evolution strategy reduces the average training time by approximately 81%. On the other hand, there is a small decrease of the classifier efficacy in all cases.

Table 10: English text chunking using ETL with template evolution.

	Acc. (%)	Prec. (%)	Rec. (%)	$F_{\beta=1}$ (%)	TTR (%)
ETL <sub>WS=3</sub>	<b>95.21</b>	<b>92.14</b>	<b>92.53</b>	<b>92.34</b>	77.2
ETL <sub>WS=5</sub>	94.98	91.84	92.25	92.04	80.8
ETL <sub>WS=7</sub>	95.03	91.89	92.28	92.09	83.0
ETL <sub>WS=9</sub>	95.01	91.87	92.21	92.04	84.5

Table 11 shows the results of using a committee composed by the eight ETL classifiers reported in this section. Table 11 also shows the results for a SVM model presented in (Wu et al., 2006). SVM’s results are the state-of-the-art for the Text chunking task. On the other hand, using a committee of ETL classifiers, we produce very competitive results and maintain the advantages of using a rule based system.

Table 11: English text Chunking using a committee of eight ETL classifiers.

### 3.4 Hindi text chunking

The data used in the Hindi text chunking experiments is the SPSAL-2007 corpus, which is described in (Bharati and Mannem, 2007). This corpus is pre-divided into a 20000-tokens training set, a 5000-tokens development set and a 5000-tokens test set. This corpus is tagged with both POS and chunk tags.

To fairly compare our approach with the ones presented in the SPSAL-2007, the POS tags of the test corpus were replaced by the ones predicted by an ETL-based Hindi POS Tagger. The description of our ETL pos tagger is beyond the scope of this work. Since the amount of training data is very small (20000 tokens), the accuracy of the ETL Hindi POS tagger is low, 77.50% for the test set.

The results are reported in terms of chunking accuracy, the same performance measure used in the SPSAL-2007. Table 13 compares the results of ETL with DT and TBL for Hindi text chunking. ETL produces better results than DT and achieves the same performance of TBL using 60% less templates. We believe that ETL performance is not as good as in the other tasks mainly because of the small amount of training data, which increases the sparsity problem.

We do not use template evolution for Hindi text

chunking. Since the training corpus is very small, the training time reduction is not significant.

Table 13: Hindi text Chunking.

	Accuracy (%)	# Templates
BLS	70.05	–
DT <sub>WS=5</sub>	78.20	–
TBL	<b>78.53</b>	100
ETL <sub>WS=5</sub>	<b>78.53</b>	30

Table 14 compares the results of ETL with the two best Hindi text chunkers at SPSAL-2007 (Bharati and Mannem, 2007). The first one is a combination of Hidden Markov Models (HMM) and Conditional Random Fields (CRF) (PVS and Gali, 2007). The second is based in Maximum Entropy Models (MaxEnt) (Dandapat, 2007). ETL performs better than MaxEnt and worst than HMM+CRF. It is important to note that the accuracy of the POS tagger used by (PVS and Gali, 2007) (78.66%) is better than ours (77.50%). The POS tagging quality directly affects the chunking accuracy.

Table 14: Comparison with best systems of SPSAL-2007

	Accuracy (%)
HMM + CRF	<b>80.97</b>
ETL <sub>WS=5</sub>	78.53
MaxEnt	74.92

## 4 Conclusions

In this paper, we approach the phrase chunking task using Entropy Guided Transformation Learning (ETL). We carry out experiments with four phrase chunking tasks: Portuguese noun phrase chunking, English base noun phrase chunking, English text chunking and Hindi text chunking. In all four tasks, ETL shows better results than Decision Trees and also than TBL with hand-crafted templates. ETL provides a new training strategy that accelerates transformation learning. For the English text chunking task this corresponds to a factor of five speedup. For Portuguese noun phrase chunking, ETL shows the best reported results for the task. For the other

three linguistic tasks, ETL shows competitive results and maintains the advantages of using a rule based system.

## Abstract

Traditional wisdom holds that once documents are turned into bag-of-words (unigram count) vectors, word orders are completely lost. We introduce an approach that, perhaps surprisingly, is able to learn a bigram language model from a set of bag-of-words documents. At its heart, our approach is an EM algorithm that seeks a model which maximizes the regularized marginal likelihood of the bag-of-words documents. In experiments on seven corpora, we observed that our learned bigram language models: i) achieve better test set perplexity than unigram models trained on the same bag-of-words documents, and are not far behind “oracle bigram models” trained on the corresponding ordered documents; ii) assign higher probabilities to sensible bigram word pairs; iii) improve the accuracy of ordered-document recovery from a bag-of-words. Our approach opens the door to novel phenomena, for example, privacy leakage from index files.

## 1 Introduction

A bag-of-words (BOW) is a basic document representation in natural language processing. In this paper, we consider a BOW in its simplest form, i.e., a *unigram count vector* or word histogram over the vocabulary. When performing the counting, word order is ignored. For example, the phrases “really neat” and “neat really” contribute equally to a BOW. Obviously, once a set of documents is turned into a set of BOWs, the word order information within them is completely lost—or is it?

In this paper, we show that one can in fact partly recover the order information. Specifically, *given a set of documents in unigram-count BOW representation, one can recover a non-trivial bigram language model (LM)*<sup>1</sup>, which has part of the power of a bigram LM trained on ordered documents. At first glance this seems impossible: How can one learn bigram information from unigram counts? However, we will demonstrate that *multiple* BOW documents enable us to recover some higher-order information.

Our results have implications in a wide range of natural language problems, in particular document privacy. With the wide adoption of natural language applications like desktop search engines, software programs are increasingly indexing computer users’ personal files for fast processing. Most index files include some variant of the BOW. As we demonstrate in this paper, if a malicious party gains access to BOW index files, it can recover more than just unigram frequencies: (i) the malicious party can recover a higher-order LM; (ii) with the LM it may attempt to recover the original ordered document from a BOW by finding the most-likely word permutation<sup>2</sup>. Future research will quantify the extent to which such a privacy breach is possible in theory, and will find solutions to prevent it.

There is a vast literature on language modeling; see, e.g., (Rosenfeld, 2000; Chen and Goodman, 1999; Brants et al., 2007; Roark et al., 2007). How-

<sup>1</sup>A trivial bigram LM is a unigram LM which ignores history:  $P(v|u) = P(v)$ .

<sup>2</sup>It is possible to use a generic higher-order LM, e.g., a trigram LM trained on standard English corpora, for this purpose. However, incorporating a user-specific LM helps.

ever, to the best of our knowledge, none addresses this reverse direction of learning higher-order LMs from lower-order data. This work is inspired by recent advances in inferring network structure from co-occurrence data, for example, for computer networks and biological pathways (Rabbat et al., 2007).

## 2 Problem Formulation and Identifiability

We assume that a vocabulary of size  $W$  is given. For notational convenience, we include in the vocabulary a special “begin-of-document” symbol  $\langle d \rangle$  which appears only at the beginning of each document. The training corpus consists of a collection of  $n$  BOW documents  $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ . Each BOW  $\mathbf{x}_i$  is a vector  $(x_{i1}, \dots, x_{iW})$  where  $x_{iu}$  is the number of times word  $u$  occurs in document  $i$ . Our goal is to learn a bigram LM  $\theta$ , represented as a  $W \times W$  transition matrix with  $\theta_{uv} = P(v|u)$ , from the BOW corpus. Note  $P(v|\langle d \rangle)$  corresponds to the initial state probability for word  $v$ , and  $P(\langle d \rangle|u) = 0, \forall u$ .

It is worth noting that traditionally one needs *ordered documents* to learn a bigram LM. A natural question that arises in our problem is whether or not a bigram LM can be recovered from the BOW corpus with any guarantee. Let  $\mathcal{X}$  denote the space of all possible BOWs. As a toy example, consider  $W = 3$  with the vocabulary  $\{\langle d \rangle, A, B\}$ . Assuming all documents have equal length  $|\mathbf{x}| = 4$  (including  $\langle d \rangle$ ), then  $\mathcal{X} = \{(\langle d \rangle:1, A:3, B:0), (\langle d \rangle:1, A:2, B:1), (\langle d \rangle:1, A:1, B:2), (\langle d \rangle:1, A:0, B:3)\}$ . Our training BOW corpus, when sufficiently large, provides the marginal distribution  $\hat{p}(\mathbf{x})$  for  $\mathbf{x} \in \mathcal{X}$ . Can we recover a bigram LM from  $\hat{p}(\mathbf{x})$ ?

To answer this question, we first need to introduce a generative model for the BOWs. We assume that the BOW corpus is generated from a bigram LM  $\theta$  in two steps: (i) An *ordered* document is generated from the bigram LM  $\theta$ ; (ii) The document’s unigram counts are collected to produce the BOW  $\mathbf{x}$ . Therefore, the probability of a BOW  $\mathbf{x}$  being generated by  $\theta$  can be computed by marginalizing over *unique orderings*  $\mathbf{z}$  of  $\mathbf{x}$ :

$$P(\mathbf{x}|\theta) = \sum_{\mathbf{z} \in \sigma(\mathbf{x})} P(\mathbf{z}|\theta) = \sum_{\mathbf{z} \in \sigma(\mathbf{x})} \prod_{j=2}^{|\mathbf{x}|} \theta_{z_{j-1}, z_j},$$

where  $\sigma(\mathbf{x})$  is the set of unique orderings, and  $|\mathbf{x}|$  is the document length. For example, if  $\mathbf{x} = (\langle d \rangle:1,$

A:2, B:1) then  $\sigma(\mathbf{x}) = \{\mathbf{z}_1, \mathbf{z}_2, \mathbf{z}_3\}$  with  $\mathbf{z}_1 = \langle d \rangle A A B$ ,  $\mathbf{z}_2 = \langle d \rangle A B A$ ,  $\mathbf{z}_3 = \langle d \rangle B A A$ . Bigram LM recovery then amounts to finding a  $\theta$  that satisfies the system of marginal-matching equations

$$P(\mathbf{x}|\theta) = \hat{p}(\mathbf{x}), \quad \forall \mathbf{x} \in \mathcal{X}. \quad (1)$$

As a concrete example where *one can exactly recover a bigram LM from BOWs*, consider our toy example again. We know there are only three free variables in our  $3 \times 3$  bigram LM  $\theta$ :  $r = \theta_{\langle d \rangle A}$ ,  $p = \theta_{AA}$ ,  $q = \theta_{BB}$ , since the rest are determined by normalization. Suppose the documents are generated from a bigram LM with true parameters  $r = 0.25, p = 0.9, q = 0.5$ . If our BOW corpus is very large, we will observe that 20.25% of the BOWs are  $(\langle d \rangle:1, A:3, B:0)$ , 37.25% are  $(\langle d \rangle:1, A:2, B:1)$ , and 18.75% are  $(\langle d \rangle:1, A:0, B:3)$ . These numbers are computed using the definition of  $P(\mathbf{x}|\theta)$ . We solve the reverse problem of finding  $r, p, q$  from the system of equations (1), now explicitly written as

$$\begin{cases} rp^2 = 0.2025 \\ rp(1-p) + r(1-p)(1-q) \\ \quad + (1-r)(1-q)p = 0.3725 \\ (1-r)q^2 = 0.1875. \end{cases}$$

The above system has only one valid solution, which is the correct set of bigram LM parameters  $(r, p, q) = (0.25, 0.9, 0.5)$ .

However, if the true parameters were  $(r, p, q) = (0.1, 0.2, 0.3)$  with proportions of BOWs being 0.4%, 19.8%, 8.1%, respectively, it is easy to verify that the system would have multiple valid solutions:  $(0.1, 0.2, 0.3)$ ,  $(0.8819, 0.0673, 0.8283)$ , and  $(0.1180, 0.1841, 0.3030)$ . In general, if  $\hat{p}(\mathbf{x})$  is known from the training BOW corpus, when can we *guarantee* to uniquely recover the bigram LM  $\theta$ ? This is the question of *identifiability*, which means the transition matrix  $\theta$  satisfying (1) exists and is unique. Identifiability is related to finding unique solutions of a system of polynomial equations since (1) is such a system in the elements of  $\theta$ . The details are beyond the scope of this paper, but applying the technique in (Basu and Boston, 2000), it is possible to show that for  $W = 3$  (including  $\langle d \rangle$ ) we need longer documents ( $|\mathbf{x}| \geq 5$ ) to ensure identifiability. The identifiability of more general cases is still an open research question.

### 3 Bigram Recovery Algorithm

In practice, the documents are not truly generated from a bigram LM, and the BOW corpus may be small. We therefore seek a maximum likelihood estimate of  $\theta$  or a regularized version of it. Equivalently, we no longer require equality in (1), but instead find  $\theta$  that makes the distribution  $P(\mathbf{x}|\theta)$  as close to  $\hat{p}(\mathbf{x})$  as possible. We formalize this notion below.

#### 3.1 The Objective Function

Given a BOW corpus  $\{\mathbf{x}_1, \dots, \mathbf{x}_n\}$ , its normalized log likelihood under  $\theta$  is  $\ell(\theta) \equiv \frac{1}{C} \sum_{i=1}^n \log P(\mathbf{x}_i|\theta)$ , where  $C = \sum_{i=1}^n (|\mathbf{x}_i| - 1)$  is the corpus length excluding  $\langle d \rangle$ 's. The idea is to find  $\theta$  that maximizes  $\ell(\theta)$ . This also brings  $P(\mathbf{x}|\theta)$  closest to  $\hat{p}(\mathbf{x})$  in the KL-divergence sense. However, to prevent overfitting, we regularize the problem so that  $\theta$  prefers to be close to a ‘‘prior’’ bigram LM  $\phi$ . The prior  $\phi$  is also estimated from the BOW corpus, and is discussed in Section 3.4. We define the regularizer to be an asymmetric dissimilarity  $\mathcal{D}(\phi, \theta)$  between the prior  $\phi$  and the learned model  $\theta$ . The dissimilarity is 0 if  $\theta = \phi$ , and increases as they diverge. Specifically, the KL-divergence between two word distributions conditioned on the same history  $u$  is  $KL(\phi_u \parallel \theta_u) = \sum_{v=1}^W \phi_{uv} \log \frac{\phi_{uv}}{\theta_{uv}}$ . We define  $\mathcal{D}(\phi, \theta)$  to be the average KL-divergence over all histories:  $\mathcal{D}(\phi, \theta) \equiv \frac{1}{W} \sum_{u=1}^W KL(\phi_u \parallel \theta_u)$ , which is convex in  $\theta$  (Cover and Thomas, 1991). We will use the following derivative later:  $\partial \mathcal{D}(\phi, \theta) / \partial \theta_{uv} = -\phi_{uv} / (W \theta_{uv})$ .

We are now ready to define the regularized optimization problem for recovering a bigram LM  $\theta$  from the BOW corpus:

$$\begin{aligned} \max_{\theta} \quad & \ell(\theta) - \lambda \mathcal{D}(\phi, \theta) \\ \text{subject to} \quad & \theta \mathbf{1} = \mathbf{1}, \quad \theta \geq 0. \end{aligned} \quad (2)$$

The weight  $\lambda$  controls the strength of the prior. The constraints ensure that  $\theta$  is a valid bigram matrix, where  $\mathbf{1}$  is an all-one vector, and the non-negativity constraint is element-wise. Equivalently, (2) can be viewed as the *maximum a posteriori* (MAP) estimate of  $\theta$ , with independent Dirichlet priors for each row of  $\theta$ :  $p(\theta_u) = \text{Dir}(\theta_u | \alpha_u)$  and hyperparameters  $\alpha_{uv} = \frac{\lambda C}{W} \phi_{uv} + 1$ .

The summation over hidden ordered documents  $\mathbf{z}$  in  $P(\mathbf{x}|\theta)$  couples the variables and makes (2) a non-concave problem. We optimize  $\theta$  using an EM algorithm.

#### 3.2 The EM Algorithm

We derive the EM algorithm for the optimization problem (2). Let  $\mathcal{O}(\theta) \equiv \ell(\theta) - \lambda \mathcal{D}(\phi, \theta)$  be the objective function. Let  $\theta^{(t-1)}$  be the bigram LM at iteration  $t - 1$ . We can lower-bound  $\mathcal{O}$  as follows:

$$\begin{aligned} \mathcal{O}(\theta) &= \frac{1}{C} \sum_{i=1}^n \log \sum_{\mathbf{z} \in \sigma(\mathbf{x}_i)} P(\mathbf{z}|\theta^{(t-1)}, \mathbf{x}_i) \frac{P(\mathbf{z}|\theta)}{P(\mathbf{z}|\theta^{(t-1)}, \mathbf{x}_i)} \\ &\quad - \lambda \mathcal{D}(\phi, \theta) \\ &\geq \frac{1}{C} \sum_{i=1}^n \sum_{\mathbf{z} \in \sigma(\mathbf{x}_i)} P(\mathbf{z}|\theta^{(t-1)}, \mathbf{x}_i) \log \frac{P(\mathbf{z}|\theta)}{P(\mathbf{z}|\theta^{(t-1)}, \mathbf{x}_i)} \\ &\quad - \lambda \mathcal{D}(\phi, \theta) \\ &\equiv \mathcal{L}(\theta, \theta^{(t-1)}). \end{aligned}$$

We used Jensen’s inequality above since  $\log(\cdot)$  is concave. The lower bound  $\mathcal{L}$  involves  $P(\mathbf{z}|\theta^{(t-1)}, \mathbf{x})$ , the probability of hidden orderings of the BOW under the previous iteration’s model. In the E-step of EM we compute  $P(\mathbf{z}|\theta^{(t-1)}, \mathbf{x})$ , which will be discussed in Section 3.3. One can verify that  $\mathcal{L}(\theta, \theta^{(t-1)})$  is *concave* in  $\theta$ , unlike the original objective  $\mathcal{O}(\theta)$ . In addition, the lower bound ‘‘touches’’ the objective at  $\theta^{(t-1)}$ , i.e.,  $\mathcal{L}(\theta^{(t-1)}, \theta^{(t-1)}) = \mathcal{O}(\theta^{(t-1)})$ .

The EM algorithm iteratively maximizes the lower bound, which is now a concave optimization problem:  $\max_{\theta} \mathcal{L}(\theta, \theta^{(t-1)})$ , subject to  $\theta \mathbf{1} = \mathbf{1}$ . The non-negativity constraints turn out to be automatically satisfied. Introducing Lagrange multipliers  $\beta_u$  for each history  $u = 1 \dots W$ , we form the Lagrangian  $\Delta$ :

$$\Delta \equiv \mathcal{L}(\theta, \theta^{(t-1)}) - \sum_{u=1}^W \beta_u \left( \sum_{v=1}^W \theta_{uv} - 1 \right).$$

Taking the partial derivative with respect to  $\theta_{uv}$  and setting it to zero:  $\partial \Delta / \partial \theta_{uv} = 0$ , we arrive at the following update:

$$\theta_{uv} \propto \sum_{i=1}^n \sum_{\mathbf{z} \in \sigma(\mathbf{x}_i)} P(\mathbf{z}|\theta^{(t-1)}, \mathbf{x}_i) c_{uv}(\mathbf{z}) + \frac{\lambda C}{W} \phi_{uv}. \quad (3)$$

--

Table 1: The EM algorithm

The normalization is over  $v = 1 \dots W$ . We use  $c_{uv}(\mathbf{z})$  to denote the number of times the bigram “ $uv$ ” appears in the ordered document  $\mathbf{z}$ . This is the M-step of EM. Intuitively, the first term counts how often the bigram “ $uv$ ” occurs, weighing each ordering by its probability under the previous model; the second term pulls the parameter towards the prior. If the weight of the prior  $\lambda \rightarrow \infty$ , we would have  $\theta_{uv} = \phi_{uv}$ . The update is related to the MAP estimate for a multinomial distribution with a Dirichlet prior, where we use the expected counts.

We initialize the EM algorithm with  $\theta^{(0)} = \phi$ . The EM algorithm is summarized in Table 1.

### 3.3 Approximate E-step

The E-step needs to compute the expected bigram counts of the form

$$\sum_{\mathbf{z} \in \sigma(\mathbf{x})} P(\mathbf{z}|\theta, \mathbf{x}) c_{uv}(\mathbf{z}). \quad (4)$$

However, this poses a computational problem. The summation is over unique ordered documents. The number of unique ordered documents can be on the order of  $|\mathbf{x}|!$ , i.e., all permutations of the BOW. For a short document of length 15, this number is already  $10^{12}$ . Clearly, brute-force enumeration is only feasible for very short documents. Approximation is necessary to handle longer ones.

A simple Monte Carlo approximation to (4) would involve sampling ordered documents  $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_L$  according to  $\mathbf{z}_i \sim P(\mathbf{z}|\theta, \mathbf{x})$ , and replacing (4) with  $\sum_{i=1}^L c_{uv}(\mathbf{z}_i)/L$ . This estimate is unbiased, and the variance decreases linearly

with the number of samples,  $L$ . However, sampling directly from  $P$  is difficult.

Instead, we sample ordered documents  $\mathbf{z}_i \sim R(\mathbf{z}_i|\theta, \mathbf{x})$  from a distribution  $R$  which is easy to generate, and construct an approximation using *importance sampling* (see, e.g., (Liu, 2001)). With each sample,  $\mathbf{z}_i$ , we associate a weight  $w_i \propto P(\mathbf{z}_i|\theta, \mathbf{x})/R(\mathbf{z}_i|\theta, \mathbf{x})$ . The importance sampling approximation to (4) is then given by  $(\sum_{i=1}^L w_i c_{uv}(\mathbf{z}_i))/(\sum_{i=1}^L w_i)$ . Re-weighting the samples in this fashion accounts for the fact that we are using a sampling distribution  $R$  which is different from the target distribution  $P$ , and guarantees that our approximation is asymptotically unbiased.

The quality of an importance sampling approximation is closely related to how closely  $R$  resembles  $P$ ; the more similar they are, the better the approximation, in general. Given a BOW  $\mathbf{x}$  and our current bigram model estimate,  $\theta$ , we generate one sample (an ordered document  $\mathbf{z}_i$ ) by sequentially drawing words from the bag, with probabilities proportional to  $\theta$ , but properly normalized to form a distribution based on which words remain in the bag. For example, suppose  $\mathbf{x} = (\langle d \rangle:1, A:2, B:1, C:1)$ . Then we set  $z_{i1} = \langle d \rangle$ , and sample  $z_{i2} = A$  with probability  $2\theta_{\langle d \rangle A}/(2\theta_{\langle d \rangle A} + \theta_{\langle d \rangle B} + \theta_{\langle d \rangle C})$ . Similarly, if  $z_{i(j-1)} = u$  and if  $v$  is in the original BOW that hasn’t been sampled yet, then we set the next word in the ordered document  $z_{ij}$  equal to  $v$  with probability proportional to  $c_v \theta_{uv}$ , where  $c_v$  is the count of  $v$  in the remaining BOW. For this scheme, one can verify (Rabbat et al., 2007) that the importance weight corresponding to a sampled ordered document  $\mathbf{z}_i = (z_{i1}, \dots, z_{i|\mathbf{x}|})$  is given by  $w_i = \prod_{t=2}^{|\mathbf{x}|} \sum_{i=t}^{|\mathbf{x}|} \theta_{z_{t-1} z_i}$ . In our implementation, the number of importance samples used for a document  $\mathbf{x}$  is  $10|\mathbf{x}|^2$  if the length of the document  $|\mathbf{x}| > 8$ ; otherwise we enumerate  $\sigma(\mathbf{x})$  without importance sampling.

### 3.4 Prior Bigram LM $\phi$

The quality of the EM solution  $\theta$  can depend on the prior bigram LM  $\phi$ . To assess bigram recoverability from a BOW corpus alone, we consider only priors estimated from the corpus itself<sup>3</sup>. Like  $\theta$ ,  $\phi$  is a  $W \times W$  transition matrix with  $\phi_{uv} = P(v|u)$ . When

<sup>3</sup>Priors based on general English text or domain-specific knowledge could be used in specific applications.

appropriate, we set the initial probability  $\phi_{\langle d \rangle v}$  proportional to the number of times word  $v$  appears in the BOW corpus. We consider three prior models:

**Prior 1: Unigram  $\phi^{unigram}$ .** The most naïve  $\phi$  is a unigram LM which ignores word history. The probability for word  $v$  is estimated from the BOW corpus frequency of  $v$ , with add-1 smoothing:  $\phi_{uv}^{unigram} \propto 1 + \sum_{i=1}^n x_{iv}$ . We should point out that the unigram prior is an asymmetric bigram, i.e.,  $\phi_{uv}^{unigram} \neq \phi_{vu}^{unigram}$ .

**Prior 2: Frequency of Document Co-occurrence (FDC)  $\phi^{fdc}$ .** Let  $\delta(u, v | \mathbf{x}) = 1$  if words  $u \neq v$  co-occur (regardless of their counts) in BOW  $\mathbf{x}$ , and 0 otherwise. In the case  $u = v$ ,  $\delta(u, u | \mathbf{x}) = 1$  only if  $u$  appears at least twice in  $\mathbf{x}$ . Let  $c_{uv}^{fdc} = \sum_{i=1}^n \delta(u, v | \mathbf{x}_i)$  be the number of BOWs in which  $u, v$  co-occur. The FDC prior is  $\phi_{uv}^{fdc} \propto c_{uv}^{fdc} + 1$ . The co-occurrence counts  $c^{fdc}$  are symmetric, but  $\phi^{fdc}$  is asymmetric because of normalization. FDC captures some notion of potential transitions from  $u$  to  $v$ . FDC is in spirit similar to Kneser-Ney smoothing (Kneser and Ney, 1995) and other methods that accumulate indicators of document membership.

**Prior 3: Permutation-Based (Perm)  $\phi^{perm}$ .** Recall that  $c_{uv}(\mathbf{z})$  is the number of times the bigram “ $uv$ ” appears in an ordered document  $\mathbf{z}$ . We define  $c_{uv}^{perm} = \sum_{i=1}^n \mathbb{E}_{\mathbf{z} \in \sigma(\mathbf{x}_i)} [c_{uv}(\mathbf{z})]$ , where the expectation is with respect to all unique orderings of each BOW. We make the zero-knowledge assumption of uniform probability over these orderings, rather than  $P(\mathbf{z} | \theta)$  as in the EM algorithm described above. EM will refine these estimates, though, so this is a natural starting point. Space precludes a full discussion, but it can be proven that  $c_{uv}^{perm} = \sum_{i=1}^n x_{iu}x_{iv} / |\mathbf{x}_i|$  if  $u \neq v$ , and  $c_{uu}^{perm} = \sum_{i=1}^n x_{iu}(x_{iu} - 1) / |\mathbf{x}_i|$ . Finally,  $\phi_{uv}^{perm} \propto c_{uv}^{perm} + 1$ .

### 3.5 Decoding Ordered Documents from BOWs

Given a BOW  $\mathbf{x}$  and a bigram LM  $\theta$ , we formulate document recovery as the problem  $\mathbf{z}^* = \operatorname{argmax}_{\mathbf{z} \in \sigma(\mathbf{x})} P(\mathbf{z} | \theta)$ . In fact, we can generate the top  $N$  candidate ordered documents in terms of  $P(\mathbf{z} | \theta)$ . We use A\* search to construct such an N-best list (Russell and Norvig, 2003). Each state is an ordered, partial document. Its successor states append one more unused word in  $\mathbf{x}$  to

the partial document. The actual cost  $g$  from the start (empty document) to a state is the log probability of the partial document under bigram  $\theta$ . We design a heuristic cost  $h$  from the state to the goal (complete document) that is *admissible*: the idea is to over-use the best bigram history for the remaining words in  $\mathbf{x}$ . Let the partial document end with word  $w_e$ . Let the count vector for the remaining BOW be  $(c_1, \dots, c_W)$ . One admissible heuristic is  $h = \log \prod_{u=1}^W P(u | bh(u); \theta)^{c_u}$ , where the “best history” for word type  $u$  is  $bh(u) = \operatorname{argmax}_v \theta_{vu}$ , and  $v$  ranges over the word types with non-zero counts in  $(c_1, \dots, c_W)$ , plus  $w_e$ . It is easy to see that  $h$  is an upper bound on the bigram log probability that the remaining words in  $\mathbf{x}$  can achieve.

We use a memory-bounded A\* search similar to (Russell, 1992), because long BOWs would otherwise quickly exhaust memory. When the priority queue grows larger than the bound, the worst states (in terms of  $g + h$ ) in the queue are purged. This necessitates a double-ended priority queue that can pop either the maximum or minimum item. We use an efficient implementation with Splay trees (Chong and Sahni, 2000). We continue running A\* after popping the goal state from its priority queue. Repeating this  $N$  times gives the N-best list.

## 4 Experiments

We show experimentally that the proposed algorithm is indeed able to recover reasonable bigram LMs from BOW corpora. We observe:

**1. Good test set perplexity:** Using test (held-out) set perplexity (PP) as an objective measure of LM quality, we demonstrate that our recovered bigram LMs are much better than naïve unigram LMs trained on the same BOW corpus. Furthermore, they are not far behind the “oracle” bigram LMs trained on *ordered documents* that correspond to the BOWs.

**2. Sensible bigram pairs:** We inspect the recovered bigram LMs and find that they assign higher probabilities to sensible bigram pairs (e.g., “i mean”, “oh boy”, “that’s funny”), and lower probabilities to nonsense pairs (e.g., “i yep”, “you let’s”, “right lot”).

**3. Document recovery from BOW:** With the bigram LMs, we show improved accuracy in recovering ordered documents from BOWs.

We describe these experiments in detail below.

Corpus	$ V $	# Docs	# Tokens	$ \bar{x} $
SV10	10	6775	7792	1.2
SV25	25	9778	13324	1.4
SV50	50	12442	20914	1.7
SV100	100	14602	28611	2.0
SV250	250	18933	51950	2.7
SV500	500	23669	89413	3.8
SumTime	882	3341	68815	20.6

Table 2: Corpora statistics: vocabulary size, document count, total token count, and mean document length.

#### 4.1 Corpora and Protocols

We note that although in principle our algorithm works on large corpora, the current implementation does not scale well (Table 3 last column). We therefore experimented on seven corpora with relatively small vocabulary sizes, and with short documents (mostly one sentence per document). Table 2 lists statistics describing the corpora. The first six contain text transcripts of conversational telephone speech from the small vocabulary “SVitchboard 1” data set. King et al. constructed each corpus from the full Switchboard corpus, with the restriction that the sentences use only words in the corresponding vocabulary (King et al., 2005). We refer to these corpora as SV10, SV25, SV50, SV100, SV250, and SV500. The seventh corpus comes from the SumTime-Meteo data set (Sripada et al., 2003), which contains real weather forecasts for offshore oil rigs in the North Sea. For the SumTime corpus, we performed sentence segmentation to produce documents, removed punctuation, and replaced numeric digits with a special token.

For each of the seven corpora, we perform 5-fold cross validation. We use four folds other than the  $k$ -th fold as the training set to train (recover) bigram LMs, and the  $k$ -th fold as the test set for evaluation. This is repeated for  $k = 1 \dots 5$ , and we report the average cross validation results. We distinguish the original *ordered documents* (training set  $\mathbf{z}_1, \dots, \mathbf{z}_n$ , test set  $\mathbf{z}_{n+1}, \dots, \mathbf{z}_m$ ) and the corresponding BOWs (training set  $\mathbf{x}_1 \dots \mathbf{x}_n$ , test set  $\mathbf{x}_{n+1} \dots \mathbf{x}_m$ ). In all experiments, we simply set the weight  $\lambda = 1$  in (2). Given a training set and a test set, we perform the following steps:

1. Build prior LMs  $\phi^X$  from the training BOW corpus  $\mathbf{x}_1, \dots, \mathbf{x}_n$ , for  $X = \text{unigram}, \text{fdc}, \text{perm}$ .
2. Recover the bigram LMs  $\theta^X$  with the EM al-

gorithm in Table 1, from the training BOW corpus  $\mathbf{x}_1, \dots, \mathbf{x}_n$  and using the prior from step 1.

3. Compute the MAP bigram LM from the *ordered* training documents  $\mathbf{z}_1, \dots, \mathbf{z}_n$ . We call this the “oracle” bigram LM because it uses order information (not available to our algorithm), and we use it as a lower-bound on perplexity.

4. Test all LMs on  $\mathbf{z}_{n+1}, \dots, \mathbf{z}_m$  by perplexity.

#### 4.2 Good Test Set Perplexity

Table 3 reports the 5-fold cross validation mean-test-set-PP values for all corpora, and the run time per EM iteration. Because of the long running time, we adopt the rule-of-thumb stopping criterion of “two EM iterations”. First, we observe that all bigram LMs perform better than unigram LMs  $\phi^{\text{unigram}}$  even though they are trained on the same BOW corpus. Second, all recovered bigram LMs  $\theta^X$  improved upon their corresponding baselines  $\phi^X$ . The difference across *every* row is statistically significant according to a two-tailed paired  $t$ -test with  $p < 0.05$ . The differences among  $\text{PP}(\theta^X)$  for the same corpus are also significant (except between  $\theta^{\text{unigram}}$  and  $\theta^{\text{perm}}$  for SV500). Finally, we observe that  $\theta^{\text{perm}}$  tends to be best for the smaller vocabulary corpora, whereas  $\theta^{\text{fdc}}$  dominates as the vocabulary grows.

To see how much better we could do if we had *ordered* training documents  $\mathbf{z}_1, \dots, \mathbf{z}_n$ , we present the mean-test-set-PP of “oracle” bigram LMs in Table 4. We used three smoothing methods to obtain oracle LMs: absolute discounting using a constant of 0.5 (we experimented with other values, but 0.5 worked best), Good-Turing, and interpolated Witten-Bell as implemented in the SRILM toolkit (Stolcke, 2002). We see that our recovered LMs (trained on *unordered* BOW documents), especially for small vocabulary corpora, are close to the oracles (trained on *ordered* documents). For the larger datasets, the recovery task is more difficult, and the gap between the oracle LMs and the  $\theta$  LMs widens. Note that the oracle LMs do much better than the recovered LMs on the SumTime corpus; we suspect the difference is due to the larger vocabulary and significantly higher average sentence length (see Table 2).

#### 4.3 Sensible Bigram Pairs

The next set of experiments compares the recovered bigram LMs to their corresponding prior LMs

Corpus	$X$	$PP(\phi^X)$	$PP(\theta^X)$	Time/ Iter
SV10	unigram	7.48	6.95	< 1s
	fdc	6.52	6.47	< 1s
	perm	6.50	6.45	< 1s
SV25	unigram	16.4	12.8	0.1s
	fdc	12.3	11.8	0.1s
	perm	12.2	11.7	0.1s
SV50	unigram	29.1	19.7	2s
	fdc	19.6	17.8	4s
	perm	19.5	17.7	5s
SV100	unigram	45.4	27.8	7s
	fdc	29.5	25.3	11s
	perm	30.0	25.6	11s
SV250	unigram	91.8	51.2	5m
	fdc	60.0	47.3	8m
	perm	65.4	49.7	8m
SV500	unigram	149.1	87.2	3h
	fdc	104.8	80.1	3h
	perm	123.9	87.4	3h
SumTime	unigram	129.7	81.8	4h
	fdc	103.2	77.7	4h
	perm	187.9	85.4	3h

Table 3: Mean test set perplexities of prior LMs and bigram LMs recovered after 2 EM iterations.

in terms of how they assign probabilities to word pairs. One naturally expects probabilities for frequently occurring bigrams to increase, while rare or nonsensical bigrams’ probabilities should decrease. For a prior-bigram pair  $(\phi, \theta)$ , we evaluate the change in probabilities by computing the ratio  $\rho_{hw} = \frac{P(w|h, \theta)}{P(w|h, \phi)} = \frac{\theta_{hw}}{\phi_{hw}}$ . For a given history  $h$ , we sort words  $w$  by this ratio rather than by actual bigram probability because the bigrams with the highest and lowest probabilities tend to stay the same, while the changes accounting for differences in PP scores are more noticeable by considering the ratio.

Due to space limitation, we present one specific result (FDC prior, fold 1) for the SV500 corpus in Table 5. Other results are similar. The table lists a few most frequent unigrams as history words  $h$  (left), and the words  $w$  with the smallest (center) and largest (right)  $\rho_{hw}$  ratio. Overall we see that our EM algorithm is forcing meaningless bigrams (e.g., “i goodness”, “oh thing”) to have lower probabilities, while assigning higher probabilities to sensible bigram pairs (e.g., “really good”, “that’s funny”). Note that the reverse of some common expressions (e.g., “right that’s”) also rise in probability, suggesting the algorithm detects that the two words are of-

Corpus	Absolute Discount	Good-Turing	Witten-Bell	$\theta^*$
SV10	6.27	6.28	6.27	6.45
SV25	10.5	10.6	10.5	11.7
SV50	14.8	14.9	14.8	17.7
SV100	20.0	20.1	20.0	25.3
SV250	33.7	33.7	33.8	47.3
SV500	50.9	50.9	51.3	80.1
SumTime	10.8	10.5	10.6	77.7

Table 4: Mean test set perplexities for oracle bigram LMs trained on  $\mathbf{z}_1, \dots, \mathbf{z}_n$  and tested on  $\mathbf{z}_{n+1}, \dots, \mathbf{z}_m$ . For reference, the rightmost column lists the best result using a recovered bigram LM ( $\theta^{perm}$  for the first three corpora,  $\theta^{fdc}$  for the latter four).

ten adjacent, but lacks sufficient information to nail down the exact order.

#### 4.4 Document Recovery from BOW

We now play the role of the malicious party mentioned in the introduction. We show that, compared to their corresponding prior LMs, our recovered bigram LMs are better able to reconstruct ordered documents out of test BOWs  $\mathbf{x}_{n+1}, \dots, \mathbf{x}_m$ . We perform document recovery using 1-best A\* decoding. We use “document accuracy” and “ $n$ -gram accuracy” (for  $n = 2, 3$ ) as our evaluation criteria. We define document accuracy ( $Acc^{doc}$ ) as the fraction of documents<sup>4</sup> for which the decoded document matches the true ordered document exactly. Similarly,  $n$ -gram accuracy ( $Acc^n$ ) measures the fraction of all  $n$ -grams in test documents (with  $n$  or more words) that are recovered correctly.

For this evaluation, we compare models built for the SV500 corpus. Table 6 presents 5-fold cross validation average test-set accuracies. For each accuracy measure, we compare the prior LM with the recovered bigram LM. It is interesting to note that the FDC and Perm priors reconstruct documents surprisingly well, but we can always improve them by running our EM algorithm. The accuracies obtained by  $\theta$  are statistically significantly better (via two-tailed paired  $t$ -tests with  $p < 0.05$ ) than their corresponding priors  $\phi$  in all cases except  $Acc^{doc}$  for  $\theta^{perm}$  versus  $\phi^{perm}$ . Furthermore,  $\theta^{fdc}$  and  $\theta^{perm}$  are significantly better than all other models in terms of all three reconstruction accuracy measures.

<sup>4</sup>We omit single-word documents from these computations.

really	now, more, yep, work, you're	sad, neat, not, good, it's

Table 5: The recovered bigram LM  $\theta^{fdc}$  decreases nonsense bigram probabilities (center column) and increases sensible ones (right column) compared to the prior  $\phi^{fdc}$  on the SV500 corpus.

$\phi^{perm}$ reconstructions of test BOWs	$\theta^{perm}$ reconstructions of test BOWs
just it's it's it's just going it's probably out there else something the the have but it doesn't you to talking nice was it yes that's well that's what i'm saying a little more here home take and they can very be nice too i think well that's great i'm but was he because only always that's think i don't i no that in and it it's interesting <b>that's right that's right that's difficult</b> <b>so just not quite a year</b> <b>well it is a big dog</b> <b>so do you have a car</b>	<b>it's just it's just it's going</b> <b>it's probably something else out there</b> <b>but it doesn't have the the</b> <b>yes it was nice talking to you</b> <b>well that's that's what i'm saying</b> <b>a little more take home here</b> <b>and they can be very nice too</b> <b>well i think that's great i'm</b> <b>but only because he was always</b> <b>no i don't i think that's</b> <b>and it it's interesting that in</b> right that's that's right that's difficult so just not a quite year well it is big a dog so you do have a car

Table 7: Subset of SV500 documents that only  $\phi^{perm}$  or  $\theta^{perm}$  (but not both) reconstructs correctly. The correct reconstructions are in bold.

$X$	$Acc^{doc}$		$Acc^2$		$Acc^3$	
	$\phi^X$	$\theta^X$	$\phi^X$	$\theta^X$	$\phi^X$	$\theta^X$
unigram	11.1	26.8	17.7	32.8	2.7	11.8
fdc	30.2	31.0	33.0	35.1	11.4	13.3
perm	30.9	31.5	32.7	34.8	11.5	13.1

Table 6: Percentage of correctly reconstructed documents, 2-grams and 3-grams from test BOWs in SV500, 5-fold cross validation. The same trends continue for 4-grams and 5-grams (not shown).

We conclude our experiments with a closer look at some BOWs for which  $\phi$  and  $\theta$  reconstruct differently. As a representative example, we compare  $\theta^{perm}$  to  $\phi^{perm}$  on one test set of the SV500 corpus. There are 92 documents that are correctly reconstructed by  $\theta^{perm}$  but not by  $\phi^{perm}$ . In contrast, only 65 documents are accurately reordered by  $\phi^{perm}$  but not by  $\theta^{perm}$ . Table 7 presents a subset of these documents with six or more words. Overall, we conclude that the recovered bigram LMs do a better job at reconstructing BOW documents.

## 5 Conclusions and Future Work

We presented an algorithm that learns bigram language models from BOWs. We plan to: i) investigate ways to speed up our algorithm; ii) extend it to trigram and higher-order models; iii) handle the mixture of BOW documents and some ordered documents (or phrases) when available; iv) adapt a general English LM to a special domain using only BOWs from that domain; and v) explore novel applications of our algorithm.

## Acknowledgments

## Abstract

This paper provides evidence that the use of more unlabeled data in semi-supervised learning can improve the performance of Natural Language Processing (NLP) tasks, such as part-of-speech tagging, syntactic chunking, and named entity recognition. We first propose a simple yet powerful semi-supervised discriminative model appropriate for handling large scale unlabeled data. Then, we describe experiments performed on widely used test collections, namely, PTB III data, CoNLL'00 and '03 shared task data for the above three NLP tasks, respectively. We incorporate up to 1G-words (one billion tokens) of unlabeled data, which is the largest amount of unlabeled data ever used for these tasks, to investigate the performance improvement. In addition, our results are superior to the best reported results for all of the above test collections.

## 1 Introduction

Today, we can easily find a large amount of unlabeled data for many supervised learning applications in Natural Language Processing (NLP). Therefore, to improve performance, the development of an effective framework for semi-supervised learning (SSL) that uses both labeled and unlabeled data is attractive for both the machine learning and NLP communities. We expect that such SSL will replace most supervised learning in real world applications.

In this paper, we focus on traditional and important NLP tasks, namely part-of-speech (POS) tagging, syntactic chunking, and named entity recognition (NER). These are also typical supervised learning applications in NLP, and are referred to as sequential labeling and segmentation problems. In some cases, these tasks have relatively large

amounts of labeled training data. In this situation, supervised learning can provide competitive results, and it is difficult to improve them any further by using SSL. In fact, few papers have succeeded in showing significantly better results than state-of-the-art supervised learning. Ando and Zhang (2005) reported a substantial performance improvement compared with state-of-the-art supervised learning results for syntactic chunking with the CoNLL'00 shared task data (Tjong Kim Sang and Buchholz, 2000) and NER with the CoNLL'03 shared task data (Tjong Kim Sang and Meulder, 2003).

One remaining question is the behavior of SSL when using as much labeled and unlabeled data as possible. This paper investigates this question, namely, the use of a large amount of unlabeled data in the presence of (fixed) large labeled data.

To achieve this, it is paramount to make the SSL method scalable with regard to the size of unlabeled data. We first propose a scalable model for SSL. Then, we apply our model to widely used test collections, namely Penn Treebank (PTB) III data (Marcus et al., 1994) for POS tagging, CoNLL'00 shared task data for syntactic chunking, and CoNLL'03 shared task data for NER. We used up to 1G-words (one billion tokens) of unlabeled data to explore the performance improvement with respect to the unlabeled data size. In addition, we investigate the performance improvement for 'unseen data' from the viewpoint of unlabeled data coverage. Finally, we compare our results with those provided by the best current systems.

The contributions of this paper are threefold. First, we present a simple, scalable, but powerful task-independent model for semi-supervised sequential labeling and segmentation. Second, we report the best current results for the widely used test

collections described above. Third, we confirm that the use of more unlabeled data in SSL can really lead to further improvements.

## 2 Conditional Model for SSL

We design our model for SSL as a natural semi-supervised extension of conventional supervised conditional random fields (CRFs) (Lafferty et al., 2001). As our approach for incorporating unlabeled data, we basically follow the idea proposed in (Suzuki et al., 2007).

### 2.1 Conventional Supervised CRFs

Let  $\mathbf{x} \in \mathcal{X}$  and  $\mathbf{y} \in \mathcal{Y}$  be an input and output, where  $\mathcal{X}$  and  $\mathcal{Y}$  represent the set of possible inputs and outputs, respectively.  $\mathcal{C}$  stands for the set of cliques in an undirected graphical model  $\mathcal{G}(\mathbf{x}, \mathbf{y})$ , which indicates the interdependency of a given  $\mathbf{x}$  and  $\mathbf{y}$ .  $\mathbf{y}_c$  denotes the output from the corresponding clique  $c$ . Each clique  $c \in \mathcal{C}$  has a *potential function*  $\Psi_c$ . Then, the CRFs define the conditional probability  $p(\mathbf{y}|\mathbf{x})$  as a product of  $\Psi_c$ s. In addition, let  $\mathbf{f} = (f_1, \dots, f_I)$  be a feature vector, and  $\boldsymbol{\lambda} = (\lambda_1, \dots, \lambda_I)$  be a parameter vector, whose lengths are  $I$ .  $p(\mathbf{y}|\mathbf{x}; \boldsymbol{\lambda})$  on a CRF is defined as follows:

$$p(\mathbf{y}|\mathbf{x}; \boldsymbol{\lambda}) = \frac{1}{Z(\mathbf{x})} \prod_c \Psi_c(\mathbf{y}_c, \mathbf{x}; \boldsymbol{\lambda}), \quad (1)$$

where  $Z(\mathbf{x}) = \sum_{\mathbf{y} \in \mathcal{Y}} \prod_{c \in \mathcal{C}} \Psi_c(\mathbf{y}_c, \mathbf{x}; \boldsymbol{\lambda})$  is the partition function. We generally assume that the potential function is a non-negative real value function. Therefore, the exponentiated weighted sum over the features of a clique is widely used, so that,  $\Psi_c(\mathbf{y}_c, \mathbf{x}; \boldsymbol{\lambda}) = \exp(\boldsymbol{\lambda} \cdot \mathbf{f}_c(\mathbf{y}_c, \mathbf{x}))$  where  $\mathbf{f}_c(\mathbf{y}_c, \mathbf{x})$  is a feature vector obtained from the corresponding clique  $c$  in  $\mathcal{G}(\mathbf{x}, \mathbf{y})$ .

### 2.2 Semi-supervised Extension for CRFs

Suppose we have  $J$  kinds of probability models (PMs). The  $j$ -th joint PM is represented by  $p_j(\mathbf{x}_j, \mathbf{y}; \boldsymbol{\theta}_j)$  where  $\boldsymbol{\theta}_j$  is a model parameter.  $\mathbf{x}_j = \mathcal{T}_j(\mathbf{x})$  is simply an input  $\mathbf{x}$  transformed by a pre-defined function  $\mathcal{T}_j$ . We assume  $\mathbf{x}_j$  has the same graph structure as  $\mathbf{x}$ . This means  $p_j(\mathbf{x}_j, \mathbf{y})$  can be factorized by the cliques  $c$  in  $\mathcal{G}(\mathbf{x}, \mathbf{y})$ . That is,  $p_j(\mathbf{x}_j, \mathbf{y}; \boldsymbol{\theta}_j) = \prod_c p_j(\mathbf{x}_{jc}, \mathbf{y}_c; \boldsymbol{\theta}_j)$ . Thus, we can incorporate generative models such as Bayesian networks including (1D and 2D) hidden Markov models (HMMs) as these joint PMs. Actually, there is

a difference in that generative models are *directed* graphical models while our conditional PM is an *undirected*. However, this difference causes no violations when we construct our approach.

Let us introduce  $\boldsymbol{\lambda}' = (\lambda_1, \dots, \lambda_I, \lambda_{I+1}, \dots, \lambda_{I+J})$ , and  $\mathbf{h} = (f_1, \dots, f_I, \log p_1, \dots, \log p_J)$ , which is the concatenation of feature vector  $\mathbf{f}$  and the log-likelihood of  $J$ -joint PMs. Then, we can define a new potential function by embedding the joint PMs;

$$\begin{aligned} \Psi'_c(\mathbf{y}_c, \mathbf{x}; \boldsymbol{\lambda}', \boldsymbol{\Theta}) &= \exp(\boldsymbol{\lambda}' \cdot \mathbf{f}_c(\mathbf{y}_c, \mathbf{x})) \cdot \prod_j p_j(\mathbf{x}_{jc}, \mathbf{y}_c; \boldsymbol{\theta}_j)^{\lambda_{I+j}} \\ &= \exp(\boldsymbol{\lambda}' \cdot \mathbf{h}_c(\mathbf{y}_c, \mathbf{x})). \end{aligned}$$

where  $\boldsymbol{\Theta} = \{\boldsymbol{\theta}_j\}_{j=1}^J$ , and  $\mathbf{h}_c(\mathbf{y}_c, \mathbf{x})$  is  $\mathbf{h}$  obtained from the corresponding clique  $c$  in  $\mathcal{G}(\mathbf{x}, \mathbf{y})$ . Since each  $p_j(\mathbf{x}_{jc}, \mathbf{y}_c)$  has range  $[0, 1]$ , which is non-negative,  $\Psi'_c$  can also be used as a potential function. Thus, the conditional model for our SSL can be written as:

$$P(\mathbf{y}|\mathbf{x}; \boldsymbol{\lambda}', \boldsymbol{\Theta}) = \frac{1}{Z'(\mathbf{x})} \prod_c \Psi'_c(\mathbf{y}_c, \mathbf{x}; \boldsymbol{\lambda}', \boldsymbol{\Theta}), \quad (2)$$

where  $Z'(\mathbf{x}) = \sum_{\mathbf{y} \in \mathcal{Y}} \prod_{c \in \mathcal{C}} \Psi'_c(\mathbf{y}_c, \mathbf{x}; \boldsymbol{\lambda}', \boldsymbol{\Theta})$ . Hereafter in this paper, we refer to this conditional model as a ‘*Joint probability model Embedding style Semi-Supervised Conditional Model*’, or **JESS-CM** for short.

Given labeled data,  $\mathcal{D}_l = \{(\mathbf{x}^n, \mathbf{y}^n)\}_{n=1}^N$ , the MAP estimation of  $\boldsymbol{\lambda}'$  under a fixed  $\boldsymbol{\Theta}$  can be written as:

$$\mathcal{L}^1(\boldsymbol{\lambda}'|\boldsymbol{\Theta}) = \sum_n \log P(\mathbf{y}^n|\mathbf{x}^n; \boldsymbol{\lambda}', \boldsymbol{\Theta}) + \log p(\boldsymbol{\lambda}'),$$

where  $p(\boldsymbol{\lambda}')$  is a prior probability distribution of  $\boldsymbol{\lambda}'$ . Clearly, JESS-CM shown in Equation 2 has exactly the same form as Equation 1. With a fixed  $\boldsymbol{\Theta}$ , the log-likelihood,  $\log p_j$ , can be seen simply as the feature functions of JESS-CM as with  $f_i$ . Therefore, embedded joint PMs do not violate the global convergence conditions. As a result, as with supervised CRFs, it is guaranteed that  $\boldsymbol{\lambda}'$  has a value that achieves the global maximum of  $\mathcal{L}^1(\boldsymbol{\lambda}'|\boldsymbol{\Theta})$ . Moreover, we can obtain the same form of gradient as that of supervised CRFs (Sha and Pereira, 2003), that is,

$$\begin{aligned} \nabla \mathcal{L}^1(\boldsymbol{\lambda}'|\boldsymbol{\Theta}) &= E_{\tilde{P}(\mathcal{Y}, \mathcal{X}; \boldsymbol{\lambda}', \boldsymbol{\Theta})}[\mathbf{h}(\mathcal{Y}, \mathcal{X})] \\ &\quad - \sum_n E_{P(\mathcal{Y}|\mathbf{x}^n; \boldsymbol{\lambda}', \boldsymbol{\Theta})}[\mathbf{h}(\mathcal{Y}, \mathbf{x}^n)] + \nabla \log p(\boldsymbol{\lambda}'). \end{aligned}$$

Thus, we can easily optimize  $\mathcal{L}^1$  by using the forward-backward algorithm since this paper solely

focuses on a sequence model and a gradient-based optimization algorithm in the same manner as those used in supervised CRF parameter estimation.

We cannot naturally incorporate unlabeled data into standard discriminative learning methods since the correct outputs  $\mathbf{y}$  for unlabeled data are unknown. On the other hand with a generative approach, a well-known way to achieve this incorporation is to use maximum marginal likelihood (MML) parameter estimation, i.e., (Nigam et al., 2000). Given unlabeled data  $\mathcal{D}_u = \{\mathbf{x}^m\}_{m=1}^M$ , MML estimation in our setting maximizes the marginal distribution of a joint PM over a missing (hidden) variable  $\mathbf{y}$ , namely, it maximizes  $\sum_m \log \sum_{\mathbf{y} \in \mathcal{Y}} p(\mathbf{x}^m, \mathbf{y}; \theta)$ .

Following this idea, there have been introduced a parameter estimation approach for non-generative approaches that can effectively incorporate unlabeled data (Suzuki et al., 2007). Here, we refer to it as ‘Maximum Discriminant Functions sum’ (MDF) parameter estimation. MDF estimation substitutes  $p(\mathbf{x}, \mathbf{y})$  with discriminant functions  $g(\mathbf{x}, \mathbf{y})$ . Therefore, to estimate the parameter  $\Theta$  of JESS-CM by using MDF estimation, the following objective function is maximized with a fixed  $\lambda'$ :

$$\mathcal{L}^2(\Theta|\lambda') = \sum_m \log \sum_{\mathbf{y} \in \mathcal{Y}} g(\mathbf{x}^m, \mathbf{y}; \lambda', \Theta) + \log p(\Theta),$$

where  $p(\Theta)$  is a prior probability distribution of  $\Theta$ . Since the normalization factor does not affect the determination of  $\mathbf{y}$ , the discriminant function of JESS-CM shown in Equation 2 is defined as  $g(\mathbf{x}, \mathbf{y}; \lambda', \Theta) = \prod_{c \in \mathcal{C}} \Psi'_c(\mathbf{y}_c, \mathbf{x}; \lambda', \Theta)$ . With a fixed  $\lambda'$ , the local maximum of  $\mathcal{L}^2(\Theta|\lambda')$  around the initialized value of  $\Theta$  can be estimated by an iterative computation such as the EM algorithm (Dempster et al., 1977).

### 2.3 Scalability: Efficient Training Algorithm

A parameter estimation algorithm of  $\lambda'$  and  $\Theta$  can be obtained by maximizing the objective functions  $\mathcal{L}^1(\lambda'|\Theta)$  and  $\mathcal{L}^2(\Theta|\lambda')$  iteratively and alternately. Figure 1 summarizes an algorithm for estimating  $\lambda'$  and  $\Theta$  for JESS-CM.

This paper considers a situation where there are many more unlabeled data  $M$  than labeled data  $N$ , that is,  $N \ll M$ . This means that the calculation cost for unlabeled data is dominant. Thus, in order to make the overall parameter estimation procedure

---

**Input:** training data  $\mathcal{D} = \{\mathcal{D}_l, \mathcal{D}_u\}$   
 where labeled data  $\mathcal{D}_l = \{(\mathbf{x}^n, \mathbf{y}^n)\}_{n=1}^N$ ,  
 and unlabeled data  $\mathcal{D}_u = \{\mathbf{x}^m\}_{m=1}^M$

**Initialize:**  $\Theta^{(0)} \leftarrow$  uniform distribution,  $t \leftarrow 0$

**do**

1.  $t \leftarrow t + 1$
2. (Re)estimate  $\lambda'$ :  
 maximize  $\mathcal{L}^1(\lambda'|\Theta)$  with fixed  $\Theta \leftarrow \Theta^{(t-1)}$  using  $\mathcal{D}_l$ .
3. Estimate  $\Theta^{(t)}$ : (Initial values =  $\Theta^{(t-1)}$ )  
 update one step toward maximizing  $\mathcal{L}^2(\Theta|\lambda')$   
 with fixed  $\lambda'$  using  $\mathcal{D}_u$ .

**do.until**  $\frac{|\Theta^{(t)} - \Theta^{(t-1)}|}{|\Theta^{(t-1)}|} < \epsilon$ .

Reestimate  $\lambda'$ : perform the same procedure as 1.

**Output:** a JESS-CM,  $P(\mathbf{y}|\mathbf{x}, \lambda', \Theta^{(t)})$ .

---

Figure 1: Parameter estimation algorithm for JESS-CM.

scalable for handling large scale unlabeled data, we only perform one step of MDF estimation for each  $t$  as explained on 3. in Figure 1. In addition, the calculation cost for estimating parameters of embedded joint PMs (HMMs) is independent of the number of HMMs,  $J$ , that we used (Suzuki et al., 2007). As a result, the cost for calculating the JESS-CM parameters,  $\lambda'$  and  $\Theta$ , is essentially the same as executing  $T$  iterations of the MML estimation for a single HMM using the EM algorithm plus  $T + 1$  time optimizations of the MAP estimation for a conventional supervised CRF if it converged when  $t = T$ . In addition, our parameter estimation algorithm can be easily performed in parallel computation.

### 2.4 Comparison with Hybrid Model

SSL based on a hybrid generative/discriminative approach proposed in (Suzuki et al., 2007) has been defined as a log-linear model that discriminatively combines several discriminative models,  $p_i^D$ , and generative models,  $p_j^G$ , such that:

$$R(\mathbf{y}|\mathbf{x}; \Lambda, \Theta, \Gamma) = \frac{\prod_i p_i^D(\mathbf{y}|\mathbf{x}; \lambda_i)^{\gamma_i} \prod_j p_j^G(\mathbf{x}_j, \mathbf{y}; \theta_j)^{\gamma_j}}{\sum_{\mathbf{y}} \prod_i p_i^D(\mathbf{y}|\mathbf{x}; \lambda_i)^{\gamma_i} \prod_j p_j^G(\mathbf{x}_j, \mathbf{y}; \theta_j)^{\gamma_j}},$$

where  $\Lambda = \{\lambda_i\}_{i=1}^I$ , and  $\Gamma = \{\{\gamma_i\}_{i=1}^I, \{\gamma_j\}_{j=I+1}^{I+J}\}$ .

With the hybrid model, if we use the same labeled training data to estimate both  $\Lambda$  and  $\Gamma$ ,  $\gamma_j$ s will become negligible (zero or nearly zero) since  $p_i^D$  is already fitted to the labeled training data while  $p_j^G$  are trained by using unlabeled data. As a solution, a given amount of labeled training data is divided into two distinct sets, i.e., 4/5 for estimating  $\Lambda$ , and the

remaining 1/5 for estimating  $\Gamma$  (Suzuki et al., 2007). Moreover, it is necessary to split features into several sets, and then train several corresponding discriminative models separately and preliminarily. In contrast, JESS-CM is free from this kind of additional process, and the entire parameter estimation procedure can be performed in a single pass. Surprisingly, although JESS-CM is a simpler version of the hybrid model in terms of model structure and parameter estimation procedure, JESS-CM provides  $F$ -scores of 94.45 and 88.03 for CoNLL’00 and ’03 data, respectively, which are 0.15 and 0.83 points higher than those reported in (Suzuki et al., 2007) for the same configurations. This performance improvement is basically derived from the full benefit of using labeled training data for estimating the parameter of the conditional model while the combination weights,  $\Gamma$ , of the hybrid model are estimated solely by using 1/5 of the labeled training data. These facts indicate that JESS-CM has several advantageous characteristics compared with the hybrid model.

### 3 Experiments

In our experiments, we report POS tagging, syntactic chunking and NER performance incorporating up to 1G-words of unlabeled data.

#### 3.1 Data Set

To compare the performance with that of previous studies, we selected widely used test collections. For our POS tagging experiments, we used the Wall Street Journal in PTB III (Marcus et al., 1994) with the same data split as used in (Shen et al., 2007). For our syntactic chunking and NER experiments, we used exactly the same training, development and test data as those provided for the shared tasks of CoNLL’00 (Tjong Kim Sang and Buchholz, 2000) and CoNLL’03 (Tjong Kim Sang and Meulder, 2003), respectively. The training, development and test data are detailed in Table 1<sup>1</sup>.

The unlabeled data for our experiments was taken from the Reuters corpus, TIPSTER corpus (LDC93T3C) and the English Gigaword corpus, third edition (LDC2007T07). As regards the TIP-

<sup>1</sup>The second-order encoding used in our NER experiments is the same as that described in (Sha and Pereira, 2003) except removing IOB-tag of previous position label.

(a) POS-tagging: (WSJ in PTB III)			
# of labels			45
Data set	(WSJ sec. IDs)	# of sent.	# of words
Training	0–18	38,219	912,344

Table 2: Unlabeled data used in our experiments

STER corpus, we extracted all the Wall Street Journal articles published between 1990 and 1992. With the English Gigaword corpus, we extracted articles from five news sources published between 1994 and 1996. The unlabeled data used in this paper is detailed in Table 2. Note that the total size of the unlabeled data reaches 1G-words (one billion tokens).

#### 3.2 Design of JESS-CM

We used the same graph structure as the linear chain CRF for JESS-CM. As regards the design of the feature functions  $f_i$ , Table 3 shows the feature templates used in our experiments. In the table,  $s$  indicates a focused token position.  $X_{s-1:s}$  represents the bi-gram of feature  $X$  obtained from  $s-1$  and  $s$  positions.  $\{X_u\}_{u=A}^B$  indicates that  $u$  ranges from  $A$  to  $B$ . For example,  $\{X_u\}_{u=s-2}^{s+2}$  is equal to five feature templates,  $\{X_{s-2}, X_{s-1}, X_s, X_{s+1}, X_{s+2}\}$ . ‘word type’ or wtp represents features of a word such as capitalization, the existence of digits, and punctuation as shown in (Sutton et al., 2006) without regular expressions. Although it is common to use external

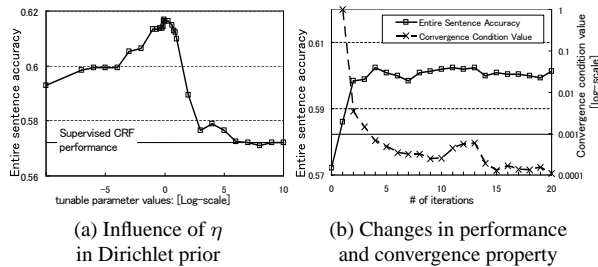

Figure 2: Typical behavior of tunable parameters

resources such as gazetteers for NER, we used none. All our features can be automatically extracted from the given training data.

### 3.3 Design of Joint PMs (HMMs)

We used first order HMMs for embedded joint PMs since we assume that they have the same graph structure as JESS-CM as described in Section 2.2.

To reduce the required human effort, we simply used the feature templates shown in Table 3 to generate the features of the HMMs. With our design, one feature template corresponded to one HMM. This design preserves the feature whereby each HMM emits a single symbol from a single state (or transition). We can easily ignore overlapping features that appear in a single HMM. As a result, 47, 39 and 79 distinct HMMs are embedded in the potential functions of JESS-CM for POS tagging, chunking and NER experiments, respectively.

### 3.4 Tunable Parameters

In our experiments, we selected Gaussian and Dirichlet priors as the prior distributions in  $\mathcal{L}^1$  and

$\mathcal{L}^2$ , respectively. This means that JESS-CM has two tunable parameters,  $\sigma^2$  and  $\eta$ , in the Gaussian and Dirichlet priors, respectively. The values of these tunable parameters are chosen by employing a binary line search. We used the value for the best performance with the development set<sup>2</sup>. However, it may be computationally unrealistic to retrain the entire procedure several times using 1G-words of unlabeled data. Therefore, these tunable parameter values are selected using a relatively small amount of unlabeled data (17M-words), and we used the selected values in all our experiments. The left graph in Figure 2 shows typical  $\eta$  behavior. The left end is equivalent to optimizing  $\mathcal{L}^2$  without a prior, and the right end is almost equivalent to considering  $p_j(\mathbf{x}_j, \mathbf{y})$  for all  $j$  to be a uniform distribution. This is why it appears to be bounded by the performance obtained from supervised CRF. We omitted the influence of  $\sigma^2$  because of space constraints, but its behavior is nearly the same as that of supervised CRF.

Unfortunately,  $\mathcal{L}^2(\Theta|\lambda')$  may have two or more local maxima. Our parameter estimation procedure does not guarantee to provide either the global optimum or a convergence solution in  $\Theta$  and  $\lambda'$  space. An example of non-convergence is the oscillation of the estimated  $\Theta$ . That is,  $\Theta$  traverses two or more local maxima. Therefore, we examined its convergence property experimentally. The right graph in Figure 2 shows a typical convergence property. Fortunately, in all our experiments, JESS-CM converged in a small number of iterations. No oscillation is observed here.

## 4 Results and Discussion

### 4.1 Impact of Unlabeled Data Size

Table 4 shows the performance of JESS-CM using 1G-words of unlabeled data and the performance gain compared with supervised CRF, which is trained under the same conditions as JESS-CM except that joint PMs are not incorporated. We emphasize that our model achieved these large improvements solely using unlabeled data as additional resources, without introducing a sophisticated model, deep feature engineering, handling external hand-

<sup>2</sup>Since CoNLL'00 shared task data has no development set, we divided the labeled training data into two distinct sets, 4/5 for training and the remainder for the development set, and determined the tunable parameters in preliminary experiments.

Figure 3: Performance changes with respect to unlabeled data size in JESS-CM

crafted resources, or task dependent human knowledge (except for the feature design). Our method can greatly reduce the human effort needed to obtain a high performance tagger or chunker.

Figure 3 shows the learning curves of JESS-CM with respect to the size of the unlabeled data, where the x-axis is on the logarithmic scale of the unlabeled data size (Mega-word). The scale at the top of the graph shows the ratio of the unlabeled data size to the labeled data size. We observe that a small amount of unlabeled data hardly improved the performance since the supervised CRF results are competitive. It seems that we require at least dozens of times more unlabeled data than labeled training data to provide a significant performance improvement. The most important and interesting behavior is that the performance improvements against the unlabeled data size are almost linear on a logarithmic scale within the size of the unlabeled data used in our experiments. Moreover, there is a possibility that the performance is still unsaturated at the 1G-word unlabeled data point. This suggests that increasing the unlabeled data in JESS-CM may further improve the performance.

Suppose  $J=1$ , the discriminant function of JESS-CM is  $g(x, \mathbf{y}) = \mathcal{A}(x, \mathbf{y})p_1(x_1, \mathbf{y}; \theta_1)^{\lambda_{I+1}}$  where  $\mathcal{A}(x, \mathbf{y}) = \exp(\lambda \cdot \sum_c \mathbf{f}_c(\mathbf{y}_c, x))$ . Note that both  $\mathcal{A}(x, \mathbf{y})$  and  $\lambda_{I+j}$  are given and fixed during the MDF estimation of joint PM parameters  $\Theta$ . Therefore, the MDF estimation in JESS-CM can be re-

garded as a variant of the MML estimation (see Section 2.2), namely, it is MML estimation with a bias,  $\mathcal{A}(x, \mathbf{y})$ , and smooth factors,  $\lambda_{I+j}$ . MML estimation can be seen as modeling  $p(x)$  since it is equivalent to maximizing  $\sum_m \log p(x^m)$  with marginalized hidden variables  $\mathbf{y}$ , where  $\sum_{\mathbf{y} \in \mathcal{Y}} p(x, \mathbf{y}) = p(x)$ . Generally, more data will lead to a more accurate model of  $p(x)$ . With our method, as with modeling  $p(x)$  in MML estimation, more unlabeled data is preferable since it may provide more accurate modeling. This also means that it provides better ‘clusters’ over the output space since  $\mathcal{Y}$  is used as hidden states in HMMs. These are intuitive explanations as to why more unlabeled data in JESS-CM produces better performance.

## 4.2 Expected Performance for Unseen Data

We try to investigate the impact of unlabeled data on the performance of unseen data. We divide the test set (or the development set) into two disjoint sets: L.app and L.neg app. **L.app** is a set of sentences constructed by words that all **appeared** in the Labeled training data. **L.-app** is a set of sentences that have at least one word that does **not appear** in the Labeled training data.

Table 5 shows the performance with these two sets obtained from both supervised CRF and JESS-CM with 1G-word unlabeled data. As the supervised CRF results, the performance of the L.-app sets is consistently much lower than that of the cor-

eval. data	(a) POS tagging				(b) Chunking		(c) NER			
	development		test		test		development		test	
	L. $\neg$ app (46.1%)	L.app (53.9%)	L. $\neg$ app (40.4%)	L.app (59.6%)	L. $\neg$ app (70.7%)	L.app (29.3%)	L. $\neg$ app (54.3%)	L.app (45.7%)	L. $\neg$ app (64.3%)	L.app (35.7%)

reu(Oct.)	1.3M	20M	93.04	71.0%	88.82	72.0%
reu(Nov.)	1.2M	18M	92.94	68.7%	89.08	74.3%
reu(Dec.)*	9M	15M	92.91	67.0%	89.29	84.4%

Table 6: Influence of U.app in NER experiments: \*(excluding Dec. 06-07)

responding L.app sets. Moreover, we can observe that the ratios of L. $\neg$ app are not so small; nearly half (46.1% and 40.4%) in the PTB III data, and more than half (70.7%, 54.3% and 64.3%) in CoNLL'00 and '03 data, respectively. This indicates that words not appearing in the labeled training data are really harmful for supervised learning. Although the performance with L. $\neg$ app sets is still poorer than with L.app sets, the JESS-CM results indicate that the introduction of unlabeled data effectively improves the performance of L. $\neg$ app sets, even more than that of L.app sets. These improvements are essentially very important; when a tagger and chunker are actually used, input data can be obtained from anywhere and this may mostly include words that do not appear in the given labeled training data since the labeled training data is limited and difficult to increase. This means that the improved performance of L. $\neg$ app can link directly to actual use.

Table 5 also shows the ratios of sentences that are constructed from words that all **appeared** in the 1G-word Unlabeled data used in our experiments (**U.app**) in the L. $\neg$ app and L.app. This indicates that most of the words in the development or test sets are covered by the 1G-word unlabeled data. This may be the main reason for JESS-CM providing large performance gains for both the overall and L. $\neg$ app set performance of all three tasks.

Table 6 shows the relation between JESS-CM performance and U.app in the NER experiments. The development data and test data were obtained from

system	dev.	test	additional resources
<b>JESS-CM</b> (CRF/HMM)	<b>97.35</b>	<b>97.40</b>	1G-word unlabeled data

(Zhang et al., 2002)	94.17	full parser output
(Kudo and Matsumoto, 2001)	93.91	–
[supervised CRF (baseline)]	93.88	–

Table 8: Syntactic chunking results of the previous top systems for CoNLL'00 shared task data ( $F_{\beta=1}$  score)

30-31 Aug. 1996 and 6-7 Dec. 1996 Reuters news articles, respectively. We find that temporal proximity leads to better performance. This aspect can also be explained as U.app. Basically, the U.app increase leads to improved performance.

The evidence provided by the above experiments implies that increasing the coverage of unlabeled data offers the strong possibility of increasing the expected performance of unseen data. Thus, it strongly encourages us to use an SSL approach that includes JESS-CM to construct a general tagger and chunker for actual use.

## 5 Comparison with Previous Top Systems and Related Work

In POS tagging, the previous best performance was reported by (Shen et al., 2007) as summarized in Table 7. Their method uses a novel sophisticated model that learns both decoding order and labeling, while our model uses a standard first order Markov model. Despite using such a simple model, our method can provide a better result with the help of unlabeled data.

system	dev.	test	additional resources
<b>JESS-CM (CRF/HMM)</b>	<b>94.48</b>	<b>89.92</b>	1G-word unlabeled data

[sup. CRF (baseline)]	91.74	86.35	-

Table 9: NER results of the previous top systems for CoNLL’03 shared task data evaluated by  $F_{\beta=1}$  score

As shown in Tables 8 and 9, the previous best performance for syntactic chunking and NER was reported by (Ando and Zhang, 2005), and is referred to as ‘ASO-semi’. ASO-semi also incorporates unlabeled data solely as additional information in the same way as JESS-CM. ASO-semi uses unlabeled data for constructing auxiliary problems that are expected to capture a good feature representation of the target problem. As regards syntactic chunking, JESS-CM significantly outperformed ASO-semi for the same 15M-word unlabeled data size obtained from the Wall Street Journal in 1991 as described in (Ando and Zhang, 2005). Unfortunately with NER, JESS-CM is slightly inferior to ASO-semi for the same 27M-word unlabeled data size extracted from the Reuters corpus. In fact, JESS-CM using 37M-words of unlabeled data provided a comparable result. We observed that ASO-semi prefers ‘nugget extraction’ tasks to ‘field segmentation’ tasks (Grenager et al., 2005). We cannot provide details here owing to the space limitation. Intuitively, their word prediction auxiliary problems can capture only a limited number of characteristic behaviors because the auxiliary problems are constructed by a limited number of ‘binary’ classifiers. Moreover, we should remember that ASO-semi used the human knowledge that ‘named entities mostly consist of nouns or adjectives’ during the auxiliary problem construction in their NER experiments. In contrast, our results require no such additional knowledge or limitation. In addition, the design and training of auxiliary problems as well as calculating SVD are too costly when the size of the unlabeled data increases. These facts imply that our SSL framework is rather appropriate for handling large scale unlabeled data.

On the other hand, ASO-semi and JESS-CM have an important common feature. That is, both meth-

ods discriminatively combine models trained by using unlabeled data in order to create informative feature representation for discriminative learning. Unlike self/co-training approaches (Blum and Mitchell, 1998), which use estimated labels as ‘correct labels’, this approach automatically judges the reliability of additional features obtained from unlabeled data in terms of discriminative training. Ando and Zhang (2007) have also pointed out that this methodology seems to be one key to achieving higher performance in NLP applications.

There is an approach that combines individually and independently trained joint PMs into a discriminative model (Li and McCallum, 2005). There is an essential difference between this method and JESS-CM. We categorize their approach as an ‘indirect approach’ since the outputs of the target task,  $\mathbf{y}$ , are not considered during the unlabeled data incorporation. Note that ASO-semi is also an ‘indirect approach’. On the other hand, our approach is a ‘direct approach’ because the distribution of  $\mathbf{y}$  obtained from JESS-CM is used as ‘seeds’ of hidden states during MDF estimation for joint PM parameters (see Section 4.1). In addition, MDF estimation over unlabeled data can effectively incorporate the ‘labeled’ training data information via a ‘bias’ since  $\lambda$  included in  $\mathcal{A}(\mathbf{x}, \mathbf{y})$  is estimated from labeled training data.

## 6 Conclusion

We proposed a simple yet powerful semi-supervised conditional model, which we call JESS-CM. It is applicable to large amounts of unlabeled data, for example, at the giga-word level. Experimental results obtained by using JESS-CM incorporating 1G-words of unlabeled data have provided the current best performance as regards POS tagging, syntactic chunking, and NER for widely used large test collections such as PTB III, CoNLL’00 and ’03 shared task data, respectively. We also provided evidence that the use of more unlabeled data in SSL can lead to further improvements. Moreover, our experimental analysis revealed that it may also induce an improvement in the expected performance for unseen data in terms of the unlabeled data coverage. Our results may encourage the adoption of the SSL method for many other real world applications.

## Abstract

Paraphrases have proved to be useful in many applications, including Machine Translation, Question Answering, Summarization, and Information Retrieval. Paraphrase acquisition methods that use a single monolingual corpus often produce only syntactic paraphrases. We present a method for obtaining surface paraphrases, using a 150GB (25 billion words) monolingual corpus. Our method achieves an accuracy of around 70% on the paraphrase acquisition task. We further show that we can use these paraphrases to generate surface patterns for relation extraction. Our patterns are much more precise than those obtained by using a state of the art baseline and can extract relations with more than 80% precision for each of the test relations.

## 1 Introduction

Paraphrases are textual expressions that convey the same meaning using different surface words. For example consider the following sentences:

Google *acquired* YouTube. (1)

Google *completed the acquisition of* YouTube. (2)

Since they convey the same meaning, sentences (1) and (2) are sentence level paraphrases, and the phrases “*acquired*” and “*completed the acquisition of*” in (1) and (2) respectively are phrasal paraphrases.

Paraphrases provide a way to capture the variability of language and hence play an important

role in many natural language processing (NLP) applications. For example, in question answering, paraphrases have been used to find multiple patterns that pinpoint the same answer (Ravichandran and Hovy, 2002); in statistical machine translation, they have been used to find translations for unseen source language phrases (Callison-Burch et al., 2006); in multi-document summarization, they have been used to identify phrases from different sentences that express the same information (Barzilay et al., 1999); in information retrieval they have been used for query expansion (Anick and Tipirneni, 1999).

Learning paraphrases requires one to ensure identity of meaning. Since there are no adequate semantic interpretation systems available today, paraphrase acquisition techniques use some other mechanism as a kind of “pivot” to (help) ensure semantic identity. Each pivot mechanism selects phrases with similar meaning in a different characteristic way. A popular method, the so-called distributional similarity, is based on the dictum of Zelig Harris “you shall know the words by the company they keep”: given highly discriminating left and right contexts, only words with very similar meaning will be found to fit in between them. For paraphrasing, this has been often used to find syntactic transformations in parse trees that preserve (semantic) meaning. Another method is to use a bilingual dictionary or translation table as pivot mechanism: all source language words or phrases that translate to a given foreign word/phrase are deemed to be paraphrases of one another. In this paper we call the paraphrases that contain only words as surface paraphrases and those

---

\*Work done during an internship at Google Inc.

that contain paths in a syntax tree as syntactic paraphrases.

We here, present a method to acquire surface paraphrases from a single monolingual corpus. We use a large corpus (about 150GB) to overcome the data sparseness problem. To overcome the scalability problem, we pre-process the text with a simple parts-of-speech (POS) tagger and then apply locality sensitive hashing (LSH) (Charikar, 2002; Ravichandran et al., 2005) to speed up the remaining computation for paraphrase acquisition. Our experiments show results to verify the following main claim:

***Claim 1:** Highly precise surface paraphrases can be obtained from a very large monolingual corpus.*

With this result, we further show that these paraphrases can be used to obtain high precision surface patterns that enable the discovery of relations in a minimally supervised way. Surface patterns are templates for extracting information from text. For example, if one wanted to extract a list of company acquisitions, “⟨ACQUIRER⟩ *acquired* ⟨ACQUIREE⟩” would be one surface pattern with “⟨ACQUIRER⟩” and “⟨ACQUIREE⟩” as the slots to be extracted. Thus we can claim:

***Claim 2:** These paraphrases can then be used for generating high precision surface patterns for relation extraction.*

## 2 Related Work

Most recent work in paraphrase acquisition is based on automatic acquisition. Barzilay and McKeown (2001) used a monolingual parallel corpus to obtain paraphrases. Bannard and Callison-Burch (2005) and Zhou et al. (2006) both employed a bilingual parallel corpus in which each foreign language word or phrase was a pivot to obtain source language paraphrases. Dolan et al. (2004) and Barzilay and Lee (2003) used comparable news articles to obtain sentence level paraphrases. All these approaches rely on the presence of parallel or comparable corpora and are thus limited by their availability and size.

Lin and Pantel (2001) and Szpektor et al. (2004) proposed methods to obtain entailment templates by using a single monolingual resource. While both differ in their approaches, they both end up finding syntactic paraphrases. Their methods cannot be used if

we cannot parse the data (either because of scale or data quality). Our approach on the other hand, finds surface paraphrases; it is more scalable and robust due to the use of simple POS tagging. Also, our use of locality sensitive hashing makes finding similar phrases in a large corpus feasible.

Another task related to our work is relation extraction. Its aim is to extract instances of a given relation. Hearst (1992) the pioneering paper in the field used a small number of hand selected patterns to extract instances of hyponymy relation. Berland and Charniak (1999) used a similar method for extracting instances of meronymy relation. Ravichandran and Hovy (2002) used seed instances of a relation to automatically obtain surface patterns by querying the web. But their method often finds patterns that are too general (e.g., *X and Y*), resulting in low precision extractions. Rosenfeld and Feldman (2006) present a somewhat similar web based method that uses a combination of seed instances and seed patterns to learn good quality surface patterns. Both these methods differ from ours in that they learn relation patterns on the fly (from the web). Our method however, pre-computes paraphrases for a large set of surface patterns using distributional similarity over a large corpus and then obtains patterns for a relation by simply finding paraphrases (offline) for a few seed patterns. Using distributional similarity avoids the problem of obtaining overly general patterns and the pre-computation of paraphrases means that we can obtain the set of patterns for any relation instantaneously.

Romano et al. (2006) and Sekine (2006) used syntactic paraphrases to obtain patterns for extracting relations. While procedurally different, both methods depend heavily on the performance of the syntax parser and require complex syntax tree matching to extract the relation instances. Our method on the other hand acquires surface patterns and thus avoids the dependence on a parser and syntactic matching. This also makes the extraction process scalable.

## 3 Acquiring Paraphrases

This section describes our model for acquiring paraphrases from text.

### 3.1 Distributional Similarity

Harris’s distributional hypothesis (Harris, 1954) has played an important role in lexical semantics. It states that words that appear in similar contexts tend to have similar meanings. In this paper, we apply the distributional hypothesis to phrases i.e. word n-grams.

For example, consider the phrase “*acquired*” of the form “ $X$  *acquired*  $Y$ ”. Considering the context of this phrase, we might find {Google, eBay, Yahoo,...} in position  $X$  and {YouTube, Skype, Overture,...} in position  $Y$ . Now consider another phrase “*completed the acquisition of*”, again of the form “ $X$  *completed the acquisition of*  $Y$ ”. For this phrase, we might find {Google, eBay, Hilton Hotel corp.,...} in position  $X$  and {YouTube, Skype, Bally Entertainment Corp.,...} in position  $Y$ . Since the contexts of the two phrases are similar, our extension of the distributional hypothesis would assume that “*acquired*” and “*completed the acquisition of*” have similar meanings.

### 3.2 Paraphrase Learning Model

Let  $p$  be a phrase (n-gram) of the form  $X p Y$ , where  $X$  and  $Y$  are the placeholders for words occurring on either side of  $p$ . Our first task is to find the set of phrases that are similar in meaning to  $p$ . Let  $P = \{p_1, p_2, p_3, \dots, p_l\}$  be the set of all phrases of the form  $X p_i Y$  where  $p_i \in P$ . Let  $S_{i,X}$  be the set of words that occur in position  $X$  of  $p_i$  and  $S_{i,Y}$  be the set of words that occur in position  $Y$  of  $p_i$ . Let  $V_i$  be the vector representing  $p_i$  such that  $V_i = S_{i,X} \cup S_{i,Y}$ . Each word  $f \in V_i$  has an associated score that measures the strength of the association of the word  $f$  with phrase  $p_i$ ; as do many others, we employ pointwise mutual information (Cover and Thomas, 1991) to measure this strength of association.

$$pmi(p_i; f) = \log \frac{P(p_i, f)}{P(p_i)P(f)} \quad (1)$$

The probabilities in equation (1) are calculated by using the maximum likelihood estimate over our corpus.

Once we have the vectors for each phrase  $p_i \in P$ , we can find the paraphrases for each  $p_i$  by finding its nearest neighbors. We use cosine similarity, which

is a commonly used measure for finding similarity between two vectors.

If we have two phrases  $p_i \in P$  and  $p_j \in P$  with the corresponding vectors  $V_i$  and  $V_j$  constructed as described above, the similarity between the two phrases is calculated as:

$$sim(p_i; p_j) = \frac{V_i \cdot V_j}{|V_i| * |V_j|} \quad (2)$$

Each word in  $V_i$  (and  $V_j$ ) has with it an associated flag which indicates whether the word came from  $S_{i,X}$  or  $S_{i,Y}$ . Hence for each phrase  $p_i$  of the form  $X p_i Y$ , we have a corresponding phrase  $-p_i$  that has the form  $Y p_i X$ . This is important to find certain kinds of paraphrases. The following example will illustrate. Consider the sentences:

Google *acquired* YouTube. (3)

YouTube *was bought by* Google. (4)

From sentence (3), we obtain two phrases:

1.  $p_i =$  *acquired* which has the form “ $X$  *acquired*  $Y$ ” where “ $X =$  Google” and “ $Y =$  YouTube”
2.  $-p_i =$  *-acquired* which has the form “ $Y$  *acquired*  $X$ ” where “ $X =$  YouTube” and “ $Y =$  Google”

Similarly, from sentence (4) we obtain two phrases:

1.  $p_j =$  *was bought by* which has the form “ $X$  *was bought by*  $Y$ ” where “ $X =$  YouTube” and “ $Y =$  Google”
2.  $-p_j =$  *-was bought by* which has the form “ $Y$  *was bought by*  $X$ ” where “ $X =$  Google” and “ $Y =$  YouTube”

The switching of  $X$  and  $Y$  positions in (3) and (4) ensures that “*acquired*” and “*-was bought by*” are found to be paraphrases by the algorithm.

### 3.3 Locality Sensitive Hashing

As described in Section 3.2, we find paraphrases of a phrase  $p_i$  by finding its nearest neighbors based on cosine similarity between the feature vector of  $p_i$  and other phrases. To do this for all the phrases in the corpus, we’ll have to compute the similarity between all vector pairs. If  $n$  is the number of vectors and  $d$  is the dimensionality of the vector space, finding cosine similarity between each pair of vectors has time complexity  $O(n^2 d)$ . This computation is infeasible for our corpus, since both  $n$  and  $d$  are large.

To solve this problem, we make use of Locality Sensitive Hashing (LSH). The basic idea behind LSH is that a LSH function creates a fingerprint for each vector such that if two vectors are similar, they are likely to have similar fingerprints. The LSH function we use here was proposed by Charikar (2002). It represents a  $d$  dimensional vector by a stream of  $b$  bits ( $b \ll d$ ) and has the property of preserving the cosine similarity between vectors, which is exactly what we want. Ravichandran et al. (2005) have shown that by using the LSH nearest neighbors calculation can be done in  $O(nd)$  time.<sup>1</sup>

## 4 Learning Surface Patterns

Let  $r$  be a target relation. Our task is to find a set of surface patterns  $S = \{s_1, s_2, \dots, s_n\}$  that express the target relation. For example, consider the relation  $r = \text{“acquisition”}$ . We want to find the set of patterns  $S$  that express this relation:

$$S = \{ \langle \text{ACQUIRER} \rangle \text{ acquired } \langle \text{ACQUIREE} \rangle, \langle \text{ACQUIRER} \rangle \text{ bought } \langle \text{ACQUIREE} \rangle, \langle \text{ACQUIREE} \rangle \text{ was bought by } \langle \text{ACQUIRER} \rangle, \dots \}.$$

The remainder of the section describes our model for learning surface patterns for target relations.

### 4.1 Model Assumption

Paraphrases express the same meaning using different surface forms. So if one knew a pattern that expresses a target relation, one could build more patterns for that relation by finding paraphrases for the surface phrase(s) in that pattern. This is the basic assumption of our model.

For example, consider the seed pattern “ $\langle \text{ACQUIRER} \rangle$  *acquired*  $\langle \text{ACQUIREE} \rangle$ ” for the target relation “*acquisition*”. The surface phrase in the seed pattern is “*acquired*”. Our model then assumes that we can obtain more surface patterns for “*acquisition*” by replacing “*acquired*” in the seed pattern with its paraphrases i.e.  $\{ \text{bought}, -\text{was bought by}^2, \dots \}$ . The resulting surface patterns are:

<sup>1</sup>The details of the algorithm are omitted, but interested readers are encouraged to read Charikar (2002) and Ravichandran et al. (2005)

<sup>2</sup>The “-” in “-was bought by” indicates that the  $\langle \text{ACQUIRER} \rangle$  and  $\langle \text{ACQUIREE} \rangle$  arguments of the input phrase “*acquired*” need to be switched for the phrase “was bought by”.

$$\{ \langle \text{ACQUIRER} \rangle \text{ bought } \langle \text{ACQUIREE} \rangle, \langle \text{ACQUIREE} \rangle \text{ was bought by } \langle \text{ACQUIRER} \rangle, \dots \}$$

### 4.2 Surface Pattern Model

Let  $r$  be a target relation. Let  $SEED = \{seed_1, seed_2, \dots, seed_n\}$  be the set of seed patterns that express the target relation. For each  $seed_i \in SEED$ , we obtain the corresponding set of new patterns  $PAT_i$  in two steps:

1. We find the surface phrase,  $p_i$ , using a seed and find the corresponding set of paraphrases,  $P_i = \{p_{i,1}, p_{i,2}, \dots, p_{i,m}\}$ . Each paraphrase,  $p_{i,j} \in P_i$ , has with it an associated score which is similarity between  $p_i$  and  $p_{i,j}$ .
2. In seed pattern,  $seed_i$ , we replace the surface phrase,  $p_i$ , with its paraphrases and obtain the set of new patterns  $PAT_i = \{pat_{i,1}, pat_{i,2}, \dots, pat_{i,m}\}$ . Each pattern has with it an associated score, which is the same as the score of the paraphrase from which it was obtained<sup>3</sup>. The patterns are ranked in the decreasing order of their scores.

After we obtain  $PAT_i$  for each  $seed_i \in SEED$ , we obtain the complete set of patterns,  $PAT$ , for the target relation  $r$  as the union of all the individual pattern sets, i.e.,  $PAT = PAT_1 \cup PAT_2 \cup \dots \cup PAT_n$ .

## 5 Experimental Methodology

In this section, we describe experiments to validate the main claims of the paper. We first describe paraphrase acquisition, we then summarize our method for learning surface patterns, and finally describe the use of patterns for extracting relation instances.

### 5.1 Paraphrases

Finding surface variations in text requires a large corpus. The corpus needs to be orders of magnitude larger than that required for learning syntactic variations, since surface phrases are sparser than syntactic phrases.

For our experiments, we used a corpus of about 150GB (25 billion words) obtained from Google News<sup>4</sup>. It consists of few years worth of news data.

<sup>3</sup>If a pattern is generated from more than one seed, we assign it its average score.

<sup>4</sup>The corpus was cleaned to remove duplicate articles.

We POS tagged the corpus using Tnt tagger (Brants, 2000) and collected all phrases (n-grams) in the corpus that contained at least one verb, and had a noun or a noun-noun compound on either side. We restricted the phrase length to at most five words.

We build a vector for each phrase as described in Section 3. To mitigate the problem of sparseness and co-reference to a certain extent, whenever we have a noun-noun compound in the  $X$  or  $Y$  positions, we treat it as bag of words. For example, in the sentence “Google Inc. *acquired* YouTube”, “Google” and “Inc.” will be treated as separate features in the vector<sup>5</sup>.

Once we have constructed all the vectors, we find the paraphrases for every phrase by finding its nearest neighbors as described in Section 3. For our experiments, we set the number of random bits in the LSH function to 3000, and the similarity cut-off between vectors to 0.15. We eventually end up with a resource containing over 2.5 million phrases such that each phrase is connected to its paraphrases.

## 5.2 Surface Patterns

One claim of this paper is that we can find good surface patterns for a target relation by starting with a seed pattern. To verify this, we study two target relations<sup>6</sup>:

1. **Acquisition:** *We define this as the relation between two companies such that one company acquired the other.*
2. **Birthplace:** *We define this as the relation between a person and his/her birthplace.*

For “*acquisition*” relation, we start with the surface patterns containing only the words *buy* and *acquire*:

1. “⟨ACQUIRER⟩ *bought* ⟨ACQUIREE⟩” (and its variants, i.e. *buy*, *buys* and *buying*)
2. “⟨ACQUIRER⟩ *acquired* ⟨ACQUIREE⟩” (and its variants, i.e. *acquire*, *acquires* and *acquiring*)

<sup>5</sup>This adds some noise in the vectors, but we found that this results in better paraphrases.

<sup>6</sup>Since we have to do all the annotations for evaluations on our own, we restricted our experiments to only two commonly used relations.

This results in a total of eight seed patterns.

For “*birthplace*” relation, we start with two seed patterns:

1. “⟨PERSON⟩ *was born in* ⟨LOCATION⟩”
2. “⟨PERSON⟩ *was born at* ⟨LOCATION⟩”.

We find other surface patterns for each of these relations by replacing the surface words in the seed patterns by their paraphrases, as described in Section 4.

## 5.3 Relation Extraction

The purpose of learning surface patterns for a relation is to extract instances of that relation. We use the surface patterns obtained for the relations “*acquisition*” and “*birthplace*” to extract instances of these relations from the LDC North American News Corpus. This helps us to extrinsically evaluate the quality of the surface patterns.

## 6 Experimental Results

In this section, we present the results of the experiments and analyze them.

### 6.1 Baselines

It is hard to construct a baseline for comparing the quality of paraphrases, as there isn’t much work in extracting surface level paraphrases using a monolingual corpus. To overcome this, we show the effect of reduction in corpus size on the quality of paraphrases, and compare the results informally to the other methods that produce syntactic paraphrases.

To compare the quality of the extraction patterns, and relation instances, we use the method presented by Ravichandran and Hovy (2002) as the baseline. For each of the given relations, “*acquisition*” and “*birthplace*”, we use 10 seed instances, download the top 1000 results from the Google search engine for each instance, extract the sentences that contain the instances, and learn the set of baseline patterns for each relation. We then apply these patterns to the test corpus and extract the corresponding baseline instances.

### 6.2 Evaluation Criteria

Here we present the evaluation criteria we used to evaluate the performance on the different tasks.

## Paraphrases

We estimate the quality of paraphrases by annotating a random sample as correct/incorrect and calculating the accuracy. However, estimating the recall is difficult given that we do not have a complete set of paraphrases for the input phrases. Following Szpektor et al. (2004), instead of measuring recall, we calculate the average number of correct paraphrases per input phrase.

## Surface Patterns

We can calculate the precision ( $P$ ) of learned patterns for each relation by annotating the extracted patterns as correct/incorrect. However calculating the recall is a problem for the same reason as above. But we can calculate the relative recall ( $RR$ ) of the system against the baseline and vice versa. The relative recall  $RR_{S|B}$  of system  $S$  with respect to system  $B$  can be calculated as:

$$RR_{S|B} = \frac{C_S \cap C_B}{C_B}$$

where  $C_S$  is the number of correct patterns found by our system and  $C_B$  is the number of correct patterns found by the baseline.  $RR_{B|S}$  can be found in a similar way.

## Relation Extraction

We estimate the precision ( $P$ ) of the extracted instances by annotating a random sample of instances as correct/incorrect. While calculating the true recall here is not possible, even calculating the true relative recall of the system against the baseline is not possible as we can annotate only a small sample. However, following Pantel et al. (2004), we assume that the recall of the baseline is 1 and estimate the relative recall  $RR_{S|B}$  of the system  $S$  with respect to the baseline  $B$  using their respective precision scores  $P_S$  and  $P_B$  and number of instances extracted by them  $|S|$  and  $|B|$  as:

$$RR_{S|B} = \frac{P_S * |S|}{P_B * |B|}$$

## 6.3 Gold Standard

In this section, we describe the creation of gold standard for the different tasks.

### Paraphrases

We created the gold standard paraphrase test set by randomly selecting 50 phrases and their corresponding paraphrases from our collection of 2.5 million

phrases. For each test phrase, we asked two annotators to annotate its paraphrases as correct/incorrect. The annotators were instructed to look for strict paraphrases i.e. equivalent phrases that can be substituted for each other.

To obtain the inter-annotator agreement, the two annotators annotated the test set separately. The kappa statistic (Siegal and Castellan Jr., 1988) was  $\kappa = 0.63$ . The interesting thing is that the annotators got this respectable kappa score without any prior training, which is hard to achieve when one annotates for a similar task like textual entailment.

### Surface Patterns

For the target relations, we asked two annotators to annotate the patterns for each relation as either “precise” or “vague”. The annotators annotated the system as well as the baseline outputs. We consider the “precise” patterns as correct and the “vague” as incorrect. The intuition is that applying the vague patterns for extracting target relation instances might find some good instances, but will also find many bad ones. For example, consider the following two patterns for the “*acquisition*” relation:

⟨ACQUIRER⟩ *acquired* ⟨ACQUIREE⟩ (5)

⟨ACQUIRER⟩ *and* ⟨ACQUIREE⟩ (6)

Example (5) is a precise pattern as it clearly identifies the “*acquisition*” relation while example (6) is a vague pattern because it is too general and says nothing about the “*acquisition*” relation. The kappa statistic between the two annotators for this task was  $\kappa = 0.72$ .

### Relation Extraction

We randomly sampled 50 instances of the “*acquisition*” and “*birthplace*” relations from the system and the baseline outputs. We asked two annotators to annotate the instances as correct/incorrect. The annotators marked an instance as correct only if both the entities and the relation between them were correct. To make their task easier, the annotators were provided the context for each instance, and were free to use any resources at their disposal (including a web search engine), to verify the correctness of the instances. The annotators found that the annotation for this task was much easier than the previous two; the few disagreements they had were due to ambiguity of some of the instances. The kappa statistic for this task was  $\kappa = 0.91$ .

Annotator	Accuracy	Average # correct paraphrases
Annotator 1	67.31%	4.2
Annotator 2	74.27%	4.28

will be distributed to all	approved a new

Table 2: Example paraphrases

## 6.4 Result Summary

Table 1 shows the results of annotating the paraphrases test set. We do not have a baseline to compare against but we can analyze them in light of numbers reported previously for syntactic paraphrases. DIRT (Lin and Pantel, 2001) and TEASE (Szpektor et al., 2004) report accuracies of 50.1% and 44.3% respectively compared to our average accuracy across two annotators of 70.79%. The average number of paraphrases per phrase is however 10.1 and 5.5 for DIRT and TEASE respectively compared to our 4.2. One reason why this number is lower is that our test set contains completely random phrases from our set (2.5 million phrases): some of these phrases are rare and have very few paraphrases. Table 2 shows some paraphrases generated by our system for the phrases “*are being distributed to*” and “*approved a revision to the*”.

Table 3 shows the results on the quality of surface patterns for the two relations. It can be observed that our method outperforms the baseline by a wide margin in both precision and relative recall. Table 4 shows some example patterns learned by our system.

Table 5 shows the results of the quality of extracted instances. Our system obtains very high precision scores but suffers in relative recall given that the baseline with its very general patterns is likely to find a huge number of instances (though a very small portion of them are correct). Table 6 shows some example instances we extracted.

acquisition	birthplace
<i>X agreed to buy Y</i>	<i>X , who was born in Y</i>
<i>X , which acquired Y</i>	<i>X , was born in Y</i>
<i>X completed its acquisition of Y</i>	<i>X was raised in Y</i>
<i>X has acquired Y</i>	<i>X was born in NNNN<sup>a</sup> in Y</i>
<i>X purchased Y</i>	<i>X , born in Y</i>

<sup>a</sup>Each “N” here is a placeholder for a number from 0 to 9.

Table 4: Example extraction templates

acquisition	birthplace
1. <i>Huntington Bancshares Inc. agreed to acquire Reliance Bank</i>	1. <i>Cyril Andrew Ponnampereuma was born in Galle</i>
2. <i>Sony bought Columbia Pictures</i>	2. <i>Cook was born in NNNN in Devonshire</i>
3. <i>Hanson Industries buys Kidde Inc.</i>	3. <i>Tansey was born in Cincinnati</i>
4. <i>Casino America inc. agreed to buy Grand Palais</i>	4. <i>Tsoi was born in NNNN in Uzbekistan</i>
5. <i>Tidewater inc. acquired Hornbeck Offshore Services Inc.</i>	5. <i>Mrs. Totenberg was born in San Francisco</i>

## 6.5 Discussion and Error Analysis

We studied the effect of the decrease in size of the available raw corpus on the quality of the acquired paraphrases. We used about 10% of our original corpus to learn the surface paraphrases and evaluated them. The precision, and the average number of correct paraphrases are calculated on the same test set, as described in Section 6.2. The performance drop on using 10% of the original corpus is significant (11.41% precision and on an average 1 correct paraphrase per phrase), which shows that we indeed need a large amount of data to learn good quality surface paraphrases. One reason for this drop is also that when we use only 10% of the original data, for some of the phrases from the test set, we do not find any paraphrases (thus resulting in 0% accuracy for them). This is not unexpected, as the larger resource would have a much larger recall, which again points at the advantage of using a large data set. Another reason for this performance drop could be the parameter settings: We found that the quality of learned paraphrases depended greatly on the various cut-offs used. While we adjusted our model

Relation	Method	# Patterns	Annotator 1		Annotator 2	
			<i>P</i>	<i>RR</i>	<i>P</i>	<i>RR</i>
Acquisition	Baseline	160	55%	13.02%	60%	11.16%
	Paraphrase Method	231	<b>83.11%</b>	<b>28.40%</b>	<b>93.07%</b>	<b>25%</b>
Birthplace	Baseline	16	31.35%	15.38%	31.25%	15.38%
	Paraphrase Method	16	<b>81.25%</b>	<b>40%</b>	<b>81.25%</b>	<b>40%</b>

	Paraphrase Method	1811	<b>98%</b>	4.53%	<b>98%</b>	9.06%

Table 5: Quality of instances

parameters for working with smaller sized data, it is conceivable that we did not find the ideal setting for them. So we consider these numbers to be a lower bound. But even then, these numbers clearly indicate the advantage of using more data.

We also manually inspected our paraphrases. We found that the problem of “antonyms” was somewhat less pronounced due to our use of a large corpus, but they still were the major source of error. For example, our system finds the phrase “*sell*” as a paraphrase for “*buy*”. We need to deal with this problem separately in the future (may be as a post-processing step using a list of antonyms).

Moving to the task of relation extraction, we see from table 5 that our system has a much lower relative recall compared to the baseline. This was expected as the baseline method learns some very general patterns, which are likely to extract some good instances, even though they result in a huge hit to its precision. However, our system was able to obtain this performance using very few seeds. So an increase in the number of input seeds, is likely to increase the relative recall of the resource. The question however remains as to what good seeds might be. It is clear that it is much harder to come up with good seed patterns (that our system needs), than seed instances (that the baseline needs). But there are some obvious ways to overcome this problem. One way is to bootstrap. We can look at the paraphrases of the seed patterns and use them to obtain more patterns. Our initial experiments with this method using handpicked seeds showed good promise. However,

we need to investigate automating this approach. Another method is to use the good patterns from the baseline system and use them as seeds for our system. We plan to investigate this approach as well. One reason, why we have seen good preliminary results using these approaches (for improving recall), we believe, is that the precision of the paraphrases is good. So either a seed doesn’t produce any new patterns or it produces good patterns, thus keeping the precision of the system high while increasing relative recall.

## 7 Conclusion

Paraphrases are an important technique to handle variations in language. Given their utility in many NLP tasks, it is desirable that we come up with methods that produce good quality paraphrases. We believe that the paraphrase acquisition method presented here is a step towards this very goal. We have shown that high precision surface paraphrases can be obtained by using distributional similarity on a large corpus. We made use of some recent advances in theoretical computer science to make this task scalable. We have also shown that these paraphrases can be used to obtain high precision extraction patterns for information extraction. While we believe that more work needs to be done to improve the system recall (some of which we are investigating), this seems to be a good first step towards developing a minimally supervised, easy to implement, and scalable relation extraction system.

## Abstract

The validity of semantic inferences depends on the contexts in which they are applied. We propose a generic framework for handling contextual considerations within applied inference, termed *Contextual Preferences*. This framework defines the various context-aware components needed for inference and their relationships. Contextual preferences extend and generalize previous notions, such as selectional preferences, while experiments show that the extended framework allows improving inference quality on real application data.

## 1 Introduction

Applied semantic inference is typically concerned with inferring a target meaning from a given text. For example, to answer “*Who wrote Idomeneo?*”, Question Answering (QA) systems need to infer the target meaning ‘Mozart wrote Idomeneo’ from a given text “*Mozart composed Idomeneo*”. Following common Textual Entailment terminology (Giampiccolo et al., 2007), we denote the target meaning by  $h$  (for *hypothesis*) and the given text by  $t$ .

A typical applied inference operation is *matching*. Sometimes,  $h$  can be directly matched in  $t$  (in the example above, if the given sentence would be literally “*Mozart wrote Idomeneo*”). Generally, the target meaning can be expressed in  $t$  in many different ways. Indirect matching is then needed, using inference knowledge that may be captured through rules, termed here *entailment rules*. In our example, ‘Mozart wrote Idomeneo’ can be inferred using the rule ‘ $X$  compose  $Y \rightarrow X$  write  $Y$ ’. Recently,

several algorithms were proposed for automatically learning entailment rules and paraphrases (viewed as bi-directional entailment rules) (Lin and Pantel, 2001; Ravichandran and Hovy, 2002; Shinyama et al., 2002; Szpektor et al., 2004; Sekine, 2005).

A common practice is to try matching the structure of  $h$ , or of the left-hand-side of a rule  $r$ , within  $t$ . However, context should be considered to allow valid matching. For example, suppose that to find acquisitions of companies we specify the target *template hypothesis* (a hypothesis with variables) ‘ $X$  acquire  $Y$ ’. This  $h$  should not be matched in “*children acquire language quickly*”, because in this context  $Y$  is not a company. Similarly, the rule ‘ $X$  charge  $Y \rightarrow X$  accuse  $Y$ ’ should not be applied to “*This store charged my account*”, since the assumed sense of ‘charge’ in the rule is different than its sense in the text. Thus, the intended contexts for  $h$  and  $r$  and the context within the given  $t$  should be properly matched to verify valid inference.

Context matching at inference time was often approached in an application-specific manner (Harabagiu et al., 2003; Patwardhan and Riloff, 2007). Recently, some generic methods were proposed to handle context-sensitive inference (Dagan et al., 2006; Pantel et al., 2007; Downey et al., 2007; Connor and Roth, 2007), but these usually treat only a single aspect of context matching (see Section 6). We propose a comprehensive framework for handling various contextual considerations, termed *Contextual Preferences*. It extends and generalizes previous work, defining the needed contextual components and their relationships. We also present and implement concrete representation models and un-

supervised matching methods for these components. While our presentation focuses on semantic inference using lexical-syntactic structures, the proposed framework and models seem suitable for other common types of representations as well.

We applied our models to a test set derived from the ACE 2005 event detection task, a standard Information Extraction (IE) benchmark. We show the benefits of our extended framework for textual inference and present component-wise analysis of the results. To the best of our knowledge, these are also the first unsupervised results for event argument extraction in the ACE 2005 dataset.

## 2 Contextual Preferences

### 2.1 Notation

As mentioned above, we follow the generic Textual Entailment (TE) setting, testing whether a target meaning hypothesis  $h$  can be inferred from a given text  $t$ . We allow  $h$  to be either a text or a *template*, a text fragment with variables. For example, “*The stock rose 8%*” entails an instantiation of the template hypothesis ‘ $X$  gain  $Y$ ’. Typically,  $h$  represents an information need requested in some application, such as a target predicate in IE.

In this paper, we focus on parse-based lexical-syntactic representation of texts and hypotheses, and on the basic inference operation of *matching*. Following common practice (de Salvo Braz et al., 2005; Romano et al., 2006; Bar-Haim et al., 2007),  $h$  is syntactically matched in  $t$  if it can be embedded in  $t$ ’s parse tree. For template hypotheses, the matching induces a mapping between  $h$ ’s variables and their instantiation in  $t$ .

Matching  $h$  in  $t$  can be performed either directly or indirectly using entailment rules. An *entailment rule*  $r$ : ‘ $LHS \rightarrow RHS$ ’ is a directional entailment relation between two templates.  $h$  is matched in  $t$  using  $r$  if  $LHS$  is matched in  $t$  and  $h$  matches  $RHS$ . In the example above,  $r$ : ‘ $X$  rise  $Y \rightarrow X$  gain  $Y$ ’ allows us to entail ‘ $X$  gain  $Y$ ’, with “stock” and “8%” instantiating  $h$ ’s variables. We denote  $vars(z)$  the set of variables of  $z$ , where  $z$  is a template or a rule.

### 2.2 Motivation

When matching considers only the structure of hypotheses, texts and rules it may result in incorrect

inference due to contextual mismatches. For example, an IE system may identify mentions of public demonstrations using the hypothesis  $h$ : ‘ $X$  demonstrate’ . However,  $h$  should not be matched in “*Engineers demonstrated the new system*”, due to a mismatch between the intended sense of ‘demonstrate’ in  $h$  and its sense in  $t$ . Similarly, when looking for physical attack mentions using the hypothesis ‘ $X$  attack  $Y$ ’, we should not utilize the rule  $r$ : ‘ $X$  accuse  $Y \rightarrow X$  attack  $Y$ ’, due to a mismatch between a verbal attack in  $r$  and an intended physical attack in  $h$ . Finally,  $r$ : ‘ $X$  produce  $Y \rightarrow X$  lay  $Y$ ’ (applicable when  $X$  refers to poultry and  $Y$  to eggs) should not be matched in  $t$ : “*Bugatti produce the fastest cars*”, due to a mismatch between the meanings of ‘produce’ in  $r$  and  $t$ . Overall, such incorrect inferences may be avoided by considering contextual information for  $t$ ,  $h$  and  $r$  during their matching process.

### 2.3 The Contextual Preferences Framework

We propose the *Contextual Preferences* (CP) framework for addressing context at inference time. In this framework, the representation of an object  $z$ , where  $z$  may be a text, a template or an entailment rule, is enriched with contextual information denoted  $cp(z)$ . This information helps constraining or disambiguating the meaning of  $z$ , and is used to validate proper matching between pairs of objects.

We consider two components within  $cp(z)$ : (a) a representation for the global (“topical”) context in which  $z$  typically occurs, denoted  $cp_g(z)$ ; (b) a representation for the preferences and constraints (“hard” preferences) on the possible terms that can instantiate variables within  $z$ , denoted  $cp_v(z)$ . For example,  $cp_v(‘X$  produce  $Y \rightarrow X$  lay  $Y$ ’) may specify that  $X$ ’s instantiations should be similar to “chicken” or “duck”.

Contextual Preferences are used when entailment is assessed between a text  $t$  and a hypothesis  $h$ , either directly or by utilizing an entailment-rule  $r$ . On top of structural matching, we now require that the Contextual Preferences of the participants in the inference will also match. When  $h$  is directly matched in  $t$ , we require that each component in  $cp(h)$  will be matched with its counterpart in  $cp(t)$ . When  $r$  is utilized, we additionally require that  $cp(r)$  will be matched with both  $cp(t)$  and  $cp(h)$ . Figure 1 summarizes the matching relationships between the CP

Figure 1: The directional matching relationships between a hypothesis ( $h$ ), an entailment rule ( $r$ ) and a text ( $t$ ) in the Contextual Preferences framework.

components of  $h$ ,  $t$  and  $r$ .

Like Textual Entailment inference, Contextual Preferences matching is directional. When matching  $h$  with  $t$  we require that the global context preferences specified by  $cp_g(h)$  would subsume those induced by  $cp_g(t)$ , and that the instantiations of  $h$ 's variables in  $t$  would adhere to the preferences in  $cp_v(h)$  (since  $t$  should entail  $h$ , but not necessarily vice versa). For example, if the preferred global context of a hypothesis is sports, it would match a text that discusses the more specific topic of basketball.

To implement the CP framework, concrete models are needed for each component, specifying its representation, how it is constructed, and an appropriate matching procedure. Section 3 describes the specific CP models that were implemented in this paper.

The CP framework provides a generic view of contextual modeling in applied semantic inference. Mapping from a specific application to the generic framework follows the mappings assumed in the Textual Entailment paradigm. For example, in QA the hypothesis to be proved corresponds to the affirmative template derived from the question (e.g.  $h$ : 'X invented the PC' for "Who invented the PC?"). Thus,  $cp_g(h)$  can be constructed with respect to the question's focus while  $cp_v(h)$  may be generated from the expected answer type (Moldovan et al., 2000; Harabagiu et al., 2003). Construction of hypotheses' CP for IE is demonstrated in Section 4.

### 3 Contextual Preferences Models

This section presents the current models that we implemented for the various components of the CP framework. For each component type we describe its representation, how it is constructed, and a cor-

responding unsupervised match score. Finally, the different component scores are combined to yield an overall match score, which is used in our experiments to rank inference instances by the likelihood of their validity. Our goal in this paper is to cover the entire scope of the CP framework by including specific models that were proposed in previous work, where available, and elsewhere propose initial models to complete the CP scope.

#### 3.1 Contextual Preferences for Global Context

To represent the global context of an object  $z$  we utilize Latent Semantic Analysis (LSA) (Deerwester et al., 1990), a well-known method for representing the contextual-usage of words based on corpus statistics. We use LSA analysis of the BNC corpus<sup>1</sup>, in which every term is represented by a normalized vector of the top 100 SVD dimensions, as described in (Gliozzo, 2005).

To construct  $cp_g(z)$  we first collect a set of terms that are representative for the preferred general context of  $z$ . Then, the (single) vector which is the sum of the LSA vectors of the representative terms becomes the representation of  $cp_g(z)$ . This LSA vector captures the "average" typical contexts in which the representative terms occur.

The set of representative terms for a text  $t$  consists of all the nouns and verbs in it, represented by their lemma and part of speech. For a rule  $r$ : ' $LHS \rightarrow RHS$ ', the representative terms are the words appearing in  $LHS$  and in  $RHS$ . For example, the representative terms for ' $X$  divorce  $Y \rightarrow X$  marry  $Y$ ' are  $\{divorce:v, marry:v\}$ . As mentioned earlier, construction of hypotheses and their contextual preferences depends on the application at hand. In our experiments these are defined manually, as described in Section 4, derived from the manual definitions of target meanings in the IE data.

The score of matching the  $cp_g$  components of two objects, denoted by  $m_g(\cdot, \cdot)$ , is the Cosine similarity of their LSA vectors. Negative values are set to 0.

#### 3.2 Contextual Preferences for Variables

##### 3.2.1 Representation

For comparison with prior work, we follow (Pantel et al., 2007) and represent preferences for vari-

<sup>1</sup><http://www.natcorp.ox.ac.uk/>

able instantiations using a distributional approach, and in addition incorporate a standard specification of named-entity types. Thus,  $cp_v$  is represented by two lists. The first list, denoted  $cp_{v:e}$ , contains examples for valid instantiations of that variable. For example,  $cp_{v:e}(X \text{ kill } Y \rightarrow Y \text{ die of } X)$  may be  $[X: \{\textit{snakebite}, \textit{disease}\}, Y: \{\textit{man}, \textit{patient}\}]$ . The second list, denoted  $cp_{v:n}$ , contains the variable’s preferred named-entity types (if any). For example,  $cp_{v:n}(X \text{ born in } Y)$  may be  $[X: \{\textit{Person}\}, Y: \{\textit{Location}\}]$ . We denote  $cp_{v:e}(z)[j]$  and  $cp_{v:n}(z)[j]$  as the lists for a specific variable  $j$  of the object  $z$ .

For a text  $t$ , in which a template  $p$  is matched, the preference  $cp_{v:e}(t)$  for each template variable is simply its instantiation in  $t$ . For example, when ‘ $X$  eat  $Y$ ’ is matched in  $t$ : “*Many Americans eat fish regularly*”, we construct  $cp_{v:e}(t) = [X: \{\textit{Many Americans}\}, Y: \{\textit{fish}\}]$ . Similarly,  $cp_{v:n}(t)$  for each variable is the named-entity type of its instantiation in  $t$  (if it is a named entity). We identify entity types using the default Lingpipe<sup>2</sup> Named-Entity Recognizer (NER), which recognizes the types *Location*, *Person* and *Organization*. In the above example,  $cp_{v:n}(t)[X]$  would be  $\{\textit{Person}\}$ .

For a rule  $r: LHS \rightarrow RHS$ , we automatically add to  $cp_{v:e}(r)$  all the variable instantiations that were found common for both  $LHS$  and  $RHS$  in a corpus (see Section 4), as in (Pantel et al., 2007; Pennacchiotti et al., 2007). To construct  $cp_{v:n}(r)$ , we currently use a simple approach where each individual term in  $cp_{v:e}(r)$  is analyzed by the NER system, and its type (if any) is added to  $cp_{v:n}(r)$ .

For a template hypothesis, we currently represent  $cp_v(h)$  only by its list of preferred named-entity types,  $cp_{v:n}$ . Similarly to  $cp_g(h)$ , the preferred types for each template variable were adapted from those defined in our IE data (see Section 4).

To allow compatible comparisons with previous work (see Sections 5 and 6), we utilize in this paper only  $cp_{v:e}$  when matching between  $cp_v(r)$  and  $cp_v(t)$ , as only this representation was examined in prior work on context-sensitive rule applications.  $cp_{v:n}$  is utilized for context matches involving  $cp_v(h)$ . We denote the score of matching two  $cp_v$  components by  $m_v(\cdot, \cdot)$ .

<sup>2</sup><http://www.alias-i.com/lingpipe/>

### 3.2.2 Matching $cp_{v:e}$

Our primary matching method is based on replicating the best-performing method reported in (Pantel et al., 2007), which utilizes the CBC distributional word clustering algorithm (Pantel, 2003). In short, this method extends each  $cp_{v:e}$  list with CBC clusters that contain at least one term in the list, scoring them according to their “relevancy”. The score of matching two  $cp_{v:e}$  lists, denoted here  $S_{CBC}(\cdot, \cdot)$ , is the score of the highest scoring member that appears in both lists.

We applied the final binary match score presented in (Pantel et al., 2007), denoted here  $binaryCBC: m_{v:e}(r, t)$  is 1 if  $S_{CBC}(r, t)$  is above a threshold and 0 otherwise. As a more natural ranking method, we also utilize  $S_{CBC}$  directly, denoted  $rankedCBC$ , having  $m_{v:e}(r, t) = S_{CBC}(r, t)$ .

In addition, we tried a simpler method that directly compares the terms in two  $cp_{v:e}$  lists, utilizing the commonly-used term similarity metric of (Lin, 1998a). This method, denoted  $LIN$ , uses the same raw distributional data as CBC but computes only pair-wise similarities, without any clustering phase. We calculated the scores of the 1000 most similar terms for every term in the Reuters RVC1 corpus<sup>3</sup>. Then, a directional similarity of term  $a$  to term  $b$ ,  $s(a, b)$ , is set to be their similarity score if  $a$  is in  $b$ ’s 1000 most similar terms and 0 otherwise. The final score of matching  $r$  with  $t$  is determined by a nearest-neighbor approach, as the score of the most similar pair of terms in the corresponding two lists of the same variable:  $m_{v:e}(r, t) = \max_{j \in vars(r)} [\max_{a \in cp_{v:e}(t)[j], b \in cp_{v:e}(r)[j]} [s(a, b)]]$ .

### 3.2.3 Matching $cp_{v:n}$

We use a simple scoring mechanism for comparing between two named-entity types  $a$  and  $b$ ,  $s(a, b)$ : 1 for identical types and 0.8 otherwise.

A variable  $j$  has a single preferred entity type in  $cp_{v:n}(t)[j]$ , the type of its instantiation in  $t$ . However, it can have several preferred types for  $h$ . When matching  $h$  with  $t$ ,  $j$ ’s match score is that of its highest scoring type, and the final score is the product of all variable scores:  $m_{v:n}(h, t) = \prod_{j \in vars(h)} (\max_{a \in cp_{v:n}(h)[j]} [s(a, cp_{v:n}(t)[j])])$ .

Variable  $j$  may also have several types in  $r$ , the

<sup>3</sup><http://about.reuters.com/researchandstandards/corpus/>

types of the common arguments in  $cp_{v:e}(r)$ . When matching  $h$  with  $r$ ,  $s(a, cp_{v:n}(t)[j])$  is replaced with the average score for  $a$  and each type in  $cp_{v:n}(r)[j]$ .

### 3.3 Overall Score for a Match

A final score for a given match, denoted  $allCP$ , is obtained by the product of all six matching scores of the various CP components (multiplying by 1 if a component score is missing). The six scores are the results of matching any of the two components of  $h$ ,  $t$  and  $r$ :  $m_g(h, t)$ ,  $m_v(h, t)$ ,  $m_g(h, r)$ ,  $m_v(h, r)$ ,  $m_g(r, t)$  and  $m_v(r, t)$  (as specified above,  $m_v(r, t)$  is based on matching  $cp_{v:e}$  while  $m_v(h, r)$  and  $m_v(h, t)$  are based on matching  $cp_{v:n}$ ). We use  $rankedCBC$  for calculating  $m_v(r, t)$ .

Unlike previous work (e.g. (Pantel et al., 2007)), we also utilize the *prior* score of a rule  $r$ , which is provided by the rule-learning algorithm (see next section). We denote by  $allCP+pr$  the final match score obtained by the product of the  $allCP$  score with the prior score of the matched rule.

## 4 Experimental Settings

Evaluating the contribution of Contextual Preferences models requires: (a) a sample of test hypotheses, and (b) a corresponding corpus that contains sentences which entail these hypotheses, where all hypothesis matches (either direct or via rules) are annotated. We found that the available event mention annotations in the ACE 2005 training set<sup>4</sup> provide a useful test set that meets these generic criteria, with the added value of a standard real-world dataset.

The ACE annotation includes 33 types of events, for which all event mentions are annotated in the corpus. The annotation of each mention includes the instantiated arguments for the predicates, which represent the participants in the event, as well as general attributes such as time and place. ACE guidelines specify for each event type its possible arguments, where all arguments are optional. Each argument is associated with a semantic role and a list of possible named-entity types. For instance, an *Injure* event may have the arguments  $\{Agent, Victim, Instrument, Time, Place\}$ , where *Victim* should be a person.

For each event type we manually created a small set of template hypotheses that correspond to the

given event predicate, and specified the appropriate semantic roles for each variable. We considered only binary hypotheses, due to the type of available entailment rules (see below). For *Injure*, the set of hypotheses included ‘*A injure V*’ and ‘*injure V in T*’ where  $role(A)=\{Agent, Instrument\}$ ,  $role(V)=\{Victim\}$ , and  $role(T)=\{Time, Place\}$ . Thus, correct match of an argument corresponds to correct role identification. The templates were represented as Minipar (Lin, 1998b) dependency parse-trees.

The Contextual Preferences for  $h$  were constructed manually: the named-entity types for  $cp_{v:n}(h)$  were set by adapting the entity types given in the guidelines to the types supported by the Lingpipe NER (described in Section 3.2).  $cp_g(h)$  was generated from a short list of nouns and verbs that were extracted from the verbal event definition in the ACE guidelines. For *Injure*, this list included  $\{injure:v, injury:n, wound:v\}$ . This assumes that when writing down an event definition the user would also specify such representative keywords.

Entailment-rules for a given  $h$  (rules in which *RHS* is equal to  $h$ ) were learned automatically by the *DIRT* algorithm (Lin and Pantel, 2001), which also produces a quality score for each rule. We implemented a canonized version of *DIRT* (Szpektor and Dagan, 2007) on the Reuters corpus parsed by Minipar. Each rule’s arguments for  $cp_v(r)$  were also collected from this corpus.

We assessed the CP framework by its ability to correctly rank, for each predicate (event), all the candidate entailing mentions that are found for it in the test corpus. Such ranking evaluation is suitable for unsupervised settings, with a perfect ranking placing all correct mentions before any incorrect ones. The candidate mentions are found in the parsed test corpus by matching the specified event hypotheses, either directly or via the given set of entailment rules, using a syntactic matcher similar to the one in (Szpektor and Dagan, 2007). Finally, the mentions are ranked by their match scores, as described in Section 3.3. As detailed in the next section, those candidate mentions which are also annotated as mentions of the same event in ACE are considered correct.

The evaluation aims to assess the correctness of inferring a target semantic meaning, which is de-

<sup>4</sup><http://projects ldc.upenn.edu/ace/>

noted by a specific predicate. Therefore, we eliminated four ACE event types that correspond to multiple distinct predicates. For instance, the *Transfer-Money* event refers to both *donating* and *lending* money, which are not distinguished by the ACE annotation. We also omitted three events with less than 10 mentions and two events for which the given set of learned rules could not match any mention. We were left with 24 event types for evaluation, which amount to 4085 event mentions in the dataset. Out of these, our binary templates can correctly match only mentions with at least two arguments, which appear 2076 times in the dataset.

Comparing with previous evaluation methodologies, in (Szpektor et al., 2007; Pantel et al., 2007) proper context matching was evaluated by post-hoc judgment of a sample of rule applications for a sample of rules. Such annotation needs to be repeated each time the set of rules is changed. In addition, since the corpus annotation is not exhaustive, recall could not be computed. By contrast, we use a standard real-world dataset, in which all mentions are annotated. This allows immediate comparison of different rule sets and matching methods, without requiring any additional (post-hoc) annotation.

## 5 Results and Analysis

We experimented with three rule setups over the ACE dataset, in order to measure the contribution of the CP framework. In the first setup no rules are used, applying only direct matches of template hypotheses to identify event mentions. In the other two setups we also utilized *DIRT*'s top 50 or 100 rules for each hypothesis.

A match is considered correct when all matched arguments are extracted correctly according to their annotated event roles. This main measurement is denoted *All*. As an additional measurement, denoted *Any*, we consider a match as correct if at least one argument is extracted correctly.

Once event matches are extracted, we first measure for each event its Recall, the number of correct mentions identified out of all annotated event mentions<sup>5</sup> and Precision, the number of correct matches out of all extracted candidate matches. These figures

<sup>5</sup>For Recall, we ignored mentions with less than two arguments, as they cannot be correctly matched by binary templates.

quantify the baseline performance of the *DIRT* rule set used. To assess our ranking quality, we measure for each event the commonly used Average Precision (AP) measure (Voorhees and Harmann, 1998), which is the area under the non-interpolated recall-precision curve, while considering for each setup all correct extracted matches as 100% Recall. Overall, we report *Mean Average Precision (MAP)*, macro average *Precision* and macro average *Recall* over the ACE events. Tables 1 and 2 summarize the main results of our experiments. As far as we know, these are the first published unsupervised results for identifying event arguments in the ACE 2005 dataset.

Examining Recall, we see that it increases substantially when rules are applied: by more than 100% for the top 50 rules, and by about 150% for the top 100, showing the benefit of entailment-rules to covering language variability. The difference between *All* and *Any* results shows that about 65% of the rules that correctly match one argument also match correctly both arguments.

We use two baselines for measuring the CP ranking contribution: Precision, which corresponds to the expected MAP of random ranking, and MAP of ranking using the *prior* rule score provided by *DIRT*. Without rules, the baseline *All* Precision is 34.1%, showing that even the manually constructed hypotheses, which correspond directly to the event predicate, extract event mentions with limited accuracy when context is ignored. When rules are applied, Precision is very low. But ranking is considerably improved using only the prior score (from 1.4% to 22.7% for 50 rules), showing that the prior is an informative indicator for valid matches.

Our main result is that the *allCP* and *allCP+pr* methods rank matches statistically significantly better than the baselines in all setups (according to the Wilcoxon double-sided signed-ranks test at the level of 0.01 (Wilcoxon, 1945)). In the *All* setup, ranking is improved by 70% for direct matching (Table 1). When entailment-rules are also utilized, prior-only ranking is improved by about 35% and 50% when using *allCP* and *allCP+pr*, respectively (Table 2). Figure 2 presents the average Recall-Precision curve of the '50 Rules, All' setup for applying *allCP* or *allCP+pr*, compared to prior-only ranking baseline (other setups behave similarly). The improvement in ranking is evident: the drop in precision is signif-

	R	P	MAP (%)		
	(%)	(%)	$cp_v$	$cp_g$	$allCP$
All	14.0	34.1	46.5	52.2	60.2
Any	21.8	66.0	72.2	80.5	84.1

Table 1: Recall (R), Precision (P) and Mean Average Precision (MAP) when only matching template hypotheses directly.

	#	R	P	MAP (%)

All	50	29.6	1.4	22.7	30.6	34.1
	100	34.9	0.7	20.5	26.3	30.2
Any	50	46.5	3.5	41.2	43.7	48.6
	100	52.9	1.8	35.5	35.1	40.8

Table 2: Recall (R), Precision (P) and Mean Average Precision (MAP) when also using rules for matching.

icantly slower when CP is used. The behavior of CP with and without the prior is largely the same up to 50% Recall, but later on our implemented CP models are noisier and should be combined with the prior rule score.

Templates are incorrectly matched for several reasons. First, there are context mismatches which are not scored sufficiently low by our models. Another main cause is incorrect learned rules in which  $LHS$  and  $RHS$  are topically related, e.g. ‘ $X$  convict  $Y \rightarrow X$  arrest  $Y$ ’, or rules that are used in the wrong entailment direction, e.g. ‘ $X$  marry  $Y \rightarrow X$  divorce  $Y$ ’ ( $DIRT$  does not learn rule direction). As such rules do correspond to plausible contexts of the hypothesis, their matches obtain relatively high CP scores. In addition, some incorrect matches are caused by our syntactic matcher, which currently does not handle certain phenomena such as co-reference, modality or negation, and due to Minipar parse errors.

## 5.1 Component Analysis

Table 3 displays the contribution of different CP components to ranking, when adding only that component’s match score to the baselines, and under ablation tests, when using all CP component scores except the tested component, with or without the prior.

As it turns out, matching  $h$  with  $t$  (i.e.  $cp(h, t)$ , which combines  $cp_g(h, t)$  and  $cp_v(h, t)$ ) is most useful. With our current models, using only  $cp(h, t)$  along with the prior, while ignoring  $cp(r)$ , achieves

Figure 2: Recall-Precision curves for ranking using: (a) only the prior (baseline); (b)  $allCP$ ; (c)  $allCP+pr$ .

the highest score in the table. The strong impact of matching  $h$  and  $t$ ’s preferences is also evident in Table 1, where ranking based on either  $cp_g$  or  $cp_v$  substantially improves precision, while their combination provides the best ranking. These results indicate that the two CP components capture complementary information and both are needed to assess the correctness of a match.

When ignoring the prior rule score,  $cp(r, t)$  is the major contributor over the baseline Precision. For  $cp_v(r, t)$ , this is in synch with the result in (Pantel et al., 2007), which is based on this single model without utilizing prior rule scores. On the other hand,  $cp_v(r, t)$  does not improve the ranking when the prior is used, suggesting that this contextual model for the rule’s variables is not stronger than the context-insensitive prior rule score. Furthermore, relative to this  $cp_v(r, t)$  model from (Pantel et al., 2007), our combined  $allCP$  model, with or without the prior (first row of Table 2), obtains statistically significantly better ranking (at the level of 0.01).

Comparing between the algorithms for matching  $cp_{v:e}$  (Section 3.2.2) we found that while  $rankedCBC$  is statistically significantly better than  $binaryCBC$ ,  $rankedCBC$  and  $LIN$  generally achieve the same results. When considering the tradeoffs between the two,  $LIN$  is based on a much simpler learning algorithm while  $CBC$ ’s output is more compact and allows faster CP matches.

	Addition To		Ablation From	
	P	prior	<i>allCP</i>	<i>allCP+pr</i>
Baseline	1.4	22.7	30.6	34.1
$cp_g(h, t)$	*10.4	*35.4	32.4	33.7
$cp_v(h, t)$	*11.0	29.9	27.6	32.9
$cp(h, t)$	*8.9	<b>*37.5</b>	28.6	30.0
$cp_g(r, t)$	*4.2	*30.6	<b>32.5</b>	35.4
$cp_v(r, t)$	*21.7	21.9	*12.9	33.6
$cp(r, t)$	*26.0	*29.6	*17.9	<b>36.8</b>
$cp_g(h, r)$	*8.1	22.4	31.9	34.3
$cp_v(h, r)$	*10.7	22.7	*27.9	34.4
$cp(h, r)$	*16.5	22.4	*29.2	34.4
$cp_g(h, r, t)$	*7.7	*30.2	*27.5	*29.2
$cp_v(h, r, t)$	<b>*27.5</b>	29.2	*7.7	30.2

\* Indicates statistically significant changes compared to the baseline, according to the Wilcoxon test at the level of 0.01.

Table 3: MAP(%), under the ‘50 rules, All’ setup, when adding component match scores to Precision (P) or prior-only MAP baselines, and when ranking with *allCP* or *allCP+pr* methods but ignoring that component scores.

Currently, some models do not improve the results when the prior is used. Yet, we would like to further weaken the dependency on the prior score, since it is biased towards frequent contexts. We aim to properly identify also infrequent contexts (or meanings) at inference time, which may be achieved by better CP models. More generally, when used on top of all other components, some of the models slightly degrade performance, as can be seen by those figures in the ablation tests which are higher than the corresponding baseline. However, due to their different roles, each of the matching components might capture some unique preferences. For example,  $cp(h, r)$  should be useful to filter out rules that don’t match the intended meaning of the given  $h$ . Overall, this suggests that future research for better models should aim to obtain a marginal improvement by each component.

## 6 Related Work

Context sensitive inference was mainly investigated in an application-dependent manner. For example, (Harabagiu et al., 2003) describe techniques for identifying the question focus and the answer type in QA. (Patwardhan and Riloff, 2007) propose a supervised approach for IE, in which relevant text regions

for a target relation are identified prior to applying extraction rules.

Recently, the need for context-aware inference was raised (Szpektor et al., 2007). (Pantel et al., 2007) propose to learn the preferred instantiations of rule variables, termed Inferential Selectional Preferences (ISP). Their clustering-based model is the one we implemented for  $m_v(r, t)$ . A similar approach is taken in (Pennacchiotti et al., 2007), where LSA similarity is used to compare between the preferred variable instantiations for a rule and their instantiations in the matched text. (Downey et al., 2007) use HMM-based similarity for the same purpose. All these methods are analogous to matching  $cp_v(r)$  with  $cp_v(t)$  in the CP framework.

(Dagan et al., 2006; Connor and Roth, 2007) proposed generic approaches for identifying valid applications of lexical rules by classifying the surrounding global context of a word as valid or not for that rule. These approaches are analogous to matching  $cp_g(r)$  with  $cp_g(t)$  in our framework.

## 7 Conclusions

We presented the Contextual Preferences (CP) framework for assessing the validity of inferences in context. CP enriches the representation of textual objects with typical contextual information that constrains or disambiguates their meaning, and provides matching functions that compare the preferences of objects involved in the inference. Experiments with our implemented CP models, over real-world IE data, show significant improvements relative to baselines and some previous work.

In future research we plan to investigate improved models for representing and matching CP, and to extend the experiments to additional applied datasets. We also plan to apply the framework to lexical inference rules, for which it seems directly applicable.

## Abstract

We present a novel framework for the discovery and representation of general semantic relationships that hold between lexical items. We propose that each such relationship can be identified with a cluster of patterns that captures this relationship. We give a fully unsupervised algorithm for pattern cluster discovery, which searches, clusters and merges high-frequency words-based patterns around randomly selected hook words. Pattern clusters can be used to extract instances of the corresponding relationships. To assess the quality of discovered relationships, we use the pattern clusters to automatically generate SAT analogy questions. We also compare to a set of known relationships, achieving very good results in both methods. The evaluation (done in both English and Russian) substantiates the premise that our pattern clusters indeed reflect relationships perceived by humans.

## 1 Introduction

Semantic resources can be very useful in many NLP tasks. Manual construction of such resources is labor intensive and susceptible to arbitrary human decisions. In addition, manually constructed semantic databases are not easily portable across text domains or languages. Hence, there is a need for developing semantic acquisition algorithms that are as unsupervised and language independent as possible.

A fundamental type of semantic resource is that of concepts (represented by sets of lexical items) and their inter-relationships. While there is relatively good agreement as to what concepts are

and which concepts should exist in a lexical resource, identifying types of important lexical relationships is a rather difficult task. Most established resources (e.g., WordNet) represent only the main and widely accepted relationships such as hypernymy and meronymy. However, there are many other useful relationships between concepts, such as noun-modifier and inter-verb relationships. Identifying and representing these explicitly can greatly assist various tasks and applications. There are already applications that utilize such knowledge (e.g., (Tatu and Moldovan, 2005) for textual entailment).

One of the leading methods in semantics acquisition is based on patterns (see e.g., (Hearst, 1992; Pantel and Pennacchiotti, 2006)). The standard process for pattern-based relation extraction is to start with hand-selected patterns or word pairs expressing a particular relationship, and iteratively scan the corpus for co-appearances of word pairs in patterns and for patterns that contain known word pairs. This methodology is semi-supervised, requiring pre-specification of the desired relationship or hand-coding initial seed words or patterns. The method is quite successful, and examining its results in detail shows that concept relationships are often being manifested by several different patterns.

In this paper, unlike the majority of studies that use patterns in order to find instances of given relationships, we use sets of patterns as the *definitions* of lexical relationships. We introduce *pattern clusters*, a novel framework in which each cluster corresponds to a relationship that can hold between the lexical items that fill its patterns' slots. We present a fully unsupervised algorithm to compute pat-

tern clusters, not requiring any, even implicit, pre-specification of relationship types or word/pattern seeds. Our algorithm does not utilize preprocessing such as POS tagging and parsing. Some patterns may be present in several clusters, thus indirectly addressing pattern ambiguity.

The algorithm is comprised of the following stages. First, we randomly select hook words and create a context corpus (hook corpus) for each hook word. Second, we define a meta-pattern using high frequency words and punctuation. Third, in each hook corpus, we use the meta-pattern to discover concrete patterns and target words co-appearing with the hook word. Fourth, we cluster the patterns in each corpus according to co-appearance of the target words. Finally, we merge clusters from different hook corpora to produce the final structure. We also propose a way to label each cluster by word pairs that represent it best.

Since we are dealing with relationships that are unspecified in advance, assessing the quality of the resulting pattern clusters is non-trivial. Our evaluation uses two methods: SAT tests, and comparison to known relationships. We used instances of the discovered relationships to automatically generate analogy SAT tests in two languages, English and Russian<sup>1</sup>. Human subjects answered these and real SAT tests. English grades were 80% for our test and 71% for the real test (83% and 79% for Russian), showing that our relationship definitions indeed reflect human notions of relationship similarity. In addition, we show that among our pattern clusters there are clusters that cover major known noun-compound and verb-verb relationships.

In the present paper we focus on the pattern cluster resource itself and how to evaluate its intrinsic quality. In (Davidov and Rappoport, 2008) we show how to *use* the resource for a known task of a totally different nature, classification of relationships between nominals (based on annotated data), obtaining superior results over previous work.

Section 2 discusses related work, and Section 3 presents the pattern clustering and labeling algorithm. Section 4 describes the corpora we used and the algorithm's parameters in detail. Sections 5 and

6 present SAT and comparison evaluation results.

## 2 Related Work

Extraction of relation information from text is a large sub-field in NLP. Major differences between pattern approaches include the relationship types sought (including domain restrictions), the degrees of supervision and required preprocessing, and evaluation method.

### 2.1 Relationship Types

There is a large body of related work that deals with discovery of basic relationship types represented in useful resources such as WordNet, including hypernymy (Hearst, 1992; Pantel et al., 2004; Snow et al., 2006), synonymy (Davidov and Rappoport, 2006; Widdows and Dorow, 2002) and meronymy (Berland and Charniak, 1999; Girju et al., 2006).

Since named entities are very important in NLP, many studies define and discover relations between named entities (Hasegawa et al., 2004; Hassan et al., 2006). Work was also done on relations between verbs (Chklovski and Pantel, 2004). There is growing research on relations between nominals (Moldovan et al., 2004; Girju et al., 2007).

### 2.2 Degree of Supervision and Preprocessing

While numerous studies attempt to discover one or more pre-specified relationship types, very little previous work has directly attempted the discovery of which main types of generic relationships actually exist in an unrestricted domain. Turney (2006) provided a pattern distance measure that allows a fully unsupervised measurement of relational similarity between two pairs of words; such a measure could in principle be used by a clustering algorithm in order to deduce relationship types, but this was not discussed. Unlike (Turney, 2006), we do not perform any pattern ranking. Instead we produce (possibly overlapping) hard clusters, where each pattern cluster represents a relationship discovered in the domain. Banko et al. (2007) and Rosenfeld and Feldman (2007) find relationship instances where the relationships are not specified in advance. They aim to find relationship instances rather than identify generic semantic relationships. Thus, their representation is very different from ours. In addition, (Banko et al., 2007) utilize supervised tools such

as a POS tagger and a shallow parser. Davidov et al. (2007) proposed a method for unsupervised discovery of concept-specific relations. That work, like ours, relies on pattern clusters. However, it requires initial word seeds and targets the discovery of relationships specific for some given concept, while we attempt to discover and define generic relationships that exist in the entire domain.

Studying relationships between tagged named entities, (Hasegawa et al., 2004; Hassan et al., 2006) proposed unsupervised clustering methods that assign given sets of pairs into several clusters, where each cluster corresponds to one of a known set of relationship types. Their classification setting is thus very different from our unsupervised discovery one.

Several recent papers discovered relations on the web using seed patterns (Pantel et al., 2004), rules (Etzioni et al., 2004), and word pairs (Pasca et al., 2006; Alfonseca et al., 2006). The latter used the notion of hook which we also use in this paper. Several studies utilize some preprocessing, including parsing (Hasegawa et al., 2004; Hassan et al., 2006) and usage of syntactic (Suchanek et al., 2006) and morphological (Pantel et al., 2004) information in patterns. Several algorithms use manually-prepared resources, including WordNet (Moldovan et al., 2004; Costello et al., 2006) and Wikipedia (Strube and Ponzetto, 2006). In this paper, we do not utilize any language-specific preprocessing or any other resources, which makes our algorithm relatively easily portable between languages, as we demonstrate in our bilingual evaluation.

### 2.3 Evaluation Method

Evaluation for hypernymy and synonymy usually uses WordNet (Lin and Pantel, 2002; Widdows and Dorow, 2002; Davidov and Rappoport, 2006). For more specific lexical relationships like relationships between verbs (Chklovski and Pantel, 2004), nominals (Girju et al., 2004; Girju et al., 2007) or meronymy subtypes (Berland and Charniak, 1999) there is still little agreement which important relationships should be defined. Thus, there are more than a dozen different type hierarchies and tasks proposed for noun compounds (and nominals in general), including (Nastase and Szpakowicz, 2003; Girju et al., 2005; Girju et al., 2007).

There are thus two possible ways for a fair eval-

uation. A study can develop its own relationship definitions and dataset, like (Nastase and Szpakowicz, 2003), thus introducing a possible bias; or it can accept the definition and dataset prepared by another work, like (Turney, 2006). However, this makes it impossible to work on new relationship types. Hence, when exploring very specific relationship types or very generic, but not widely accepted, types (like verb strength), many researchers resort to manual human-based evaluation (Chklovski and Pantel, 2004). In our case, where relationship types are not specified in advance, creating an unbiased benchmark is very problematic, so we rely on human subjects for relationship evaluation.

## 3 Pattern Clustering Algorithm

Our algorithm first discovers and clusters patterns in which a single ('hook') word participates, and then merges the resulting clusters to form the final structure. In this section we detail the algorithm. The algorithm utilizes several parameters, whose selection is detailed in Section 4. We refer to a pattern contained in our clusters (a pattern type) as a 'pattern' and to an occurrence of a pattern in the corpus (a pattern token) as a 'pattern instance'.

### 3.1 Hook Words and Hook Corpora

As a first step, we randomly select a set of hook words. Hook words were used in e.g. (Alfonseca et al., 2006) for extracting general relations starting from given seed word pairs. Unlike most previous work, our hook words are not provided in advance but selected randomly; the goal in those papers is to discover relationships between given word pairs, while we use hook words in order to discover relationships that generally occur in the corpus.

Only patterns in which a hook word actually participates will eventually be discovered. Hence, in principle we should select as many hook words as possible. However, words whose frequency is very high are usually ambiguous and are likely to produce patterns that are too noisy, so we do not select words with frequency higher than a parameter  $F_C$ . In addition, we do not select words whose frequency is below a threshold  $F_B$ , to avoid selection of typos and other noise that frequently appear on the web.

We also limit the total number  $N$  of hook words.

Our algorithm merges clusters originating from different hook words. Using too many hook words increases the chance that some of them belong to a noisy part in the corpus and thus lowers the quality of our resulting clusters.

For each hook word, we now create a hook corpus, the set of the contexts in which the word appears. Each context is a window containing  $W$  words or punctuation characters before and after the hook word. We avoid extracting text from clearly unformatted sentences and our contexts do not cross paragraph boundaries.

The size of each hook corpus is much smaller than that of the whole corpus, easily fitting into main memory; the corpus of a hook word occurring  $h$  times in the corpus contains at most  $2hW$  words. Since most operations are done on each hook corpus separately, computation is very efficient.

Note that such context corpora can in principle be extracted by focused querying on the web, making the system dynamically scalable. It is also possible to restrict selection of hook words to a specific domain or word type, if we want to discover only a desired subset of existing relationships. Thus we could sample hook words from nouns, verbs, proper names, or names of chemical compounds if we are only interested in discovering relationships between these. Selecting hook words randomly allows us to avoid using any language-specific data at this step.

### 3.2 Pattern Specification

In order to reduce noise and to make the computation more efficient, we did not consider all contexts of a hook word as pattern candidates, only contexts that are instances of a specified meta-pattern type. Following (Davidov and Rappoport, 2006), we classified words into high-frequency words (HFWs) and content words (CWs). A word whose frequency is more (less) than  $F_H$  ( $F_C$ ) is considered to be a HFW (CW). Unlike (Davidov and Rappoport, 2006), we consider all punctuation characters as HFWs. Our patterns have the general form

**[Prefix]**  $CW_1$  **[Infix]**  $CW_2$  **[Postfix]**

where Prefix, Infix and Postfix contain only HFWs. To reduce the chance of catching  $CW_i$ 's that are parts of a multiword expression, we require Prefix and Postfix to have at least one word (HFW), while

Infix is allowed to contain any number of HFWs (but recall that the total length of a pattern is limited by window size). A pattern example is '*such X as Y and*'. During this stage we only allow single words to be in CW slots<sup>2</sup>.

### 3.3 Discovery of Target Words

For each of the hook corpora, we now extract all pattern instances where one CW slot contains the hook word and the other CW slot contains some other ('target') word. To avoid the selection of common words as target words, and to avoid targets appearing in pattern instances that are relatively fixed multiword expressions, we sort all target words in a given hook corpus by pointwise mutual information between hook and target, and drop patterns obtained from pattern instances containing the lowest and highest  $L$  percent of target words.

### 3.4 Local Pattern Clustering

We now have for each hook corpus a set of patterns. All of the corresponding pattern instances share the hook word, and some of them also share a target word. We cluster patterns in a two-stage process. First, we group in clusters all patterns whose instances share the same target word, and ignore the rest. For each target word we have a single pattern cluster. Second, we merge clusters that share more than  $S$  percent of their patterns. A pattern can appear in more than a single cluster. Note that clusters contain pattern *types*, obtained through examining pattern *instances*.

### 3.5 Global Cluster Merging

The purpose of this stage is to create clusters of patterns that express generic relationships rather than ones specific to a single hook word. In addition, the technique used in this stage reduces noise. For each created cluster we will define *core* patterns and *unconfirmed* patterns, which are weighed differently during cluster labeling (see Section 3.6). We merge clusters from different hook corpora using the following algorithm:

1. Remove all patterns originating from a single hook corpus.

<sup>2</sup>While for pattern clusters creation we use only single words as CWs, later during evaluation we allow multiword expressions in CW slots of previously acquired patterns.

2. Mark all patterns of all present clusters as unconfirmed.
3. While there exists some cluster  $C_1$  from corpus  $D_X$  containing only unconfirmed patterns:
  - (a) Select a cluster with a minimal number of patterns.
  - (b) For each corpus  $D$  different from  $D_X$ :
    - i. Scan  $D$  for clusters  $C_2$  that share at least  $S$  percent of their patterns, and all of their core patterns, with  $C_1$ .
    - ii. Add all patterns of  $C_2$  to  $C_1$ , setting all shared patterns as core and all others as unconfirmed.
    - iii. Remove cluster  $C_2$ .
  - (c) If all of  $C_1$ 's patterns remain unconfirmed remove  $C_1$ .
4. If several clusters have the same set of core patterns merge them according to rules (i,ii).

We start from the smallest clusters because we expect these to be more precise; the best patterns for semantic acquisition are those that belong to small clusters, and appear in many different clusters. At the end of this algorithm, we have a set of pattern clusters where for each cluster there are two subsets, core patterns and unconfirmed patterns.

### 3.6 Labeling of Pattern Clusters

To label pattern clusters we define a HITS measure that reflects the affinity of a given word pair to a given cluster. For a given word pair  $(w_1, w_2)$  and cluster  $C$  with  $n$  core patterns  $P_{core}$  and  $m$  unconfirmed patterns  $P_{unconf}$ ,

$$Hits(C, (w_1, w_2)) = \frac{|\{p; (w_1, w_2) \text{ appears in } p \in P_{core}\}|}{n} + \alpha \times \frac{|\{p; (w_1, w_2) \text{ appears in } p \in P_{unconf}\}|}{m}.$$

In this formula, ‘appears in’ means that the word pair appears in instances of this pattern extracted from the original corpus or retrieved from the web during evaluation (see Section 5.2). Thus if some pair appears in most of patterns of some cluster it receives a high HITS value for this cluster. The top 5 pairs for each cluster are selected as its labels.  $\alpha \in (0..1)$  is a parameter that lets us modify the relative weight of core and unconfirmed patterns.

## 4 Corpora and Parameters

In this section we describe our experimental setup, and discuss in detail the effect of each of the algorithms’ parameters.

### 4.1 Languages and Corpora

The evaluation was done using corpora in English and Russian. The English corpus (Gabrilovich and Markovitch, 2005) was obtained through crawling the URLs in the Open Directory Project (dmoz.org). It contains about 8.2G words and its size is about 68GB of untagged plain text. The Russian corpus was collected over the web, comprising a variety of domains, including news, web pages, forums, novels and scientific papers. It contains 7.5G words of size 55GB untagged plain text. Aside from removing noise and sentence duplicates, we did not apply any text preprocessing or tagging.

### 4.2 Parameters

Our algorithm uses the following parameters:  $F_C$ ,  $F_H$ ,  $F_B$ ,  $W$ ,  $N$ ,  $L$ ,  $S$  and  $\alpha$ . We used part of the Russian corpus as a development set for determining the parameters. On our development set we have tested various parameter settings. A detailed analysis of the involved parameters is beyond the scope of this paper; below we briefly discuss the observed qualitative effects of parameter selection. Naturally, the parameters are not mutually independent.

$F_C$  (upper bound for content word frequency in patterns) influences which words are considered as hook and target words. More ambiguous words generally have higher frequency. Since content words determine the joining of patterns into clusters, the more ambiguous a word is, the noisier the resulting clusters. Thus, higher values of  $F_C$  allow more ambiguous words, increasing cluster recall but also increasing cluster noise, while lower ones increase cluster precision at the expense of recall.

$F_H$  (lower bound for HFW frequency in patterns) influences the specificity of patterns. Higher values restrict our patterns to be based upon the few most common HFWs (like ‘the’, ‘of’, ‘and’) and thus yield patterns that are very generic. Lowering the values, we obtain increasing amounts of pattern clusters for more specific relationships. The value we use for  $F_H$  is lower than that used for  $F_C$ , in order to allow as HFWs function words of relatively low frequency (e.g., ‘through’), while allowing as content words some frequent words that participate in meaningful relationships (e.g., ‘game’). However, this way we may also introduce more noise.

$F_B$  (lower bound for hook words) filters hook words that do not appear enough times in the corpus. We have found that this parameter is essential for removing typos and other words that do not qualify as hook words.

$N$  (number of hook words) influences relationship coverage. With higher  $N$  values we discover more relationships roughly of the same specificity level, but computation becomes less efficient and more noise is introduced.

$W$  (window size) determines the length of the discovered patterns. Lower values are more efficient computationally, but values that are too low result in drastic decrease in coverage. Higher values would be more useful when we allow our algorithm to support multiword expressions as hooks and targets.

$L$  (target word mutual information filter) helps in avoiding using as targets common words that are unrelated to hooks, while still catching as targets frequent words that are related. Low  $L$  values decrease pattern precision, allowing patterns like ‘give  $X$  please  $Y$  more’, where  $X$  is the hook (e.g., ‘Alex’) and  $Y$  the target (e.g., ‘some’). High values increase pattern precision at the expense of recall.

$S$  (minimal overlap for cluster merging) is a clusters merge filter. Higher values cause more strict merging, producing smaller but more precise clusters, while lower values start introducing noise. In extreme cases, low values can start a chain reaction of total merging.

$\alpha$  (core vs. unconfirmed weight for HITS labeling) allows lower quality patterns to complement higher quality ones during labeling. Higher values increase label noise, while lower ones effectively ignore unconfirmed patterns during labeling.

In our experiments we have used the following values (again, determined using a development set) for these parameters:  $F_C$ : 1,000 words per million (wpm);  $F_H$ : 100 wpm;  $F_B$ : 1.2 wpm;  $N$ : 500 words;  $W$ : 5 words;  $L$ : 30%;  $S$ : 2/3;  $\alpha$ : 0.1.

## 5 SAT-based Evaluation

As discussed in Section 2, the evaluation of semantic relationship structures is non-trivial. The goal of our evaluation was to assess whether pattern clusters indeed represent meaningful, precise and different relationships. There are two complementary perspec-

tives that a pattern clusters quality assessment needs to address. The first is the quality (precision/recall) of individual pattern clusters: does each pattern cluster capture lexical item pairs of the same semantic relationship? does it recognize many pairs of the same semantic relationship? The second is the quality of the cluster set as whole: does the pattern clusters set allow identification of important known semantic relationships? do several pattern clusters describe the same relationship?

Manually examining the resulting pattern clusters, we saw that the majority of sampled clusters indeed clearly express an interesting specific relationship. Examples include familiar hypernymy clusters such as<sup>3</sup> {‘such  $X$  as  $Y$ ’, ‘ $X$  such as  $Y$ ’, ‘ $Y$  and other  $X$ ’,} with label (*pets, dogs*), and much more specific clusters like {‘buy  $Y$  accessory for  $X$ !’, ‘shipping  $Y$  for  $X$ ’, ‘ $Y$  is available for  $X$ ’, ‘ $Y$  are available for  $X$ ’, ‘ $Y$  are available for  $X$  systems’, ‘ $Y$  for  $X$ ’}, labeled by (*phone, charger*). Some clusters contain overlapping patterns, like ‘ $Y$  for  $X$ ’, but represent different relationships when examined as a whole.

We addressed the evaluation questions above using a SAT-like analogy test automatically generated from word pairs captured by our clusters (see below in this section). In addition, we tested coverage and overlap of pattern clusters with a set of 35 known relationships, and we compared our patterns to those found useful by other algorithms (the next section).

Quantitatively, the final number of clusters is 508 (470) for English (Russian), and the average cluster size is 5.5 (6.1) pattern types. 55% of the clusters had no overlap with other clusters.

### 5.1 SAT Analogy Choice Test

Our main evaluation method, which is also a useful application by itself, uses our pattern clusters to automatically generate SAT analogy questions. The questions were answered by human subjects.

We randomly selected 15 clusters. This allowed us to assess the precision of the whole cluster set as well as of the internal coherence of separate clusters (see below). For each cluster, we constructed a SAT analogy question in the following manner. The header of the question is a word pair that is one of the label pairs of the cluster. The five multiple

<sup>3</sup>For readability, we omit punctuations in Prefix and Postfix.

choice items include: (1) another label of the cluster (the ‘correct’ answer); (2) three labels of other clusters among the 15; and (3) a pair constructed by randomly selecting words from those making up the various cluster labels.

In our sample there were no word pairs assigned as labels to more than one cluster<sup>4</sup>. As a baseline for comparison, we have mixed these questions with 15 real SAT questions taken from English and Russian SAT analogy tests. In addition, we have also asked our subjects to write down one example pair of the same relationship for each question in the test.

As an example, from one of the 15 clusters we have randomly selected the label (*glass, water*). The correct answer selected from the same cluster was (*schoolbag, book*). The three pairs randomly selected from the other 14 clusters were (*war, death*), (*request, license*) and (*mouse, cat*). The pair randomly selected from a cluster not among the 15 clusters was (*milk, drink*). Among the subjects’ proposals for this question were (*closet, clothes*) and (*wallet, money*).

We computed accuracy of SAT answers, and the correlation between answers for our questions and the real ones (Table 1). Three things are demonstrated about our system when humans are capable of selecting the correct answer. First, our clusters are internally coherent in the sense of expressing a certain relationship, because people identified that the pairs in the question header and in the correct answer exhibit the same relationship. Second, our clusters distinguish between different relationships, because the three pairs not expressing the same relationship as the header were not selected by the evaluators. Third, our cluster labeling algorithm produces results that are usable by people.

The test was performed in both English and Russian, with 10 (6) subjects for English (Russian). The subjects (biology and CS students) were not involved with the research, did not see the clusters, and did not receive any special training as preparation. Inter-subject agreement and Kappa were 0.82, 0.72 (0.9, 0.78) for English (Russian). As reported in (Turney, 2005), an average high-school SAT grade is 57. Table 1 shows the final English and Rus-

<sup>4</sup>But note that a pair can certainly obtain a positive HITS value for several clusters.

	Our method	Real SAT	Correlation
English	<b>80%</b>	71%	0.85
Russian	<b>83%</b>	79%	0.88

Table 1: Pattern cluster evaluation using automatically generated SAT analogy choice questions.

sian grade average for ours and real SAT questions.

We can see that for both languages, around 80% of the choices were correct (the random choice baseline is 20%). Our subjects are university students, so results higher than 57 are expected, as we can see from real SAT performance. The difference in grades between the two languages might be attributed to the presence of relatively hard and uncommon words. It also may result from the Russian test being easier because there is less verb-noun ambiguity in Russian.

We have observed a high correlation between true grades and ours, suggesting that our automatically generated test reflects the ability to recognize analogies and can be potentially used for automated generation of SAT-like tests.

The results show that our pattern clusters indeed mirror a human notion of relationship similarity and represent meaningful relationships. They also show that as intended, different clusters describe different relationships.

## 5.2 Analogy Invention Test

To assess recall of separate pattern clusters, we have asked subjects to provide (if possible) an additional pair for each SAT question. On each such pair we have automatically extracted a set of pattern instances that capture this pair by using automated web queries. Then we calculated the HITS value for each of the selected pairs and assigned them to clusters with highest HITS value. The numbers of pairs provided were 81 for English and 43 for Russian.

We have estimated precision for this task as macro-average of percentage of correctly assigned pairs, obtaining 87% for English and 82% for Russian (the random baseline of this 15-class classification task is 6.7%). It should be noted however that the human-provided additional relationship examples in this test are not random so it may introduce bias. Nevertheless, these results confirm that our pattern clusters are able to recognize new in-

30 Noun Compound Relationships		
	Avg. num of clusters	Overlap
Russian	1.8	0.046
English	1.7	0.059
5 Verb Verb Relationships		
Russian	1.4	0.01
English	1.2	0

Table 2: Patterns clusters discovery of known relationships.

stances of relationships of the same type.

## 6 Evaluation Using Known Information

We also evaluated our pattern clusters using relevant information reported in related work.

### 6.1 Discovery of Known Relationships

To estimate recall of our pattern cluster set, we attempted to estimate whether (at least) a subset of known relationships have corresponding pattern clusters. As a testing subset, we have used 35 relationships for both English and Russian. 30 relations are noun compound relationships as proposed in the (Nastase and Szpakowicz, 2003) classification scheme, and 5 relations are verb-verb relations proposed by (Chklovski and Pantel, 2004). We have manually created sets of 5 unambiguous sample pairs for each of these 35 relationships. For each such pair we have assigned the pattern cluster with best HITS value.

The middle column of Table 2 shows the average number of clusters per relationship. Ideally, if for each relationship all 5 pairs are assigned to the same cluster, the average would be 1. In the worst case, when each pair is assigned to a different cluster, the average would be 5. We can see that most of the pairs indeed fall into one or two clusters, successfully recognizing that similarly related pairs belong to the same cluster. The column on the right shows the overlap between different clusters, measured as the average number of shared pairs in two randomly selected clusters. The baseline in this case is essentially 5, since there are more than 400 clusters for 5 word pairs. We see a very low overlap between assigned clusters, which shows that these clusters indeed separate well between defined relations.

### 6.2 Discovery of Known Pattern Sets

We compared our clusters to lists of patterns reported as useful by previous papers. These lists included patterns expressing hypernymy (Hearst, 1992; Pantel et al., 2004), meronymy (Berland and Charniak, 1999; Girju et al., 2006), synonymy (Widdows and Dorow, 2002; Davidov and Rapoport, 2006), and verb strength + verb happens-before (Chklovski and Pantel, 2004). In all cases, we discovered clusters containing all of the reported patterns (including their refinements with domain-specific prefix or postfix) and not containing patterns of competing relationships.

## 7 Conclusion

We have proposed a novel way to define and identify generic lexical relationships as clusters of patterns. Each such cluster is set of patterns that can be used to identify, classify or capture new instances of some unspecified semantic relationship. We showed how such pattern clusters can be obtained automatically from text corpora without any seeds and without relying on manually created databases or language-specific text preprocessing. In an evaluation based on an automatically created analogy SAT test we showed on two languages that pairs produced by our clusters indeed strongly reflect human notions of relation similarity. We also showed that the obtained pattern clusters can be used to recognize new examples of the same relationships. In an additional test where we assign labeled pairs to pattern clusters, we showed that they provide good coverage for known noun-noun and verb-verb relationships for both tested languages.

While our algorithm shows good performance, there is still room for improvement. It utilizes a set of constants that affect precision, recall and the granularity of the extracted cluster set. It would be beneficial to obtain such parameters automatically and to create a multilevel relationship hierarchy instead of a flat one, thus combining different granularity levels. In this study we applied our algorithm to a generic domain, while the same method can be used for more restricted domains, potentially discovering useful domain-specific relationships.

## Abstract

Web search engines today typically show results as a list of titles and short snippets that summarize how the retrieved documents are related to the query. However, recent research suggests that longer summaries can be preferable for certain types of queries. This paper presents empirical evidence that judges can predict appropriate search result summary lengths, and that perceptions of search result quality can be affected by varying these result lengths. These findings have important implications for search results presentation, especially for natural language queries.

## 1 Introduction

Search results listings on the web have become standardized as a list of information summarizing the retrieved documents. This summary information is often referred to as the document's *surrogate* (Marchionini et al., 2008).

In older search systems, such as those used in news and legal search, the document surrogate typically consisted of the title and important metadata, such as date, author, source, and length of the article, as well as the document's manually written abstract. In most cases, the full text content of the document was not available to the search engine and so no extracts could be made.

In web search, document surrogates typically show the web page's title, a URL, and information extracted from the full text contents of the document. This latter part is referred to by several different names, including *summary*, *abstract*, *extract*,

and *snippet*. Today it is standard for web search engines to show these summaries as one or two lines of text, often with ellipses separating sentence fragments. However, there is evidence that the ideal result length is often longer than the standard snippet length, and that furthermore, result length depends on the type of answer being sought.

In this paper, we systematically examine the question of search result length preference, comparing different result lengths for different query types. We find evidence that desired answer length is sensitive to query type, and that for some queries longer answers are judged to be of higher quality.

In the following sections we summarize the related work on result length variation and on query topic classification. We then describe two studies. In the first, judges examined queries and made predictions about the expected answer types and the ideal answer lengths. In the second study, judges rated answers of different lengths for these queries. The studies find evidence supporting the idea that different query types are best answered with summaries of different lengths.

## 2 Related Work

### 2.1 Query-biased Summaries

In the early days of the web, the result summary consisted of the first few lines of text, due both to concerns about intellectual property, and because often that was the only part of the full text that the search engines retained from their crawls. Eventually, search engines started showing what are known variously as *query-biased summaries*, *keyword-in-*

context (KWIC) extractions, and *user-directed summaries* (Tombros and Sanderson, 1998). In these summaries, sentence fragments, full sentences, or groups of sentences that contain query terms are extracted from the full text. Early versions of this idea were developed in the Snippet Search tool (Pedersen et al., 1991) and the Superbook tool's Table-of-Contents view (Egan et al., 1989).

A query-biased summary shows sentences that summarize the ways the query terms are used within the document. In addition to showing which subsets of query terms occur in a retrieved document, this display also exposes the context in which the query terms appear with respect to one another.

Research suggests that query-biased summaries are superior to showing the first few sentences from documents. Tombros & Sanderson (1998), in a study with 20 participants using TREC *ad hoc* data, found higher precision and recall and higher subjective preferences for query-biased summaries over summaries showing the first few sentences. Similar results for timing and subjective measurements were found by White et al. (2003) in a study with 24 participants. White et al. (2003) also describe experiments with different sentence selection mechanisms, including giving more weight to sentences that contained query words along with text formatting.

There are significant design questions surrounding how best to formulate and display query-biased summaries. As with standard document summarization and extraction, there is an inherent trade-off between showing long, informative summaries and minimizing the screen space required by each search hit. There is also a tension between showing short snippets that contain all or most of the query terms and showing coherent stretches of text. If the query terms do not co-occur near one another, then the extract has to become very long if full sentences and all query terms are to be shown. Many web search engine snippets compromise by showing fragments instead of sentences.

## 2.2 Studies Comparing Results Lengths

Recently, a few studies have analyzed the results of varying search summary length.

In the question-answering context (as opposed to general web search), Lin et al. (2003) conducted

a usability study with 32 computer science students comparing four types of answer context: exact answer, answer-in-sentence, answer-in-paragraph, and answer-in-document. To remove effects of incorrect answers, they used a system that produced only correct answers, drawn from an online encyclopedia. Participants viewed answers for 8 question scenarios. Lin et al. (2003) found no significant differences in task completion times, but they did find differences in subjective responses. Most participants (53%) preferred paragraph-sized chunks, noting that a sentence wasn't much more information beyond the exact answer, and a full document was often-times too long. That said, 23% preferred full documents, 20% preferred sentences, and one participant preferred exact answer, thus suggesting that there is considerable individual variation.

Paek et al. (2004) experimented with showing differing amounts of summary information in results listings, controlling the study design so that only one result in each list of 10 was relevant. For half the test questions, the target information was visible in the original snippet, and for the other half, the participant needed to use their mouse to view more information from the relevant search result. They compared three interface conditions:

- (i) a standard search results listing, in which a mouse click on the title brings up the full text of the web page,
- (ii) "instant" view, for which a mouseclick expanded the document summary to show additional sentences from the document, and those sentences contained query terms and the answer to the search task, and
- (iii) a "dynamic" view that responded to a mouse hover, and dynamically expanded the summary with a few words at a time.

Eleven out of 18 participants preferred instant view over the other two views, and on average all participants produced faster and more accurate results with this view. Seven participants preferred dynamic view over the others, but many others found this view disruptive. The dynamic view suffered from the problem that, as the text expanded, the mouse no longer covered the selected results, and

so an unintended, different search result sometimes started to expand. Notably, none of the participants preferred the standard results listing view.

Cutrell & Guan (2007), compared search summaries of varying length: short (1 line of text), medium (2-3 lines) and long (6-7 lines) using search engine-produced snippets (it is unclear if the summary text was contiguous or included ellipses). They also compared 6 navigational queries (where the goal is to find a website's homepage), with 6 informational queries (e.g., "find when the Titanic set sail for its only voyage and what port it left from," "find out how long the Las Vegas monorail is"). In a study with 22 participants, they found that participants were 24 seconds faster on average with the long view than with the short and medium view. They also found that participants were 10 seconds slower on average with the long view for the navigational tasks. They present eye tracking evidence which suggests that on the navigational task, the extra text distracts the eye from the URL. They did not report on subjective responses to the different answer lengths.

Rose et al. (2007) varied search results summaries along several dimensions, finding that text chopiness and sentence truncation had negative effects, and genre cues had positive effects. They did not find effects for varying summary length, but they only compared relatively similar summary lengths (2 vs. 3 vs. 4 lines long).

### 2.3 Categorizing Questions by Expected Answer Types

In the field of automated question-answering, much effort has been expended on automatically determining the kind of answer that is expected for a given question. The candidate answer types are often drawn from the types of questions that have appeared in the TREC Question Answering track (Voorhees, 2003). For example, the Webclopedia project created a taxonomy of 180 types of question targets (Hovy et al., 2002), and the FALCON project (Harabagiu et al., 2003) developed an answer taxonomy with 33 top level categories (such as PERSON, TIME, REASON, PRODUCT, LOCATION, NUMERICAL VALUE, QUOTATION), and these were further refined into an unspecified number of additional categories. Ramakrishnan et al.

(2004) show an automated method for determining expected answer types using syntactic information and mapping query terms to WordNet.

### 2.4 Categorizing Web Queries

A different line of research is the query log categorization problem. In query logs, the queries are often much more terse and ill-defined than in the TREC QA track, and, accordingly, the taxonomies used to classify what is called the query intent have been much more general.

In an attempt to demonstrate how information needs for web search differ from the assumptions of pre-web information retrieval systems, Broder (2002) created a taxonomy of web search goals, and then estimated frequency of such goals by a combination of an online survey (3,200 responses, 10% response rate) and a manual analysis of 1,000 query from the AltaVista query logs. This taxonomy has been heavily influential in discussions of query types on the Web.

Rose & Levinson (2004) followed up on Broder's work, again using web query logs, but developing a taxonomy that differed somewhat from Broder's. They manually classified a set of 1,500 AltaVista search engine log queries. For two sets of 500 queries, the labeler saw just the query and the retrieved documents; for the third set the labeler also saw information about which item(s) the searcher clicked on. They found that the classifications that used the extra information about clickthrough did not change the proportions of assignments to each category. Because they did not directly compare judgments with and without click information on the same queries, this is only weak evidence that query plus retrieved documents is sufficient to classify query intent.

Alternatively, queries from web query logs can be classified according to the *topic* of the query, independent of the type of information need. For example, a search involving the topic of weather can consist of the simple information need of looking at today's forecast, or the rich and complex information need of studying meteorology. Over many years, Spink & Jansen et al. (2006; 2007) have manually analyzed samples of query logs to track a number of different trends. One of the most notable is the change in topic mix. As an alternative to man-

ual classification of query topics, Shen et al. (2005) described an algorithm for automatically classifying web queries into a set of pre-defined topics. More recently, Broder et al. (2007) presented a highly accurate method (around .7 F-score) for classifying short, rare queries into a taxonomy of 6,000 categories.

### 3 Study Goals

Related work suggests that longer results are preferable, but not for all query types. The goal of our efforts was to determine preferred result length for search results, depending on type of query. To do this, we performed two studies:

1. We asked a set of judges to categorize a large set of web queries according to their expected preferred response type and expected preferred response length.
2. We then developed high-quality answer passages of different lengths for a subset of these queries by selecting appropriate passages from the online encyclopedia Wikipedia, and asked judges to rate the quality of these answers.

The results of this study should inform search interface designers about what the best presentation format is.

#### 3.1 Using Mechanical Turk

For these studies, we make use of a web service offered by Amazon.com called Mechanical Turk, in which participants (called “turkers”) are paid small sums of money in exchange for work on “Human Intelligence tasks” (HITs).<sup>1</sup> These HITs are generated from an XML description of the task created by the investigator (called a “requester”). The participants can come from any walk of life, and their identity is not known to the requesters. We have in past work found the results produced by these judges to be of high quality, and have put into place various checks to detect fraudulent behavior. Other researchers have investigated the efficacy of language

<sup>1</sup>Website: <http://www.mturk.com>. For experiment 1, approximately 38,000 HITs were completed at a cost of about \$1,500. For experiment 2, approximately 7,300 HITs were completed for about \$170. Turkers were paid between \$.01 and \$.05 per HIT depending on task complexity; Amazon imposes additional charges.

annotation using this service and have found that the results are of high quality (Su et al., 2007).

#### 3.2 Estimating Ideal Answer Length and Type

We developed a set of 12,790 queries, drawn from Powerset’s in house query database which contains representative subsets of queries from different search engines’ query logs, as well as hand-edited query sets used for regression testing. There are a disproportionately large number of natural language queries in this set compared with query sets from typical keyword engines. Such queries are often complete questions and are sometimes grammatical fragments (e.g., “date of next US election”) and so are likely to be amenable to interesting natural language processing algorithms, which is an area of in-

Answer Type	Answer Length					
	Phrase	Sentence	Paragraphs	Article	List	Combination
Person	1,362	735	570	378	419	68
Organization	153	172	295	165	432	51
Time	964	486	176	65	126	21
Number	2,075	964	362	88	158	50
GeoLocation	552	399	269	126	389	78
Place	128	121	173	87	295	33
Resource	104	136	733	273	959	256
Website	243	168	101	52	297	61

Gossip	86	133	366	156	85	51
NatLang	946	479	186	21	171	26
GeneralInfo	396	861	3,197	3,244	1,075	359
Advice	43	164	1,257	1,086	357	151
ReasonCause	50	102	755	546	88	69
YesNo	392	281	306	73	12	8
Other	115	61	140	157	88	29
Unjudgable	59	47	36	18	18	556

Figure 1: Results of the first experiment. The y-axis shows the semantic type of the predicted answer, in the same order as listed in Table 1; the x-axis shows the preferred length as listed in Table 2. Three bars with length greater than 1,500 are trimmed to the maximum size to improve readability (GeneralInfo/Paragraphs, GeneralInfo/Article, and Number/Phrase).

terest of our research. The average number of words per query (as determined by white space separation) was 5.8 (sd. 2.9) and the average number of characters (including punctuation and white space) was 32.3 (14.9). This is substantially longer than the current average for web search query, which was approximately 2.8 in 2005 (Jansen et al., 2007); this is due to the existence of natural language queries.

Judges were asked to classify each query according to its expected response type into one of 17 categories (see Table 1). These categories include answer types used in question answering research as well as (to better capture the diverse nature of web queries) several more general response types such as *Advice* and *General Information*. Additionally, we asked judges to anticipate what the best result length would be for the query, as shown in Table 2.

Each of the 12,790 queries received three assessments by MTurk judges. For answer types, the number of times all three judges agreed was 4537 (35.4%); two agreed 6030 times (47.1%), and none

agreed 2223 times (17.4%). Not surprisingly, there was significant overlap between the label *General-Info* and the other categories. For answer length estimations, all three judges agreed in 2361 cases (18.5%), two agreed in 7210 cases (56.4%) and none 3219 times (25.2%).

Figure 1 summarizes expected length judgments by estimated answer category. Distribution of the length categories differs a great deal across the individual expected response categories. In general, the results are intuitive: judges preferred short responses for “precise queries” (e.g., those asking for numbers) and they preferred longer responses for queries in broad categories like *Advice* or *General-Info*. But some results are less intuitive: for example, judges preferred different response lengths for queries categorized as *Person* and *Organization* – in fact for the latter the largest single selection made was *List*. Reviewing the queries for these two categories, we note that most queries about organizations in our collection asked for companies

length type	average	std dev
Word or Phrase	38.1	25.8
Sentence	148.1	71.4
Paragraph	490.5	303.1
Section	1574.2	1251.1

Table 3: Average number of characters for each answer length type for the stimuli used in the second experiment.

(e.g. “around the world travel agency”) and for these there usually is more than one correct answer, whereas the queries about persons (“CEO of microsoft”) typically only had one relevant answer. The results of this table show that there are some trends but not definitive relationships between query type (as classified in this study) and expected answer length. More detailed classifications might help resolve some of the conflicts.

### 3.3 Result Length Study

The purpose of the second study was twofold: first, to see if doing a larger study confirms what is hinted at in the literature: that search result lengths longer than the standard snippet may be desirable for at least a subset of queries. Second, we wanted to see if judges’ predictions of desirable results lengths would be confirmed by other judges’ responses to search results of different lengths.

#### 3.3.1 Method

It has been found that obtaining judges’ agreement on intent of a query from a log can be difficult (Rose and Levinson, 2004; Kellar et al., 2007). In order to make the task of judging query relevance easier, for the next phase of the study we focused on only those queries for which all three assessors in the first experiment agreed both on the category label and on the estimated ideal length. There were 1099 such high-confidence queries, whose average number of words was 6.3 (2.9) and average number of characters was 34.5 (14.3).

We randomly selected a subset of the high-agreement queries from the first experiment and manually excluded queries for which it seemed obvious that no responses could be found in Wikipedia. These included queries about song lyrics, since intellectual property restrictions prevent these being posted, and crossword puzzle questions such as “a four letter word for water.”

The remaining set contained 170 queries. MTurk annotators were asked to find one good text passage (in English) for each query from the Wikipedia online encyclopedia. They were also asked to subdivide the text of this answer into each of the following lengths: a word or phrase, a sentence, a paragraph, a section or an entire article.<sup>2</sup> Thus, the shorter answer passages are subsumed by the longer ones.

Table 3 shows the average lengths and standard deviations of each result length type. Table 4 contains sample answers for the shorter length formats for one query. For 24 of the 170 queries the annotators could not find a suitable response in Wikipedia, e.g., “How many miles between NY and Milwaukee?” We collected two to five results for each of the remaining 146 queries and manually chose the best of these answer passages. Note that, by design, all responses were factually correct; they only differed in their length.

Ten MTurk judges saw each query/answer length pair, and for each of these, were told: “Below you see a search engine query and a possible response. We would like you to give us your opinion about the response. We are especially interested in the length of the response. Is it suitable for the query? Is there too much or not enough information? Please rate the response on a scale from 0 (very bad response) to 10 (very good response).” There were 124 judges in total; of these, 16 did more than 146 HITS, meaning they saw the same query more than one time (but with different lengths). Upon examination of the results, we determined that two of these high-volume judges were not trying to do the task properly, and so we dropped their judgments from the final analysis.

#### 3.3.2 Results

Our results show that judges prefer results of different lengths, depending on the query. The results also suggest that judges’ estimates of a preferred result length in the first experiment are accurate predictors when there is strong agreement among them. Figure 2 shows in four diagrams

<sup>2</sup>Note the slight difference between the length categories in the first and second experiment: The *List* and *Other* options were dropped for the second experiment because we wanted to concentrate on textual length. Additionally, to provide more than one option between *Sentence* and *Article*, the category *One or more paragraphs* was split up into two: *(One) Paragraph* and *(One) Section*.

<b>query</b>	Who was the first person to scale K2?
<b>Paragraph</b>	An Italian expedition finally succeeded in ascending to the summit of K2 on July 31, 1954. The expedition was led by Ardito Desio, although the two climbers who actually reached the top were Lino Lacedelli and Achille Compagnoni. The team included a Pakistani member, Colonel Muhammad Ata-ullah. He had been a part of an earlier 1953 American expedition which failed to make the summit because of a storm which killed a key climber, Art Gilkey. On the expedition also was the famous Italian climber Walter Bonatti. He proved vital to the expeditions success in that he carried vital oxygen to 26,600ft for Lacedelli and Compagnoni. His dramatic bivouac, at that altitude with the equipment, wrote another chapter in the saga of Himalayan climbing.
<b>Sentence</b>	The expedition was led by Ardito Desio, although the two climbers who actually reached the top were Lino Lacedelli and Achille Compagnoni.
<b>Phrase</b>	Lino Lacedelli and Achille Compagnoni

Table 4: Sample answers of differing lengths used as input for the second study. Note that the shorter answers are contained in the longer ones. For the full article case, judges were asked to follow a hyperlink to an article.

Figure 2: Results of the second experiment, where each query/answer-length pair was assessed by 8–10 judges using a scale of 0 (‘very bad’) to 10 (‘very good’). Marks indicate means and standard errors. The top left graph shows responses of different lengths for queries that were classified as *best answered with a phrase* in the first experiment. The upper right shows responses for queries predicted to be *best answered with a sentence*, lower left for *best answered with one or more paragraphs* and lower right for *best answered with an article*.

	Slope	Std. Error	p-value
Phrase	-0.850	0.044	< 0.0001
Sentence	-0.550	0.050	< 0.0001
Paragraph	0.328	0.049	< 0.0001
Article	0.856	0.053	< 0.0001

Table 5: Results of unweighted linear regression on the data for the second experiment, which was separated into four groups based on the predicted preferred length.

how queries assigned by judges to one of the four length categories from the first experiment were judged when presented with responses of the five answer lengths from the second experiment. The graphs show the means and standard error of the judges' scores across all queries for each predicted-length/presented-length combination.

In order to test whether these results are significant we performed four separate linear regressions; one for each of the predicted preferred length categories. The snippet length, the independent variable, was coded as 1-5, shortest to longest. The score for each query-snippet pair is the dependent variable. Table 5 shows that for each group there is evidence to reject the null hypothesis that the slope is equal to 0 at the 99% confidence level. High scores are associated with shorter snippet lengths for queries with predicted preferred length *phrase* or *sentence* and also with longer snippet lengths for queries with predicted preferred length *paragraphs* or *article*. These associations are strongest for the queries with the most extreme predicted preferred lengths (*phrase* and *article*).

Our results also suggest the intuition that the best answer lengths do not form strictly distinct classes, but rather lie on a continuum. If the ideal response is from a certain category (e.g., a sentence), returning a result from an adjacent category (a phrase or a paragraph) is not strongly penalized by judges, whereas retuning a result from a category further up or down the scale (an article) is.

One potential drawback of this study format is that we do not show judges a list of results for queries, as is standard in search engines, and so they do not experience the tradeoff effect of longer results requiring more scrolling if the desired answer is not shown first. However, the earlier results of Cutrell & Guan (2007) and Paek et al. (2004) suggest that the

preference for longer results occurs even in contexts that require looking through multiple results. Another potential drawback of the study is that judges only view one relevant result; the effects of showing a list of long non-relevant results may be more negative than that of showing short non-relevant results; this study would not capture that effect.

## 4 Conclusions and Future Work

Our studies suggest that different queries are best served with different response lengths (Experiment 1), and that for a subset of especially clear queries, human judges can predict the preferred result lengths (Experiment 2). The results furthermore support the contention that standard results listings are too short in many cases, at least assuming that the summary shows information that is relevant for the query. These findings have important implications for the design of search results presentations, suggesting that as user queries become more expressive, search engine results should become more responsive to the type of answer desired. This may mean showing more context in the results listing, or perhaps using more dynamic tools such as expand-on-mouseover to help answer the query in place.

The obvious next step is to determine how to automatically classify queries according to their predicted result length and type. For classifying according to expected length, we have run some initial experiments based on unigram word counts which correctly classified 78% of 286 test queries (on 805 training queries) into one of three length bins. We plan to pursue this further in future work. For classifying according to type, as discussed above, most automated query classification for web logs have been based on the topic of the query rather than on the intended result type, but the question answering literature has intensively investigated how to predict appropriate answer types. It is likely that the techniques from these two fields can be productively combined to address this challenge.

**Acknowledgments.** This work was supported in part by Powerset, Inc., and in part by Microsoft Research through the MSR European PhD Scholarship Programme. We would like to thank Susan Gruber and Bonnie Webber for their helpful comments and suggestions.

## Abstract

Online forum discussions often contain vast amounts of questions that are the focuses of discussions. Extracting contexts and answers together with the questions will yield not only a coherent forum summary but also a valuable QA knowledge base. In this paper, we propose a general framework based on Conditional Random Fields (CRFs) to detect the contexts and answers of questions from forum threads. We improve the basic framework by Skip-chain CRFs and 2D CRFs to better accommodate the features of forums for better performance. Experimental results show that our techniques are very promising.

## 1 Introduction

Forums are web virtual spaces where people can ask questions, answer questions and participate in discussions. The availability of vast amounts of thread discussions in forums has promoted increasing interests in knowledge acquisition and summarization for forum threads. Forum thread usually consists of an initiating post and a number of reply posts. The initiating post usually contains several questions and the reply posts usually contain answers to the questions and perhaps new questions. Forum participants are not physically co-present, and thus reply may not happen immediately after questions are posted. The asynchronous nature and multi-participants make multiple questions and answers

Figure 1: An example thread with question-context-answer annotated

interweaved together, which makes it more difficult to summarize.

In this paper, we address the problem of detecting the contexts and answers from forum threads for the questions identified in the same threads. Figure 1 gives an example of a forum thread with questions, contexts and answers annotated. It contains three *question* sentences, S3, S5 and S6. Sentences S1 and S2 are *contexts* of *question* 1 (S3). Sentence S4 is the *context* of *questions* 2 and 3, but not 1. Sentence S8 is the answer to question 3. (S4-S5-S10) is one example of question-context-answer triple that we want to detect in the thread. As shown in the example, a forum question usually requires contextual information to provide background or constraints.

Moreover, it sometimes **needs contextual information to provide explicit link to its answers**. For example, S8 is an answer of *question 1*, but they cannot be linked with any common word. Instead, S8 shares word *pet* with S1, which is a context of *question 1*, and thus S8 could be linked with *question 1* through S1. We call contextual information the *context* of a question in this paper.

A summary of forum threads in the form of question-context-answer can not only highlight the main content, but also provide a user-friendly organization of threads, which will make the access to forum information easier.

Another motivation of detecting contexts and answers of the questions in forum threads is that it could be used to enrich the knowledge base of community-based question and answering (CQA) services such as Live QnA and Yahoo! Answers, where *context* is comparable with the question description while *question* corresponds to the question title. For example, there were about 700,000 questions in the Yahoo! Answers travel category as of January 2008. We extracted about 3,000,000 travel related questions from six online travel forums. One would expect that a CQA service with large QA data will attract more users to the service. To enrich the knowledge base, not only the answers, but also the contexts are critical; otherwise the answer to a question such as *How much is the taxi* would be useless without context in the database.

However, it is challenging to detecting contexts and answers for questions in forum threads. We assume the questions have been identified in a forum thread using the approach in (Cong et al., 2008). Although identifying questions in a forum thread is also nontrivial, it is beyond the focus of this paper.

First, detecting contexts of a question is important and non-trivial. We found that 74% of questions in our corpus, which contain 1,064 questions from 579 forum threads about travel, need contexts. However, relative position information is far from adequate to solve the problem. For example, in our corpus 63% of sentences preceding questions are contexts and they only represent 34% of all correct contexts. To effectively detect contexts, the dependency between sentences is important. For example in Figure 1, both S1 and S2 are contexts of *question 1*. S1 could be labeled as context based on word similarity, but it

is not easy to link S2 with the question directly. S1 and S2 are linked by the common word *family*, and thus S2 can be linked with *question 1* through S1. The challenge here is how to model and utilize the dependency for context detection.

Second, it is difficult to link answers with questions. In forums, multiple questions and answers can be discussed in parallel and are interweaved together while the reply relationship between posts is usually unavailable. To detect answers, we need to handle two kinds of dependencies. One is the dependency relationship between contexts and answers, which should be leveraged especially when questions alone do not provide sufficient information to find answers; the other is the dependency between answer candidates (similar to sentence dependency described above). The challenge is how to model and utilize these two kinds of dependencies.

In this paper we propose a novel approach for detecting contexts and answers of the questions in forum threads. To our knowledge this is the first work on this. We make the following contributions:

First, we employ Linear Conditional Random Fields (CRFs) to identify contexts and answers, which can capture the relationships between contiguous sentences.

Second, we also found that context is very important for answer detection. To capture the dependency between contexts and answers, we introduce Skip-chain CRF model for answer detection. We also extend the basic model to 2D CRFs to model dependency between contiguous questions in a forum thread for context and answer identification.

Finally, we conducted experiments on forum data. Experimental results show that 1) Linear CRFs outperform SVM and decision tree in both context and answer detection; 2) Skip-chain CRFs outperform Linear CRFs for answer finding, which demonstrates that **context improves answer finding**; 3) 2D CRF model improves the performance of Linear CRFs and the combination of 2D CRFs and Skip-chain CRFs achieves better performance for context detection.

The rest of this paper is organized as follows: The next section discusses related work. Section 3 presents the proposed techniques. We evaluate our techniques in Section 4. Section 5 concludes this paper and discusses future work.

## 2 Related Work

There is some research on summarizing discussion threads and emails. Zhou and Hovy (2005) segmented internet relay chat, clustered segments into subtopics, and identified responding segments of the first segment in each sub-topic by assuming the first segment to be focus. In (Nenkova and Bagga, 2003; Wan and McKeown, 2004; Rambow et al., 2004), email summaries were organized by extracting overview sentences as discussion issues. Carenini et al (2007) leveraged both quotation relation and clue words for email summarization. In contrast, given a forum thread, we extract questions, their contexts, and their answers as summaries.

Shrestha and McKeown (2004)’s work on email summarization is closer to our work. They used RIPPER as a classifier to detect interrogative questions and their answers and used the resulting question and answer pairs as summaries. However, it did not consider contexts of questions and dependency between answer sentences.

We also note the existing work on extracting knowledge from discussion threads. Huang et al.(2007) used SVM to extract *input-reply* pairs from forums for chatbot knowledge. Feng et al. (2006a) used cosine similarity to match students’ query with reply posts for discussion-bot. Feng et al. (2006b) identified the most important message in online classroom discussion board. Our problem is quite different from the above work.

Detecting context for question in forums is related to the context detection problem raised in the QA roadmap paper commissioned by ARDA (Burger et al., 2006). To our knowledge, none of the previous work addresses the problem of context detection. The method of finding follow-up questions (Yang et al., 2006) from TREC context track could be adapted for context detection. However, the follow-up relationship is limited between questions while context is not. In our other work (Cong et al., 2008), we proposed a supervised approach for question detection and an unsupervised approach for answer detection without considering context detection.

Extensive research has been done in question-answering, e.g. (Berger et al., 2000; Jeon et al., 2005; Cui et al., 2005; Harabagiu and Hickl, 2006; Dang et al., 2007). They mainly focus on con-

structing answer for certain types of question from a large document collection, and usually apply sophisticated linguistic analysis to both questions and the documents in the collection. Soricut and Brill (2006) used statistical translation model to find the appropriate answers from their QA pair collections from FAQ pages for the posted question. In our scenario, we not only need to find answers for various types of questions in forum threads but also their contexts.

## 3 Context and Answer Detection

A question is a linguistic expression used by a questioner to request information in the form of an answer. The sentence containing request focus is called *question*. *Context* are the sentences containing constraints or background information to the question, while *answer* are that provide solutions. In this paper, we use sentences as the detection segment though it is applicable to other kinds of segments.

Given a thread and a set of  $m$  detected questions  $\{Q_i\}_{i=1}^m$ , our task is to find the contexts and answers for each question. We first discuss using Linear CRFs for context and answer detection, and then extend the basic framework to Skip-chain CRFs and 2D CRFs to better model our problem. Finally, we will briefly introduce CRF models and the features that we used for CRF model.

### 3.1 Using Linear CRFs

For ease of presentation, we focus on detecting contexts using Linear CRFs. The model could be easily extended to answer detection.

**Context detection.** As discussed in Introduction that context detection cannot be trivially solved by position information (See Section 4.2 for details), and dependency between sentences is important for context detection. Recall that in Figure 1, S2 could be labeled as context of Q1 if we consider the dependency between S2 and S1, and that between S1 and Q1, while it is difficult to establish connection between S2 and Q1 without S1. Table 1 shows that the correlation between the labels of contiguous sentences is significant. In other words, when a sentence  $Y_t$ ’s previous  $Y_{t-1}$  is not a context ( $Y_{t-1} \neq C$ ) then it is very likely that  $Y_t$  (i.e.  $Y_t \neq C$ ) is also not a context. It is clear that the candidate contexts are not independent and there are strong dependency rela-

Contiguous sentences	$y_t = C$	$y_t \neq C$
$y_{t-1} = C$	901	1,081
$y_{t-1} \neq C$	1,081	47,190

Table 1: Contingency table( $\chi^2 = 9,386, p\text{-value} < 0.001$ )

tionships between contiguous sentences in a thread. Therefore, a desirable model should be able to capture the dependency.

The context detection can be modeled as a classification problem. Traditional classification tools, e.g. SVM, can be employed, where each pair of question and candidate context will be treated as an instance. However, they cannot capture the dependency relationship between sentences.

To this end, we proposed a general framework to detect contexts and answers based on Conditional Random Fields (Lafferty et al., 2001) (CRFs) which are able to model the sequential dependencies between contiguous nodes. A CRF is an undirected graphical model  $G$  of the conditional distribution  $P(\mathbf{Y}|\mathbf{X})$ .  $\mathbf{Y}$  are the random variables over the labels of the nodes that are globally conditioned on  $\mathbf{X}$ , which are the random variables of the observations. (See Section 3.4 for more about CRFs)

Linear CRF model has been successfully applied in NLP and text mining tasks (McCallum and Li, 2003; Sha and Pereira, 2003). However, our problem cannot be modeled with Linear CRFs in the same way as other NLP tasks, where one node has a unique label. In our problem, each node (sentence) might have multiple labels since one sentence could be the context of multiple questions in a thread. Thus, it is difficult to find a solution to tag context sentences for all questions in a thread in single pass.

Here we assume that questions in a given thread are independent and are found, and then we can label a thread with  $m$  questions one-by-one in  $m$ -passes. In each pass, one question  $Q_i$  is selected as focus and each other sentence in the thread will be labeled as *context*  $C$  of  $Q_i$  or not using Linear CRF model. The graphical representations of Linear CRFs is shown in Figure2(a). The linear-chain edges can capture the dependency between two contiguous nodes. The observation sequence  $\mathbf{x} = \langle \mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_t \rangle$ , where  $t$  is the number of sentences in a thread, represents predictors (to be described in Section 3.5), and the tag sequence  $\mathbf{y} = \langle y_1, \dots, y_t \rangle$ , where

$y_i \in \{C, P\}$ , determines whether a sentence is plain text  $P$  or context  $C$  of question  $Q_i$ .

**Answer detection.** Answers usually appear in the posts after the post containing the question. There are also strong dependencies between contiguous answer segments. Thus, position and similarity information alone are not adequate here. To cope with the dependency between contiguous answer segments, Linear CRFs model are employed as in context detection.

### 3.2 Leveraging Context for Answer Detection Using Skip-chain CRFs

We observed in our corpus 74% questions lack constraints or background information which are very useful to link question and answers as discussed in Introduction. Therefore, contexts should be leveraged to detect answers. The Linear CRF model can capture the dependency between contiguous sentences. However, it cannot capture the long distance dependency between contexts and answers.

One straightforward method of leveraging context is to detect contexts and answers in two phases, i.e. to first identify contexts, and then label answers using both the context and question information (e.g. the similarity between context and answer can be used as features in CRFs). The two-phase procedure, however, still cannot capture the non-local dependency between contexts and answers in a thread.

To model the long distance dependency between contexts and answers, we will use Skip-chain CRF model to detect context and answer together. Skip-chain CRF model is applied for entity extraction and meeting summarization (Sutton and McCallum, 2006; Galley, 2006). The graphical representation of a Skip-chain CRF given in Figure2(b) consists of two types of edges: linear-chain ( $y_{t-1}$  to  $y_t$ ) and skip-chain edges ( $y_i$  to  $y_j$ ).

Ideally, the skip-chain edges will establish the connection between candidate pairs with high probability of being context and answer of a question. To introduce skip-chain edges between any pairs of non-contiguous sentences will be computationally expensive, and also introduce noise. To make the cardinality and number of cliques in the graph manageable and also eliminate noisy edges, we would like to generate edges only for sentence pairs with high possibility of being context and answer. This is

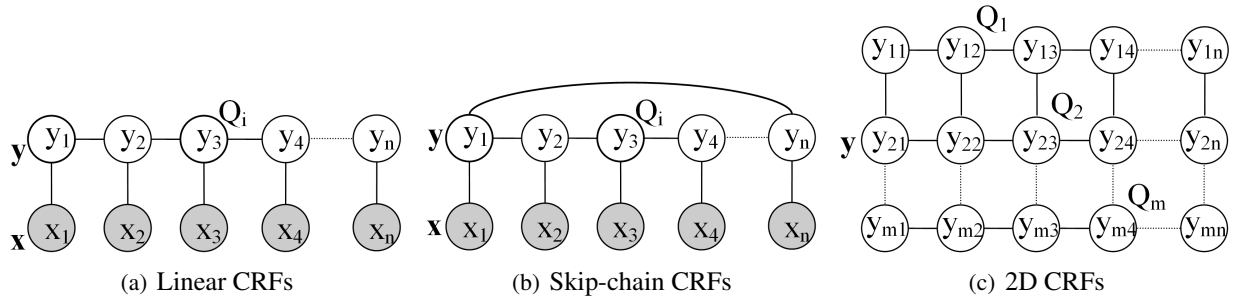

Figure 2: CRF Models

Skip-Chain	$y_v = A$	$y_v \neq A$
$y_u = C$	4,105	5,314
$y_u \neq C$	3,744	9,740

Table 2: Contingence table( $\chi^2=615.8, p\text{-value} < 0.001$ )

achieved as follows. Given a question  $Q_i$  in post  $P_j$  of a thread with  $n$  posts, its contexts usually occur within post  $P_j$  or before  $P_j$  while answers appear in the posts after  $P_j$ . We will establish an edge between each candidate answer  $v$  and one candidate context in  $\{P_k\}_{k=1}^j$  such that they have the highest possibility of being a context-answer pair of question  $Q_i$ :

$$u = \underset{u \in \{P_k\}_{k=1}^j}{\operatorname{argmax}} \operatorname{sim}(x_u, Q_i) \cdot \operatorname{sim}(x_v, \{x_u, Q_i\})$$

here, we use the product of  $\operatorname{sim}(x_u, Q_i)$  and  $\operatorname{sim}(x_v, \{x_u, Q_i\})$  to estimate the possibility of being a context-answer pair for  $(u, v)$ , where  $\operatorname{sim}(\cdot, \cdot)$  is the semantic similarity calculated on WordNet as described in Section 3.5. Table 2 shows that  $y_u$  and  $y_v$  in the skip chain generated by our heuristics influence each other significantly.

Skip-chain CRFs improve the performance of answer detection due to the introduced skip-chain edges that represent the joint probability conditioned on the question, which is exploited by skip-chain feature function:  $f(y_u, y_v, Q_i, \mathbf{x})$ .

### 3.3 Using 2D CRF Model

Both Linear CRFs and Skip-chain CRFs label the contexts and answers for each question in separate passes by assuming that questions in a thread are independent. Actually the assumption does not hold in many cases. Let us look at an example. As in Figure 1, sentence S10 is an answer for both question Q2 and Q3. S10 could be recognized as the answer of Q2 due to the shared word *areas* and *Causeway*

bay (in Q2’s context, S4), but there is no direct relation between Q3 and S10. To label S10, we need consider the dependency relation between Q2 and Q3. In other words, the question-answer relation between Q3 and S10 can be captured by a joint modeling of the dependency among S10, Q2 and Q3. The labels of the same sentence for two contiguous questions in a thread would be conditioned on the dependency relationship between the questions. Such a dependency cannot be captured by both Linear CRFs and Skip-chain CRFs.

To capture the dependency between the contiguous questions, we employ 2D CRFs to help context and answer detection. 2D CRF model is used in (Zhu et al., 2005) to model the neighborhood dependency in blocks within a web page. As shown in Figure2(c), 2D CRF models the labeling task for all questions in a thread. For each thread, there are  $m$  rows in the grid, where the  $i$ th row corresponds to one pass of Linear CRF model (or Skip-chain model) which labels contexts and answers for question  $Q_i$ . The vertical edges in the figure represent the joint probability conditioned on the contiguous questions, which will be exploited by 2D feature function:  $f(y_{i,j}, y_{i+1,j}, Q_i, Q_{i+1}, \mathbf{x})$ . Thus, the information generated in single CRF chain could be propagated over the whole grid. In this way, context and answer detection for all questions in the thread could be modeled together.

### 3.4 Conditional Random Fields (CRFs)

The Linear, Skip-Chain and 2D CRFs can be generalized as pairwise CRFs, which have two kinds of cliques in graph  $G$ : 1) node  $y_t$  and 2) edge  $(y_u, y_v)$ . The joint probability is defined as:

$$p(\mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left\{\sum_{k,t} \lambda_k f_k(y_t, \mathbf{x}) + \sum_{k,t} \mu_k g_k(y_u, y_v, \mathbf{x})\right\}$$

where  $Z(\mathbf{x})$  is the normalization factor,  $f_k$  is the feature on nodes,  $g_k$  is on edges between  $u$  and  $v$ , and  $\lambda_k$  and  $\mu_k$  are parameters.

Linear CRFs are based on the first order Markov assumption that the contiguous nodes are dependent. The pairwise edges in Skip-chain CRFs represent the long distance dependency between the skipped nodes, while the ones in 2D CRFs represent the dependency between the neighboring nodes.

**Inference and Parameter Estimation.** For Linear CRFs, dynamic programming is used to compute the *maximum a posteriori* (MAP) of  $\mathbf{y}$  given  $\mathbf{x}$ . However, for more complicated graphs with cycles, exact inference needs the junction tree representation of the original graph and the algorithm is exponential to the treewidth. For fast inference, loopy Belief Propagation (Pearl, 1988) is implemented.

Given the training Data  $D = \{\mathbf{x}^{(i)}, \mathbf{y}^{(i)}\}_{i=1}^n$ , the parameter estimation is to determine the parameters based on maximizing the log-likelihood  $L_\lambda = \sum_{i=1}^n \log p(\mathbf{y}^{(i)} | \mathbf{x}^{(i)})$ . In Linear CRF model, dynamic programming and L-BFGS (limited memory Broyden-Fletcher-Goldfarb-Shanno) can be used to optimize objective function  $L_\lambda$ , while for complicated CRFs, Loopy BP are used instead to calculate the marginal probability.

### 3.5 Features used in CRF models

The main features used in Linear CRF models for context detection are listed in Table 3.

The similarity feature is to capture the word similarity and semantic similarity between candidate contexts and answers. The word similarity is based on cosine similarity of TF/IDF weighted vectors. The semantic similarity between words is computed based on Wu and Palmer’s measure (Wu and Palmer, 1994) using WordNet (Fellbaum, 1998).<sup>1</sup> The similarity between contiguous sentences will be used to capture the dependency for CRFs. In addition, to bridge the lexical gaps between question and context, we learned top-3 context terms for each question term from 300,000 question-description pairs obtained from Yahoo! Answers using mutual information (Berger et al., 2000) (question description in Yahoo! Answers is comparable to contexts in fo-

<sup>1</sup>The semantic similarity between sentences is calculated as in (Yang et al., 2006).

<p><u>Similarity features:</u></p> <ul style="list-style-type: none"> <li>· Cosine similarity with the question</li> <li>· Similarity with the question using WordNet</li> <li>· Cosine similarity between contiguous sentences</li> <li>· Similarity between contiguous sentences using WordNet</li> <li>· Cosine similarity with the expanded question using the lexical matching words</li> </ul> <p><u>Structural features:</u></p> <ul style="list-style-type: none"> <li>· The relative position to current question</li> <li>· Is its author the same with that of the question?</li> <li>· Is it in the same paragraph with its previous sentence?</li> </ul> <p><u>Discourse and lexical features:</u></p> <ul style="list-style-type: none"> <li>· The number of Pronouns in the question</li> <li>· The presence of fillers, fluency devices (e.g. “uh”, “ok”)</li> <li>· The presence of acknowledgment tokens</li> <li>· The number of non-stopwords</li> <li>· Whether the question has a noun or not?</li> <li>· Whether the question has a verb or not?</li> </ul>
--

Table 3: Features for Linear CRFs. Unless otherwise mentioned, we refer to features of the sentence whose label to be predicted

ums), and then use them to expand question and compute cosine similarity.

The structural features of forums provide strong clues for contexts. For example, contexts of a question usually occur in the post containing the question or preceding posts.

We extracted the discourse features from a question, such as the number of pronouns in the question. A more useful feature would be to find the entity in surrounding sentences referred by a pronoun. We tried GATE (Cunningham et al., 2002) for anaphora resolution of the pronouns in questions, but the performance became worse with the feature, which is probably due to the difficulty of anaphora resolution in forum discourse. We also observed that questions often need context if the question do not contain a noun or a verb.

In addition, we use similarity features between skip-chain sentences for Skip-chain CRFs and similarity features between questions for 2D CRFs.

## 4 Experiments

### 4.1 Experimental setup

**Corpus.** We obtained about 1 million threads from TripAdvisor forum; we randomly selected 591 threads and removed 22 threads which has more than 40 sentences and 6 questions; the remaining 579 forum threads form our corpus<sup>2</sup>. Each thread in our

<sup>2</sup>Tripadvisor (<http://www.tripadvisor.com/ForumHome>) is one of the most popular travel forums; the list of 579 urls is

Model	Prec(%)	Rec(%)	F <sub>1</sub> (%)
Context Detection			
SVM	75.27	68.80	71.32
C4.5	70.16	64.30	67.21
L-CRF	<b>75.75</b>	<b>72.84</b>	<b>74.45</b>
Answer Detection			
SVM	<b>73.31</b>	47.35	57.52
C4.5	65.36	46.55	54.37
L-CRF	63.92	<b>58.74</b>	<b>61.22</b>

Table 4: Context and Answer Detection

corpus contains at least two posts and on average each thread consists of 3.87 posts. Two annotators were asked to tag questions, their contexts, and answers in each thread. The kappa statistic for identifying question is 0.96, for linking context and question given a question is 0.75, and for linking answer and question given a question is 0.69. We conducted experiments on both the union and intersection of the two annotated data. The experimental results on both data are qualitatively comparable. We only report results on union data due to space limitation. The union data contains 1,064 questions, 1,458 contexts and 3,534 answers.

**Metrics.** We calculated precision, recall, and F<sub>1</sub>-score for all tasks. All the experimental results are obtained through the average of 5 trials of 5-fold cross validation.

## 4.2 Experimental results

### Linear CRFs for Context and Answer Detection.

This experiment is to evaluate Linear CRF model (Section 3.1) for context and answer detection by comparing with SVM and C4.5(Quinlan, 1993). For SVM, we use SVM<sup>light</sup>(Joachims, 1999). We tried linear, polynomial and RBF kernels and report the results on polynomial kernel using default parameters since it performs the best in the experiment. SVM and C4.5 use the same set of features as Linear CRFs. As shown in Table 4, Linear CRF model outperforms SVM and C4.5 for both context and answer detection. The main reason for the improvement is that CRF models can capture the sequential dependency between segments in forums as discussed in Section 3.1.

given in <http://homepages.inf.ed.ac.uk/gcong/ac108/>; Removing the 22 long threads can greatly reduce the training and test time.

position	Prec(%)	Rec(%)	F <sub>1</sub> (%)
Context Detection			
Previous One	63.69	34.29	44.58
Previous All	43.48	76.41	55.42
Answer Detection			
Following One	66.48	19.98	30.72
Following All	31.99	100	48.48

Table 5: Using position information for detection

Context	Prec(%)	Rec(%)	F <sub>1</sub> (%)
No context	63.92	58.74	61.22
Prev. sentence	61.41	62.50	61.84
Real context	63.54	66.40	64.94
L-CRF+context	65.51	63.13	64.06

Table 6: Contextual Information for Answer Detection. Prev. sentence uses one previous sentence of the current question as context. RealContext uses the context annotated by experts. L-CRF+context uses the context found by Linear CRFs

We next report a baseline of context detection using previous sentences in the same post with its question since contexts often occur in the question post or preceding posts. Similarly, we report a baseline of answer detecting using following segments of a question as answers. The results given in Table 5 show that location information is far from adequate to detect contexts and answers.

**The usefulness of contexts.** This experiment is to evaluate the usefulness of contexts in answer detection, by adding the similarity between the context (obtained with different methods) and candidate answer as an extra feature for CRFs. Table 6 shows the impact of context on answer detection using Linear CRFs. Linear CRFs with contextual information perform better than those without context. L-CRF+context is close to that using real context, while it is better than CRFs using the previous sentence as context. The results clearly shows that contextual information greatly improves the performance of answer detection.

**Improved Models.** This experiment is to evaluate the effectiveness of Skip-Chain CRFs (Section 3.2) and 2D CRFs (Section 3.3) for our tasks. The results are given in Table 7 and Table 8.

In context detection, Skip-Chain CRFs have simi-

Model	Prec(%)	Rec(%)	F <sub>1</sub> (%)
L-CRF+Context	75.75	72.84	74.45
Skip-chain	74.18	74.90	74.42
2D	75.92	76.54	76.41
2D+Skip-chain	<b>76.27</b>	<b>78.25</b>	<b>77.34</b>

Table 7: Skip-chain and 2D CRFs for context detection

lar results as Linear CRFs, i.e. the inter-dependency captured by the skip chains generated using the heuristics in Section 3.2 does not improve the context detection. The performance of Linear CRFs is improved in 2D CRFs (by 2%) and 2D+Skip-chain CRFs (by 3%) since they capture the dependency between contiguous questions.

In answer detection, as expected, Skip-chain CRFs outperform L-CRF+context since Skip-chain CRFs can model the inter-dependency between contexts and answers while in L-CRF+context the context can only be reflected by the features on the observations. We also observed that 2D CRFs improve the performance of L-CRF+context due to the dependency between contiguous questions. In contrast with our expectation, the 2D+Skip-chain CRFs does not improve Skip-chain CRFs in terms of answer detection. The possible reason could be that the structure of the graph is very complicated and too many parameters need to be learned on our training data.

**Evaluating Features.** We also evaluated the contributions of each category of features in Table 3 to context detection. We found that similarity features are the most important and structural feature the next. We also observed the same trend for answer detection. We omit the details here due to space limitation.

As a summary, 1) our CRF model outperforms SVM and C4.5 for both context and answer detections; 2) context is very useful in answer detection; 3) the Skip-chain CRF method is effective in leveraging context for answer detection; and 4) 2D CRF model improves the performance of Linear CRFs for both context and answer detection.

## 5 Discussions and Conclusions

We presented a new approach to detecting contexts and answers for questions in forums with good performance. We next discuss our experience not covered by the experiments, and future work.

Model	Prec(%)	Rec(%)	F <sub>1</sub> (%)
L-CRF+context	65.51	63.13	64.06
Skip-chain	<b>67.59</b>	<b>71.06</b>	<b>69.40</b>
2D	65.77	68.17	67.34
2D+Skip-chain	66.90	70.56	68.89

Table 8: Skip-chain and 2D CRFs for answer detection

Since contexts of questions are largely unexplored in previous work, we analyze the contexts in our corpus and classify them into three categories: 1) context contains the main content of question while question contains no constraint, e.g. “*i will visit NY at Oct, looking for a cheap hotel but convenient. Any good suggestion?* ”; 2) contexts explain or clarify part of the question, such as a definite noun phrase, e.g. “*We are going on the Taste of Paris. Does anyone know if it is advisable to take a suitcase with us on the tour.*”, where the first sentence is to describe *the tour*; and 3) contexts provide constraint or background for question that is syntactically complete, e.g. “*We are interested in visiting the Great Wall(and flying from London). Can anyone recommend a tour operator.*” In our corpus, about 26% questions do not need context, 12% questions need Type 1 context, 32% need Type 2 context and 30% Type 3. We found that our techniques often do not perform well on Type 3 questions.

We observed that factoid questions, one of focuses in the TREC QA community, take less than 10% question in our corpus. It would be interesting to revisit QA techniques to process forum data.

Other future work includes: 1) to summarize multiple threads using the triples extracted from individual threads. This could be done by clustering question-context-answer triples; 2) to use the traditional text summarization techniques to summarize the multiple answer segments; 3) to integrate the Question Answering techniques as features of our framework to further improve answer finding; 4) to reformulate questions using its context to generate more user-friendly questions for CQA services; and 5) to evaluate our techniques on more online forums in various domains.

# Learning to Rank Answers on Large Online QA Collections

Mihai Surdeanu, Massimiliano Ciaramita, Hugo Zaragoza

Barcelona Media Innovation Center, Yahoo! Research Barcelona

mihai.surdeanu@barcelonamedia.org, {massi, hugo}@yahoo-inc.com

## Abstract

This work describes an answer ranking engine for non-factoid questions built using a large online community-generated question-answer collection (Yahoo! Answers). We show how such collections may be used to effectively set up large supervised learning experiments. Furthermore we investigate a wide range of feature types, some exploiting NLP processors, and demonstrate that using them in combination leads to considerable improvements in accuracy.

## 1 Introduction

The problem of Question Answering (QA) has received considerable attention in the past few years. Nevertheless, most of the work has focused on the task of factoid QA, where questions match short answers, usually in the form of named or numerical entities. Thanks to international evaluations organized by conferences such as the Text REtrieval Conference (TREC)<sup>1</sup> or the Cross Language Evaluation Forum (CLEF) Workshop<sup>2</sup>, annotated corpora of questions and answers have become available for several languages, which has facilitated the development of robust machine learning models for the task.

The situation is different once one moves beyond the task of factoid QA. Comparatively little research has focused on QA models for non-factoid questions such as causation, manner, or reason questions. Because virtually no training data is available for this problem, most automated systems train either

on small hand-annotated corpora built in house (Higashinaka and Isozaki, 2008) or on question-answer pairs harvested from Frequently Asked Questions (FAQ) lists or similar resources (Soricut and Brill, 2006). None of these situations is ideal: the cost of building the training corpus in the former setup is high; in the latter scenario the data tends to be domain-specific, hence unsuitable for the learning of open-domain models.

On the other hand, recent years have seen an explosion of user-generated content (or social media). Of particular interest in our context are community-driven question-answering sites, such as Yahoo! Answers<sup>3</sup>, where users answer questions posed by other users and best answers are selected manually either by the asker or by all the participants in the thread. The data generated by these sites has significant advantages over other web resources: (a) it has a high growth rate and it is already abundant; (b) it covers a large number of topics, hence it offers a better

<sup>3</sup><http://answers.yahoo.com>

approximation of open-domain content; and (c) it is available for many languages. Community QA sites, similar to FAQs, provide large number of question-answer pairs. Nevertheless, this data has a significant drawback: it has high variance of quality, i.e., answers range from very informative to completely irrelevant or even abusive. Table 1 shows some examples of both high and low quality content.

In this paper we address the problem of answer ranking for non-factoid questions from social media content. Our research objectives focus on answering the following two questions:

1. *Is it possible to learn an answer ranking model for complex questions from such noisy data?* This is an interesting question because a positive answer indicates that a plethora of training data is readily available to QA researchers and system developers.
2. *Which features are most useful in this scenario?* Are similarity models as effective as models that learn question-to-answer transformations? Does syntactic and semantic information help? For generality, we focus only on textual features extracted from the answer text and we ignore all meta data information that is not generally available.

Notice that we concentrate on one component of a possible social-media QA system. In addition to answer ranking, a complete system would have to search for similar questions already answered (Jeon et al., 2005), and rank content quality using "social" features such as the authority of users (Jeon et al., 2006; Agichtein et al., 2008). This is not the focus of our work: here we investigate the problem of learning an answer ranking model capable of dealing with complex questions, using a large number of, possible noisy, question-answer pairs. By focusing exclusively on textual content we increase the portability of our approach to other collections where "social" features might not be available, e.g., Web search.

The paper is organized as follows. We describe our approach, including all the features explored for answer modeling, in Section 2. We introduce the corpus used in our empirical analysis in Section 3. We detail our experiments and analyze the results in Section 4. We overview related work in Section 5 and conclude the paper in Section 6.

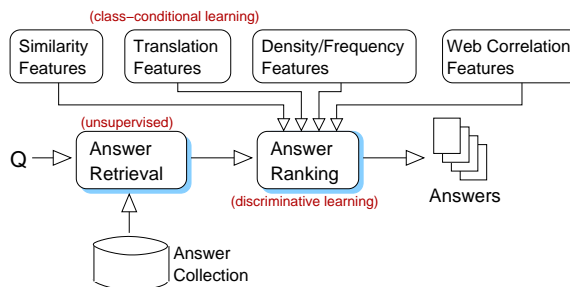

Figure 1: System architecture.

## 2 Approach

The architecture of the QA system analyzed in the paper, summarized in Figure 1, follows that of the most successful TREC systems. The first component, answer retrieval, extracts a set of candidate answers  $\mathbf{A}$  for question  $Q$  from a large collection of answers,  $\mathbf{C}$ , provided by a community-generated question-answering site. The retrieval component uses a state-of-the-art information retrieval (IR) model to extract  $\mathbf{A}$  given  $Q$ . Since our focus is on exploring the usability of the answer content, we do not perform retrieval by finding similar questions already answered (Jeon et al., 2005), i.e., our answer collection  $\mathbf{C}$  contains only the site’s answers without the corresponding questions answered.

The second component, answer ranking, assigns to each answer  $A_i \in \mathbf{A}$  a score that represents the likelihood that  $A_i$  is a correct answer for  $Q$ , and ranks all answers in descending order of these scores. The scoring function is a linear combination of four different classes of features (detailed in Section 2.2). This function is the focus of the paper. To answer our first research objective we will compare the quality of the rankings provided by this component against the rankings generated by the IR model used for answer retrieval. To answer the second research objective we will analyze the contribution of the proposed feature set to this function. Again, since our interest is in investigating the utility of the answer textual content, we use only information extracted from the answer text when learning the scoring function. We do not use any meta information (e.g., answerer credibility, click counts, etc.) (Agichtein et al., 2008; Jeon et al., 2006).

Our QA approach combines three types of machine learning methodologies (as highlighted in Figure 1): the answer retrieval component uses un-

supervised IR models, the answer ranking is implemented using discriminative learning, and finally, some of the ranking features are produced by question-to-answer translation models, which use class-conditional learning.

## 2.1 Ranking Model

Learning with user-generated content can involve arbitrarily large amounts of data. For this reason we choose as a ranking algorithm the Perceptron which is both accurate and efficient and can be trained with online protocols. Specifically, we implement the ranking Perceptron proposed by Shen and Joshi (2005), which reduces the ranking problem to a binary classification problem. The general intuition is to exploit the pairwise preferences induced from the data by training on pairs of patterns, rather than independently on each pattern. Given a weight vector  $\alpha$ , the score for a pattern  $\mathbf{x}$  (a candidate answer) is simply the inner product between the pattern and the weight vector:

$$f_{\alpha}(\mathbf{x}) = \langle \mathbf{x}, \alpha \rangle \quad (1)$$

However, the error function depends on pairwise scores. In training, for each pair  $(\mathbf{x}_i, \mathbf{x}_j) \in \mathbf{A}$ , the score  $f_{\alpha}(\mathbf{x}_i - \mathbf{x}_j)$  is computed; note that if  $f$  is an inner product  $f_{\alpha}(\mathbf{x}_i - \mathbf{x}_j) = f_{\alpha}(\mathbf{x}_i) - f_{\alpha}(\mathbf{x}_j)$ . Given a margin function  $g(i, j)$  and a positive rate  $\tau$ , if  $f_{\alpha}(\mathbf{x}_i - \mathbf{x}_j) \leq g(i, j)\tau$ , an update is performed:

$$\alpha^{t+1} = \alpha^t + (\mathbf{x}_i - \mathbf{x}_j)\tau g(i, j) \quad (2)$$

By default we use  $g(i, j) = (\frac{1}{i} - \frac{1}{j})$ , as a margin function, as suggested in (Shen and Joshi, 2005), and find  $\tau$  empirically on development data. Given that there are only two possible ranks in our setting, this function only generates two possible values. For regularization purposes, we use as a final model the average of all Perceptron models posited during training (Freund and Schapire, 1999).

## 2.2 Features

In the scoring model we explore a rich set of features inspired by several state-of-the-art QA systems. We investigate how such features can be adapted and combined for non-factoid answer ranking, and perform a comparative feature analysis using a significant amount of real-world data. For clarity, we group the features into four sets: features that model

the similarity between questions and answers (FG1), features that encode question-to-answer transformations using a translation model (FG2), features that measure keyword density and frequency (FG3), and features that measure the correlation between question-answer pairs and other collections (FG4). Wherever applicable, we explore different syntactic and semantic representations of the textual content, e.g., extracting the dependency-based representation of the text or generalizing words to their WordNet supersenses (WNSS) (Ciaramita and Altun, 2006). We detail each of these feature groups next.

### FG1: Similarity Features

We measure the similarity between a question  $Q$  and an answer  $A$  using the length-normalized *BM25* formula (Robertson and Walker, 1997). We chose this similarity formula because, out of all the IR models we tried, it provided the best ranking at the output of the answer retrieval component. For completeness we also include in the feature set the value of the *tf · idf* similarity measure. For both formulas we use the implementations available in the Terrier IR platform<sup>4</sup> with the default parameters.

To understand the contribution of our syntactic and semantic processors we compute the above similarity features for five different representations of the question and answer content:

*Words (W)* - this is the traditional IR view where the text is seen as a bag of words.

*Dependencies (D)* - the text is represented as a bag of binary syntactic dependencies. The relative syntactic processor is detailed in Section 3. Dependencies are fully lexicalized but unlabeled and we currently extract dependency paths of length 1, i.e., direct head-modifier relations (this setup achieved the best performance).

*Generalized dependencies (D<sub>g</sub>)* - same as above, but the words in dependencies are generalized to their WNSS, if detected.

*Bigrams (B)* - the text is represented as a bag of bigrams (larger  $n$ -grams did not help). We added this view for a fair analysis of the above syntactic views.

*Generalized bigrams (B<sub>g</sub>)* - same as above, but the words are generalized to their WNSS.

<sup>4</sup><http://ir.dcs.gla.ac.uk/terrier>

In all these representations we skip stop words and normalize all words to their WordNet lemmas.

## FG2: Translation Features

Berger et al. (2000) showed that similarity-based models are doomed to perform poorly for QA because they fail to “bridge the lexical chasm” between questions and answers. One way to address this problem is to learn question-to-answer transformations using a translation model (Berger et al., 2000; Echihiabi and Marcu, 2003; Soricut and Brill, 2006; Riezler et al., 2007). In our model, we incorporate this approach by adding the probability that the question  $Q$  is a translation of the answer  $A$ ,  $P(Q|A)$ , as a feature. This probability is computed using IBM’s Model 1 (Brown et al., 1993):

$$P(Q|A) = \prod_{q \in Q} P(q|A) \quad (3)$$

$$P(q|A) = (1 - \lambda)P_{ml}(q|A) + \lambda P_{ml}(q|C) \quad (4)$$

$$P_{ml}(q|A) = \sum_{a \in A} (T(q|a)P_{ml}(a|A)) \quad (5)$$

where the probability that the question term  $q$  is generated from answer  $A$ ,  $P(q|A)$ , is smoothed using the prior probability that the term  $q$  is generated from the entire collection of answers  $C$ ,  $P_{ml}(q|C)$ .  $\lambda$  is the smoothing parameter.  $P_{ml}(q|C)$  is computed using the maximum likelihood estimator.  $P_{ml}(q|A)$  is computed as the sum of the probabilities that the question term  $q$  is a translation of an answer term  $a$ ,  $T(q|a)$ , weighted by the probability that  $a$  is generated from  $A$ . The translation table for  $T(q|a)$  is computed using the EM-based algorithm implemented in the GIZA++ toolkit<sup>5</sup>.

Similarly with the previous feature group, we add translation-based features for the five different text representations introduced above. By moving beyond the bag-of-words representation we hope to learn relevant transformations of structures, e.g., from the “squeaky”  $\rightarrow$  “door” dependency to “spray”  $\leftarrow$  “WD-40” in the Table 1 example.

## FG3: Density and Frequency Features

These features measure the density and frequency of question terms in the answer text. Variants of these features were used previously for either answer or passage ranking in factoid QA (Moldovan et al., 1999; Harabagiu et al., 2000).

<sup>5</sup><http://www.fjoch.com/GIZA++.html>

*Same word sequence* - computes the number of non-stop question words that are recognized in the same order in the answer.

*Answer span* - the largest distance (in words) between two non-stop question words in the answer.

*Same sentence match* - number of non-stop question terms matched in a single sentence in the answer.

*Overall match* - number of non-stop question terms matched in the complete answer.

These last two features are computed also for the other four text representations previously introduced ( $B$ ,  $B_g$ ,  $D$ , and  $D_g$ ). Counting the number of matched dependencies is essentially a simplified tree kernel for QA (e.g., see (Moschitti et al., 2007)) matching only trees of depth 2. Experiments with full dependency tree kernels based on several variants of the convolution kernels of Collins and Duffy (2001) did not yield improvements. We conjecture that the mistakes of the syntactic parser may be amplified in tree kernels, which consider an exponential number of sub-trees.

*Informativeness* - we model the amount of information contained in the answer by counting the number of non-stop nouns, verbs, and adjectives in the answer text that do not appear in the question.

## FG4: Web Correlation Features

Previous work has shown that the redundancy of a large collection (e.g., the web) can be used for answer validation (Brill et al., 2001; Magnini et al., 2002). In the same spirit, we add features that measure the correlation between question-answer pairs and large external collections:

*Web correlation* - we measure the correlation between the question-answer pair and the web using the Corrected Conditional Probability (CCP) formula of Magnini et al. (2002):  $CCP(Q, A) = hits(Q + A) / (hits(Q) hits(A)^{2/3})$  where *hits* returns the number of page hits from a search engine. When a query returns zero hits we iteratively relax it by dropping the keyword with the smallest priority. Keyword priorities are assigned using the heuristics of Moldovan et al. (1999).

*Query-log correlation* - as in (Ciaramita et al., 2008) we also compute the correlation between question-answer pairs and a search-engine query-log corpus of more than 7.5 million queries, which shares

roughly the same time stamp with the community-generated question-answer corpus. We compute the Pointwise Mutual Information (PMI) and Chi square ( $\chi^2$ ) association measures between each question-answer word pair in the query-log corpus. The largest and the average values are included as features, as well as the number of QA word pairs which appear in the top 10, 5, and 1 percentile of the PMI and  $\chi^2$  word pair rankings.

### 3 The Corpus

The corpus is extracted from a sample of the U.S. Yahoo! Answers logs. In this paper we focus on the subset of advice or “how to” questions due to their frequency and importance in social communities.<sup>6</sup> To construct our corpus, we implemented the following successive filtering steps:

Step 1: from the full corpus we keep only questions that match the regular expression:

```
how (to|do|did|does|can|would|could|should)
and have an answer selected as best either by
the asker or by the participants in the thread.
The outcome of this step is a set of 364,419
question-answer pairs.
```

Step 2: from the above corpus we remove the questions and answers of obvious low quality. We implement this filter with a simple heuristic by keeping only questions and answers that have at least 4 words each, out of which at least 1 is a noun and at least 1 is a verb. This step filters out questions like “How to be excellent?” and answers such as “I don’t know”. The outcome of this step forms our answer collection C. C contains 142,627 question-answer pairs.<sup>7</sup>

Arguably, all these filters could be improved. For example, the first step can be replaced by a question classifier (Li and Roth, 2005). Similarly, the second step can be implemented with a statistical classifier that ranks the quality of the content using both the textual and non-textual information available in the database (Jeon et al., 2006; Agichtein et al., 2008). We plan to further investigate these issues which are not the main object of this work.

<sup>6</sup>Nevertheless, the approach proposed here is independent of the question type. We will explore answer ranking for other non-factoid question types in future work.

<sup>7</sup>The data will be available through the Yahoo! Webscope program (research-data-requests@yahoo-inc.com).

The data was processed as follows. The text was split at the sentence level, tokenized and PoS tagged, in the style of the Wall Street Journal Penn Tree-Bank (Marcus et al., 1993). Each word was morphologically simplified using the morphological functions of the WordNet library<sup>8</sup>. Sentences were annotated with WNSS categories, using the tagger of Ciaramita and Altun (2006)<sup>9</sup>, which annotates text with a 46-label tagset. These tags, defined by WordNet lexicographers, provide a broad semantic categorization for nouns and verbs and include labels for nouns such as food, animal, body and feeling, and for verbs labels such as communication, contact, and possession. Next, we parsed all sentences with the dependency parser of Attardi et al. (2007)<sup>10</sup>. It is important to realize that the output of all mentioned processing steps is noisy and contains plenty of mistakes, since the data has huge variability in terms of quality, style, genres, domains etc., and domain adaptation for the NLP tasks involved is still an open problem (Dredze et al., 2007).

We used 60% of the questions for training, 20% for development, and 20% for test. The candidate answer set for a given question is composed by one positive example, i.e., its corresponding best answer, and as negative examples all the other answers retrieved in the top  $N$  by the retrieval component.

### 4 Experiments

We evaluate our results using two measures: mean Precision at rank=1 (P@1) – i.e., the percentage of questions with the correct answer on the first position – and Mean Reciprocal Rank (MRR) – i.e., the score of a question is  $1/k$ , where  $k$  is the position of the correct answer. We use as baseline the output of our answer retrieval component (Figure 1). This component uses the BM25 criterion, the highest performing IR model in our experiments.

Table 2 lists the results obtained using this baseline and our best model (“Ranking” in the table) on the testing partition. Since we are interested in the performance of the ranking model, we evaluate on the subset of questions where the correct answer is retrieved by answer retrieval in the top  $N$  answers (similar to Ko et al. (2007)). In the table we report

<sup>8</sup><http://wordnet.princeton.edu>

<sup>10</sup><http://sourceforge.net/projects/desr>

	MRR				P@1			
	$N = 10$	$N = 15$	$N = 25$	$N = 50$	$N = 10$	$N = 15$	$N = 25$	$N = 50$
recall@N	26.25%	29.04%	32.81%	38.09%	26.25%	29.04%	32.81%	38.09%
Baseline	61.33	56.12	50.31	43.74	45.94	41.48	36.74	31.66
Ranking	<b>68.72</b> $\pm 0.01$	<b>63.84</b> $\pm 0.01$	<b>57.76</b> $\pm 0.07$	<b>50.72</b> $\pm 0.01$	<b>54.22</b> $\pm 0.01$	<b>49.59</b> $\pm 0.03$	<b>43.98</b> $\pm 0.09$	<b>37.99</b> $\pm 0.01$
Improvement	+12.04%	+13.75%	+14.80%	+15.95%	+18.02%	+19.55%	+19.70%	+19.99%

Table 2: Overall results for the test partition.

results for several  $N$  values. For completeness, we show the percentage of questions that match this criterion in the “recall@N” row.

Our ranking model was tuned strictly on the development set (i.e., feature selection and parameters of the translation models). During training, the presentation of the training instances is randomized, which generates a randomized ranking algorithm. We exploit this property to estimate the variance in the results produced by each model and report the average result over 10 trials together with an estimate of the standard deviation.

The baseline result shows that, for  $N = 15$ , BM25 alone can retrieve in first rank 41% of the correct answers, and MRR tells us that the correct answer is often found within the first three answers (this is not so surprising if we remember that in this configuration only questions with the correct answer in the first 15 were kept for the experiment). The baseline results are interesting because they indicate that the problem is not hopelessly hard, but it is far from trivial. In principle, we see much room for improvement over bag-of-word methods.

Next we see that learning a weighted combination of features yields consistently marked improvements: for example, for  $N = 15$ , the best model yields a 19% relative improvement in P@1 and 14% in MRR. More importantly, the results indicate that the model learned is stable: even though for the model analyzed in Table 2 we used  $N = 15$  in training, we measure approximately the same relative improvement as  $N$  increases during evaluation.

These results provide robust evidence that: (a) we can use publicly available online QA collections to investigate features for answer ranking without the need for costly human evaluation, (b) we can exploit large and noisy online QA collections to improve the accuracy of answer ranking systems and (c) readily available and scalable NLP technology can be used

Iter.	Feature Set	MRR	P@1
0	BM25(W)	56.06	41.12%
1	+ translation( $B_g$ )	61.13	46.24%
2	+ overall match(D)	62.50	48.34%
3	+ translation(W)	63.00	49.08%

16	+ query-log avg(PMI)	64.60	50.88%
17	+ overall match(W)	64.65	50.91%

Table 3: Summary of the model selection process.

to improve lexical matching and translation models. In the remaining of this section we analyze the performance of the different features.

Table 3 summarizes the outcome of our automatic greedy feature selection process on the development set. Where applicable, we show within parentheses the text representation for the corresponding feature. The process is initialized with a single feature that replicates the baseline model (BM25 applied to the bag-of-words (W) representation). The algorithm incrementally adds to the feature set the feature that provides the highest MRR improvement in the development partition. The process stops when no features yield any improvement. The table shows that, while the features selected span all the four feature groups introduced, the lion’s share is taken by the translation features: approximately 60% of the MRR

	W	B	$B_g$	D	$D_g$	W + B	W + B + $B_g$	W + B + $B_g$ + D	W + B + $B_g$ + D + $D_g$
FG1 (Similarity)	0	<b>+1.06</b>	-2.01	+0.84	-1.75	+1.06	+1.06	+1.06	+1.06
FG2 (Translation)	+4.95	+4.73	+5.06	+4.63	+4.66	+5.80	+6.01	<b>+6.36</b>	+6.36
FG3 (Frequency)	+2.24	+2.33	+2.39	+2.27	+2.41	+3.56	+3.56	<b>+3.62</b>	+3.62

Table 4: Contribution of NLP processors. Scores are MRR improvements on the development set.

improvement is achieved by these features. The frequency/density features are responsible for approximately 23% of the improvement. The rest is due to the query-log correlation features. This indicates that, even though translation models are the most useful, it is worth exploring approaches that combine several strategies for answer ranking.

Note that if some features do not appear in Table 3 it does not necessarily mean that they are useless. In some cases such features are highly correlated with features previously selected, which already exploited their signal. For example, most similarity features (FG1) are correlated. Because BM25(W) is part of the baseline model, the selection process chooses another FG1 feature only much later (iteration 9) when the model is significantly changed. On the other hand, some features do not provide a useful signal at all. A notable example in this class is the web-based CCP feature, which was designed originally for factoid answer validation and does not adapt well to our problem. Because the length of non-factoid answers is typically significantly larger than in the factoid QA task, we have to discard a large part of the query when computing  $hits(Q+A)$  to reach non-zero counts. This means that the final hit counts, hence the CCP value, are generally uncorrelated with the original (Q,A) tuple.

One interesting observation is that the first two features chosen by our model selection process use information from the NLP processors. The first chosen feature is the translation probability computed between the  $B_g$  question and answer representations (bigrams with words generalized to their WNSS tags). The second feature selected measures the number of syntactic dependencies from the question that are matched in the answer. These results provide empirical evidence that coarse semantic disambiguation and syntactic parsing have a positive contribution to non-factoid QA, even in broad-coverage noisy settings based on Web data.

The above observation deserves a more detailed

analysis. Table 4 shows the performance of our first three feature groups when they are applied to each of the five text representations or incremental combinations of representations. For each model corresponding to a table cell we use only the features from the corresponding feature group and representation to avoid the correlation with features from other groups. We generate each best model using the same feature selection process described above.

The left part of Table 4 shows that, generally, the models using representations that include the output of our NLP processors ( $B_g$ , D and  $D_g$ ) improve over the baseline (FG1 and W).<sup>11</sup> However, comparable improvements can be obtained with the simpler bigram representation (B). This indicates that, in terms of individual contributions, our NLP processors can be approximated with simpler  $n$ -gram models in this task. Hence, is it fair to say that syntactic and semantic analysis is useful for such Web QA tasks? While the above analysis seems to suggest a negative answer, the right-hand side of Table 4 tells a more interesting story. It shows that the NLP analysis provides *complementary* information to the  $n$ -gram-based models. The best models for the FG2 and FG3 feature groups are obtained when combining the  $n$ -gram representations with the representations that use the output of the NLP processors (W + B +  $B_g$  + D). The improvements are relatively small, but remarkable (e.g., see FG2) if we take into account the significant scale of the evaluation. This observation correlates well with the analysis shown in Table 3, which shows that features using semantic ( $B_g$ ) and syntactic (D) representations contribute the most *on top* of the IR model (BM25(W)).

<sup>11</sup>The exception to this rule are the models FG1( $B_g$ ) and FG1( $D_g$ ). This is caused by the fact that the BM25 formula is less forgiving with errors of the NLP processors (due to the high *idf* scores assigned to bigrams and dependencies), and the WNSS tagger is the least robust component in our pipeline.

## 5 Related Work

Content from community-built question-answer sites can be retrieved by searching for similar questions already answered (Jeon et al., 2005) and ranked using meta-data information like answerer authority (Jeon et al., 2006; Agichtein et al., 2008). Here we show that the answer text can be successfully used to improve answer ranking quality. Our method is complementary to the above approaches. In fact, it is likely that an optimal retrieval engine from social media should combine all these three methodologies. Moreover, our approach might have applications outside of social media (e.g., for open-domain web-based QA), because the ranking model built is based only on open-domain knowledge and the analysis of textual content.

In the QA literature, answer ranking for non-factoid questions has typically been performed by learning question-to-answer transformations, either using translation models (Berger et al., 2000; Soricut and Brill, 2006) or by exploiting the redundancy of the Web (Agichtein et al., 2001). Girju (2003) extracts non-factoid answers by searching for certain semantic structures, e.g., causation relations as answers to causation questions. In this paper we combine several methodologies, including the above, into a single model. This approach allowed us to perform a systematic feature analysis on a large-scale real-world corpus and a comprehensive feature set.

Recent work has showed that structured retrieval improves answer ranking for factoid questions: Bilotti et al. (2007) showed that matching predicate-argument frames constructed from the question and the expected answer types improves answer ranking. Cui et al. (2005) learned transformations of dependency paths from questions to answers to improve passage ranking. However, both approaches use similarity models at their core because they require the matching of the lexical elements in the search structures. On the other hand, our approach allows the learning of full transformations from question structures to answer structures using translation models applied to different text representations.

Our answer ranking framework is closest in spirit to the system of Ko et al. (2007) or Higashinaka et al. (2008). However, the former was applied only to factoid QA and both are limited to similarity, re-

dundancy and gazetteer-based features. Our model uses a larger feature set that includes correlation and transformation-based features and five different content representations. Our evaluation is also carried out on a larger scale. Our work is also related to that of Riezler et al. (2007) where SMT-based query expansion methods are used on data from FAQ pages.

## 6 Conclusions

In this work we described an answer ranking engine for non-factoid questions built using a large community-generated question-answer collection. On one hand, this study shows that we can effectively exploit large amounts of available Web data to do research on NLP for non-factoid QA systems, without any annotation or evaluation cost. This provides an excellent framework for large-scale experimentation with various models that otherwise might be hard to understand or evaluate. On the other hand, we expect the outcome of this process to help several applications, such as open-domain QA on the Web and retrieval from social media. For example, on the Web our ranking system could be combined with a passage retrieval system to form a QA system for complex questions. On social media, our system should be combined with a component that searches for similar questions already answered; this output can possibly be filtered further by a content-quality module that explores “social” features such as the authority of users, etc.

We show that the best ranking performance is obtained when several strategies are combined into a single model. We obtain the best results when similarity models are aggregated with features that model question-to-answer transformations, frequency and density of content, and correlation of QA pairs with external collections. While the features that model question-to-answer transformations provide most benefits, we show that the combination is crucial for improvement.

Lastly, we show that syntactic dependency parsing and coarse semantic disambiguation yield a small, yet statistically significant performance increase on top of the traditional bag-of-words and  $n$ -gram representation. We obtain these results using only off-the-shelf NLP processors that were not adapted in any way for our task.

## Abstract

Morphological disambiguation proceeds in 2 stages: (1) an analyzer provides all possible analyses for a given token and (2) a stochastic disambiguation module picks the most likely analysis in context. When the analyzer does not recognize a given token, we hit the problem of unknowns. In large scale corpora, unknowns appear at a rate of 5 to 10% (depending on the genre and the maturity of the lexicon).

We address the task of computing the distribution  $p(t|w)$  for unknown words for full morphological disambiguation in Hebrew. We introduce a novel algorithm that is language independent: it exploits a maximum entropy letters model trained over the known words observed in the corpus and the distribution of the unknown words in known tag contexts, through iterative approximation. The algorithm achieves 30% error reduction on disambiguation of unknown words over a competitive baseline (to a level of 70% accurate full disambiguation of unknown words). We have also verified that taking advantage of a strong language-specific model of morphological patterns provides the same level of disambiguation. The algorithm we have developed exploits distributional information latent in a wide-coverage lexicon and large quantities of unlabeled data.

## 1 Introduction

The term *unknowns* denotes tokens in a text that cannot be resolved in a given lexicon. For the task of full morphological analysis, the lexicon must provide all possible morphological analyses for any given token. In this case, unknown tokens can be categorized into two classes of missing information: *unknown tokens* are not recognized at all by the lexicon, and *unknown analyses*, where the set of analyses for a lexeme does not contain the correct analysis for a given token. Despite efforts on improving the underlying lexicon, unknowns typically represent 5% to 10% of the number of tokens in large-scale corpora. The alternative to continuously investing manual effort in improving the lexicon is to design methods to learn possible analyses for unknowns from observable features: their letter structure and their context. In this paper, we investigate the characteristics of Hebrew unknowns for full morphological analysis, and propose a new method for handling such unavoidable lack of information. Our method generates a distribution of possible analyses for unknowns. In our evaluation, these learned distributions include the correct analysis for unknown words in 85% of the cases, contributing an error reduction of over 30% over a competitive baseline for the overall task of full morphological analysis in Hebrew.

The task of a morphological analyzer is to produce all possible analyses for a given token. In Hebrew, the analysis for each token is of the form lexeme-and-features<sup>1</sup>: lemma, affixes, lexical cate-

---

<sup>1</sup>In contrast to the prefix-stem-suffix analysis format of

gory (POS), and a set of inflection properties (according to the POS) – gender, number, person, status and tense. In this work, we refer to the morphological analyzer of MILA – the Knowledge Center for Processing Hebrew<sup>2</sup> (hereafter *KC analyzer*). It is a synthetic analyzer, composed of two data resources – a lexicon of about 2,400 lexemes, and a set of generation rules (see (Adler, 2007, Section 4.2)). In addition, we use an unlabeled text corpus, composed of stories taken from three Hebrew daily news papers (Aruts 7, Haaretz, The Marker), of 42M tokens. We observed 3,561 different composite tags (*e.g.*, noun-sing-fem-prepPrefix:be) over this corpus. These 3,561 tags form the large tagset over which we train our learner. On the one hand, this tagset is much larger than the largest tagset used in English (from 17 tags in most unsupervised POS tagging experiments, to the 46 tags of the WSJ corpus and the about 150 tags of the LOB corpus). On the other hand, our tagset is intrinsically factored as a set of dependent sub-features, which we explicitly represent.

The task we address in this paper is morphological disambiguation: given a sentence, obtain the list of all possible analyses for each word from the analyzer, and disambiguate each word in context. On average, each token in the 42M corpus is given 2.7 possible analyses by the analyzer (much higher than the average 1.41 POS tag ambiguity reported in English (Dermatas and Kokkinakis, 1995)). In previous work, we report disambiguation rates of 89% for full morphological disambiguation (using an unsupervised EM-HMM model) and 92.5% for part of speech and segmentation (without assigning all the inflectional features of the words).

In order to estimate the importance of unknowns in Hebrew, we analyze tokens in several aspects: (1) the number of unknown tokens, as observed on the corpus of 42M tokens; (2) a manual classification of a sample of 10K unknown token types out of the 200K unknown types identified in the corpus; (3) the number of unknown analyses, based on an annotated corpus of 200K tokens, and their classification.

About 4.5% of the 42M token instances in the

Buckwalter’s Arabic analyzer (2004), which looks for any legal combination of prefix-stem-suffix, but does not provide full morphological features such as gender, number, case etc.

<sup>2</sup><http://mila.cs.technion.ac.il/html>

training corpus were unknown tokens (45% of the 450K token types). For less edited text, such as random text sampled from the Web, the percentage is much higher – about 7.5%. In order to classify these unknown tokens, we sampled 10K unknown token types and examined them manually. The classification of these tokens with their distribution is shown in Table 1<sup>3</sup>. As can be seen, there are two main classes of unknown token types: Neologisms (32%) and Proper nouns (48%), which cover about 80% of the unknown token instances. The POS distribution of the unknown tokens of our annotated corpus is shown in Table 2. As expected, most unknowns are open class words: proper names, nouns or adjectives.

Regarding unknown analyses, in our annotated corpus, we found 3% of the 100K token instances were missing the correct analysis in the lexicon (3.65% of the token types). The POS distribution of the unknown analyses is listed in Table 2. The high rate of unknown analyses for prepositions at about 3% is a specific phenomenon in Hebrew, where prepositions are often prefixes agglutinated to the first word of the noun phrase they head. We observe the very low rate of unknown verbs (2%) – which are well marked morphologically in Hebrew, and where the rate of neologism introduction seems quite low.

This evidence illustrates the need for resolution of unknowns: The naive policy of selecting ‘proper name’ for all unknowns will cover only half of the errors caused by unknown tokens, *i.e.*, 30% of the whole unknown tokens and analyses. The other 70% of the unknowns ( 5.3% of the words in the text in our experiments) will be assigned a wrong tag.

As a result of this observation, our strategy is to focus on full morphological analysis for unknown tokens and apply a proper name classifier for unknown analyses and unknown tokens. In this paper, we investigate various methods for achieving full morphological analysis distribution for unknown tokens. The methods are not based on an annotated corpus, nor on hand-crafted rules, but instead exploit the distribution of words in an available lexicon and the letter similarity of the unknown words with known words.

## 2 Previous Work

Most of the work that dealt with unknowns in the last decade focused on unknown tokens (OOV). A naive approach would assign all possible analyses for each unknown token with uniform distribution, and continue disambiguation on the basis of a learned model with this initial distribution. The performance of a tagger with such a policy is actually poor: there are dozens of tags in the tagset (3,561 in the case of Hebrew full morphological disambiguation) and only a few of them may match a given token. Several heuristics were developed to reduce the possibility space and to assign a distribution for the remaining analyses.

Weischedel et al. (1993) combine several heuristics in order to estimate the token generation probability according to various types of information – such as the characteristics of particular tags with respect to unknown tokens (basically the distribution shown in Table 2), and simple spelling features: capitalization, presence of hyphens and specific suffixes. An accuracy of 85% in resolving unknown tokens was reported. Dermatas and Kokkinakis (1995) suggested a method for guessing unknown tokens based on the distribution of the hapax legomenon, and reported an accuracy of 66% for English. Mikheev (1997) suggested a guessing-rule technique, based on prefix morphological rules, suffix morphological rules, and ending-guessing rules. These rules are learned automatically from raw text. They reported a tagging accuracy of about 88%. Thede and Harper (1999) extended a second-order HMM model with a  $C = c_{k,i}$  matrix, in order to encode the probability of a token with a suffix  $s_k$  to be generated by a tag  $t_i$ . An accuracy of about 85% was reported.

Nakagawa (2004) combine word-level and character-level information for Chinese and Japanese word segmentation. At the word level, a segmented word is attached to a POS, where the character model is based on the observed characters and their classification: **B**egin of word, **I**n the middle of a word, **E**nd of word, the character is a word itself **S**. They apply Baum-Welch training over a segmented corpus, where the segmentation of each word and its character classification is observed, and the POS tagging is ambiguous. The segmentation

(of all words in a given sentence) and the POS tagging (of the known words) is based on a Viterbi search over a lattice composed of all possible word segmentations and the possible classifications of all observed characters. Their experimental results show that the method achieves high accuracy over state-of-the-art methods for Chinese and Japanese word segmentation. Hebrew also suffers from ambiguous segmentation of agglutinated tokens into significant words, but word formation rules seem to be quite different from Chinese and Japanese. We also could not rely on the existence of an annotated corpus of segmented word forms.

Habash and Rambow (2006) used the root+pattern+features representation of Arabic tokens for morphological analysis and generation of Arabic dialects, which have no lexicon. They report high recall (95%–98%) but low precision (37%–63%) for token types and token instances, against gold-standard morphological analysis. We also exploit the morphological patterns characteristic of semitic morphology, but extend the guessing of morphological features by using contextual features. We also propose a method that relies exclusively on learned character-level features and contextual features, and eventually reaches the same performance as the patterns-based approach.

Mansour et al. (2007) combine a lexicon-based tagger (such as MorphTagger (Bar-Haim et al., 2005)), and a character-based tagger (such as the data-driven ArabicSVM (Diab et al., 2004)), which includes character features as part of its classification model, in order to extend the set of analyses suggested by the analyzer. For a given sentence, the lexicon-based tagger is applied, selecting one tag for a token. In case the ranking of the tagged sentence is lower than a threshold, the character-based tagger is applied, in order to produce new possible analyses. They report a very slight improvement on Hebrew and Arabic supervised POS taggers.

Resolution of Hebrew unknown tokens, over a large number of tags in the tagset (3,561) requires a much richer model than the heuristics used for English (for example, the capitalization feature which is dominant in English does not exist in Hebrew). Unlike Nakagawa, our model does not use any segmented text, and, on the other hand, it aims to select full morphological analysis for each token,

including unknowns.

### 3 Method

Our objective is: given an unknown word, provide a distribution of possible tags that can serve as the analysis of the unknown word. This unknown analysis step is performed at training and testing time. We do not attempt to disambiguate the word – but only to provide a distribution of tags that will be disambiguated by the regular EM-HMM mechanism.

We examined three models to construct the distribution of tags for unknown words, that is, whenever the KC analyzer does not return any candidate analysis, we apply these models to produce possible tags for the token  $p(t|w)$ :

**Letters** A maximum entropy model is built for all unknown tokens in order to estimate their tag distribution. The model is trained on the known tokens that appear in the corpus. For each analysis of a known token, the following features are extracted: (1) unigram, bigram, and trigram letters of the base-word (for each analysis, the base-word is the token without prefixes), together with their index relative to the start and end of the word. For example, the n-gram features extracted for the word abc are { a:1 b:2 c:3 a:-3 b:-2 c:-1 ab:1 bc:2 ab:-2 bc:-1 abc:1 abc:-1 }; (2) the prefixes of the base-word (as a single feature); (3) the length of the base-word. The class assigned to this set of features, is the analysis of the base-word. The model is trained on all the known tokens of the corpus, each token is observed with its possible POS-tags once for each of its occurrences. When an unknown token is found, the model is applied as follows: all the possible linguistic prefixes are extracted from the token (one of the 76 prefix sequences that can occur in Hebrew); if more than one such prefix is found, the token is analyzed for each possible prefix. For each possible such segmentation, the full feature vector is constructed, and submitted to the Maximum Entropy model. We hypothesize a uniform distribution among the possible segmentations and aggregate a distribution of possible tags for the analysis. If the proposed tag of the base-word is never found in the corpus preceded by the identified prefix, we remove this possible analysis. The eventual outcome of the

model application is a set of possible full morphological analyses for the token – in exactly the same format as the morphological analyzer provides.

**Patterns** Word formation in Hebrew is based on root+pattern and affixation. Patterns can be used to identify the lexical category of unknowns, as well as other inflectional properties. Nir (1993) investigated word-formation in Modern Hebrew with a special focus on neologisms; the most common word-formation patterns he identified are summarized in Table 3. A naive approach for unknown resolution would add all analyses that fit any of these patterns, for any given unknown token. As recently shown by Habash and Rambow (2006), the precision of such a strategy can be pretty low. To address this lack of precision, we learn a maximum entropy model on the basis of the following binary features: one feature for each pattern listed in column **Formation** of Table 3 (40 distinct patterns) and one feature for “no pattern”.

**Pattern-Letters** This maximum entropy model is learned by combining the features of the letters model and the patterns model.

**Linear-Context-based  $p(t|c)$  approximation** The three models above are context free. The linear-context model exploits information about the lexical context of the unknown words: to estimate the probability for a tag  $t$  given a context  $c$  –  $p(t|c)$  – based on all the words in which a context occurs, the algorithm works on the known words in the corpus, by starting with an initial tag-word estimate  $p(t|w)$  (such as the morpho-lexical approximation, suggested by Levinger et al. (1995)), and iteratively re-estimating:

$$\begin{aligned}\hat{p}(t|c) &= \frac{\sum_{w \in W} p(t|w)p(w|c)}{Z} \\ \hat{p}(t|w) &= \frac{\sum_{c \in C} p(t|c)p(c|w)allow(t, w)}{Z}\end{aligned}$$

where  $Z$  is a normalization factor,  $W$  is the set of all words in the corpus,  $C$  is the set of contexts.  $allow(t, w)$  is a binary function indicating whether  $t$  is a valid tag for  $w$ .  $p(c|w)$  and  $p(w|c)$  are estimated via raw corpus counts.

Loosely speaking, the probability of a tag given a context is the average probability of a tag given any

Table 4: Evaluation of unknown token full morphological analysis.

of the words appearing in that context, and similarly the probability of a tag given a word is the averaged probability of that tag in all the (reliable) contexts in which the word appears. We use the function  $allow(t, w)$  to control the tags (ambiguity class) allowed for each word, as given by the lexicon.

For a given word  $w_i$  in a sentence, we examine two types of contexts: **word context**  $w_{i-1}, w_{i+1}$ , and **tag context**  $t_{i-1}, t_{i+1}$ . For the case of word context, the estimation of  $p(w|c)$  and  $p(c|w)$  is simply the relative frequency over all the events  $w1, w2, w3$  occurring at least 10 times in the corpus. Since the corpus is not tagged, the relative frequency of the tag contexts is not observed, instead, we use the context-free approximation of each word-tag, in order to determine the frequency weight of each tag context event. For example, given the sequence תגובה לעומתית למדי *tgubah l'umatit lmadai* (a quite oppositional response), and the analyses set produced by the context-free approximation: *tgubah* [NN 1.0] *l'umatit* [] *lmadai* [RB 0.8, P1-NN 0.2]. The frequency weight of the context {NN RB} is  $1 * 0.8 = 0.8$  and the frequency weight of the context {NN P1-NN} is  $1 * 0.2 = 0.2$ .

## 4 Evaluation

For testing, we manually tagged the text which is used in the Hebrew Treebank (consisting of about 90K tokens), according to our tagging guideline (?).

We measured the effectiveness of the three models with respect to the tags that were assigned to the unknown tokens in our test corpus (the 'correct tag'),

according to three parameters: (1) The coverage of the model, *i.e.*, we count cases where  $p(t|w)$  contains the correct tag with a probability larger than 0.01; (2) the ambiguity level of the model, *i.e.*, the average number of analyses suggested for each token; (3) the average probability of the 'correct tag', according to the predicted  $p(t|w)$ . In addition, for each experiment, we run the full morphology disambiguation system where unknowns are analyzed according to the model.

Our baseline proposes the most frequent tag (proper name) for all possible segmentations of the token, in a uniform distribution. We compare the following models: the 3 context free models (patterns, letters and the combined patterns and letters) and the same models combined with the word and tag context models. Note that the context models have low coverage (about 40% for the word context and 80% for the tag context models), and therefore, the context models cannot be used on their own. The highest coverage is obtained for the combined model (tag context, pattern, letter) at 86.1%.

We first show the results for full morphological disambiguation, over 3,561 distinct tags in Table 4. The highest coverage is obtained for the model combining the tag context, patterns and letters models. The tag context model is more effective because it covers 80% of the unknown words, whereas the word context model only covers 40%. As expected, our simple baseline has the highest precision, since the most frequent proper name tag covers over 50% of the unknown words. The eventual effectiveness of

Model	Analysis Set			POS Tagging
	Coverage	Ambiguity	Probability	
Baseline	52.9%	<b>1.5</b>	<b>0.52</b>	60.6%
Pattern	87.4%	8.7	0.19	76.0%
Letter	80%	4.0	0.39	77.6%
Pattern-Letter	86.7%	6.2	0.32	<b>78.5%</b>
WordContext-Pattern	88.7%	8.8	0.21	75.8%
TagContext-Pattern	<b>89.5%</b>	9.1	0.14	73.8%
WordContext-Letter	83.8%	4.5	0.37	<b>78.2%</b>
TagContext-Letter	87.1%	5.7	0.28	75.2%
WordContext-Pattern-Letter	87.8	6.5	0.32	77.5%
TagContext-Pattern-Letter	89.0%	7.2	0.25	74%

Table 5: Evaluation of unknown token POS tagging.

the method is measured by its impact on the eventual disambiguation of the unknown words. For full morphological disambiguation, our method achieves an error reduction of 30% (57% to 70%). Overall, with the level of 4.5% of unknown words observed in our corpus, the algorithm we have developed contributes to an error reduction of 5.5% for full morphological disambiguation.

The best result is obtained for the model combining pattern and letter features. However, the model combining the word context and letter features achieves almost identical results. This is an interesting result, as the pattern features encapsulate significant linguistic knowledge, which apparently can be approximated by a purely distributional approximation.

While the disambiguation level of 70% is lower than the rate of 85% achieved in English, it must be noted that the task of full morphological disambiguation in Hebrew is much harder – we manage to select one tag out of 3,561 for unknown words as opposed to one out of 46 in English. Table 5 shows the result of the disambiguation when we only take into account the POS tag of the unknown tokens. The same models reach the best results in this case as well (Pattern+Letters and WordContext+Letters). The best disambiguation result is 78.5% – still much lower than the 85% achieved in English. The main reason for this lower level is that the task in Hebrew includes segmentation of prefixes and suffixes in addition to POS classification. We are currently investigating models that will take into account the

specific nature of prefixes in Hebrew (which encode conjunctions, definite articles and prepositions) to better predict the segmentation of unknown words.

## 5 Conclusion

We have addressed the task of computing the distribution  $p(t|w)$  for unknown words for full morphological disambiguation in Hebrew. The algorithm we have proposed is language independent: it exploits a maximum entropy letters model trained over the known words observed in the corpus and the distribution of the unknown words in known tag contexts, through iterative approximation. The algorithm achieves 30% error reduction on disambiguation of unknown words over a competitive baseline (to a level of 70% accurate full disambiguation of unknown words). We have also verified that taking advantage of a strong language-specific model of morphological patterns provides the same level of disambiguation. The algorithm we have developed exploits distributional information latent in a wide-coverage lexicon and large quantities of unlabeled data.

We observe that the task of analyzing unknown tokens for POS in Hebrew remains challenging when compared with English (78% vs. 85%). We hypothesize this is due to the highly ambiguous pattern of prefixation that occurs widely in Hebrew and are currently investigating syntagmatic models that exploit the specific nature of agglutinated prefixes in Hebrew.

Massachusetts Institute of Technology

{bsnyder, regina}@csail.mit.edu

## Abstract

For centuries, the deep connection between languages has brought about major discoveries about human communication. In this paper we investigate how this powerful source of information can be exploited for unsupervised language learning. In particular, we study the task of morphological segmentation of multiple languages. We present a non-parametric Bayesian model that jointly induces morpheme segmentations of each language under consideration and at the same time identifies cross-lingual morpheme patterns, or *abstract morphemes*. We apply our model to three Semitic languages: Arabic, Hebrew, Aramaic, as well as to English. Our results demonstrate that learning morphological models in tandem reduces error by up to 24% relative to monolingual models. Furthermore, we provide evidence that our joint model achieves better performance when applied to languages from the same family.

## 1 Introduction

For centuries, the deep connection between human languages has fascinated linguists, anthropologists and historians (Eco, 1995). The study of this connection has made possible major discoveries about human communication: it has revealed the evolution of languages, facilitated the reconstruction of proto-languages, and led to understanding language universals.

The connection between languages should be a powerful source of information for automatic linguistic analysis as well. In this paper we investigate two questions: (i) Can we exploit cross-lingual correspondences to improve unsupervised language

learning? (ii) Will this joint analysis provide more or less benefit when the languages belong to the same family?

We study these two questions in the context of unsupervised morphological segmentation, the automatic division of a word into morphemes (the basic units of meaning). For example, the English word *misunderstanding* would be segmented into *mis - understand - ing*. This task is an informative testbed for our exploration, as strong correspondences at the morphological level across various languages have been well-documented (Campbell, 2004).

The model presented in this paper automatically induces a segmentation and morpheme alignment from a multilingual corpus of short parallel phrases.<sup>1</sup> For example, given parallel phrases meaning *in my land* in English, Arabic, Hebrew, and Aramaic, we wish to segment and align morphemes as follows:

English:	<i>in my land</i>
Arabic:	<i>fy ard - y</i>
Hebrew:	<i>b - arš - y</i>
Aramaic:	<i>b - ar<sup>c</sup> - y</i>

This example illustrates the potential benefits of unsupervised multilingual learning. The three Semitic languages use cognates (words derived from a common ancestor) to represent the word *land*. They also use an identical suffix (-y) to represent the first person possessive pronoun (*my*). These similarities in form should guide the model by constraining

<sup>1</sup>In this paper, we focus on bilingual models. The model can be extended to handle several languages simultaneously as in this example.

the space of joint segmentations. The corresponding English phrase lacks this resemblance to its Semitic counterparts. However, in this as in many cases, no segmentation is required for English as all the morphemes are expressed as individual words. For this reason, English should provide a strong source of disambiguation for highly inflected languages, such as Arabic and Hebrew.

In general, we pose the following question. In which scenario will multilingual learning be most effective? Will it be for related languages, which share a common core of linguistic features, or for distant languages, whose linguistic divergence can provide strong sources of disambiguation?

As a first step towards answering this question, we propose a model which can take advantage of both similarities and differences across languages. This joint bilingual model identifies optimal morphemes for two languages and at the same time finds compact multilingual representations. For each language in the pair, the model favors segmentations which yield high frequency morphemes. Moreover, bilingual morpheme pairs which consistently share a common semantic or syntactic function are treated as *abstract morphemes*, generated by a single language-independent process. These abstract morphemes are induced automatically by the model from recurring bilingual patterns. For example, in the case above, the tuple  $(in, fy, b-, b-)$  would constitute one of three abstract morphemes in the phrase. When a morpheme occurs in one language without a direct counterpart in the other language, our model can explain away the stray morpheme as arising through a language-specific process.

To achieve this effect in a probabilistic framework, we formulate a hierarchical Bayesian model with Dirichlet Process priors. This framework allows us to define priors over the infinite set of possible morphemes in each language. In addition, we define a prior over abstract morphemes. This prior can incorporate knowledge of the phonetic relationship between the two alphabets, giving potential cognates greater prior likelihood. The resulting posterior distributions concentrate their probability mass on a small group of recurring and stable patterns within and between languages.

We test our model on a multilingual corpus of short parallel phrases drawn from the Hebrew Bible

and Arabic, Aramaic, and English translations. The Semitic language family, of which Hebrew, Arabic, and Aramaic are members, is known for a highly productive morphology (Bravmann, 1977). Our results indicate that cross-lingual patterns can indeed be exploited successfully for the task of unsupervised morphological segmentation. When modeled in tandem, gains are observed for all language pairs, reducing relative error by as much as 24%. Furthermore, our experiments show that both related and unrelated language pairs benefit from multilingual learning. However, when common structures such as phonetic correspondences are explicitly modeled, related languages provide the most benefit.

## 2 Related Work

**Multilingual Language Learning** Recently, the availability of parallel corpora has spurred research on multilingual analysis for a variety of tasks ranging from morphology to semantic role labeling (Yarowsky et al., 2000; Diab and Resnik, 2002; Xi and Hwa, 2005; Padó and Lapata, 2006). Most of this research assumes that one language has annotations for the task of interest. Given a parallel corpus, the annotations are projected from this source language to its counterpart, and the resulting annotations are used for supervised training in the target language. In fact, Rogati et al., (2003) employ this method to learn arabic morphology assuming annotations provided by an English stemmer.

An alternative approach has been proposed by Feldman, Hana and Brew (2004; 2006). While their approach does not require a parallel corpus it does assume the availability of annotations in one language. Rather than being fully projected, the source annotations provide co-occurrence statistics used by a model in the resource-poor target language. The key assumption here is that certain distributional properties are invariant across languages from the same language families. An example of such a property is the distribution of part-of-speech bigrams. Hana et al., (2004) demonstrate that adding such statistics from an annotated Czech corpus improves the performance of a Russian part-of-speech tagger over a fully unsupervised version.

The approach presented here differs from previous work in two significant ways. First, we do

not assume supervised data in any of the languages. Second, we learn a single multilingual model, rather than asymmetrically handling one language at a time. This design allows us to capitalize on structural regularities across languages for the mutual benefit of each language.

### Unsupervised Morphological Segmentation

Unsupervised morphology is an active area of research (Schone and Jurafsky, 2000; Goldsmith, 2001; Adler and Elhadad, 2006; Creutz and Lagus, 2007; Dasgupta and Ng, 2007).

Most existing algorithms derive morpheme lexicons by identifying recurring patterns in string distribution. The goal is to optimize the compactness of the data representation by finding a small lexicon of highly frequent strings. Our work builds on probabilistic segmentation approaches such as Morfessor (Creutz and Lagus, 2007). In these approaches, models with short description length are preferred. Probabilities are computed for both the morpheme lexicon and the representation of the corpus conditioned on the lexicon. A locally optimal segmentation is identified using a task-specific greedy search.

In contrast to previous approaches, our model induces morphological segmentation for multiple related languages simultaneously. By representing morphemes abstractly through the simultaneous alignment and segmentation of data in two languages, our algorithm capitalizes on deep connections between morpheme usage across different languages.

### 3 Multilingual Morphological Segmentation

The underlying assumption of our work is that structural commonality across different languages is a powerful source of information for morphological analysis. In this section, we provide several examples that motivate this assumption.

The main benefit of joint multilingual analysis is that morphological structure ambiguous in one language is sometimes explicitly marked in another language. For example, in Hebrew, the preposition meaning “in”, *b-*, is always prefixed to its nominal argument. On the other hand, in Arabic, the most common corresponding particle is *fy*, which appears as a separate word. By modeling cross-

lingual morpheme alignments while simultaneously segmenting, the model effectively propagates information between languages and in this case would be encouraged to segment the Hebrew prefix *b-*.

Cognates are another important means of disambiguation in the multilingual setting. Consider translations of the phrase “...and they wrote it...”:

- Hebrew: *w-ktb-w ath*
- Arabic: *f-ktb-w-ha*

In both languages, the trilateral root *ktb* is used to express the act of writing. By considering the two phrases simultaneously, the model can be encouraged to split off the respective Hebrew and Arabic prefixes *w-* and *f-* in order to properly align the cognate root *ktb*.

In the following section, we describe a model that can model both generic cross-lingual patterns (*fy* and *b-*), as well as cognates between related languages (*ktb* for Hebrew and Arabic).

## 4 Model

**Overview** In order to simultaneously model probabilistic dependencies across languages as well as morpheme distributions within each language, we employ a hierarchical Bayesian model.<sup>2</sup>

Our segmentation model is based on the notion that stable recurring string patterns within words are indicative of morphemes. In addition to learning independent morpheme patterns for each language, the model will prefer, when possible, to join together frequently occurring bilingual morpheme pairs into single *abstract morphemes*. The model is fully unsupervised and is driven by a preference for stable and high frequency cross-lingual morpheme patterns. In addition the model can incorporate character-to-character phonetic correspondences between alphabets as prior information, thus allowing the implicit modeling of cognates.

Our aim is to induce a model which concentrates probability on highly frequent patterns while still allowing for the possibility of those previously unseen. Dirichlet processes are particularly suitable for such conditions. In this framework, we can encode

<sup>2</sup>In (Snyder and Barzilay, 2008) we consider the use of this model in the case where supervised data in one or more languages is available.

prior knowledge over the infinite sets of possible morpheme strings as well as abstract morphemes. Distributions drawn from a Dirichlet process nevertheless produce sparse representations with most probability mass concentrated on a small number of observed and predicted patterns. Our model utilizes a Dirichlet process prior for each language, as well as for the cross-lingual links (*abstract morphemes*). Thus, a distribution over morphemes and morpheme alignments is first drawn from the set of Dirichlet processes and then produces the observed data. In practice, we never deal with such distributions directly, but rather integrate over them during Gibbs sampling.

In the next section we describe our model’s “generative story” for producing the data we observe. We formalize our model in the context of two languages  $\mathcal{E}$  and  $\mathcal{F}$ . However, the formulation can be extended to accommodate evidence from multiple languages as well. We provide an example of parallel phrase generation in Figure 1.

**High-level Generative Story** We have a parallel corpus of several thousand short phrases in the two languages  $\mathcal{E}$  and  $\mathcal{F}$ . Our model provides a generative story explaining how these parallel phrases were probabilistically created. The core of the model consists of three components: a distribution  $A$  over bilingual morpheme pairs (*abstract morphemes*), a distribution  $E$  over stray morphemes in language  $\mathcal{E}$  occurring without a counterpart in language  $\mathcal{F}$ , and a similar distribution  $F$  for stray morphemes in language  $\mathcal{F}$ .

As usual for hierarchical Bayesian models, the generative story begins by drawing the model parameters themselves – in our case the three distributions  $A$ ,  $E$ , and  $F$ . These three distributions are drawn from three separate Dirichlet processes, each with appropriately defined base distributions. The Dirichlet processes ensure that the resulting distributions concentrate their probability mass on a small number of morphemes while holding out reasonable probability for unseen possibilities.

Once  $A$ ,  $E$ , and  $F$  have been drawn, we model our parallel corpus of short phrases as a series of independent draws from a phrase-pair generation model. For each new phrase-pair, the model first chooses the number and type of morphemes to be

generated. In particular, it must choose how many unaligned stray morphemes from language  $\mathcal{E}$ , unaligned stray morphemes from language  $\mathcal{F}$ , and abstract morphemes are to compose the parallel phrases. These three numbers, respectively denoted as  $m$ ,  $n$ , and  $k$ , are drawn from a Poisson distribution. This step is illustrated in Figure 1 part (a).

The model then proceeds to independently draw  $m$  language  $\mathcal{E}$  morphemes from distribution  $E$ ,  $n$  language- $\mathcal{F}$  morphemes from distribution  $F$ , and  $k$  abstract morphemes from distribution  $A$ . This step is illustrated in part (b) of Figure 1.

The  $m + k$  resulting language- $\mathcal{E}$  morphemes are then ordered and fused to form a phrase in language  $\mathcal{E}$ , and likewise for the  $n + k$  resulting language- $\mathcal{F}$  morphemes. The ordering and fusing decisions are modeled as draws from a uniform distribution over the set of all possible orderings and fusings for sizes  $m$ ,  $n$ , and  $k$ . These final steps are illustrated in parts (c)-(d) of Figure 1. Now we describe the model more formally.

**Stray Morpheme Distributions** Sometimes a morpheme occurs in a phrase in one language without a corresponding foreign language morpheme in the parallel phrase. We call these “stray morphemes,” and we employ language-specific morpheme distributions to model their generation.

For each language, we draw a distribution over all possible morphemes (finite-length strings composed of characters in the appropriate alphabet) from a Dirichlet process with concentration parameter  $\alpha$  and base distribution  $P_e$  or  $P_f$  respectively:

$$\begin{aligned} E|\alpha, P_e &\sim DP(\alpha, P_e) \\ F|\alpha, P_f &\sim DP(\alpha, P_f) \end{aligned}$$

The base distributions  $P_e$  and  $P_f$  can encode prior knowledge about the properties of morphemes in each of the two languages, such as length and character n-grams. For simplicity, we use a geometric distribution over the length of the string with a final end-morpheme character. The distributions  $E$  and  $F$  which result from the respective Dirichlet processes place most of their probability mass on a small number of morphemes with the degree of concentration

Figure 1: Generation process for a parallel bilingual phrase, with Hebrew shown on top and Arabic on bottom. (a) First the numbers of stray ( $m$  and  $n$ ) and abstract ( $k$ ) morphemes are drawn from a Poisson distribution. (b) Stray morphemes are then drawn from  $E$  and  $F$  (language-specific distributions) and abstract morphemes are drawn from  $A$ . (c) The resulting morphemes are ordered. (d) Finally, some of the contiguous morphemes are fused into words.

controlled by the prior  $\alpha$ . Nevertheless, some non-zero probability is reserved for every possible string.

We note that these single-language morpheme distributions also serve as monolingual segmentation models, and similar models have been successfully applied to the task of word boundary detection (Goldwater et al., 2006).

**Abstract Morpheme Distribution** To model the connections between morphemes across languages, we further define a model for bilingual morpheme pairs, or *abstract morphemes*. This model assigns probabilities to all pairs of morphemes – that is, all pairs of finite strings from the respective alphabets –  $(e, f)$ . Intuitively, we wish to assign high probability to pairs of morphemes that play similar syntactic or semantic roles (e.g.  $(fy, b-)$  for “in” in Arabic and Hebrew). These morpheme pairs can thus be viewed as representing *abstract morphemes*. As with the stray morpheme models, we wish to define a distribution which concentrates probability mass on a small number of highly co-occurring morpheme pairs while still holding out some probability for all other pairs.

We define this abstract morpheme model  $A$  as a draw from another Dirichlet process:

$$\begin{aligned}
 A | \alpha', P' &\sim DP(\alpha', P') \\
 (e, f) &\sim A
 \end{aligned}$$

As before, the resulting distribution  $A$  will give non-zero probability to all abstract morphemes

$(e, f)$ . The base distribution  $P'$  acts as a prior on such pairs. To define  $P'$ , we can simply use a mixture of geometric distributions in the lengths of the component morphemes. However, if the languages  $\mathcal{E}$  and  $\mathcal{F}$  are related and the regular phonetic correspondences between the letter in the two alphabets are known, then we can use  $P'$  to assign higher likelihood to potential cognates. In particular we define the prior  $P'(e, f)$  to be the probabilistic string-edit distance (Ristad and Yianilos, 1998) between  $e$  and  $f$ , using the known phonetic correspondences to parameterize the string-edit model. In particular, insertion and deletion probabilities are held constant for all characters, and substitution probabilities are determined based on the known sound correspondences.

We report results for both the simple geometric prior as well as the string-edit prior.

**Phrase Generation** To generate a bilingual parallel phrase, we first draw  $m$ ,  $n$ , and  $k$  independently from a Poisson distribution. These three integers represent the number and type of the morphemes that compose the parallel phrase, giving the number of stray morphemes in each language  $\mathcal{E}$  and  $\mathcal{F}$  and the number of coupled bilingual morpheme pairs, respectively.

$$m, n, k \sim \text{Poisson}(\lambda)$$

Given these values, we now draw the appropriate number of stray and abstract morphemes from the corresponding distributions:

$$\begin{aligned}
e_1, \dots, e_m &\sim E \\
f_1, \dots, f_n &\sim F \\
(e'_1, f'_1), \dots, (e'_k, f'_k) &\sim A
\end{aligned}$$

The sets of morphemes drawn for each language are then ordered:

$$\begin{aligned}
\tilde{e}_1, \dots, \tilde{e}_{m+k} &\sim ORDER|e_1, \dots, e_m, e'_1, \dots, e'_k \\
\tilde{f}_1, \dots, \tilde{f}_{n+k} &\sim ORDER|f_1, \dots, f_n, f'_1, \dots, f'_k
\end{aligned}$$

Finally the ordered morphemes are fused into the words that form the parallel phrases:

$$\begin{aligned}
w_1, \dots, w_s &\sim FUSE|\tilde{e}_1, \dots, \tilde{e}_{m+k} \\
v_1, \dots, v_t &\sim FUSE|\tilde{f}_1, \dots, \tilde{f}_{n+k}
\end{aligned}$$

To keep the model as simple as possible, we employ uniform distributions over the sets of orderings and fusings. In other words, given a set of  $r$  morphemes (for each language), we define the distribution over permutations of the morphemes to simply be  $ORDER(\cdot|r) = \frac{1}{r!}$ . Then, given a fixed morpheme order, we consider fusing each adjacent morpheme into a single word. Again, we simply model the distribution over the  $r - 1$  fusing decisions uniformly as  $FUSE(\cdot|r) = \frac{1}{2^{r-1}}$ .

**Implicit Alignments** Note that nowhere do we explicitly assign probabilities to morpheme alignments between parallel phrases. However, our model allows morphemes to be generated in precisely one of two ways: as a lone stray morpheme or as part of a bilingual abstract morpheme pair. Thus, our model implicitly assumes that each morpheme is either unaligned, or aligned to exactly one morpheme in the opposing language.

If we are given a parallel phrase with already segmented morphemes we can easily induce the distribution over alignments implied by our model. As we will describe in the next section, drawing from these induced alignment distributions plays a crucial role in our inference procedure.

**Inference** Given our corpus of short parallel bilingual phrases, we wish to make segmentation decisions which yield a set of morphemes with high joint probability. To assess the probability of a potential morpheme set, we need to marginalize over all possible alignments (i.e. possible abstract morpheme pairings and stray morpheme assignments). We also need to marginalize over all possible draws of the distributions  $A$ ,  $E$ , and  $F$  from their respective Dirichlet process priors. We achieve these aims by performing Gibbs sampling.

**Sampling** We follow (Neal, 1998) in the derivation of our blocked and collapsed Gibbs sampler. Gibbs sampling starts by initializing all random variables to arbitrary starting values. At each iteration, the sampler selects a random variable  $X_i$ , and draws a new value for  $X_i$  from the conditional distribution of  $X_i$  given the current value of the other variables:  $P(X_i|X_{-i})$ . The stationary distribution of variables derived through this procedure is guaranteed to converge to the true joint distribution of the random variables. However, if some variables can be jointly sampled, then it may be beneficial to perform block sampling of these variables to speed convergence. In addition, if a random variable is not of direct interest, we can avoid sampling it directly by marginalizing it out, yielding a collapsed sampler. We utilize variable blocking by jointly sampling multiple segmentation and alignment decisions. We also collapse our Gibbs sampler in the standard way, by using predictive posteriors marginalized over all possible draws from the Dirichlet processes (resulting in Chinese Restaurant Processes).

**Resampling** For each bilingual phrase, we resample each word in the phrase in turn. For word  $w$  in language  $\mathcal{E}$ , we consider at once all possible segmentations, and for each segmentation all possible alignments. We keep fixed the previously sampled segmentation decisions for all other words in the phrase as well as sampled alignments involving morphemes in other words. We are thus considering at once: all possible segmentations of  $w$  along with all possible alignments involving morphemes in  $w$  with some subset of previously sampled language- $\mathcal{F}$  morphemes.<sup>3</sup>

<sup>3</sup>We retain morpheme identities during resampling of the morpheme alignments. This procedure is technically just-

Table 1: Precision, recall and F-score evaluated on Arabic and Hebrew. The first three rows provide baselines (random selection, an alternative state-of-the-art system, and the monolingual version of our model). The next three rows show the result of our bilingual model when one of Arabic, Hebrew, Aramaic, or English is added. The final two rows show the result of the bilingual model when character-to-character phonetic correspondences are used in the abstract morpheme prior.

The sampling formulas are easily derived as products of the relevant Chinese Restaurant Processes (with a minor adjustment to take into account the number of stray and abstract morphemes resulting from each decision). See (Neal, 1998) for general formulas for Gibbs sampling from distributions with Dirichlet process priors. All results reported are averaged over five runs using simulated annealing.

## 5 Experimental Set-Up

**Morpheme Definition** For the purpose of these experiments, we define *morphemes* to include conjunctions, prepositional and pronominal affixes, plural and dual suffixes, particles, definite articles, and roots. We do not model cases of infix morpheme transformations, as those cannot be modeled by linear segmentation.

**Dataset** As a source of parallel data, we use the Hebrew Bible and translations. For the Hebrew version, we use an edition distributed by Westminster Hebrew Institute (Groves and Lowery, 2006). This Bible edition is augmented by gold standard morphological analysis (including segmentation) performed by biblical scholars.

For the Arabic, Aramaic, and English versions,

we use the Van Dyke Arabic translation,<sup>4</sup> Targum Onkelos,<sup>5</sup> and the Revised Standard Version (Nelson, 1952), respectively. We obtained gold standard segmentations of the Arabic translation with a hand-crafted Arabic morphological analyzer which utilizes manually constructed word lists and compatibility rules and is further trained on a large corpus of hand-annotated Arabic data (Habash and Rambow, 2005). The accuracy of this analyzer is reported to be 94% for full morphological analyses, and 98%-99% when part-of-speech tag accuracy is not included. We don't have gold standard segmentations for the English and Aramaic portions of the data, and thus restrict our evaluation to Hebrew and Arabic.

To obtain our corpus of short parallel phrases, we preprocessed each language pair using the Giza++ alignment toolkit.<sup>6</sup> Given word alignments for each language pair, we extract a list of phrase pairs that form independent sets in the bipartite alignment graph. This process allows us to group together phrases like *fy şbah* in Arabic and *bbqr* in Hebrew while being reasonably certain that all the relevant morphemes are contained in the short extracted phrases. The number of words in such phrases ranges from one to four words in the Semitic languages and up to six words in English. Before performing any experiments, a manual inspection of

<sup>4</sup><http://www.arabicbible.com/bible/vandyke.htm>

<sup>5</sup><http://www.mechon-mamre.org/i/t/u/u0.htm>

<sup>6</sup><http://www.fjoch.com/GIZA++.html>

the generated parallel phrases revealed that many infrequent phrase pairs occurred merely as a result of noisy translation and alignment. Therefore, we eliminated all parallel phrases that occur fewer than five times. As a result of this process, we obtain 6,139 parallel short phrases in Arabic, Hebrew, Aramaic, and English. The average number of morphemes per word in the Hebrew data is 1.8 and is 1.7 in Arabic.

For the bilingual models which employs probabilistic string-edit distance as a prior on abstract morphemes, we parameterize the string-edit model with the chart of Semitic consonant relationships listed on page xxiv of (Thackston, 1999). All pairs of corresponding letters are given equal substitution probability, while all other letter pairs are given substitution probability of zero.

**Evaluation Methods** Following previous work, we evaluate the performance of our automatic segmentation algorithm using F-score. This measure is the harmonic mean of recall and precision, which are calculated on the basis of all possible segmentation points. The evaluation is performed on a random set of 1/5 of the parallel phrases which is unseen during the training phase. During testing, *we do not allow the models to consider any multilingual evidence*. This restriction allows us to simulate future performance on purely monolingual data.

**Baselines** Our primary purpose is to compare the performance of our bilingual model with its fully monolingual counterpart. However, to demonstrate the competitiveness of this baseline model, we also provide results using MORFESSOR (Creutz and Lagus, 2007), a state-of-the-art unsupervised system for morphological segmentation. While developed originally for Finnish, this system has been successfully applied to a range of languages including German, Turkish and English. The probabilistic formulation of this model is close to our monolingual segmentation model, but it uses a greedy search specifically designed for the segmentation task. We use the publicly available implementation of this system. To provide some idea of the inherent difficulty of this segmentation task, we also provide results from a random baseline which makes segmentation decisions based on a coin weighted with the true segmentation frequency.

## 6 Results

Table 1 shows the performance of the various automatic segmentation methods. The first three rows provide baselines, as mentioned in the previous section. Our primary baseline is MONOLINGUAL, which is the monolingual counterpart to our model and only uses the language-specific distributions  $E$  or  $F$ . The next three rows shows the performance of various bilingual models that don't use character-to-character phonetic correspondences to capture cognate information. We find that with the exception of the HEBREW(+ARAMAIC) pair, the bilingual models show marked improvement over MONOLINGUAL. We notice that in general, adding English – which has comparatively little morphological ambiguity – is about as useful as adding a more closely related Semitic language. However, once character-to-character phonetic correspondences are added as an abstract morpheme prior (final two rows), we find the performance of related language pairs outstrips English, reducing relative error over MONOLINGUAL by 10% and 24% for the Hebrew/Arabic pair.

## 7 Conclusions and Future Work

We started out by posing two questions: (i) Can we exploit cross-lingual patterns to improve unsupervised analysis? (ii) Will this joint analysis provide more or less benefit when the languages belong to the same family? The model and results presented in this paper answer the first question in the affirmative, at least for the task of morphological segmentation.

We also provided some evidence that considering closely related languages may be more beneficial than distant pairs *if* the model is able to explicitly represent shared language structure (the character-to-character phonetic correspondences in our case). In the future, we hope to apply similar multilingual models to other core unsupervised analysis tasks, including part-of-speech tagging and grammar induction, and to further investigate the role that language relatedness plays in such models.<sup>7</sup>

## Abstract

We address the task of unsupervised POS tagging. We demonstrate that good results can be obtained using the robust EM-HMM learner when provided with good initial conditions, even with incomplete dictionaries. We present a family of algorithms to compute effective initial estimations  $p(t|w)$ . We test the method on the task of full morphological disambiguation in Hebrew achieving an error reduction of 25% over a strong uniform distribution baseline. We also test the same method on the standard WSJ unsupervised POS tagging task and obtain results competitive with recent state-of-the-art methods, while using simple and efficient learning methods.

## 1 Introduction

The task of unsupervised (or semi-supervised) part-of-speech (POS) tagging is the following: given a dictionary mapping words in a language to their possible POS, and large quantities of unlabeled text data, learn to predict the correct part of speech for a given word in context. The only supervision given to the learning process is the dictionary, which in a realistic scenario, contains only part of the word types observed in the corpus to be tagged.

Unsupervised POS tagging has been traditionally approached with relative success (Merialdo, 1994; Kupiec, 1992) by HMM-based generative models, employing EM parameters estimation using the Baum-Welch algorithm. However, as recently noted

by Banko and Moore (2004), these works made use of filtered dictionaries: dictionaries in which only relatively probable analyses of a given word are preserved. This kind of filtering requires serious supervision: in theory, an expert is needed to go over the dictionary elements and filter out unlikely analyses. In practice, counts from an annotated corpus have been traditionally used to perform the filtering. Furthermore, these methods require rather comprehensive dictionaries in order to perform well.

In recent work, researchers try to address these deficiencies by using dictionaries with unfiltered POS-tags, and testing the methods on “diluted dictionaries” – in which many of the lexical entries are missing (Smith and Eisner, 2005) (SE), (Goldwater and Griffiths, 2007) (GG), (Toutanova and Johnson, 2008) (TJ).

All the work mentioned above focuses on unsupervised **English** POS tagging. The dictionaries are all derived from tagged English corpora (all recent work uses the WSJ corpus). As such, the setting of the research is artificial: there is no reason to perform unsupervised learning when an annotated corpus is available. The problem is rather approached as a workbench for exploring new learning methods. The result is a series of creative algorithms, that have steadily improved results on the same dataset: unsupervised CRF training using contrastive estimation (SE), a fully-bayesian HMM model that jointly performs clustering and sequence learning (GG), and a Bayesian LDA-based model using only observed context features to predict tag words (TJ). These sophisticated learning algorithms all outperform the traditional baseline of EM-HMM based methods,

\*This work is supported in part by the Lynn and William Frankel Center for Computer Science.

while relying on similar knowledge: the lexical context of the words to be tagged and their letter structure (e.g., presence of suffixes, capitalization and hyphenation).<sup>1</sup>

Our motivation for tackling unsupervised POS tagging is different: we are interested in developing a Hebrew POS tagger. We have access to a good Hebrew lexicon (and a morphological analyzer), and a fair amount of unlabeled training data, but hardly any annotated corpora. We actually report results on full morphological disambiguation for Hebrew, a task similar but more challenging than POS tagging: we deal with a tagset much larger than English (over 3,561 distinct tags) and an ambiguity level of about 2.7 per token as opposed to 1.4 for English. Instead of inventing a new learning framework, we go back to the traditional EM trained HMMs. We argue that the key challenge to learning an effective model is to define good enough initial conditions. Given sufficiently good initial conditions, EM trained models can yield highly competitive results. Such models have other benefits as well: they are simple, robust, and computationally more attractive.

In this paper, we concentrate on methods for deriving sufficiently good initial conditions for EM-HMM learning. Our method for learning initial conditions for the  $p(t|w)$  distributions relies on a mixture of language specific models: a paradigmatic model of similar words (where similar words are words with similar inflection patterns), simple syntagmatic constraints (e.g., the sequence V-V is extremely rare in English). These are complemented by a linear lexical context model. Such models are simple to build and test.

We present results for unsupervised PoS tagging of Hebrew text and for the common WSJ English test sets. We show that our method achieves state-of-the-art results for the English setting, even with a relatively small dictionary. Furthermore, while recent work report results on a reduced English tagset of 17 PoS tags, we also present results for the complete 45 tags tagset of the WSJ corpus. This considerably raises the bar of the EM-HMM baseline. We also report state-of-the-art results for Hebrew full mor-

phological disambiguation.

Our primary conclusion is that the problem of learning effective stochastic classifiers remains primarily a search task. Initial conditions play a dominant role in solving this task and can rely on linguistically motivated approximations. A robust learning method (EM-HMM) combined with good initial conditions based on a robust feature set can go a long way (as opposed to a more complex learning method). It seems that computing initial conditions is also the right place to capture complex linguistic intuition without fear that over-generalization could lead a learner to diverge.

## 2 Previous Work

The tagging accuracy of supervised stochastic taggers is around 96%–97% (Manning and Schutze, 1999). Merialdo (1994) reports an accuracy of 86.6% for an unsupervised token-based EM-estimated HMM, trained on a corpus of about 1M words, over a tagset of 159 tags. Elworthy (1994), in contrast, reports accuracy of 75.49%, 80.87%, and 79.12% for unsupervised word-based HMM trained on parts of the LOB corpora, with a tagset of 134 tags. With (artificially created) good initial conditions, such as a good approximation of the tag distribution for each word, Elworthy reports an improvement to 94.6%, 92.27%, and 94.51% on the same data sets. Merialdo, on the other hand, reports an improvement to 92.6% and 94.4% for the case where 100 and 2,000 sentences of the training corpus are manually tagged. Later, Banko and Moore (2004) observed that earlier unsupervised HMM-EM results were artificially high due to use of *Optimized Lexicons*, in which only frequent-enough analyses of each word were kept. Brill (1995b) proposed an unsupervised tagger based on transformation-based learning (Brill, 1995a), achieving accuracies of above 95%. This unsupervised tagger relied on an initial step in which the most probable tag for each word is chosen. Optimized lexicons and Brill’s most-probable-tag Oracle are not available in realistic unsupervised settings, yet, they show that *good initial conditions* greatly facilitate learning.

Recent work on unsupervised POS tagging for English has significantly improved the results on this task: GG, SE and most recently TJ report the best re-

<sup>1</sup>Another notable work, though within a slightly different framework, is the prototype-driven method proposed by (Haghighi and Klein, 2006), in which the dictionary is replaced with a very small seed of prototypical examples.

sults so far on the task of unsupervised POS tagging of the WSJ with diluted dictionaries. With dictionaries as small as 1249 lexical entries the LDA-based method with a strong ambiguity-class model reaches POS accuracy as high as 89.7% on a reduced tagset of 17 tags.

While these 3 methods rely on the same feature set (lexical context, spelling features) for the learning stage, the LDA approach bases its predictions entirely on observable features, and excludes the traditional hidden states sequence.

In Hebrew, Levinger *et al.* (1995) introduced the *similar-words algorithm* for estimating  $p(t|w)$  from unlabeled data, which we describe below. Our method uses this algorithm as a first step, and refines the approximation by introducing additional linguistic constraints and an iterative refinement step.

### 3 Initial Conditions For EM-HMM

The most common model for unsupervised learning of stochastic processes is Hidden Markov Models (HMM). For the case of tagging, the states correspond to the tags  $t_i$ , and words  $w_i$  are emitted each time a state is visited. The parameters of the model can be estimated by applying the Baum-Welch EM algorithm (Baum, 1972), on a large-scale corpus of unlabeled text. The estimated parameters are then used in conjunction with Viterbi search, to find the most probable sequence of tags for a given sentence. In this work, we follow Adler (2007) and use a variation of second-order HMM in which the probability of a tag is conditioned by the tag that precedes it and by the one that follows it, and the probability of an emitted word is conditioned by its tag and the tag that follows it<sup>2</sup>. In all experiments, we use the back-off smoothing method of (Thede and Harper, 1999), with additive smoothing (Chen, 1996) for the lexical probabilities.

We investigate methods to approximate the initial parameters of the  $p(t|w)$  distribution, from which we obtain  $p(w|t)$  by marginalization and Bayesian inversion. We also experiment with constraining the  $p(t|t_{-1}, t_{+1})$  distribution.

<sup>2</sup>Technically this is not Markov Model but a Dependency Net. However, bidirectional conditioning seem more suitable for language tasks, and in practice the learning and inference methods are mostly unaffected. See (Toutanova *et al.*, 2003).

**General syntagmatic constraints** We set linguistically motivated constraints on the  $p(t|t_{-1}, t_{+1})$  distribution. In our setting, these are used to force the probability of some events to 0 (e.g., “Hebrew verbs can not be followed by the *of* preposition”).

**Morphology-based  $p(t|w)$  approximation** Levinger *et al.* (1995) developed a context-free method for acquiring morpho-lexical probabilities ( $p(t|w)$ ) from an untagged corpus. The method is based on language-specific rules for constructing a *similar words* (SW) set for each analysis of a word. This set is composed of morphological variations of the word under the given analysis. For example, the Hebrew token ילד can be analyzed as either a noun (boy) or a verb (gave birth). The noun SW set for this token is composed of the definiteness and number inflections הילד, הילדים, הילדות (the boy, boys, the boys), while the verb SW set is composed of gender and tense inflections ילדה, ילדו (she/they gave birth). The approximated probability of each analysis is based on the corpus frequency of its SW set. For the complete details, refer to the original paper. Cucerzan and Yarowsky (2000) proposed a similar method for the unsupervised estimation of  $p(t|w)$  in English, relying on simple spelling features to characterize similar word classes.

**Linear-Context-based  $p(t|w)$  approximation** The method of Levinger *et al.* makes use of Hebrew inflection patterns in order to estimate context free approximation of  $p(t|w)$  by relating a word to its different inflections. However, the context in which a word occurs can also be very informative with respect to its POS-analysis (Schütze, 1995). We propose a novel algorithm for estimating  $p(t|w)$  based on the contexts in which a word occurs.<sup>3</sup>

The algorithm starts with an initial  $p(t|w)$  estimate, and iteratively re-estimates:

$$\hat{p}(t|c) = \frac{\sum_{w \in W} p(t|w)p(w|c)}{Z}$$

$$\hat{p}(t|w) = \frac{\sum_{c \in REL_C} p(t|c)p(c|w)allow(t, w)}{Z}$$

<sup>3</sup>While we rely on the same intuition, our use of context differs from earlier works on distributional POS-tagging like (Schütze, 1995), in which the purpose is to directly assign the possible POS for an unknown word. In contrast, our algorithm aims to improve the estimate for the whole distribution  $p(t|w)$ , to be further disambiguated by the EM-HMM learner.

where  $Z$  is a normalization factor,  $W$  is the set of all words in the corpus,  $C$  is the set of all contexts, and  $REL_C \subseteq C$  is a set of reliable contexts, defined below.  $allow(t, w)$  is a binary function indicating whether  $t$  is a valid tag for  $w$ .  $p(c|w)$  and  $p(w|c)$  are estimated via raw corpus counts.

Intuitively, we estimate the probability of a tag given a context as the average probability of a tag given any of the words appearing in that context, and similarly the probability of a tag given a word is the averaged probability of that tag in all the (reliable) contexts in which the word appears. At each round, we define  $REL_C$ , the set of reliable contexts, to be the set of all contexts in which  $p(t|c) > 0$  for at most  $X$  different  $ts$ .

The method is general, and can be applied to different languages. The parameters to specify for each language are: the initial estimation  $p(t|w)$ , the estimation of the  $allow$  relation for known and OOV words, and the types of contexts to consider.

## 4 Application to Hebrew

In Hebrew, several words combine into a single token in both agglutinative and fusional ways. This results in a potentially high number of tags for each token. On average, in our corpus, the number of possible analyses per known word reached 2.7, with the ambiguity level of the extended POS tagset in corpus for English (1.41) (Dermatas and Kokkinakis, 1995).

In this work, we use the morphological analyzer of MILA – Knowledge Center for Processing Hebrew (*KC analyzer*). In contrast to English tagsets, the number of tags for Hebrew, based on all combinations of the morphological attributes, can grow theoretically to about 300,000 tags. In practice, we found ‘only’ about 3,560 tags in a corpus of 40M tokens training corpus taken from Hebrew news material and Knesset transcripts. For testing, we manually tagged the text which is used in the Hebrew Treebank (Sima’an et al., 2001) (about 90K tokens), according to our tagging guidelines.

### 4.1 Initial Conditions

**General syntagmatic constraints** We define 4 syntagmatic constraints over  $p(t|t_{-1}, t_{+1})$ : (1) a construct state form cannot be followed by a verb,

preposition, punctuation, existential, modal, or copula; (2) a verb cannot be followed by the preposition  $\text{ל} \text{ } \text{של}$  (of), (3) copula and existential cannot be followed by a verb, and (4) a verb cannot be followed by another verb, unless one of them has a prefix, or the second verb is an infinitive, or the first verb is imperative and the second verb is in future tense.<sup>4</sup>

**Morphology-Based  $p(t|w)$  approximation** We extended the set of rules used in Levinger *et al.*, in order to support the wider tagset used by the KC analyzer: (1) The SW set for adjectives, copulas, existentials, personal pronouns, verbs and participles, is composed of all gender-number inflections; (2) The SW set for common nouns is composed of all number inflections, with definite article variation for absolute noun; (3) Prefix variations for proper nouns; (4) Gender variation for numerals; and (5) Gender-number variation for all suffixes (possessive, nominative and accusative).

### Linear-Context-based $p(t|w)$ approximation

For the initial  $p(t|w)$  we use either a uniform distribution based on the tags allowed in the dictionary, or the estimate obtained by using the modified Levinger *et al.* algorithm. We use contexts of the form  $L_R=w_{-1}, w_{+1}$  (the neighbouring words). We estimate  $p(w|c)$  and  $p(c|w)$  via relative frequency over all the events  $w1, w2, w3$  occurring at least 10 times in the corpus.  $allow(t, w)$  follows the dictionary. Because of the wide coverage of the Hebrew lexicon, we take  $REL_C$  to be  $C$  (all available contexts).

### 4.2 Evaluation

We run a series of experiments with 8 distinct initial conditions, as shown in Table 1: our baseline (*Uniform*) is the uniform distribution over all tags provided by the KC analyzer for each word. The *Syntagmatic* initial conditions add the  $p(t|t_{-1}, t_{+1})$  constraints described above to the uniform baseline. The *Morphology-Based* and *Linear-Context* initial conditions are computed as described above, while the *Morph+Linear* is the result of applying the linear-context algorithm over initial values computed by the Morphology-based method. We repeat

<sup>4</sup>This rule was taken from Shacham and Wintner(2007).

Initial Condition		Dist	Context-Free		EM-HMM	
			Full	Seg+Pos	Full	Seg+Pos
Uniform		60	63.8	71.9	85.5	89.8
Syntagmatic	Pair Constraints	60	/	/	85.8	89.8
	Init-Trans	60	/	/	87.9	91
Morpho-Lexical	Morph-Based	76.8	76.4	83.1	87.7	91.6
	Linear-Context	70.1	75.4	82.6	85.3	89.6

	Linear-Context	/	/	/	87.7	90.9
	Morph+Linear	/	/	/	<b>89.4</b>	<b>92.4</b>

Table 1: Accuracy (%) of Hebrew Morphological Disambiguation and POS Tagging over various initial conditions

these last 3 models with the addition of the syntagmatic constraints (*Synt+Morph*).

For each of these, we first compare the computed  $p(t|w)$  against a gold standard distribution, taken from the test corpus (90K tokens), according to the measure used by (Levinger et al., 1995) (*Dist*). On this measure, we confirm that our improved morpho-lexical approximation improves the results reported by Levinger *et al.* from 74% to about 80% on a richer tagset, and on a much larger test set (90K vs. 3,400 tokens).

We then report on the effectiveness of  $p(t|w)$  as a context-free tagger that assigns to each word the most likely tag, both for full morphological analysis (3,561 tags) (*Full*) and for the simpler task of token segmentation and POS tag selection (36 tags) (*Seg+Pos*). The best results on this task are 80.8% and 87.5% resp. achieved on the *Morph+Linear* initial conditions.

Finally, we test effectiveness of the initial conditions with EM-HMM learning. We reach 88% accuracy on full morphological and 92% accuracy for POS tagging and word segmentation, for the *Morph+Linear* initial conditions.

As expected, EM-HMM improves results (from 80% to 88%). Strikingly, EM-HMM improves the uniform initial conditions from 64% to above 85%. However, better initial conditions bring us much over this particular local maximum – with an error reduction of 20%. In all cases, the main improvement over the uniform baseline is brought by the morphology-based initial conditions. When applied on its own, the linear context brings modest improvement. But the combination of the paradigmatic morphology-based method with the linear context

improves all measures.

A most interesting observation is the detrimental contribution of the syntagmatic constraints we introduced. We found that 113,453 sentences of the corpus (about 5%) contradict these basic and apparently simple constraints. As an alternative to these common-sense constraints, we tried to use a small seed of randomly selected sentences (10K annotated tokens) in order to skew the initial uniform distribution of the state transitions. We initialize the  $p(t|t_{-1}, t_{+1})$  distribution with smoothed ML estimates based on tag trigram and bigram counts (ignoring the tag-word annotations). This small seed initialization (*InitTrans*) has a great impact on accuracy. Overall, we reach 89.4% accuracy on full morphological and 92.4% accuracy for POS tagging and word segmentation, for the *Morph+Linear* conditions – an error reduction of more than 25% from the uniform distribution baseline.

## 5 Application to English

We now apply the same technique to English semi-supervised POS tagging. Recent investigations of this task use dictionaries derived from the Penn WSJ corpus, with a reduced tag set of 17 tags<sup>5</sup> instead of the original 45-tags tagset. They experiment with full dictionaries (containing complete POS information for all the words in the text) as well as “diluted” dictionaries, from which large portions of the vocabulary are missing. These settings are very different from those used for Hebrew: the tagset is much smaller (17 vs.  $\sim 3,560$ ) and the dictionaries are either complete or extremely crippled. However, for the sake of comparison, we have reproduced the same experimental settings.

We derive dictionaries from the complete WSJ corpus<sup>6</sup>, and the exact same diluted dictionaries used in SE, TJ and GG.

<sup>5</sup>ADJ ADV CONJ DET ENDPUNC INPUNC LPUNC RPUNC N POS PRT PREP PRT TO V VBG VBN WH

<sup>6</sup>The dictionary derived from the WSJ data is very noisy: many of the stop words get wrong analyses stemming from tagging mistakes (for instance, the word *the* has 6 possible analyses in the data-derived dictionary, which we checked manually and found all but DT erroneous). Such noise is not expected in a real world dictionary, and our algorithm is not designed to accommodate it. We corrected the entries for the 20 most frequent words in the corpus. This step could probably be done automatically, but we consider it to be a non-issue in any realistic setting.

**Syntagmatic Constraints** We indirectly incorporated syntagmatic constraints through a small change to the tagset. The 17-tags English tagset allows for V-V transitions. Such a construction is generally unlikely in English. By separating modals from the rest of the verbs, and creating an additional class for the 5 *be* verbs (am, is, are, was, were), we made such transition much less probable. The new 19-tags tagset reflects the “verb can not follow a verb” constraint.

**Morphology-Based  $p(t|w)$  approximation** English morphology is much simpler compared to that of Hebrew, making direct use of the Levinger context free approximation impossible. However, some morphological cues exist in English as well, in particular common suffixation patterns. We implemented our morphology-based context-free  $p(t|w)$  approximation for English as a special case of the linear context-based algorithm described in Sect.3. Instead of generating contexts based on neighboring words, we generate them using the following 5 morphological templates:

**suff=S** The word has suffix  $S$  (suff=ing).

**L+suff=W,S** The word appears just after word  $W$ , with suffix  $S$  (L+suff=have, ed).

**R+suff=S,W** The word appears just before word  $W$ , with suffix  $S$  (R+suff=ing, to)

**wsuf=S1,S2** The word suffix is  $S1$ , the same stem is seen with suffix  $S2$  (wsuf= $\epsilon$ , s).

**suffs=SG** The word stem appears with the  $SG$  group of suffixes (suffs=ed, ing, s).

We consider a word to have a suffix only if the word stem appears with a different suffix somewhere in the text. We implemented a primitive stemmer for extracting the suffixes while preserving a usable stem by taking care of few English orthography rules (handling, e.g., bigger  $\rightarrow$  big er, nicer  $\rightarrow$  nice er, happily  $\rightarrow$  happy ly, picnicking  $\rightarrow$  picnic ing). For the immediate context  $W$  in the templates  $L+suff, R+suff$ , we consider only the 20 most frequent tokens in the corpus.

**Linear-Context-based  $p(t|w)$  approximation** We expect the context based approximation to be particularly useful in English. We use the following 3 context templates:  $LL=w_{-2}, w_{-1}$ ,  $LR=w_{-1}, w_{+1}$  and  $RR=w_{+1}, w_{+2}$ . We estimate  $p(w|c)$  and  $p(c|w)$  by relative frequency over word triplets occurring at

least twice in the unannotated training corpus.

**Combined  $p(t|w)$  approximation** This approximation combines the morphological and linear context approximations by using all the above-mentioned context templates together in the iterative process.

For all three  $p(t|w)$  approximations, we take  $REL_C$  to be contexts containing at most 4 tags.  $allow(t, w)$  follows the dictionary for known words, and is the set of all open-class POS for unknown words. We take the initial  $p(t|w)$  for each  $w$  to be uniform over all the dictionary specified tags for  $w$ . Accordingly, the initial  $p(t|w) = 0$  for  $w$  not in the dictionary. We run the process for 8 iterations.<sup>7</sup>

### Diluted Dictionaries and Unknown Words

Some of the missing dictionary elements are assigned a set of possible POS-tags and corresponding probabilities in the  $p(t|w)$  estimation process. Other unknown tokens remain with no analysis at the end of the initial process computation. For these missing elements, we assign an ambiguity class by a simple ambiguity-class guesser, and set  $p(t|w)$  to be uniform over all the tags in the ambiguity class. Our ambiguity-class guesser assigns for each word the set of all open-class tags that appeared with the word suffix in the dictionary. The word suffix is the longest (up to 3 characters) suffix of the word that also appears in the top-100 suffixes in the dictionary.

**Taggers** We test the resulting  $p(t|w)$  approximation by training 2 taggers: **CF-Tag**, a context-free tagger assigning for each word its most probable POS according to  $p(t|w)$ , with a fallback to the most probable tag in case the word does not appear in the dictionary or if  $\forall t, p(t|w) = 0$ . **EM-HMM**, a second-order EM-HMM initialized with the estimated  $p(t|w)$ .

**Baselines** As baseline, we use two EM-trained HMM taggers, initialized with a uniform  $p(t|w)$  for every word, based on the allowed tags in the dictionary. For words not in the dictionary, we take the allowed tags to be either all the open-class POS

<sup>7</sup>This is the first value we tried, and it seems to work fine. We haven’t experimented with other values. The same applies for the choice of 4 as the  $REL_C$  threshold.

(**uniform(oc)**) or the allowed tags according to our simple ambiguity-class guesser (**uniform(suf)**).

All the  $p(t|w)$  estimates and HMM models are trained on the entire WSJ corpus. We use the same 24K word test-set as used in SE, TJ and GG, as well as the same diluted dictionaries. We report the results on the same reduced tagsets for comparison, but also include the results on the full 46 tags tagset.

## 5.1 Results

Table 2 summarizes the results of our experiments.

Uniform initialization based on the simple suffix-based ambiguity class guesser yields big improvements over the uniform all-open-class initialization. However, our refined initial conditions always improve the results (by as much as 40% error reduction). As expected, the linear context is much more effective than the morphological one, especially with richer dictionaries. This seem to indicate that in English the linear context is better at refining the estimations when the ambiguity classes are known, while the morphological context is in charge of adding possible tags when the ambiguity classes are not known. Furthermore, the benefit of the morphology-context is bigger for the complete tagset setting, indicating that, while the coarse-grained POS-tags are indicated by word distribution, the finer distinctions are indicated by inflections and orthography. The combination of linear and morphology contexts is always beneficial. Syntagmatic constraints (e.g., separating *be* verbs and modals from the rest of the verbs) constantly improve results by about 1%. Note that the context-free tagger based on our  $p(t|w)$  estimates is quite accurate. As with the EM trained models, combining linear and morphological contexts is always beneficial.

To put these numbers in context, Table 3 lists current state-of-the art results for the same task. **CE+spl** is the Contrastive-Estimation CRF method of SE. **BHMM** is the completely Bayesian-HMM of GG. **PLSA+AC**, **LDA**, **LDA+AC** are the models presented in TJ, LDA+AC is a Bayesian model with a strong ambiguity class (AC) component, and is the current state-of-the-art of this task. The other models are variations excluding the Bayesian components (PLSA+AC) or the ambiguity class.

While our models are trained on the unannotated text of the entire WSJ Treebank, CE and BHMM use

much less training data (only the 24k words of the test-set). However, as noted by TJ, there is no reason one should limit the amount of unlabeled data used, and in addition other results reported in GG,SE show that accuracy does not seem to improve as more unlabeled data are used with the models. We also report results for training our EM-HMM tagger on the smaller dataset (the  $p(t|w)$  estimation is still based on the entire unlabeled WSJ).

All the abovementioned models follow the assumption that all 17 tags are valid for the unknown words. In contrast, we restrict the set of allowed tags for an unknown word to open-class tags. Closed class words are expected to be included in a dictionary, even a small one. The practice of allowing only open-class tags for unknown words goes back a long way (Weischedel et al., 1993), and proved highly beneficial also in our case.

Notice that even our simplest models, in which the initial  $p(t|w)$  distribution for each  $w$  is uniform, already outperform most of the other models, and, in the case of the diluted dictionaries, by a wide margin. Similarly, given the  $p(t|w)$  estimate, EM-HMM training on the smaller dataset (24k) is still very competitive (yet results improve with more unlabeled data). When we use our refined  $p(t|w)$  distribution as the basis of EM-HMM training, we get the best results for the complete dictionary case. With the diluted dictionaries, we are outperformed only by LDA+AC. As we outperform this model in the complete dictionary case, it seems that the advantage of this model is due to its much stronger ambiguity class model, and not its Bayesian components. Also note that while we outperform this model when using the 19-tags tagset, it is slightly better in the original 17-tags setting. It could be that the reliance of the LDA models on observed surface features instead of hidden state features is beneficial avoiding the misleading V-V transitions.

We also list the performance of our best models with a slightly more realistic dictionary setting: we take our dictionary to include information for all words occurring in section 0-18 of the WSJ corpus (43208 words). We then train on the entire unannotated corpus, and test on sections 22-24 – the standard train/test split for supervised English POS tagging. We achieve accuracy of **92.85%** for the 19-tags set, and **91.3%** for the complete 46-tags tagset.

## 6 Conclusion

We have demonstrated that unsupervised POS tagging can reach good results using the robust EM-HMM learner when provided with good initial conditions, even with incomplete dictionaries. We presented a general family of algorithms to compute effective initial conditions: estimation of  $p(t|w)$  relying on an iterative process shifting probabilities between words and their contexts. The parameters of this process (definition of the contexts and initial estimations of  $p(t|w)$ ) can safely encapsulate rich linguistic intuitions.

While recent work, such as GG, aim to use the Bayesian framework and incorporate “linguistically motivated priors”, in practice such priors currently only account for the fact that language related distributions are sparse - a very general kind of knowledge. In contrast, our method allow the incorporation of much more fine-grained intuitions.

We tested the method on the challenging task of full morphological disambiguation in Hebrew (which was our original motivation) and on the standard WSJ unsupervised POS tagging task.

In Hebrew, our model includes an improved version of the *similar words* algorithm of (Levinger et al., 1995), a model of lexical context, and a small

set of tag ngrams. The combination of these knowledge sources in the initial conditions brings an error reduction of more than 25% over a strong uniform distribution baseline. In English, our model is competitive with recent state-of-the-art results, while using simple and efficient learning methods.

The comparison with other algorithms indicates directions of potential improvement: (1) our initial-conditions method might benefit the other, more sophisticated learning algorithms as well. (2) Our models were designed under the assumption of a relatively complete dictionary. As such, they are not very good at assigning ambiguity-classes to OOV tokens when starting with a very small dictionary. While we demonstrate competitive results using a simple suffix-based ambiguity-class guesser which ignores capitalization and hyphenation information, we believe there is much room for improvement in this respect. In particular, (Haghighi and Klein, 2006) presents very strong results using a distributional-similarity module and achieve impressive tagging accuracy while starting with a mere 116 prototypical words. Experimenting with combining similar models (as well as TJ’s ambiguity class model) with our  $p(t|w)$  distribution estimation method is an interesting research direction.

## Abstract

In statistical language modeling, one technique to reduce the problematic effects of data sparsity is to partition the vocabulary into equivalence classes. In this paper we investigate the effects of applying such a technique to higher-order  $n$ -gram models trained on large corpora. We introduce a modification of the exchange clustering algorithm with improved efficiency for certain partially class-based models and a distributed version of this algorithm to efficiently obtain automatic word classifications for large vocabularies (>1 million words) using such large training corpora (>30 billion tokens). The resulting clusterings are then used in training partially class-based language models. We show that combining them with word-based  $n$ -gram models in the log-linear model of a state-of-the-art statistical machine translation system leads to improvements in translation quality as indicated by the BLEU score.

## 1 Introduction

A statistical language model assigns a probability  $P(w)$  to any given string of words  $w_1^m = w_1, \dots, w_m$ . In the case of  $n$ -gram language models this is done by factoring the probability:

$$P(w_1^m) = \prod_{i=1}^m P(w_i | w_1^{i-1})$$

and making a Markov assumption by approximating this by:

$$\prod_{i=1}^m P(w_i | w_1^{i-1}) \approx \prod_{i=1}^m p(w_i | w_{i-n+1}^{i-1})$$

Even after making the Markov assumption and thus treating all strings of preceding words as equal which

\* Parts of this research were conducted while the author studied at the Berlin Institute of Technology

do not differ in the last  $n - 1$  words, one problem  $n$ -gram language models suffer from is that the training data is too sparse to reliably estimate all conditional probabilities  $P(w_i | w_1^{i-1})$ .

Class-based  $n$ -gram models are intended to help overcome this data sparsity problem by grouping words into equivalence classes rather than treating them as distinct words and thus reducing the number of parameters of the model (Brown et al., 1990). They have often been shown to improve the performance of speech recognition systems when combined with word-based language models (Martin et al., 1998; Whittaker and Woodland, 2001). However, in the area of statistical machine translation, especially in the context of large training corpora, fewer experiments with class-based  $n$ -gram models have been performed with mixed success (Raab, 2006).

Class-based  $n$ -gram models have also been shown to benefit from their reduced number of parameters when scaling to higher-order  $n$ -grams (Goodman and Gao, 2000), and even despite the increasing size and decreasing sparsity of language model training corpora (Brants et al., 2007), class-based  $n$ -gram models might lead to improvements when increasing the  $n$ -gram order.

When training class-based  $n$ -gram models on large corpora and large vocabularies, one of the problems arising is the scalability of the typical clustering algorithms used for obtaining the word classification. Most often, variants of the *exchange algorithm* (Kneser and Ney, 1993; Martin et al., 1998) or the agglomerative clustering algorithm presented in (Brown et al., 1990) are used, both of which have prohibitive runtimes when clustering large vocabularies on the basis of large training corpora with a sufficiently high number of classes.

In this paper we introduce a modification of the exchange algorithm with improved efficiency and then present a distributed version of the modified algorithm, which makes it feasible to obtain word clas-

sifications using billions of tokens of training data. We then show that using partially class-based language models trained using the resulting classifications together with word-based language models in a state-of-the-art statistical machine translation system yields improvements despite the very large size of the word-based models used.

## 2 Class-Based Language Modeling

By partitioning all  $N_v$  words of the vocabulary into  $N_c$  sets, with  $c(w)$  mapping a word onto its equivalence class and  $c(w_i^j)$  mapping a sequence of words onto the sequence of their respective equivalence classes, a typical class-based  $n$ -gram model approximates  $P(w_i|w_1^{i-1})$  with the two following component probabilities:

$$P(w_i|w_1^{i-1}) \approx p_0(w_i|c(w_i)) \cdot p_1(c(w_i)|c(w_{i-n+1}^{i-1})) \quad (1)$$

thus greatly reducing the number of parameters in the model, since usually  $N_c$  is much smaller than  $N_v$ .

In the following, we will call this type of model a *two-sided class-based model*, as both the history of each  $n$ -gram, the sequence of words conditioned on, as well as the predicted word are replaced by their class.

Once a partition of the words in the vocabulary is obtained, two-sided class-based models can be built just like word-based  $n$ -gram models using existing infrastructure. In addition, the size of the model is usually greatly reduced.

### 2.1 One-Sided Class-Based Models

Two-sided class-based models received most attention in the literature. However, several different types of mixed word and class models have been proposed for the purpose of improving the performance of the model (Goodman, 2000), reducing its size (Goodman and Gao, 2000) as well as lowering the complexity of related clustering algorithms (Whittaker and Woodland, 2001).

In (Emami and Jelinek, 2005) a clustering algorithm is introduced which outputs a separate clustering for each word position in a trigram model. In the experimental evaluation, the authors observe the largest improvements using a specific clustering for the last word of each trigram but no clustering at all for the first two word positions. Generalizing this leads to arbitrary order class-based  $n$ -gram models of the form:

$$P(w_i|w_1^{i-1}) \approx p_0(w_i|c(w_i)) \cdot p_1(c(w_i)|w_{i-n+1}^{i-1}) \quad (2)$$

which we will call *predictive class-based models* in the following sections.

## 3 Exchange Clustering

One of the frequently used algorithms for automatically obtaining partitions of the vocabulary is the exchange algorithm (Kneser and Ney, 1993; Martin et al., 1998). Beginning with an initial clustering, the algorithm greedily maximizes the log likelihood of a two-sided class bigram or trigram model as described in Eq. (1) on the training data. Let  $V$  be the set of words in the vocabulary and  $C$  the set of classes. This then leads to the following optimization criterion, where  $N(w)$  and  $N(c)$  denote the number of occurrences of a word  $w$  or a class  $c$  in the training data and  $N(c, d)$  denotes the number of occurrences of some word in class  $c$  followed by a word in class  $d$  in the training data:

$$\begin{aligned} \hat{C} = \operatorname{argmax}_C & \sum_{w \in V} N(w) \cdot \log N(w) + \\ & + \sum_{c \in C, d \in C} N(c, d) \cdot \log N(c, d) - \\ & - 2 \cdot \sum_{c \in C} N(c) \cdot \log N(c) \end{aligned} \quad (3)$$

The algorithm iterates over all words in the vocabulary and tentatively moves each word to each cluster. The change in the optimization criterion is computed for each of these tentative moves and the exchange leading to the highest increase in the optimization criterion (3) is performed. This procedure is then repeated until the algorithm reaches a local optimum.

To be able to efficiently calculate the changes in the optimization criterion when exchanging a word, the counts in Eq. (3) are computed once for the initial clustering, stored, and afterwards updated when a word is exchanged.

Often only a limited number of iterations are performed, as letting the algorithm terminate in a local optimum can be computationally impractical.

### 3.1 Complexity

The implementation described in (Martin et al., 1998) uses a memory saving technique introducing a binary search into the complexity estimation. For the sake of simplicity, we omit this detail in the following complexity analysis. We also do not employ this optimization in our implementation.

The worst case complexity of the exchange algorithm is quadratic in the number of classes. However,

**Input:** The fixed number of clusters  $N_c$   
 Compute initial clustering  
**while** *clustering changed in last iteration* **do**  
   **forall**  $w \in V$  **do**  
     **forall**  $c \in C$  **do**  
       move word  $w$  tentatively to cluster  
        $c$   
       compute updated optimization  
       criterion  
     move word  $w$  to cluster maximizing  
     optimization criterion

**Algorithm 1:** Exchange Algorithm Outline

the average case complexity can be reduced by updating only the counts which are actually affected by moving a word from one cluster to another. This can be done by considering only those sets of clusters for which  $N(w, c) > 0$  or  $N(c, w) > 0$  for a word  $w$  about to be exchanged, both of which can be calculated efficiently when exchanging a word. The algorithm scales linearly in the size of the vocabulary.

With  $N_c^{pre}$  and  $N_c^{suc}$  denoting the average number of clusters preceding and succeeding another cluster,  $B$  denoting the number of distinct bigrams in the training corpus, and  $I$  denoting the number of iterations, the worst case complexity of the algorithm is in:

$$\mathcal{O}(I \cdot (2 \cdot B + N_v \cdot N_c \cdot (N_c^{pre} + N_c^{suc})))$$

When using large corpora with large numbers of bigrams the number of required updates can increase towards the quadratic upper bound as  $N_c^{pre}$  and  $N_c^{suc}$  approach  $N_c$ . For a more detailed description and further analysis of the complexity, the reader is referred to (Martin et al., 1998).

## 4 Predictive Exchange Clustering

Modifying the exchange algorithm in order to optimize the log likelihood of a predictive class bigram model, leads to substantial performance improvements, similar to those previously reported for another type of one-sided class model in (Whittaker and Woodland, 2001).

We use a predictive class bigram model as given in Eq. (2), for which the maximum-likelihood probability estimates for the  $n$ -grams are given by their relative frequencies:

$$\begin{aligned} P(w_i | w_1^{i-1}) &\approx p_0(w_i | c(w_i)) \cdot p_1(c(w_i) | w_{i-1}) \quad (4) \\ &= \frac{N(w_i)}{N(c(w_i))} \cdot \frac{N(w_{i-1}, c(w_i))}{N(w_{i-1})} \quad (5) \end{aligned}$$

where  $N(w)$  again denotes the number of occurrences of the word  $w$  in the training corpus and  $N(v, c)$

the number of occurrences of the word  $v$  followed by some word in class  $c$ . Then the following optimization criterion can be derived, with  $F(C)$  being the log likelihood function of the predictive class bigram model given a clustering  $C$ :

$$\begin{aligned} F(C) &= \sum_{w \in V} N(w) \cdot \log p(w | c(w)) \\ &\quad + \sum_{v \in V, c \in C} N(v, c) \cdot \log p(c | v) \quad (6) \end{aligned}$$

$$\begin{aligned} &= \sum_{w \in V} N(w) \cdot \log \frac{N(w)}{N(c(w))} \\ &\quad + \sum_{v \in V, c \in C} N(v, c) \cdot \log \frac{N(v, c)}{N(v)} \quad (7) \end{aligned}$$

$$\begin{aligned} &= \sum_{w \in V} N(w) \cdot \log N(w) \\ &\quad - \sum_{w \in V} N(w) \cdot \log N(c(w)) \\ &\quad + \sum_{v \in V, c \in C} N(v, c) \cdot \log N(v, c) \\ &\quad - \sum_{v \in V, c \in C} N(v, c) \cdot \log N(v) \quad (8) \end{aligned}$$

The very last summation of Eq. (8) now effectively sums over all occurrences of all words and thus cancels out with the first summation of (8) which leads to:

$$\begin{aligned} F(C) &= \sum_{v \in V, c \in C} N(v, c) \cdot \log N(v, c) \\ &\quad - \sum_{w \in V} N(w) \cdot \log N(c(w)) \quad (9) \end{aligned}$$

In the first summation of Eq. (9), for a given word  $v$  only the set of classes which contain at least one word  $w$  for which  $N(v, w) > 0$  must be considered, denoted by  $suc(v)$ . The second summation is equivalent to  $\sum_{c \in C} N(c) \cdot \log N(c)$ . Thus the further simplified criterion is:

$$\begin{aligned} F(C) &= \sum_{v \in V, c \in suc(v)} N(v, c) \cdot \log N(v, c) \\ &\quad - \sum_{c \in C} N(c) \cdot \log N(c) \quad (10) \end{aligned}$$

When exchanging a word  $w$  between two classes  $c$  and  $c'$ , only two summands of the second summation of Eq. (10) are affected. The first summation can be updated by iterating over all bigrams ending in the exchanged word. Throughout one iteration of the algorithm, in which for each word in the vocabulary each possible move to another class is evaluated, this

amounts to the number of distinct bigrams in the training corpus  $B$ , times the number of clusters  $N_c$ . Thus the worst case complexity using the modified optimization criterion is in:

$$\mathcal{O}(I \cdot N_c \cdot (B + N_v))$$

Using this optimization criterion has two effects on the complexity of the algorithm. The first difference is that in contrast to the exchange algorithm using a two sided class-based bigram model in its optimization criterion, only two clusters are affected by moving a word. Thus the algorithm scales linearly in the number of classes. The second difference is that  $B$  dominates the term  $B + N_v$  for most corpora and scales far less than linearly with the vocabulary size, providing a significant performance advantage over the other optimization criterion, especially when large vocabularies are used (Whittaker and Woodland, 2001).

For efficiency reasons, an exchange of a word between two clusters is separated into a *remove* and a *move* procedure. In each iteration the *remove* procedure only has to be called once for each word, while for a given word *move* is called once for every cluster to compute the consequences of the tentative exchanges. An outline of the *move* procedure is given below. The *remove* procedure is similar.

**Input:** A word  $w$ , and a destination cluster  $c$

**Result:** The change in the optimization criterion when moving  $w$  to cluster  $c$

$\delta \leftarrow N(c) \cdot \log N(c)$

$N'(c) \leftarrow N(c) - N(w)$

$\delta \leftarrow \delta - N'(c) \cdot \log N'(c)$

**if not a tentative move then**

$N(c) \leftarrow N'(c)$

**forall**  $v \in \text{suc}(w)$  **do**

$\delta \leftarrow \delta - N(v, c) \cdot \log N(v, c)$

$N'(v, c) \leftarrow N(v, c) - N(v, w)$

$\delta \leftarrow \delta + N'(v, c) \cdot \log N'(v, c)$

**if not a tentative move then**

$N(v, c) \leftarrow N'(v, c)$

**return**  $\delta$

**Procedure MoveWord**

## 5 Distributed Clustering

When training on large corpora, even the modified exchange algorithm would still require several days if not weeks of CPU time for a sufficient number of iterations.

To overcome this we introduce a novel *distributed exchange algorithm*, based on the modified exchange

algorithm described in the previous section. The vocabulary is randomly partitioned into sets of roughly equal size. With each word  $w$  in one of these sets, all words  $v$  preceding  $w$  in the corpus are stored with the respective bigram count  $N(v, w)$ .

The clusterings generated in each iteration as well as the initial clustering are stored as the set of words in each cluster, the total number of occurrences of each cluster in the training corpus, and the list of words preceding each cluster. For each word  $w$  in the predecessor list of a given cluster  $c$ , the number of times  $w$  occurs in the training corpus before any word in  $c$ ,  $N(w, c)$ , is also stored.

Together with the counts stored with the vocabulary partitions, this allows for efficient updating of the terms in Eq. (10).

The initial clustering together with all the required counts is created in an initial iteration by assigning the  $n$ -th most frequent word to cluster  $n \bmod N_c$ . While (Martin et al., 1998) and (Emami and Jelinek, 2005) observe that the initial clustering does not seem to have a noticeable effect on the quality of the resulting clustering or the convergence rate, the intuition behind this method of initialization is that it is unlikely for the most frequent words to be clustered together due to their high numbers of occurrences.

In each subsequent iteration each one of a number of workers is assigned one of the partitions of the words in the vocabulary. After loading the current clustering, it then randomly chooses a subset of these words of a fixed size. For each of the selected words the worker then determines to which cluster the word is to be moved in order to maximize the increase in log likelihood, using the count updating procedures described in the previous section. All changes a worker makes to the clustering are accumulated locally in delta data structures. At the end of the iteration all deltas are merged and applied to the previous clustering, resulting in the complete clustering loaded in the next iteration.

This algorithm fits well into the *MapReduce* programming model (Dean and Ghemawat, 2004) that we used for our implementation.

### 5.1 Convergence

While the greedy non-distributed exchange algorithm is guaranteed to converge as each exchange increases the log likelihood of the assumed bigram model, this is not necessarily true for the distributed exchange algorithm. This stems from the fact that the change in log likelihood is calculated by each worker under the assumption that no other changes to the clustering are performed by other workers in

this iteration. However, if in each iteration only a rather small and randomly chosen subset of all words are considered for exchange, the intuition is that the remaining words still define the parameters of each cluster well enough for the algorithm to converge.

In (Emami and Jelinek, 2005) the authors observe that only considering a subset of the vocabulary of half the size of the complete vocabulary in each iteration does not affect the time required by the exchange algorithm to converge. Yet each iteration is sped up by approximately a factor of two. The quality of class-based models trained using the resulting clusterings did not differ noticeably from those trained using clusterings for which the full vocabulary was considered in each iteration. Our experiments showed that this also seems to be the case for the distributed exchange algorithm. While considering very large subsets of the vocabulary in each iteration can cause the algorithm to not converge at all, considering only a very small fraction of the words for exchange will increase the number of iterations required to converge. In experiments we empirically determined that choosing a subset of roughly a third of the size of the full vocabulary is a good balance in this trade-off. We did not observe the algorithm to not converge unless we used fractions above half of the vocabulary size.

We typically ran the clustering for 20 to 30 iterations after which the number of words exchanged in each iteration starts to stabilize at less than 5 percent of the vocabulary size. Figure 1 shows the number of words exchanged in each of 34 iterations when clustering the approximately 300,000 word vocabulary of the Arabic side of the English-Arabic parallel training data into 512 and 2,048 clusters.

Despite a steady reduction in the number of words exchanged per iteration, we observed the convergence in regards to log-likelihood to be far from monotone. In our experiments we were able to achieve significantly more monotone and faster convergence by employing the following heuristic. As described in Section 5, we start out the first iteration with a random partition of the vocabulary into subsets each assigned to a specific worker. However, instead of keeping this assignment constant throughout all iterations, after each iteration the vocabulary is partitioned anew so that all words from any given cluster are considered by the same worker in the next iteration. The intuition behind this heuristic is that as the clustering becomes more coherent, the information each worker has about groups of similar words is becoming increasingly accurate. In our experiments this heuristic lead to almost monotone convergence in log-likelihood. It also reduced the

Figure 1: Number of words exchanged per iteration when clustering the vocabulary of the Arabic side of the English-Arabic parallel training data (347 million tokens).

number of iterations required to converge by up to a factor of three.

## 5.2 Resource Requirements

The runtime of the distributed exchange algorithm depends highly on the number of distinct bigrams in the training corpus. When clustering the approximately 1.5 million word vocabulary of a 405 million token English corpus into 1,000 clusters, one iteration takes approximately 5 minutes using 50 workers based on standard hardware running the Linux operating system. When clustering the 0.5 million most frequent words in the vocabulary of an English corpus with 31 billion tokens into 1,000 clusters, one iteration takes approximately 30 minutes on 200 workers.

When scaling up the vocabulary and corpus sizes, the current bottleneck of our implementation is loading the current clustering into memory. While the memory requirements decrease with each iteration, during the first few iterations a worker typically still needs approximately 2 GB of memory to load the clustering generated in the previous iteration when training 1,000 clusters on the 31 billion token corpus.

## 6 Experiments

We trained a number of predictive class-based language models on different Arabic and English corpora using clusterings trained on the complete data of the same corpus. We use the distributed training and application infrastructure described in (Brants et al., 2007) with modifications to allow the training of predictive class-based models and their application in the decoder of the machine translation system.

For all models used in our experiments, both word- and class-based, the smoothing method used was *Stupid Backoff* (Brants et al., 2007). Models with Stupid Backoff return scores rather than normalized probabilities, thus perplexities cannot be calculated for these models. Instead we report BLEU scores (Papineni et al., 2002) of the machine translation system using different combinations of word- and class-based models for translation tasks from English to Arabic and Arabic to English.

## 6.1 Training Data

For English we used three different training data sets: ***en\_target***: The English side of Arabic-English and Chinese-English parallel data provided by LDC (405 million tokens).

***en\_ldcnews***: Consists of several English news data sets provided by LDC (5 billion tokens).

***en\_webnews***: Consists of data collected up to December 2005 from web pages containing primarily English news articles (31 billion tokens).

A fourth data set, *en\_web*, was used together with the other three data sets to train the large word-based model used in the second machine translation experiment. This set consists of general web data collected in January 2006 (2 trillion tokens).

For Arabic we used the following two different training data sets:

***ar\_gigaword***: Consists of several Arabic news data sets provided by LDC (629 million tokens).

***ar\_webnews***: Consists of data collected up to December 2005 from web pages containing primarily Arabic news articles (approximately 600 million tokens).

## 6.2 Machine Translation Results

Given a sentence  $\mathbf{f}$  in the source language, the *machine translation* problem is to automatically produce a translation  $\hat{\mathbf{e}}$  in the target language. In the subsequent experiments, we use a phrase-based statistical machine translation system based on the log-linear formulation of the problem described in (Och and Ney, 2002):

$$\begin{aligned} \hat{\mathbf{e}} &= \operatorname{argmax}_{\mathbf{e}} p(\mathbf{e}|\mathbf{f}) \\ &= \operatorname{argmax}_{\mathbf{e}} \sum_{m=1}^M \lambda_m h_m(\mathbf{e}, \mathbf{f}) \end{aligned} \quad (11)$$

where  $\{h_m(\mathbf{e}, \mathbf{f})\}$  is a set of  $M$  *feature functions* and  $\{\lambda_m\}$  a set of *weights*. We use each predictive class-based language model as well as a word-based model as separate feature functions in the log-linear combination in Eq. (11). The weights are trained using

minimum error rate training (Och, 2003) with BLEU score as the objective function.

The *dev* and *test* data sets contain parts of the 2003, 2004 and 2005 Arabic NIST MT evaluation sets among other parallel data. The blind test data used is the “NIST” part of the 2006 Arabic-English NIST MT evaluation set, and is not included in the training data.

For the first experiment we trained predictive class-based 5-gram models using clusterings with 64, 128, 256 and 512 clusters<sup>1</sup> on the *en\_target* data. We then added these models as additional features to the log linear model of the Arabic-English machine translation system. The word-based language model used by the system in these experiments is a 5-gram model also trained on the *en\_target* data set.

Table 1 shows the BLEU scores reached by the translation system when combining the different class-based models with the word-based model in comparison to the BLEU scores by a system using only the word-based model on the Arabic-English translation task.

	<b>dev</b>	<b>test</b>	<b>nist06</b>
<b>word-based only</b>	0.4085	0.3498	0.5088
<b>64 clusters</b>	0.4122	0.3514	0.5114
<b>128 clusters</b>	0.4142	0.3530	0.5109
<b>256 clusters</b>	0.4141	0.3536	0.5076
<b>512 clusters</b>	0.4120	0.3504	0.5140

Table 1: BLEU scores of the Arabic English system using models trained on the English *en\_target* data set

Adding the class-based models leads to small improvements in BLEU score, with the highest improvements for both *dev* and *nist06* being statistically significant<sup>2</sup>.

In the next experiment we used two predictive class-based models, a 5-gram model with 512 clusters trained on the *en\_target* data set and a 6-gram model also using 512 clusters trained on the *en\_ldcnews* data set. We used these models in addition to a word-based 6-gram model created by combining models trained on all four English data sets.

Table 2 shows the BLEU scores of the machine translation system using only this word-based model, the scores after adding the class-based model trained on the *en\_target* data set and when using all three models.

<sup>1</sup>The *beginning of sentence*, *end of sentence* and *unknown word* tokens were each treated as separate clusters

<sup>2</sup>Differences of more than 0.0051 are statistically significant at the 0.05 level using bootstrap resampling (Noreen, 1989; Koehn, 2004)

	dev	test	nist06
<b>word-based only</b>	0.4677	0.4007	0.5672
<b>with <i>en_target</i></b>	0.4682	0.4022	0.5707
<b>all three models</b>	0.4690	0.4059	0.5748

Table 2: BLEU scores of the Arabic English system using models trained on various data sets

For our experiment with the English Arabic translation task we trained two 5-gram predictive class-based models with 512 clusters on the Arabic *ar\_gigaword* and *ar\_webnews* data sets. The word-based Arabic 5-gram model we used was created by combining models trained on the Arabic side of the parallel training data (347 million tokens), the *ar\_gigaword* and *ar\_webnews* data sets, and additional Arabic web data.

	dev	test	nist06
<b>word-based only</b>	0.2207	0.2174	0.3033
<b>with <i>ar_webnews</i></b>	0.2237	0.2136	0.3045
<b>all three models</b>	0.2257	0.2260	0.3318

Table 3: BLEU scores of the English Arabic system using models trained on various data sets

As shown in Table 3, adding the predictive class-based model trained on the *ar\_webnews* data set leads to small improvements in *dev* and *nist06* scores but causes the *test* score to decrease. However, adding the class-based model trained on the *ar\_gigaword* data set to the other class-based and the word-based model results in further improvement of the *dev* score, but also in large improvements of the *test* and *nist06* scores.

We performed experiments to eliminate the possibility of data overlap between the training data and the machine translation test data as cause for the large improvements. In addition, our experiments showed that when there is overlap between the training and test data, the class-based models lead to lower scores as long as they are trained only on data also used for training the word-based model. One explanation could be that the domain of the *ar\_gigaword* corpus is much closer to the domain of the test data than that of other training data sets used. However, further investigation is required to explain the improvements.

### 6.3 Clusters

The clusters produced by the distributed algorithm vary in their size and number of occurrences. In a clustering of the *en\_target* data set with 1,024 clusters, the cluster sizes follow a typical long-tailed distribution with the smallest cluster contain-

ing 13 words and the largest cluster containing 20,396 words. Table 4 shows some examples of the generated clusters. For each cluster we list all words occurring more than 1,000 times in the corpus.

## 7 Conclusion

In this paper, we have introduced an efficient, distributed clustering algorithm for obtaining word classifications for predictive class-based language models with which we were able to use billions of tokens of training data to obtain classifications for millions of words in relatively short amounts of time.

The experiments presented show that predictive class-based models trained using the obtained word classifications can improve the quality of a state-of-the-art machine translation system as indicated by the BLEU score in both translation tasks. When using predictive class-based models in combination with a word-based language model trained on very large amounts of data, the improvements continue to be statistically significant on the *test* and *nist06* sets. We conclude that even despite the large amounts of data used to train the large word-based model in our second experiment, class-based language models are still an effective tool to ease the effects of data sparsity.

We furthermore expect to be able to increase the gains resulting from using class-based models by using more sophisticated techniques for combining them with word-based models such as linear interpolations of word- and class-based models with coefficients depending on the frequency of the history.

Another interesting direction of further research is to evaluate the use of the presented clustering technique for language model size reduction.

## Abstract

We address the problem of translating from morphologically poor to morphologically rich languages by adding per-word linguistic information to the source language. We use the syntax of the source sentence to extract information for noun cases and verb persons and annotate the corresponding words accordingly. In experiments, we show improved performance for translating from English into Greek and Czech. For English–Greek, we reduce the error on the verb conjugation from 19% to 5.4% and noun case agreement from 9% to 6%.

## 1 Introduction

Traditional statistical machine translation methods are based on mapping on the lexical level, which takes place in a local window of a few words. Hence, they fail to produce adequate output in many cases where more complex linguistic phenomena play a role. Take the example of morphology. Predicting the correct morphological variant for a target word may not depend solely on the source words, but require additional information about its role in the sentence.

Recent research on handling rich morphology has largely focused on translating from rich morphology languages, such as Arabic, into English (Habash and Sadat, 2006). There has been less work on the opposite case, translating from English into morphologically richer languages. In a study of translation quality for languages in the Europarl corpus, Koehn (2005) reports that translating into morphologically

richer languages is more difficult than translating from them.

There are intuitive reasons why generating richer morphology from morphologically poor languages is harder. Take the example of translating noun phrases from English to Greek (or German, Czech, etc.). In English, a noun phrase is rendered the same if it is the subject or the object. However, Greek words in noun phrases are inflected based on their role in the sentence. A purely lexical mapping of English noun phrases to Greek noun phrases suffers from the lack of information about its role in the sentence, making it hard to choose the right inflected forms.

Our method is based on factored phrase-based statistical machine translation models. We focused on preprocessing the source data to acquire the needed information and then use it within the models. We mainly carried out experiments on English to Greek translation, a language pair that exemplifies the problems of translating from a morphologically poor to a morphologically rich language.

### 1.1 Morphology in Phrase-based SMT

When examining parallel sentences of such language pairs, it is apparent that for many English words and phrases which appear usually in the same form, the corresponding terms of the richer target language appear inflected in many different ways. On a single word-based probabilistic level, it is then obvious that for one specific English word  $e$  the probability  $p(f|e)$  of it being translated into a word  $f$  decreases as the number of translation candidates increase, making the decisions more uncertain.

- **English:** The president, after reading the press review and the announcements, left his office
- **Greek-1:** The president[nominative], after reading[3<sup>rd</sup>sing] the press review[accusative,sing] and the announcements[accusative,plur], left[3<sup>rd</sup>sing] his office[accusative,sing]
- **Greek-2:** The president[nominative], after reading[3<sup>rd</sup>sing] the press review[accusative,sing] and the announcements[nominative,plur], left[3<sup>rd</sup>plur] his office[accusative,sing]

Figure 1: Example of missing agreement information, affecting the meaning of the second sentence

One of the main aspects required for the fluency of a sentence is *agreement*. Certain words have to match in gender, case, number, person etc. within a sentence. The exact rules of agreement are language-dependent and are closely linked to the morphological structure of the language.

Traditional statistical machine translation models deal with this problems in two ways:

- The basic SMT approach uses the target language model as a feature in the argument maximisation function. This language model is trained on grammatically correct text, and would therefore give a good probability for word sequences that are likely to occur in a sentence, while it would penalise ungrammatical or badly ordered formations.
- Meanwhile, in phrase-based SMT models, words are mapped in chunks. This can resolve phenomena where the English side uses more than one words to describe what is denoted on the target side by one morphologically inflected term.

Thus, with respect to these methods, there is a problem when agreement needs to be applied on part of a sentence whose length exceeds the order of the of the target  $n$ -gram language model and the size of the chunks that are translated (see Figure 1 for an example).

## 1.2 Related Work

In one of the first efforts to enrich the source in word-based SMT, Ueffing and Ney (2003) used part-of-speech (POS) tags, in order to deal with the verb conjugation of Spanish and Catalan; so, POS tags were used to identify the pronoun+verb sequence and splice these two words into one term. The approach was clearly motivated by the problems occurring by a single-word-based SMT and have been solved by adopting a phrase-based model. Meanwhile, there is no handling of the case when the pronoun stays in distance with the related verb.

Minkov et al. (2007) suggested a post-processing system which uses morphological and syntactic features, in order to ensure grammatical agreement on the output. The method, using various grammatical source-side features, achieved higher accuracy when applied directly to the reference translations but it was not tested as a part of an MT system. Similarly, translating English into Turkish (Durgar El-Kahlout and Oflazer, 2006) uses POS and morph stems in the input along with rich Turkish morph tags on the target side, but improvement was gained only after augmenting the generation process with morphotactical knowledge. Habash et al. (2007) also investigated case determination in Arabic. Carpuat and Wu (2007) approached the issue as a Word Sense Disambiguation problem.

In their presentation of the factored SMT models, Koehn and Hoang (2007) describe experiments for translating from English to German, Spanish and Czech, using morphology tags added on the morphologically rich side, along with POS tags. The morphological factors are added on the morphologically rich side and scored with a 7-gram sequence model. Probabilistic models for using only source tags were investigated by Birch et al. (2007), who attached syntax hints in factored SMT models by having *Combinatorial Categorical Grammar (CCG) supertags* as factors on the input words, but in this case English was the target language.

This paper reports work that strictly focuses on translation from English to a morphologically richer language. We go one step further than just using easily acquired information (e.g. English POS or lemmata) and extract target-specific information from the source sentence context. We use syntax, not in

Figure 2: Classification of the errors on our English-Greek baseline system (ch. 4.1), as suggested by Vilar et al. (2006)

order to aid reordering (Yamada and Knight, 2001; Collins et al., 2005; Huang et al., 2006), but as a means for getting the “missing” morphology information, depending on the syntactic position of the words of interest. Then, contrary to the methods that added only output features or altered the generation procedure, we used this information in order to augment only the source side of a factored translation model, assuming that we do not have resources allowing factors or specialized generation in the target language (a common problem, when translating from English into under-resourced languages).

## 2 Methods for enriching input

We selected to focus on *noun cases agreement* and *verb person conjugation*, since they were the most frequent grammatical errors of our baseline SMT system (see full error analysis in Figure 2). Moreover, these types of inflection signify the constituents of every phrase, tightly linked to the meaning of the sentence.

### 2.1 Case agreement

The case agreement for nouns, adjectives and articles is mainly defined by the syntactic role that each noun phrase has. Nominative case is used to define the nouns which are the subject of the sentence, accusative shows usually the direct object of the verbs and dative case refers to the indirect object of bi-transitive verbs.

Therefore, the followed approach takes advantage of syntax, following a method similar to *Semantic Role Labelling* (Carreras and Marquez, 2005; Surdeanu and Turmo, 2005). English, as morphologically poor language, usually follows a fixed word order (subject-verb-object), so that a syntax parser can be easily used for identifying the subject and the object of most sentences. Considering such annotation, a factored translation model is trained to map the word-case pair to the correct inflection of the target noun. Given the agreement restriction, all words that accompany the noun (adjectives, articles, determiners) must follow the case of the noun, so their likely case needs to be identified as well.

For this purpose we use a syntax parser to acquire the syntax tree for each English sentence. The trees are parsed depth-first and the cases are identified within particular “sub-tree patterns” which are manually specified. We use the sequence of the nodes in the tree to identify the syntactic role of each noun phrase.

Figure 3: Case tags are assigned on depth-first parse of the English syntax tree, based on sub-tree patterns

To make things more clear, an example can be seen in figure 3. At first, the algorithm identifies the subtree “S-(NPB-VP)” and the *nominative* tag is applied on the NPB node, so that it is assigned to the word “we” (since a pronoun can have a case). The example of accusative shows how cases get transferred to nested subtrees. In practice, they are recursively transferred to every underlying noun phrase (NP) but not to clauses that do not need this information (e.g. prepositional phrases). Similar rules are applied for covering a wide range of node sequence patterns.

Also note that this method had to be target-

oriented in some sense: we considered the target language rules for choosing the noun case in every prepositional phrase, depending on the leading preposition. This way, almost all nouns were tagged and therefore the number of the factored words was increased, in an effort to decrease sparsity. Similarly, cases which do not actively affect morphology (e.g. dative in Greek) were not tagged during factorization.

## 2.2 Verb person conjugation

For resolving the verb conjugation, we needed to identify the person of a verb and add this piece of linguistic information as a tag. As we parse the tree top-down, on every level, we look for two discrete nodes which, somewhere in their children, include the verb and the corresponding subject. Consequently, the node which contains the subject is searched recursively until a subject is found. Then, the person is identified and the tag is assigned to the node which contains the verb, which recursively bequeaths this tag to the nested subtree.

For the subject selection, the following rules were applied:

- The verb person is directly connected to the subject of the sentence and in most cases it is directly inferred by a personal pronoun (I, you etc). Therefore, since this is usually the case, when a pronoun existed, it was directly used as a tag.
- All pronouns in a different case (e.g. *them*, *myself*) were converted into nominative case before being used as a tag.
- When the subject of the sentence is not a pronoun, but a single noun, then it is in third person. The POS tag of this noun is then used to identify if it is plural or singular. This was selectively modified for nouns which despite being in singular, take a verb in plural.
- The gender of the subject does not affect the inflection of the verb in Greek. Therefore, all three genders that are given by the third person pronouns were reduced to one.

In Figure 4 we can see an example of how the person tag is extracted from the subject of the sen-

Figure 4: Applying person tags on an English syntax tree

tence and gets passed to the relative clause. In particular, as the algorithm parses the syntax tree, it identifies the sub-tree which has NP-A as a head and includes the WHNP node. Consequently, it recursively browses the preceding NPB so as to get the subject of the sentence. The word “aspects” is found, which has a POS tag that shows it is a plural noun. Therefore, we consider the subject to be of the third person in plural (tagged by *they*) which is recursively passed to the children of the head node.

## 3 Factored Model

The factored statistical machine translation model uses a log-linear approach, in order to combine the several components, including the language model, the reordering model, the translation models and the generation models. The model is defined mathematically (Koehn and Hoang, 2007) as following:

$$p(\mathbf{f}|\mathbf{e}) = \frac{1}{Z} \exp \sum_{i=1}^n \lambda_i h_i(\mathbf{f}, \mathbf{e}) \quad (1)$$

where  $\lambda_i$  is a vector of weights determined during a tuning process, and  $h_i$  is the feature function. The feature function for a translation probability distribution is

$$h_T(\mathbf{f}|\mathbf{e}) = \sum_j \tau(\bar{e}_j, \bar{f}_j) \quad (2)$$

While factored models may use a generation step to combine the several translation components based on the output factors, we use only source factors;

therefore we don't need a generation step to combine the probabilities of the several components.

Instead, factors are added so that both words and its factor(s) are assigned the same probability. Of course, when there is not 1-1 mapping between the *word+factor* splice on the source and the inflected word on the target, the well-known issue of sparse data arises. In order to reduce these problems, decoding needed to consider alternative paths to translation tables trained with less or no factors (as Birch et al. (2007) suggested), so as to cover instances where a word appears with a factor which it has not been trained with. This is similar to back-off. The alternative paths are combined as following (fig. 5):

$$h_T(\mathbf{f}|\mathbf{e}) = \sum_j h_{T_{t(j)}}(\bar{e}_j, \bar{f}_j) \quad (3)$$

where each phrase  $j$  is translated by one translation table  $t(j)$  and each table  $i$  has a feature function  $h_{T_i}$ , as shown in eq. (2).

Figure 5: Decoding using an alternative path with different factorization

## 4 Experiments

This preprocessing led to annotated source data, which were given as an input to a factored SMT system.

### 4.1 Experiment setup

For testing the factored translation systems, we used Moses (Koehn et al., 2007), along with a 5-gram SRILM language model (Stolcke, 2002). A Greek model was trained on 440,082 aligned sentences of Europarl v.3, tuned with *Minimum Error Training* (Och, 2003). It was tuned over a development set of 2,000 Europarl sentences and tested on two sets of 2,000 sentences each, from the Europarl and a

News Commentary respectively, following the specifications made by the ACL 2007 2nd Workshop on SMT<sup>1</sup>. A Czech model was trained on 57,464 aligned sentences, tuned over 1057 sentences of the News Commentary corpus and tested on two sets of 964 sentences and 2000 sentences respectively.

The training sentences were trimmed to a length of 60 words for reducing perplexity and a standard lexicalised reordering, with distortion limit set to 6. For getting the syntax trees, the latest version of Collins' parser (Collins, 1997) was used. When needed, part-of-speech (POS) tags were acquired by using Brill's tagger (Brill, 1992) on v1.14. Results were evaluated with both BLEU (Papineni et al., 2001) and NIST metrics (NIST, 2002).

### 4.2 Results

set	BLEU		NIST	
	devtest	test07	devtest	test07
baseline	18.13	18.05	5.218	5.279
person	18.16	18.17	5.224	5.316
pos+person	18.14	18.16	5.259	5.316
person+case	18.08	18.24	5.258	5.340
<i>altpath</i> :POS	18.21	18.20	5.285	5.340

Table 1: Translating English to Greek: Using a single translation table may cause sparse data problems, which are addressed using an alternative path to a second translation table

We tested several various combinations of tags, while using a single translation component. Some combinations seem to be affected by sparse data problems and the best score is achieved by using both person and case tags. Our full method, using both factors, was more effective on the second test-set, but the best score in average was succeeded by using an alternative path to a POS-factored translation table (table 1). The NIST metric clearly shows a significant improvement, because it mostly measures difficult n-gram matches (e.g. due to the long-distance rules we have been dealing with).

<sup>1</sup>see <http://www.statmt.org/wmt07> referring to sets *dev2006* (tuning) and *devtest2006*, *test2007* (testing)

### 4.3 Error analysis

In  $n$ -gram based metrics, the scores for all words are equally weighted, so mistakes on crucial sentence constituents may be penalized the same as errors on redundant or meaningless words (Callison-Burch et al., 2006). We consider agreement on verbs and nouns an important factor for the adequacy of the result, since they adhere more to the semantics of the sentence. Since we targeted these problems, we conducted a manual error analysis focused on the success of the improved system regarding those specific phenomena.

system	verbs	errors	missing
baseline	311	19.0%	7.4%
single	295	4.7%	5.4%
alt.path	294	5.4%	2.7%

Table 2: Error analysis of 100 test sentences, focused on verb person conjugation, for using both person and case tags

system	NPs	errors	missing
baseline	469	9.0%	4.9%
single	465	6.2%	4.5%
alt. path	452	6.0%	4.0%

Table 3: Error analysis of 100 test sentences, focused on noun cases, for using both person and case tags

The analysis shows that using a system with only one phrase translation table caused a high percentage of missing or untranslated words. When a word appears with a tag with which it has not been trained, that would be considered an unseen event and remain untranslated. The use of the alternative path seems to be a good solution.

step	parsing	tagging	decoding
VPs	16.7%	25%	58.3%
NPs	39.2%	21.7%	39.1%
avg	31.4%	22.9%	45.7 %

Table 4: Analysis on which step of the translation process the agreement errors derive from, based on manual resolution on the errors of table 3

The impact of the preprocessing stage to the errors may be seen in table 4, where errors are tracked

back to the stage they derived from. Apart from the decoding errors, which may be attributed to sparse data or other statistical factors, a large part of the errors derive from the preprocessing step; either the syntax tree of the sentence was incorrectly or partially resolved, or our labelling process did not correctly match all possible sub-trees.

### 4.4 Investigating applicability to other inflected languages

The grammatical phenomena of noun cases and verb persons are quite common among many human languages. While the method was tested in Greek, there was an effort to investigate whether it is useful for other languages with similar characteristics. For this reason, the method was adapted for Czech, which needs agreement on both verb conjugation and 9 noun cases. Dative case was included for the indirect object and the rules of the prepositional phrases were adapted to tag all three cases that can be verb phrase constituents. The Czech noun cases which appear only in prepositional phrases were ignored, since they are covered by the phrase-based model.

set	BLUE		NIST	
	devtest	test	devtest	test
baseline	12.08	12.34	4.634	4.865
person+case <i>altpath</i> :POS	11.98	11.99	4.584	4.801
person <i>altpath</i> :word	12.23	12.11	4.647	4.846
case <i>altpath</i> :word	12.54	12.51	4.758	4.957

Table 5: Enriching source data can be useful when translating from English to Czech, since it is a morphologically rich language. Experiments shown improvement when using factors on noun-cases with an alternative path

In Czech, due to the small size of the corpus, it was possible to improve metric scores only by using an alternative path to a bare word-to-word translation table. Combining case and verb tags worsened the results, which suggests that, while applying the method to more languages, a different use of the attributes may be beneficial for each of them.

## 5 Conclusion

In this paper we have shown how SMT performance can be improved, when translating from English into morphologically richer languages, by adding linguistic information on the source. Although the source language misses morphology attributes required by the target language, the needed information is inherent in the syntactic structure of the source sentence. Therefore, we have shown that this information can be easily be included in a SMT model by preprocessing the source text.

Our method focuses on two linguistic phenomena which produce common errors on the output and are important constituents of the sentence. In particular, noun cases and verb persons are required by the target language, but not directly inferred by the source. For each of the sub-problems, our algorithm used heuristic syntax-based rules on the statistically generated syntax tree of each sentence, in order to address the missing information, which was consequently tagged in by means of word factors. This information was proven to improve the outcome of a factored SMT model, by reducing the grammatical agreement errors on the generated sentences.

An initial system using one translation table with additional source side factors caused sparse data problems, due to the increased number of unseen word-factor combinations. Therefore, the decoding process is given an *alternative path* towards a translation table with less or no factors.

The method was tested on translating from English into two morphologically rich languages. Note that this may be easily expanded for translating from English into many morphologically richer languages with similar attributes. Opposed to other factored translation model approaches that require target language factors, that are not easily obtainable for many languages, our approach only requires English syntax trees, which are acquired with widely available automatic parsers. The preprocessing scripts were adapted so that they provide the morphology attributes required by the target language and the best combination of factors and alternative paths was chosen.

# Learning Bilingual Lexicons from Monolingual Corpora

Aria Haghighi, Percy Liang, Taylor Berg-Kirkpatrick and Dan Klein

Computer Science Division, University of California at Berkeley

{aria42, pliang, tberg, klein}@cs.berkeley.edu

## Abstract

We present a method for learning bilingual translation lexicons from monolingual corpora. Word types in each language are characterized by purely monolingual features, such as context counts and orthographic substrings. Translations are induced using a generative model based on canonical correlation analysis, which explains the monolingual lexicons in terms of latent matchings. We show that high-precision lexicons can be learned in a variety of language pairs and from a range of corpus types.

## 1 Introduction

Current statistical machine translation systems use parallel corpora to induce translation correspondences, whether those correspondences be at the level of phrases (Koehn, 2004), treelets (Galley et al., 2006), or simply single words (Brown et al., 1994). Although parallel text is plentiful for some language pairs such as English-Chinese or English-Arabic, it is scarce or even non-existent for most others, such as English-Hindi or French-Japanese. Moreover, parallel text could be scarce for a language pair even if monolingual data is readily available for both languages.

In this paper, we consider the problem of learning translations from monolingual sources alone. This task, though clearly more difficult than the standard parallel text approach, can operate on language pairs and in domains where standard approaches cannot. We take as input two monolingual corpora and perhaps some seed translations, and we produce as output a *bilingual lexicon*, defined as a list of word

pairs deemed to be word-level translations. Precision and recall are then measured over these bilingual lexicons. This setting has been considered before, most notably in Koehn and Knight (2002) and Fung (1995), but the current paper is the first to use a probabilistic model and present results across a variety of language pairs and data conditions.

In our method, we represent each language as a *monolingual lexicon* (see figure 2): a list of word types characterized by monolingual feature vectors, such as context counts, orthographic substrings, and so on (section 5). We define a generative model over (1) a source lexicon, (2) a target lexicon, and (3) a matching between them (section 2). Our model is based on *canonical correlation analysis* (CCA)<sup>1</sup> and explains matched word pairs via vectors in a common latent space. Inference in the model is done using an EM-style algorithm (section 3).

Somewhat surprisingly, we show that it is possible to learn or extend a translation lexicon using monolingual corpora alone, in a variety of languages and using a variety of corpora, even in the absence of orthographic features. As might be expected, the task is harder when no seed lexicon is provided, when the languages are strongly divergent, or when the monolingual corpora are from different domains. Nonetheless, even in the more difficult cases, a sizable set of high-precision translations can be extracted. As an example of the performance of the system, in English-Spanish induction with our best feature set, using corpora derived from topically similar but non-parallel sources, the system obtains 89.0% precision at 33% recall.

<sup>1</sup>See Hardoon et al. (2003) for an overview.

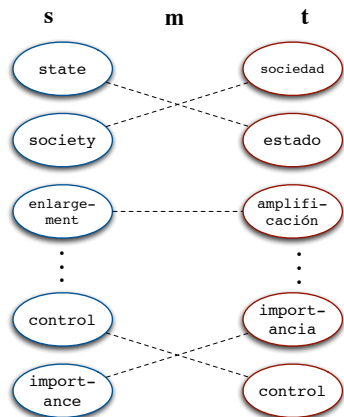

Figure 1: Bilingual lexicon induction: source word types  $s$  are listed on the left and target word types  $t$  on the right. Dashed lines between nodes indicate translation pairs which are in the matching  $\mathbf{m}$ .

## 2 Bilingual Lexicon Induction

As input, we are given a monolingual corpus  $S$  (a sequence of word tokens) in a *source* language and a monolingual corpus  $T$  in a *target* language. Let  $\mathbf{s} = (s_1, \dots, s_{n_S})$  denote  $n_S$  word types appearing in the source language, and  $\mathbf{t} = (t_1, \dots, t_{n_T})$  denote word types in the target language. Based on  $S$  and  $T$ , our goal is to output a matching  $\mathbf{m}$  between  $\mathbf{s}$  and  $\mathbf{t}$ . We represent  $\mathbf{m}$  as a set of integer pairs so that  $(i, j) \in \mathbf{m}$  if and only if  $s_i$  is matched with  $t_j$ .

### 2.1 Generative Model

We propose the following generative model over matchings  $\mathbf{m}$  and word types  $(\mathbf{s}, \mathbf{t})$ , which we call *matching canonical correlation analysis (MCCA)*.

MCCA model	
$\mathbf{m} \sim \text{MATCHING-PRIOR}$	[matching $\mathbf{m}$ ]
For each matched edge $(i, j) \in \mathbf{m}$ :	
$z_{i,j} \sim \mathcal{N}(0, I_d)$	[latent concept]
$f_S(s_i) \sim \mathcal{N}(W_S z_{i,j}, \Psi_S)$	[source features]
$f_T(t_j) \sim \mathcal{N}(W_T z_{i,j}, \Psi_T)$	[target features]
For each unmatched source word type $i$ :	
$f_S(s_i) \sim \mathcal{N}(0, \sigma^2 I_{d_S})$	[source features]
For each unmatched target word type $j$ :	
$f_T(t_j) \sim \mathcal{N}(0, \sigma^2 I_{d_T})$	[target features]

First, we generate a matching  $\mathbf{m} \in \mathcal{M}$ , where  $\mathcal{M}$  is the set of matchings in which each word type is

matched to at most one other word type.<sup>2</sup> We take MATCHING-PRIOR to be uniform over  $\mathcal{M}$ .<sup>3</sup>

Then, for each matched pair of word types  $(i, j) \in \mathbf{m}$ , we need to generate the observed feature vectors of the source and target word types,  $f_S(s_i) \in \mathbb{R}^{d_S}$  and  $f_T(t_j) \in \mathbb{R}^{d_T}$ . The feature vector of each word type is computed from the appropriate monolingual corpus and summarizes the word’s monolingual characteristics; see section 5 for details and figure 2 for an illustration. Since  $s_i$  and  $t_j$  are translations of each other, we expect  $f_S(s_i)$  and  $f_T(t_j)$  to be connected somehow by the generative process. In our model, they are related through a vector  $z_{i,j} \in \mathbb{R}^d$  representing the shared, language-independent concept.

Specifically, to generate the feature vectors, we first generate a random concept  $z_{i,j} \sim \mathcal{N}(0, I_d)$ , where  $I_d$  is the  $d \times d$  identity matrix. The source feature vector  $f_S(s_i)$  is drawn from a multivariate Gaussian with mean  $W_S z_{i,j}$  and covariance  $\Psi_S$ , where  $W_S$  is a  $d_S \times d$  matrix which transforms the language-independent concept  $z_{i,j}$  into a language-dependent vector in the source space. The arbitrary covariance parameter  $\Psi_S \succeq 0$  explains the source-specific variations which are not captured by  $W_S$ ; it does not play an explicit role in inference. The target  $f_T(t_j)$  is generated analogously using  $W_T$  and  $\Psi_T$ , conditionally independent of the source given  $z_{i,j}$  (see figure 2). For each of the remaining unmatched source word types  $s_i$  which have not yet been generated, we draw the word type features from a baseline normal distribution with variance  $\sigma^2 I_{d_S}$ , with hyperparameter  $\sigma^2 \gg 0$ ; unmatched target words are similarly generated.

If two word types are truly translations, it will be better to relate their feature vectors through the latent space than to explain them independently via the baseline distribution. However, if a source word type is not a translation of any of the target word types, we can just generate it independently without requiring it to participate in the matching.

<sup>2</sup>Our choice of  $\mathcal{M}$  permits unmatched word types, but does not allow words to have multiple translations. This setting facilitates comparison to previous work and admits simpler models.

<sup>3</sup>However, non-uniform priors could encode useful information, such as rank similarities.

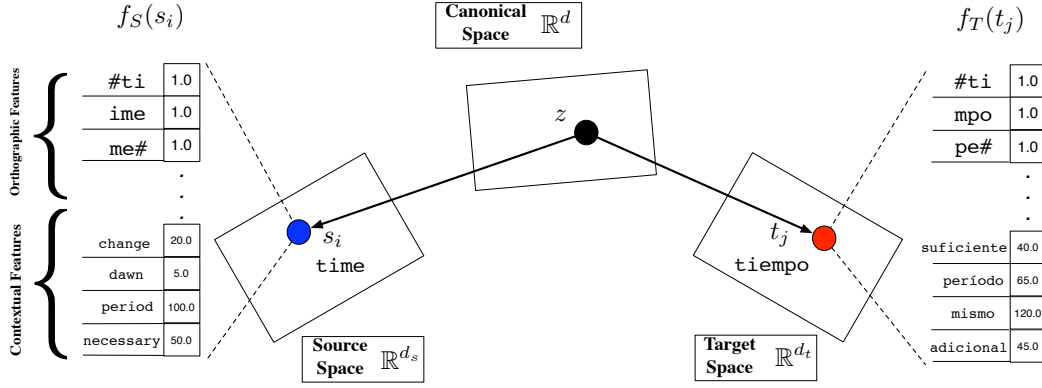

Figure 2: Illustration of our MCCA model. Each latent concept  $z_{i,j}$  originates in the canonical space. The observed word vectors in the source and target spaces are generated independently given this concept.

### 3 Inference

Given our probabilistic model, we would like to maximize the log-likelihood of the observed data  $(\mathbf{s}, \mathbf{t})$ :

$$\ell(\theta) = \log p(\mathbf{s}, \mathbf{t}; \theta) = \log \sum_{\mathbf{m}} p(\mathbf{m}, \mathbf{s}, \mathbf{t}; \theta)$$

with respect to the model parameters  $\theta = (W_S, W_T, \Psi_S, \Psi_T)$ .

We use the hard (Viterbi) EM algorithm as a starting point, but due to modeling and computational considerations, we make several important modifications, which we describe later. The general form of our algorithm is as follows:

Summary of learning algorithm

**E-step:** Find the maximum weighted (partial) bipartite matching  $\mathbf{m} \in \mathcal{M}$

**M-step:** Find the best parameters  $\theta$  by performing canonical correlation analysis (CCA)

**M-step** Given a matching  $\mathbf{m}$ , the M-step optimizes  $\log p(\mathbf{m}, \mathbf{s}, \mathbf{t}; \theta)$  with respect to  $\theta$ , which can be rewritten as

$$\max_{\theta} \sum_{(i,j) \in \mathbf{m}} \log p(s_i, t_j; \theta). \quad (1)$$

This objective corresponds exactly to maximizing the likelihood of the probabilistic CCA model presented in Bach and Jordan (2006), which proved that the maximum likelihood estimate can be computed by *canonical correlation analysis* (CCA). Intuitively, CCA finds  $d$ -dimensional subspaces  $U_S \in$

$\mathbb{R}^{d_S \times d}$  of the source and  $U_T \in \mathbb{R}^{d_T \times d}$  of the target such that the components of the projections  $U_S^\top f_S(s_i)$  and  $U_T^\top f_T(t_j)$  are maximally correlated.<sup>4</sup>

$U_S$  and  $U_T$  can be found by solving an eigenvalue problem (see Haroon et al. (2003) for details). Then the maximum likelihood estimates are as follows:  $W_S = C_{SS} U_S P^{1/2}$ ,  $W_T = C_{TT} U_T P^{1/2}$ ,  $\Psi_S = C_{SS} - W_S W_S^\top$ , and  $\Psi_T = C_{TT} - W_T W_T^\top$ , where  $P$  is a  $d \times d$  diagonal matrix of the canonical correlations,  $C_{SS} = \frac{1}{|\mathbf{m}|} \sum_{(i,j) \in \mathbf{m}} f_S(s_i) f_S(s_i)^\top$  is the empirical covariance matrix in the source domain, and  $C_{TT}$  is defined analogously.

**E-step** To perform a conventional E-step, we would need to compute the posterior over all matchings, which is #P-complete (Valiant, 1979). On the other hand, hard EM only requires us to compute the best matching under the current model:<sup>5</sup>

$$\mathbf{m} = \operatorname{argmax}_{\mathbf{m}'} \log p(\mathbf{m}', \mathbf{s}, \mathbf{t}; \theta). \quad (2)$$

We cast this optimization as a maximum weighted bipartite matching problem as follows. Define the edge weight between source word type  $i$  and target word type  $j$  to be

$$w_{i,j} = \log p(s_i, t_j; \theta) - \log p(s_i; \theta) - \log p(t_j; \theta), \quad (3)$$

<sup>4</sup>Since  $d_S$  and  $d_T$  can be quite large in practice and often greater than  $|\mathbf{m}|$ , we use Cholesky decomposition to represent the feature vectors as  $|\mathbf{m}|$ -dimensional vectors with the same dot products, which is all that CCA depends on.

<sup>5</sup>If we wanted softer estimates, we could use the agreement-based learning framework of Liang et al. (2008) to combine two tractable models.

which can be loosely viewed as a pointwise mutual information quantity. We can check that the objective  $\log p(\mathbf{m}, \mathbf{s}, \mathbf{t}; \theta)$  is equal to the weight of a matching plus some constant  $C$ :

$$\log p(\mathbf{m}, \mathbf{s}, \mathbf{t}; \theta) = \sum_{(i,j) \in \mathbf{m}} w_{i,j} + C. \quad (4)$$

To find the optimal partial matching, edges with weight  $w_{i,j} < 0$  are set to zero in the graph and the optimal full matching is computed in  $O((n_S + n_T)^3)$  time using the Hungarian algorithm (Kuhn, 1955). If a zero edge is present in the solution, we remove the involved word types from the matching.<sup>6</sup>

**Bootstrapping** Recall that the E-step produces a partial matching of the word types. If too few word types are matched, learning will not progress quickly; if too many are matched, the model will be swamped with noise. We found that it was helpful to explicitly control the number of edges. Thus, we adopt a bootstrapping-style approach that only permits high confidence edges at first, and then slowly permits more over time. In particular, we compute the optimal full matching, but only retain the highest weighted edges. As we run EM, we gradually increase the number of edges to retain.

In our context, bootstrapping has a similar motivation to the annealing approach of Smith and Eisner (2006), which also tries to alter the space of hidden outputs in the E-step over time to facilitate learning in the M-step, though of course the use of bootstrapping in general is quite widespread (Yarowsky, 1995).

## 4 Experimental Setup

In section 5, we present developmental experiments in English-Spanish lexicon induction; experiments

<sup>6</sup>Empirically, we obtained much better efficiency and even increased accuracy by replacing these marginal likelihood weights with a simple proxy, the distances between the words’ mean latent concepts:

$$w_{i,j} = A - \|z_i^* - z_j^*\|_2, \quad (5)$$

where  $A$  is a thresholding constant,  $z_i^* = \mathbb{E}(z_{i,j} \mid f_S(s_i)) = P^{1/2} U_S^\top f_S(s_i)$ , and  $z_j^*$  is defined analogously. The increased accuracy may not be an accident: whether two words are translations is perhaps better characterized directly by how close their latent concepts are, whereas log-probability is more sensitive to perturbations in the source and target spaces.

are presented for other languages in section 6. In this section, we describe the data and experimental methodology used throughout this work.

### 4.1 Data

Each experiment requires a source and target monolingual corpus. We use the following corpora:

- EN-ES-W: 3,851 Wikipedia articles with both English and Spanish bodies (generally not direct translations).
- EN-ES-P: 1st 100k sentences of text from the parallel English and Spanish Europarl corpus (Koehn, 2005).
- EN-ES(FR)-D: English: 1st 50k sentences of Europarl; Spanish (French): 2nd 50k sentences of Europarl.<sup>7</sup>
- EN-CH-D: English: 1st 50k sentences of Xinhua parallel news corpora;<sup>8</sup> Chinese: 2nd 50k sentences.
- EN-AR-D: English: 1st 50k sentences of 1994 proceedings of UN parallel corpora;<sup>9</sup> Arabic: 2nd 50k sentences.
- EN-ES-G: English: 100k sentences of English Gigaword; Spanish: 100k sentences of Spanish Gigaword.<sup>10</sup>

Note that even when corpora are derived from parallel sources, no explicit use is ever made of document or sentence-level alignments. In particular, our method is robust to permutations of the sentences in the corpora.

### 4.2 Lexicon

Each experiment requires a lexicon for evaluation. Following Koehn and Knight (2002), we consider lexicons over only noun word types, although this is not a fundamental limitation of our model. We consider a word type to be a noun if its most common tag is a noun in our monolingual corpus.<sup>11</sup> For

<sup>7</sup>Note that although the corpora here are derived from a parallel corpus, there are no parallel sentences.

<sup>8</sup>LDC catalog # 2002E18.

<sup>9</sup>LDC catalog # 2004E13.

<sup>10</sup>These corpora contain no parallel sentences.

<sup>11</sup>We use the Tree Tagger (Schmid, 1994) for all POS tagging except for Arabic, where we use the tagger described in Diab et al. (2004).

Figure 3: Example precision/recall curve of our system on EN-ES-P and EN-ES-W settings. See section 6.1.

all languages pairs except English-Arabic, we extract evaluation lexicons from the *Wiktionary* online dictionary. As we discuss in section 7, our extracted lexicons have low coverage, particularly for proper nouns, and thus all performance measures are (sometimes substantially) pessimistic. For English-Arabic, we extract a lexicon from 100k parallel sentences of UN parallel corpora by running the HMM intersected alignment model (Liang et al., 2008), adding  $(s, t)$  to the lexicon if  $s$  was aligned to  $t$  at least three times and more than any other word.

Also, as in Koehn and Knight (2002), we make use of a *seed lexicon*, which consists of a small, and perhaps incorrect, set of initial translation pairs. We used two methods to derive a seed lexicon. The first is to use the evaluation lexicon  $\mathcal{L}_e$  and select the hundred most common noun word types in the source corpus which have translations in  $\mathcal{L}_e$ . The second method is to heuristically induce, where applicable, a seed lexicon using edit distance, as is done in Koehn and Knight (2002). Section 6.2 compares the performance of these two methods.

### 4.3 Evaluation

We evaluate a proposed lexicon  $\mathcal{L}_p$  against the evaluation lexicon  $\mathcal{L}_e$  using the  $F_1$  measure in the standard fashion; precision is given by the number of proposed translations contained in the evaluation lexicon, and recall is given by the fraction of possible translation pairs proposed.<sup>12</sup> Since our model

<sup>12</sup>We should note that precision is not penalized for  $(s, t)$  if  $s$  does not have a translation in  $\mathcal{L}_e$ , and recall is not penalized for failing to recover multiple translations of  $s$ .

Setting	$p_{0.1}$	$p_{0.25}$	$p_{0.33}$	$p_{0.50}$	Best- $F_1$
EDITDIST	58.6	62.6	61.1	—	47.4
ORTHO	76.0	81.3	80.1	52.3	55.0
CONTEXT	<b>91.1</b>	81.3	80.2	65.3	58.0
MCCA	87.2	<b>89.7</b>	<b>89.0</b>	<b>89.7</b>	<b>72.0</b>

Table 1: Performance of EDITDIST and our model with various features sets on EN-ES-W. See section 5.

naturally produces lexicons in which each entry is associated with a weight based on the model, we can give a full precision/recall curve (see figure 3). We summarize these curves with both the best  $F_1$  over all possible thresholds and various precisions  $p_x$  at recalls  $x$ . All reported numbers exclude evaluation on the seed lexicon entries, regardless of how those seeds are derived or whether they are correct.

In all experiments, unless noted otherwise, we used a seed of size 100 obtained from  $\mathcal{L}_e$  and considered lexicons between the top  $n = 2,000$  most frequent source and target noun word types which were not in the seed lexicon; each system proposed an already-ranked one-to-one translation lexicon amongst these  $n$  words. Where applicable, we compare against the EDITDIST baseline, which solves a maximum bipartite matching problem where edge weights are normalized edit distances. We will use MCCA (for *matching CCA*) to denote our model using the optimal feature set (see section 5.3).

## 5 Features

In this section, we explore feature representations of word types in our model. Recall that  $f_S(\cdot)$  and  $f_T(\cdot)$  map source and target word types to vectors in  $\mathbb{R}^{d_S}$  and  $\mathbb{R}^{d_T}$ , respectively (see section 2). The features used in each representation are defined identically and derived only from the appropriate monolingual corpora. For a concrete example of a word type to feature vector mapping, see figure 2.

### 5.1 Orthographic Features

For closely related languages, such as English and Spanish, translation pairs often share many *orthographic* features. One direct way to capture orthographic similarity between word pairs is edit distance. Running EDITDIST (see section 4.3) on EN-

ES-W yielded 61.1  $p_{0.33}$ , but precision quickly degrades for higher recall levels (see EDITDIST in table 1). Nevertheless, when available, orthographic clues are strong indicators of translation pairs.

We can represent orthographic features of a word type  $w$  by assigning a feature to each substring of length  $\leq 3$ . Note that MCCA can learn regular orthographic correspondences between source and target words, which is something edit distance cannot capture (see table 5). Indeed, running our MCCA model with only orthographic features on EN-ES-W, labeled ORTHO in table 1, yielded 80.1  $p_{0.33}$ , a 31% error-reduction over EDITDIST in  $p_{0.33}$ .

## 5.2 Context Features

While orthographic features are clearly effective for historically related language pairs, they are more limited for other language pairs, where we need to appeal to other clues. One non-orthographic clue that word types  $s$  and  $t$  form a translation pair is that there is a strong correlation between the source words used with  $s$  and the target words used with  $t$ . To capture this information, we define *context* features for each word type  $w$ , consisting of counts of nouns which occur within a window of size 4 around  $w$ . Consider the translation pair (time, tiempo) illustrated in figure 2. As we become more confident about other translation pairs which have active period and periodico context features, we learn that translation pairs tend to jointly generate these features, which leads us to believe that time and tiempo might be generated by a common underlying concept vector (see section 2).<sup>13</sup>

Using context features alone on EN-ES-W, our MCCA model (labeled CONTEXT in table 1) yielded a 80.2  $p_{0.33}$ . It is perhaps surprising that context features alone, without orthographic information, can yield a best- $F_1$  comparable to EDITDIST.

## 5.3 Combining Features

We can of course combine context and orthographic features. Doing so yielded 89.03  $p_{0.33}$  (labeled MCCA in table 1); this represents a 46.4% error reduction in  $p_{0.33}$  over the EDITDIST baseline. For the remainder of this work, we will use MCCA to refer

<sup>13</sup>It is important to emphasize, however, that our current model does not directly relate a word type’s role as a participant in the matching to that word’s role as a context feature.

(a) Corpus Variation

Setting	$p_{0.1}$	$p_{0.25}$	$p_{0.33}$	$p_{0.50}$	Best- $F_1$
EN-ES-G	75.0	71.2	68.3	—	49.0
EN-ES-W	87.2	89.7	89.0	89.7	72.0
EN-ES-D	91.4	94.3	92.3	89.7	63.7
EN-ES-P	97.3	94.8	93.8	92.9	77.0

(b) Seed Lexicon Variation

Corpus	$p_{0.1}$	$p_{0.25}$	$p_{0.33}$	$p_{0.50}$	Best- $F_1$
EDITDIST	58.6	62.6	61.1	—	47.4
MCCA	91.4	94.3	92.3	89.7	63.7
MCCA-AUTO	91.2	90.5	91.8	77.5	61.7

(c) Language Variation

Languages	$p_{0.1}$	$p_{0.25}$	$p_{0.33}$	$p_{0.50}$	Best- $F_1$
EN-ES	91.4	94.3	92.3	89.7	63.7
EN-FR	94.5	89.1	88.3	78.6	61.9
EN-CH	60.1	39.3	26.8	—	30.8
EN-AR	70.0	50.0	31.1	—	33.1

to our model using both orthographic and context features.

## 6 Experiments

In this section we examine how system performance varies when crucial elements are altered.

### 6.1 Corpus Variation

There are many sources from which we can derive monolingual corpora, and MCCA performance depends on the degree of similarity between corpora. We explored the following levels of relationships between corpora, roughly in order of closest to most distant:

- **Same Sentences:** EN-ES-P
- **Non-Parallel Similar Content:** EN-ES-W
- **Distinct Sentences, Same Domain:** EN-ES-D
- **Unrelated Corpora:** EN-ES-G

Our results for all conditions are presented in table 2(a). The predominant trend is that system performance degraded when the corpora diverged in

content, presumably due to context features becoming less informative. However, it is notable that even in the most extreme case of disjoint corpora from different time periods and topics (e.g. EN-ES-G), we are still able to recover lexicons of reasonable accuracy.

## 6.2 Seed Lexicon Variation

All of our experiments so far have exploited a small seed lexicon which has been derived from the evaluation lexicon (see section 4.3). In order to explore system robustness to heuristically chosen seed lexicons, we automatically extracted a seed lexicon similarly to Koehn and Knight (2002): we ran EDIT-DIST on EN-ES-D and took the top 100 most confident translation pairs. Using this automatically derived seed lexicon, we ran our system on EN-ES-D as before, evaluating on the top 2,000 noun word types not included in the automatic lexicon.<sup>14</sup> Using the automated seed lexicon, and still evaluating against our Wiktionary lexicon, MCCA-AUTO yielded 91.8  $p_{0.33}$  (see table 2(b)), indicating that our system can produce lexicons of comparable accuracy with a heuristically chosen seed. We should note that this performance represents no knowledge given to the system in the form of gold seed lexicon entries.

## 6.3 Language Variation

We also explored how system performance varies for language pairs other than English-Spanish. On English-French, for the disjoint EN-FR-D corpus (described in section 4.1), MCCA yielded 88.3  $p_{0.33}$  (see table 2(c) for more performance measures). This verified that our model can work for another closely related language-pair on which no model development was performed.

One concern is how our system performs on language pairs where orthographic features are less applicable. Results on disjoint English-Chinese and English-Arabic are given as EN-CH-D and EN-AR in table 2(c), both using only context features. In these cases, MCCA yielded much lower precisions of 26.8 and 31.0  $p_{0.33}$ , respectively. For both languages, performance degraded compared to EN-ES-

<sup>14</sup>Note that the 2,000 words evaluated here were not identical to the words tested on when the seed lexicon is derived from the evaluation lexicon.

(a) English-Spanish			
Rank	Source	Target	Correct
1.	education	educación	Y
2.	pacto	pact	Y
3.	stability	estabilidad	Y
6.	corruption	corrupción	Y
7.	tourism	turismo	Y
9.	organisation	organización	Y

Table 3: Sample output from our (a) Spanish, (b) French, and (c) Chinese systems. We present the highest confidence system predictions, where the only editing done is to ignore predictions which consist of identical source and target words.

D and EN-FR-D, presumably due in part to the lack of orthographic features. However, MCCA still achieved surprising precision at lower recall levels. For instance, at  $p_{0.1}$ , MCCA yielded 60.1 and 70.0 on Chinese and Arabic, respectively. Figure 3 shows the highest-confidence outputs in several languages.

## 6.4 Comparison To Previous Work

There has been previous work in extracting translation pairs from non-parallel corpora (Rapp, 1995; Fung, 1995; Koehn and Knight, 2002), but generally not in as extreme a setting as the one considered here. Due to unavailability of data and specificity in experimental conditions and evaluations, it is not possible to perform exact comparisons. How-

(a) Example Non-Cognate Pairs

health	salud
traceability	rastreabilidad
youth	juventud
report	informe
advantages	ventajas

(b) Interesting Incorrect Pairs

liberal	partido
Kirkhope	Gorsel
action	reacción
Albanians	Bosnia
a.m.	horas
Netherlands	Bretaña

(a) Orthographic Feature

Source Feat.	Closest Target Feats.	Example Translation
#st	#es, est	(statue, estatua)
ty#	ad#, d#	(felicity, felicidad)
ogy	gía, gí	(geology, geología)

(b) Context Feature

Source Feat.	Closest Context Features
party	partido, izquierda
democrat	socialistas, demócratas
beijing	pekín, kioto

Table 5: Hand selected examples of source and target features which are close in canonical space: (a) orthographic feature correspondences, (b) context features.

ever, we attempted to run an experiment as similar as possible in setup to Koehn and Knight (2002), using English Gigaword and German Europarl. In this setting, our MCCA system yielded 61.7% accuracy on the 186 most confident predictions compared to 39% reported in Koehn and Knight (2002).

## 7 Analysis

We have presented a novel generative model for bilingual lexicon induction and presented results under a variety of data conditions (section 6.1) and languages (section 6.3) showing that our system can produce accurate lexicons even in highly adverse conditions. In this section, we broadly characterize and analyze the behavior of our system.

We manually examined the top 100 errors in the

English-Spanish lexicon produced by our system on EN-ES-W. Of the top 100 errors: 21 were correct translations not contained in the Wiktionary lexicon (e.g. *pintura* to painting), 4 were purely morphological errors (e.g. *airport* to *aeropuertos*), 30 were semantically related (e.g. *basketball* to *béisbol*), 15 were words with strong orthographic similarities (e.g. *coast* to *costas*), and 30 were difficult to categorize and fell into none of these categories. Since many of our ‘errors’ actually represent valid translation pairs not contained in our extracted dictionary, we supplemented our evaluation lexicon with one automatically derived from 100k sentences of parallel Europarl data. We ran the intersected HMM word-alignment model (Liang et al., 2008) and added  $(s, t)$  to the lexicon if  $s$  was aligned to  $t$  at least three times and more than any other word. Evaluating against the union of these lexicons yielded 98.0  $p_{0.33}$ , a significant improvement over the 92.3 using only the Wiktionary lexicon. Of the true errors, the most common arose from semantically related words which had strong context feature correlations (see table 4(b)).

We also explored the relationships our model learns between features of different languages. We projected each source and target feature into the shared canonical space, and for each projected source feature we examined the closest projected target features. In table 5(a), we present some of the orthographic feature relationships learned by our system. Many of these relationships correspond to phonological and morphological regularities such as the English suffix *ing* mapping to the Spanish suffix *gía*. In table 5(b), we present context feature correspondences. Here, the broad trend is for words which are either translations or semantically related across languages to be close in canonical space.

## 8 Conclusion

We have presented a generative model for bilingual lexicon induction based on probabilistic CCA. Our experiments show that high-precision translations can be mined without any access to parallel corpora. It remains to be seen how such lexicons can be best utilized, but they invite new approaches to the statistical translation of resource-poor languages.

## Abstract

Paraphrase patterns are useful in paraphrase recognition and generation. In this paper, we present a pivot approach for extracting paraphrase patterns from bilingual parallel corpora, whereby the English paraphrase patterns are extracted using the sentences in a foreign language as pivots. We propose a log-linear model to compute the paraphrase likelihood of two patterns and exploit feature functions based on maximum likelihood estimation (MLE) and lexical weighting (LW). Using the presented method, we extract over 1,000,000 pairs of paraphrase patterns from 2M bilingual sentence pairs, the precision of which exceeds 67%. The evaluation results show that: (1) The pivot approach is effective in extracting paraphrase patterns, which significantly outperforms the conventional method DIRT. Especially, the log-linear model with the proposed feature functions achieves high performance. (2) The coverage of the extracted paraphrase patterns is high, which is above 84%. (3) The extracted paraphrase patterns can be classified into 5 types, which are useful in various applications.

## 1 Introduction

Paraphrases are different expressions that convey the same meaning. Paraphrases are important in plenty of natural language processing (NLP) applications, such as question answering (QA) (Lin and Pantel, 2001; Ravichandran and Hovy, 2002), machine translation (MT) (Kauchak and Barzilay, 2006; Callison-Burch et al., 2006), multi-document

summarization (McKeown et al., 2002), and natural language generation (Iordanskaja et al., 1991).

Paraphrase patterns are sets of semantically equivalent patterns, in which a pattern generally contains two parts, i.e., the pattern words and slots. For example, in the pattern “ $X$  solves  $Y$ ”, “solves” is the pattern word, while “ $X$ ” and “ $Y$ ” are slots. One can generate a text unit (phrase or sentence) by filling the pattern slots with specific words. Paraphrase patterns are useful in both paraphrase recognition and generation. In paraphrase recognition, if two text units match a pair of paraphrase patterns and the corresponding slot-fillers are identical, they can be identified as paraphrases. In paraphrase generation, a text unit that matches a pattern  $P$  can be rewritten using the paraphrase patterns of  $P$ .

A variety of methods have been proposed on paraphrase patterns extraction (Lin and Pantel, 2001; Ravichandran and Hovy, 2002; Shinyama et al., 2002; Barzilay and Lee, 2003; Ibrahim et al., 2003; Pang et al., 2003; Szpektor et al., 2004). However, these methods have some shortcomings. Especially, the precisions of the paraphrase patterns extracted with these methods are relatively low.

In this paper, we extract paraphrase patterns from bilingual parallel corpora based on a pivot approach. We assume that if two English patterns are aligned with the same pattern in another language, they are likely to be paraphrase patterns. This assumption is an extension of the one presented in (Bannard and Callison-Burch, 2005), which was used for deriving phrasal paraphrases from bilingual corpora. Our method involves three steps: (1) corpus preprocessing, including English monolingual dependency

parsing and English-foreign language word alignment, (2) aligned patterns induction, which produces English patterns along with the aligned pivot patterns in the foreign language, (3) paraphrase patterns extraction, in which paraphrase patterns are extracted based on a log-linear model.

Our contributions are as follows. Firstly, we are the first to use a pivot approach to extract paraphrase patterns from bilingual corpora, though similar methods have been used for learning phrasal paraphrases. Our experiments show that the pivot approach significantly outperforms conventional methods. Secondly, we propose a log-linear model for computing the paraphrase likelihood. Besides, we use feature functions based on maximum likelihood estimation (MLE) and lexical weighting (LW), which are effective in extracting paraphrase patterns.

Using the proposed approach, we extract over 1,000,000 pairs of paraphrase patterns from 2M bilingual sentence pairs, the precision of which is above 67%. Experimental results show that the pivot approach evidently outperforms DIRT, a well known method that extracts paraphrase patterns from monolingual corpora (Lin and Pantel, 2001). Besides, the log-linear model is more effective than the conventional model presented in (Bannard and Callison-Burch, 2005). In addition, the coverage of the extracted paraphrase patterns is high, which is above 84%. Further analysis shows that 5 types of paraphrase patterns can be extracted with our method, which can be used in multiple NLP applications.

The rest of this paper is structured as follows. Section 2 reviews related work on paraphrase patterns extraction. Section 3 presents our method in detail. We evaluate the proposed method in Section 4, and finally conclude this paper in Section 5.

## 2 Related Work

Paraphrase patterns have been learned and used in information extraction (IE) and answer extraction of QA. For example, Lin and Pantel (2001) proposed a method (DIRT), in which they obtained paraphrase patterns from a parsed monolingual corpus based on an extended distributional hypothesis, where if two paths in dependency trees tend to occur in similar contexts it is hypothesized that the meanings of the paths are similar. The examples of obtained para-

(1)	<i>X solves Y</i> <i>Y is solved by X</i> <i>X finds a solution to Y</i> .....
(2)	<i>born in &lt;ANSWER&gt; , &lt;NAME&gt;</i> <i>&lt;NAME&gt; was born on &lt;ANSWER&gt; ,</i> <i>&lt;NAME&gt; ( &lt;ANSWER&gt; -</i> .....
(3)	<i>ORGANIZATION decides <math>\phi</math></i> <i>ORGANIZATION confirms <math>\phi</math></i> .....

Table 1: Examples of paraphrase patterns extracted with the methods of Lin and Pantel (2001), Ravichandran and Hovy (2002), and Shinyama et al. (2002).

phrase patterns are shown in Table 1 (1).

Based on the same hypothesis as above, some methods extracted paraphrase patterns from the web. For instance, Ravichandran and Hovy (2002) defined a question taxonomy for their QA system. They then used hand-crafted examples of each question type as queries to retrieve paraphrase patterns from the web. For instance, for the question type “*BIRTHDAY*”, The paraphrase patterns produced by their method can be seen in Table 1 (2).

Similar methods have also been used by Ibrahim et al. (2003) and Szpektor et al. (2004). The main disadvantage of the above methods is that the precisions of the learned paraphrase patterns are relatively low. For instance, the precisions of the paraphrase patterns reported in (Lin and Pantel, 2001), (Ibrahim et al., 2003), and (Szpektor et al., 2004) are lower than 50%. Ravichandran and Hovy (2002) did not directly evaluate the precision of the paraphrase patterns extracted using their method. However, the performance of their method is dependent on the hand-crafted queries for web mining.

Shinyama et al. (2002) presented a method that extracted paraphrase patterns from multiple news articles about the same event. Their method was based on the assumption that NEs are preserved across paraphrases. Thus the method acquired paraphrase patterns from sentence pairs that share comparable NEs. Some examples can be seen in Table 1 (3).

The disadvantage of this method is that it greatly relies on the number of NEs in sentences. The preci-

Figure 1: Examples of paraphrase patterns extracted by Barzilay and Lee (2003) and Pang et al. (2003).

sion of the extracted patterns may sharply decrease if the sentences do not contain enough NEs.

Barzilay and Lee (2003) applied multi-sequence alignment (MSA) to parallel news sentences and induced paraphrase patterns for generating new sentences (Figure 1 (1)). Pang et al. (2003) built finite state automata (FSA) from semantically equivalent translation sets based on syntactic alignment. The learned FSAs could be used in paraphrase representation and generation (Figure 1 (2)). Obviously, it is difficult for a sentence to match such complicated patterns, especially if the sentence is not from the same domain in which the patterns are extracted.

Bannard and Callison-Burch (2005) first exploited bilingual corpora for phrasal paraphrase extraction. They assumed that if two English phrases  $e_1$  and  $e_2$  are aligned with the same phrase  $c$  in another language, these two phrases may be paraphrases. Specifically, they computed the paraphrase probability in terms of the translation probabilities:

$$p(e_2|e_1) = \sum_c p_{MLE}(c|e_1)p_{MLE}(e_2|c) \quad (1)$$

In Equation (1),  $p_{MLE}(c|e_1)$  and  $p_{MLE}(e_2|c)$  are the probabilities of translating  $e_1$  to  $c$  and  $c$  to  $e_2$ , which are computed based on MLE:

$$p_{MLE}(c|e_1) = \frac{count(c, e_1)}{\sum_{c'} count(c', e_1)} \quad (2)$$

where  $count(c, e_1)$  is the frequency count that phrases  $c$  and  $e_1$  are aligned in the corpus.  $p_{MLE}(e_2|c)$  is computed in the same way.

This method proved effective in extracting high quality phrasal paraphrases. As a result, we extend it to paraphrase pattern extraction in this paper.

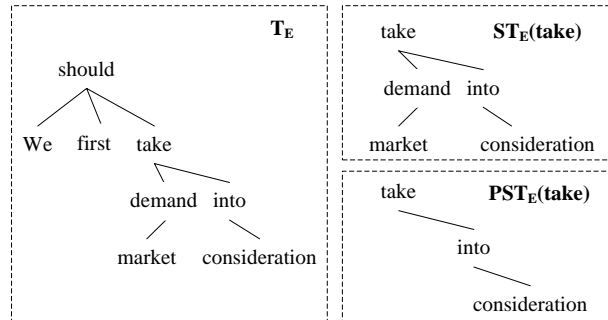

Figure 2: Examples of a subtree and a partial subtree.

### 3 Proposed Method

#### 3.1 Corpus Preprocessing

In this paper, we use English paraphrase patterns extraction as a case study. An English-Chinese (E-C) bilingual parallel corpus is employed for training. The Chinese part of the corpus is used as pivots to extract English paraphrase patterns. We conduct word alignment with Giza++ (Och and Ney, 2000) in both directions and then apply the grow-diag heuristic (Koehn et al., 2005) for symmetrization.

Since the paraphrase patterns are extracted from dependency trees, we parse the English sentences in the corpus with MaltParser (Nivre et al., 2007). Let  $S_E$  be an English sentence,  $T_E$  the parse tree of  $S_E$ ,  $e$  a word of  $S_E$ , we define the subtree and partial subtree following the definitions in (Ouangraoua et al., 2007). In detail, a subtree  $ST_E(e)$  is a particular connected subgraph of the tree  $T_E$ , which is rooted at  $e$  and includes all the descendants of  $e$ . A partial subtree  $PST_E(e)$  is a connected subgraph of the subtree  $ST_E(e)$ , which is rooted at  $e$  but does not necessarily include all the descendants of  $e$ . For instance, for the sentence “*We should first take market demand into consideration*”,  $ST_E(take)$  and  $PST_E(take)$  are shown in Figure 2<sup>1</sup>.

#### 3.2 Aligned Patterns Induction

To induce the aligned patterns, we first induce the English patterns using the subtrees and partial subtrees. Then, we extract the pivot Chinese patterns aligning to the English patterns.

<sup>1</sup>Note that, a subtree may contain several partial subtrees. In this paper, all the possible partial subtrees are considered when extracting paraphrase patterns.

**Algorithm 1: Inducing an English pattern**

```

1: Input: words in  $ST_E(e) : w_i w_{i+1} \dots w_j$ 
2: Input:  $P_E(e) = \phi$ 
3: For each  $w_k (i \leq k \leq j)$ 
4:   If  $w_k$  is in  $PST_E(e)$ 
5:     Append  $w_k$  to the end of  $P_E(e)$ 
6:   Else
7:     Append  $POS(w_k)$  to the end of  $P_E(e)$ 
8: End For

```

**Algorithm 2: Inducing an aligned pivot pattern**

```

1: Input:  $S_C = t_1 t_2 \dots t_n$ 
2: Input:  $P_C = \phi$ 
3: For each  $t_l (1 \leq l \leq n)$ 
4:   If  $t_l$  is aligned with  $w_k$  in  $S_E$ 
5:     If  $w_k$  is a word in  $P_E(e)$ 
6:       Append  $t_l$  to the end of  $P_C$ 
7:     If  $POS(w_k)$  is a slot in  $P_E(e)$ 
8:       Append  $POS(w_k)$  to the end of  $P_C$ 
9: End For

```

**Step-1 Inducing English patterns.** In this paper, an English pattern  $P_E(e)$  is a string comprising words and part-of-speech (POS) tags. Our intuition for inducing an English pattern is that a partial subtree  $PST_E(e)$  can be viewed as a unit that conveys a definite meaning, though the words in  $PST_E(e)$  may not be continuous. For example,  $PST_E(take)$  in Figure 2 contains words “take ... into consideration”. Therefore, we may extract “take X into consideration” as a pattern. In addition, the words that are in  $ST_E(e)$  but not in  $PST_E(e)$  (denoted as  $ST_E(e)/PST_E(e)$ ) are also useful for inducing patterns, since they can constrain the pattern slots. In the example in Figure 2, the word “demand” indicates that a noun can be filled in the slot X and the pattern may have the form “take NN into consideration”. Based on this intuition, we induce an English pattern  $P_E(e)$  as in Algorithm 1<sup>2</sup>.

For the example in Figure 2, the generated pattern  $P_E(take)$  is “take NN NN into consideration”. Note that the patterns induced in this way are quite specific, since the POS of each word in  $ST_E(e)/PST_E(e)$  forms a slot. Such patterns are difficult to be matched in applications. We there-

<sup>2</sup> $POS(w_k)$  in Algorithm 1 denotes the POS tag of  $w_k$ .

Figure 3: Aligned patterns with numbered slots.

fore take an additional step to simplify the patterns. Let  $e_i$  and  $e_j$  be two words in  $ST_E(e)/PST_E(e)$ , whose POS  $pos_i$  and  $pos_j$  are slots in  $P_E(e)$ . If  $e_i$  is a descendant of  $e_j$  in the parse tree, we remove  $pos_i$  from  $P_E(e)$ . For the example above, the POS of “market” is removed, since it is the descendant of “demand”, whose POS also forms a slot. The simplified pattern is “take NN into consideration”.

**Step-2 Extracting pivot patterns.** For each English pattern  $P_E(e)$ , we extract an aligned Chinese pivot pattern  $P_C$ . Let a Chinese sentence  $S_C$  be the translation of the English sentence  $S_E$ ,  $P_E(e)$  a pattern induced from  $S_E$ , we extract the pivot pattern  $P_C$  aligning to  $P_E(e)$  as in Algorithm 2. Note that the Chinese patterns are not extracted from parse trees. They are only sequences of Chinese words and POSes that are aligned with English patterns.

A pattern may contain two or more slots sharing the same POS. To distinguish them, we assign a number to each slot in the aligned E-C patterns. In detail, the slots having identical POS in  $P_C$  are numbered incrementally (i.e., 1,2,3...), while each slot in  $P_E(e)$  is assigned the same number as its aligned slot in  $P_C$ . The examples of the aligned patterns with numbered slots are illustrated in Figure 3.

### 3.3 Paraphrase Patterns Extraction

As mentioned above, if patterns  $e_1$  and  $e_2$  are aligned with the same pivot pattern  $c$ ,  $e_1$  and  $e_2$  may be paraphrase patterns. The paraphrase likelihood can be computed using Equation (1). However, we find that using only the MLE based probabilities can suffer from data sparseness. In order to exploit more and richer information to estimate the paraphrase likelihood, we propose a log-linear model:

$$score(e_2|e_1) = \sum_c \exp\left[\sum_{i=1}^N \lambda_i h_i(e_1, e_2, c)\right] \quad (3)$$

where  $h_i(e_1, e_2, c)$  is a feature function and  $\lambda_i$  is the

weight. In this paper, 4 feature functions are used in our log-linear model, which include:

$$\begin{aligned} h_1(e_1, e_2, c) &= score_{MLE}(c|e_1) \\ h_2(e_1, e_2, c) &= score_{MLE}(e_2|c) \\ h_3(e_1, e_2, c) &= score_{LW}(c|e_1) \\ h_4(e_1, e_2, c) &= score_{LW}(e_2|c) \end{aligned}$$

Feature functions  $h_1(e_1, e_2, c)$  and  $h_2(e_1, e_2, c)$  are based on MLE.  $score_{MLE}(c|e)$  is computed as:

$$score_{MLE}(c|e) = \log p_{MLE}(c|e) \quad (4)$$

$score_{MLE}(e|c)$  is computed in the same way.

$h_3(e_1, e_2, c)$  and  $h_4(e_1, e_2, c)$  are based on LW. LW was originally used to validate the quality of a phrase translation pair in MT (Koehn et al., 2003). It checks how well the words of the phrases translate to each other. This paper uses LW to measure the quality of aligned patterns. We define  $score_{LW}(c|e)$  as the logarithm of the lexical weight<sup>3</sup>:

$$score_{LW}(c|e) = \frac{1}{n} \sum_{i=1}^n \log \left( \frac{1}{|\{j|(i, j) \in a\}|} \sum_{\forall (i, j) \in a} w(c_i|e_j) \right) \quad (5)$$

where  $a$  denotes the word alignment between  $c$  and  $e$ .  $n$  is the number of words in  $c$ .  $c_i$  and  $e_j$  are words of  $c$  and  $e$ .  $w(c_i|e_j)$  is computed as follows:

$$w(c_i|e_j) = \frac{count(c_i, e_j)}{\sum_{c'_i} count(c'_i, e_j)} \quad (6)$$

where  $count(c_i, e_j)$  is the frequency count of the aligned word pair  $(c_i, e_j)$  in the corpus.  $score_{LW}(e|c)$  is computed in the same manner.

In our experiments, we set a threshold  $T$ . If the score between  $e_1$  and  $e_2$  based on Equation (3) exceeds  $T$ ,  $e_2$  is extracted as the paraphrase of  $e_1$ .

### 3.4 Parameter Estimation

Five parameters need to be estimated, i.e.,  $\lambda_1$ ,  $\lambda_2$ ,  $\lambda_3$ ,  $\lambda_4$  in Equation (3), and the threshold  $T$ . To estimate the parameters, we first construct a development set. In detail, we randomly sample 7,086

<sup>3</sup>The logarithm of the lexical weight is divided by  $n$  so as not to penalize long patterns.

groups of aligned E-C patterns that are obtained as described in Section 3.2. The English patterns in each group are all aligned with the same Chinese pivot pattern. We then extract paraphrase patterns from the aligned patterns as described in Section 3.3. In this process, we set  $\lambda_i = 1$  ( $i = 1, \dots, 4$ ) and assign  $T$  a minimum value, so as to obtain all possible paraphrase patterns.

A total of 4,162 pairs of paraphrase patterns have been extracted and manually labeled as “1” (correct paraphrase patterns) or “0” (incorrect). Here, two patterns are regarded as paraphrase patterns if they can generate paraphrase fragments by filling the corresponding slots with identical words. We use gradient descent algorithm (Press et al., 1992) to estimate the parameters. For each set of parameters, we compute the precision  $P$ , recall  $R$ , and f-measure  $F$  as:  $P = \frac{|set1 \cap set2|}{|set1|}$ ,  $R = \frac{|set1 \cap set2|}{|set2|}$ ,  $F = \frac{2PR}{P+R}$ , where  $set1$  denotes the set of paraphrase patterns extracted under the current parameters.  $set2$  denotes the set of manually labeled correct paraphrase patterns. We select the parameters that can maximize the F-measure on the development set<sup>4</sup>.

## 4 Experiments

The E-C parallel corpus in our experiments was constructed using several LDC bilingual corpora<sup>5</sup>. After filtering sentences that are too long ( $> 40$  words) or too short ( $< 5$  words), 2,048,009 pairs of parallel sentences were retained.

We used two constraints in the experiments to improve the efficiency of computation. First, only subtrees containing no more than 10 words were used to induce English patterns. Second, although any POS tag can form a slot in the induced patterns, we only focused on three kinds of POSes in the experiments, i.e., nouns (tags include NN, NNS, NNP, NNPS), verbs (VB, VBD, VBG, VBN, VBP, VBZ), and adjectives (JJ, JJS, JJR). In addition, we constrained that a pattern must contain at least one content word

<sup>4</sup>The parameters are:  $\lambda_1 = 0.0594137$ ,  $\lambda_2 = 0.995936$ ,  $\lambda_3 = -0.0048954$ ,  $\lambda_4 = 1.47816$ ,  $T = -10.002$ .

<sup>5</sup>The corpora include LDC2000T46, LDC2000T47, LDC2002E18, LDC2002T01, LDC2003E07, LDC2003E14, LDC2003T17, LDC2004E12, LDC2004T07, LDC2004T08, LDC2005E83, LDC2005T06, LDC2005T10, LDC2006E24, LDC2006E34, LDC2006E85, LDC2006E92, LDC2006T04, LDC2007T02, LDC2007T09.

Method	#PP (pairs)	Precision
LL-Model	1,058,624	67.03%
MLE-Model	1,015,533	60.60%
DIRT top-1	1,179	19.67%
DIRT top-5	5,528	18.73%

Table 2: Comparison of paraphrasing methods.

so as to filter patterns like “*the [NN\_I]*”.

#### 4.1 Evaluation of the Log-linear Model

As previously mentioned, in the log-linear model of this paper, we use both MLE based and LW based feature functions. In this section, we evaluate the log-linear model (LL-Model) and compare it with the MLE based model (MLE-Model) presented by Bannard and Callison-Burch (2005)<sup>6</sup>.

We extracted paraphrase patterns using two models, respectively. From the results of each model, we randomly picked 3,000 pairs of paraphrase patterns to evaluate the precision. The 6,000 pairs of paraphrase patterns were mixed and presented to the human judges, so that the judges cannot know by which model each pair was produced. The sampled patterns were then manually labeled and the precision was computed as described in Section 3.4.

The number of the extracted paraphrase patterns (#PP) and the precision are depicted in the first two lines of Table 2. We can see that the numbers of paraphrase patterns extracted using the two models are comparable. However, the precision of LL-Model is significantly higher than MLE-Model.

Actually, MLE-Model is a special case of LL-Model and the enhancement of the precision is mainly due to the use of LW based features. It is not surprising, since Bannard and Callison-Burch (2005) have pointed out that word alignment error is the major factor that influences the performance of the methods learning paraphrases from bilingual corpora. The LW based features validate the quality of word alignment and assign low scores to those aligned E-C pattern pairs with incorrect alignment. Hence the precision can be enhanced.

<sup>6</sup>In this experiment, we also estimated a threshold  $T'$  for MLE-Model using the development set ( $T' = -5.1$ ). The pattern pairs whose score based on Equation (1) exceed  $T'$  were extracted as paraphrase patterns.

#### 4.2 Comparison with DIRT

It is necessary to compare our method with another paraphrase patterns extraction method. However, it is difficult to find methods that are suitable for comparison. Some methods only extract paraphrase patterns using news articles on certain topics (Shinyama et al., 2002; Barzilay and Lee, 2003), while some others need seeds as initial input (Ravichandran and Hovy, 2002). In this paper, we compare our method with DIRT (Lin and Pantel, 2001), which does not need to specify topics or input seeds.

As mentioned in Section 2, DIRT learns paraphrase patterns from a parsed monolingual corpus based on an extended distributional hypothesis. In our experiment, we implemented DIRT and extracted paraphrase patterns from the English part of our bilingual parallel corpus. Our corpus is smaller than that reported in (Lin and Pantel, 2001). To alleviate the data sparseness problem, we only kept patterns appearing more than 10 times in the corpus for extracting paraphrase patterns. Different from our method, no threshold was set in DIRT. Instead, the extracted paraphrase patterns were ranked according to their scores. In our experiment, we kept top-5 paraphrase patterns for each target pattern.

From the extracted paraphrase patterns, we sampled 600 groups for evaluation. Each group comprises a target pattern and its top-5 paraphrase patterns. The sampled data were manually labeled and the top-n precision was calculated as  $\frac{\sum_{i=1}^N n_i}{N \times n}$ , where  $N$  is the number of groups and  $n_i$  is the number of correct paraphrase patterns in the top-n paraphrase patterns of the  $i$ -th group. The top-1 and top-5 results are shown in the last two lines of Table 2. Although there are more correct patterns in the top-5 results, the precision drops sequentially from top-1 to top-5 since the denominator of top-5 is 4 times larger than that of top-1.

Obviously, the number of the extracted paraphrase patterns is much smaller than that extracted using our method. Besides, the precision is also much lower. We believe that there are two reasons. First, the extended distributional hypothesis is not strict enough. Patterns sharing similar slot-fillers do not necessarily have the same meaning. They may even have the opposite meanings. For example, “*X worsens Y*” and “*X solves Y*” were extracted as para-

Type	Count	Example
trivial change	79	(e <sub>1</sub> ) <i>all the members of [NNPS_1]</i> (e <sub>2</sub> ) <i>all members of [NNPS_1]</i>
phrase replacement	267	(e <sub>1</sub> ) <i>[JJ_1] economic losses</i> (e <sub>2</sub> ) <i>[JJ_1] financial losses</i>
phrase reordering	56	(e <sub>1</sub> ) <i>[NN_1] definition</i> (e <sub>2</sub> ) <i>the definition of [NN_1]</i>
structural paraphrase	71	(e <sub>1</sub> ) <i>the admission of [NNP_1] to the wto</i> (e <sub>2</sub> ) <i>the [NNP_1] 's wto accession</i>
information + or -	27	(e <sub>1</sub> ) <i>[NNS_1] are in fact women</i> (e <sub>2</sub> ) <i>[NNS_1] are women</i>

Table 3: The statistics and examples of each type of paraphrase patterns.

phrase patterns by DIRT. The other reason is that DIRT can only be effective for patterns appearing plenty of times in the corpus. In other words, it seriously suffers from data sparseness. We believe that DIRT can perform better on a larger corpus.

### 4.3 Pivot Pattern Constraints

As described in Section 3.2, we constrain that the pattern words of an English pattern  $e$  must be extracted from a partial subtree. However, we do not have such constraint on the Chinese pivot patterns. Hence, it is interesting to investigate whether the performance can be improved if we constrain that the pattern words of a pivot pattern  $c$  must also be extracted from a partial subtree.

To conduct the evaluation, we parsed the Chinese sentences of the corpus with a Chinese dependency parser (Liu et al., 2006). We then induced English patterns and extracted aligned pivot patterns. For the aligned patterns ( $e, c$ ), if  $c$ 's pattern words were not extracted from a partial subtree, the pair was filtered. After that, we extracted paraphrase patterns, from which we sampled 3,000 pairs for evaluation.

The results show that 736,161 pairs of paraphrase patterns were extracted and the precision is 65.77%. Compared with Table 2, the number of the extracted paraphrase patterns gets smaller and the precision also gets lower. The results suggest that the performance of the method cannot be improved by constraining the extraction of pivot patterns.

### 4.4 Analysis of the Paraphrase Patterns

We sampled 500 pairs of correct paraphrase patterns extracted using our method and analyzed the types. We found that there are 5 types of paraphrase patterns, which include: (1) trivial change, such as changes of prepositions and articles, etc; (2) phrase replacement; (3) phrase reordering; (4) struc-

tural paraphrase, which contain both phrase replacements and phrase reordering; (5) adding or reducing information that does not change the meaning. Some statistics and examples are shown in Table 3.

The paraphrase patterns are useful in NLP applications. Firstly, over 50% of the paraphrase patterns are in the type of phrase replacement, which can be used in IE pattern reformulation and sentence-level paraphrase generation. Compared with phrasal paraphrases, the phrase replacements in patterns are more accurate due to the constraints of the slots.

The paraphrase patterns in the type of phrase reordering can also be used in IE pattern reformulation and sentence paraphrase generation. Especially, in sentence paraphrase generation, this type of paraphrase patterns can reorder the phrases in a sentence, which can hardly be achieved by the conventional MT-based generation method (Quirk et al., 2004).

The structural paraphrase patterns have the advantages of both phrase replacement and phrase reordering. More paraphrase sentences can be generated using these patterns.

The paraphrase patterns in the type of “information + and -” are useful in sentence compression and expansion. A sentence matching a long pattern can be compressed by paraphrasing it using shorter patterns. Similarly, a short sentence can be expanded by paraphrasing it using longer patterns.

For the 3,000 pairs of test paraphrase patterns, we also investigate the number and type of the pattern slots. The results are summarized in Table 4 and 5.

From Table 4, we can see that more than 92% of the paraphrase patterns contain only one slot, just like the examples shown in Table 3. In addition, about 7% of the paraphrase patterns contain two slots, such as “*give [NN\_1] [NN\_2]*” vs. “*give [NN\_2] to [NN\_1]*”. This result suggests that our method tends to extract short paraphrase patterns,

Slot No.	#PP	Percentage	Precision
1-slot	2,780	92.67%	66.51%
2-slots	218	7.27%	73.85%
≥3-slots	2	<1%	50.00%

Table 4: The statistics of the numbers of pattern slots.

Slot Type	#PP	Percentage	Precision
N-slots	2,376	79.20%	66.71%
V-slots	273	9.10%	70.33%
J-slots	438	14.60%	70.32%

Table 5: The statistics of the type of pattern slots.

which is mainly because the data sparseness problem is more serious when extracting long patterns.

From Table 5, we can find that near 80% of the paraphrase patterns contain noun slots, while about 9% and 15% contain verb slots and adjective slots<sup>7</sup>. This result implies that nouns are the most typical variables in paraphrase patterns.

#### 4.5 Evaluation within Context Sentences

In Section 4.1, we have evaluated the precision of the paraphrase patterns without considering context information. In this section, we evaluate the paraphrase patterns within specific context sentences.

The open test set includes 119 English sentences. We parsed the sentences with MaltParser and induced patterns as described in Section 3.2. For each pattern  $e$  in sentence  $S_E$ , we searched  $e$ 's paraphrase patterns from the database of the extracted paraphrase patterns. The result shows that 101 of the 119 sentences contain at least one pattern that can be paraphrased using the extracted paraphrase patterns, the coverage of which is 84.87%.

Furthermore, since a pattern may have several paraphrase patterns, we exploited a method to automatically select the best one in the given context sentence. In detail, a paraphrase pattern  $e'$  of  $e$  was reranked based on a language model (LM):

$$\begin{aligned} score(e'|e, S_E) = \\ \lambda score_{LL}(e'|e) + (1 - \lambda) score_{LM}(e'|S_E) \end{aligned} \quad (7)$$

<sup>7</sup>Notice that, a pattern may contain more than one type of slots, thus the sum of the percentages is larger than 1.

Here,  $score_{LL}(e'|e)$  denotes the score based on Equation (3).  $score_{LM}(e'|S_E)$  is the LM based score:  $score_{LM}(e'|S_E) = \frac{1}{n} \log P_{LM}(S'_E)$ , where  $S'_E$  is the sentence generated by replacing  $e$  in  $S_E$  with  $e'$ . The language model in the experiment was a tri-gram model trained using the English sentences in the bilingual corpus. We empirically set  $\lambda = 0.7$ .

The selected best paraphrase patterns in context sentences were manually labeled. The context information was also considered by our judges. The result shows that the precision of the best paraphrase patterns is 59.39%. To investigate the contribution of the LM based score, we ran the experiment again with  $\lambda = 1$  (ignoring the LM based score) and found that the precision is 57.09%. It indicates that the LM based reranking can improve the precision. However, the improvement is small. Further analysis shows that about 70% of the correct paraphrase substitutes are in the type of phrase replacement.

## 5 Conclusion

This paper proposes a pivot approach for extracting paraphrase patterns from bilingual corpora. We use a log-linear model to compute the paraphrase likelihood and exploit feature functions based on MLE and LW. Experimental results show that the pivot approach is effective, which extracts over 1,000,000 pairs of paraphrase patterns from 2M bilingual sentence pairs. The precision and coverage of the extracted paraphrase patterns exceed 67% and 84%, respectively. In addition, the log-linear model with the proposed feature functions significantly outperforms the conventional models. Analysis shows that 5 types of paraphrase patterns are extracted with our method, which are useful in various applications.

In the future we wish to exploit more feature functions in the log-linear model. In addition, we will try to make better use of the context information when replacing paraphrase patterns in context sentences.

# Unsupervised Learning of Narrative Event Chains

Nathanael Chambers and Dan Jurafsky

Department of Computer Science

Stanford University

Stanford, CA 94305

## Abstract

Hand-coded *scripts* were used in the 1970-80s as knowledge backbones that enabled inference and other NLP tasks requiring deep semantic knowledge. We propose unsupervised induction of similar schemata called *narrative event chains* from raw newswire text.

A narrative event chain is a partially ordered set of events related by a common protagonist. We describe a three step process to learning narrative event chains. The first uses unsupervised distributional methods to learn narrative relations between events sharing corefering arguments. The second applies a temporal classifier to partially order the connected events. Finally, the third prunes and clusters self-contained chains from the space of events. We introduce two evaluations: the *narrative cloze* to evaluate event relatedness, and an *order coherence* task to evaluate narrative order. We show a 36% improvement over baseline for narrative prediction and 25% for temporal coherence.

## 1 Introduction

This paper induces a new representation of structured knowledge called **narrative event chains** (or narrative chains). Narrative chains are partially ordered sets of events centered around a common **protagonist**. They are related to structured sequences of participants and events that have been called **scripts** (Schank and Abelson, 1977) or *Fillmorean frames*. These participants and events can be filled in and instantiated in a particular text situation to draw inferences. Chains focus on a single actor to facili-

tate learning, and thus this paper addresses the three tasks of chain induction: *narrative event induction*, *temporal ordering of events* and *structured selection* (pruning the event space into discrete sets).

Learning these prototypical schematic sequences of events is important for rich understanding of text. Scripts were central to natural language understanding research in the 1970s and 1980s for proposed tasks such as summarization, coreference resolution and question answering. For example, Schank and Abelson (1977) proposed that understanding text about restaurants required knowledge about the Restaurant Script, including the participants (Customer, Waiter, Cook, Tables, etc.), the events constituting the script (entering, sitting down, asking for menus, etc.), and the various preconditions, ordering, and results of each of the constituent actions.

Consider these two distinct narrative chains.

- <b>accused X</b>		<b>W joined</b> -
<b>X claimed</b> -		<b>W served</b> -
<b>X argued</b>		<b>W oversaw</b> -
- <b>dismissed X</b>		<b>W resigned</b>

It would be useful for question answering or textual entailment to know that ‘**X denied** -’ is also a likely event in the left chain, while ‘- **replaces W**’ temporally follows the right. Narrative chains (such as *Firing of Employee* or *Executive Resigns*) offer the structure and power to directly infer these new subevents by providing critical background knowledge. In part due to its complexity, automatic induction has not been addressed since the early non-statistical work of Mooney and DeJong (1985).

The first step to narrative induction uses an entity-based model for learning narrative relations by fol-

lowing a protagonist. As a narrative progresses through a series of events, each event is characterized by the grammatical role played by the protagonist, and by the protagonist’s shared connection to surrounding events. Our algorithm is an unsupervised distributional learning approach that uses coreferring arguments as evidence of a narrative relation. We show, using a new evaluation task called **narrative cloze**, that our protagonist-based method leads to better induction than a verb-only approach.

The next step is to order events in the same narrative chain. We apply work in the area of temporal classification to create partial orders of our learned events. We show, using a coherence-based evaluation of temporal ordering, that our partial orders lead to better coherence judgements of real narrative instances extracted from documents.

Finally, the space of narrative events and temporal orders is clustered and pruned to create discrete sets of narrative chains.

## 2 Previous Work

While previous work hasn’t focused specifically on learning narratives<sup>1</sup>, our work draws from two lines of research in summarization and anaphora resolution. In summarization, **topic signatures** are a set of terms indicative of a topic (Lin and Hovy, 2000). They are extracted from hand-sorted (by topic) sets of documents using log-likelihood ratios. These terms can capture some narrative relations, but the model requires topic-sorted training data.

Bean and Riloff (2004) proposed the use of **caseframe networks** as a kind of contextual role knowledge for anaphora resolution. A caseframe is a verb/event and a semantic role (e.g. *<patient> kidnapped*). Caseframe networks are relations between caseframes that may represent synonymy (*<patient> kidnapped* and *<patient> abducted*) or related events (*<patient> kidnapped* and *<patient> released*). Bean and Riloff learn these networks from two topic-specific texts and apply them to the problem of anaphora resolution. Our work can be seen as an attempt to generalize the intuition of caseframes (finding an entire set of events

rather than just pairs of related frames) and apply it to a different task (finding a coherent structured narrative in non-topic-specific text).

More recently, Brody (2007) proposed an approach similar to caseframes that discovers high-level relatedness between verbs by grouping verbs that share the same lexical items in subject/object positions. He calls these shared arguments *anchors*. Brody learns pairwise relations between clusters of related verbs, similar to the results with caseframes. A human evaluation of these pairs shows an improvement over baseline. This and previous caseframe work lend credence to learning relations from verbs with common arguments.

We also draw from lexical chains (Morris and Hirst, 1991), indicators of text coherence from word overlap/similarity. We use a related notion of protagonist overlap to motivate narrative chain learning.

Work on semantic similarity learning such as Chklovski and Pantel (2004) also automatically learns relations between verbs. We use similar distributional scoring metrics, but differ with our use of a protagonist as the indicator of relatedness. We also use typed dependencies and the entire space of events for similarity judgements, rather than only pairwise lexical decisions.

Finally, Fujiki et al. (2003) investigated script acquisition by extracting the 41 most frequent pairs of events from the first paragraph of newswire articles, using the assumption that the paragraph’s textual order follows temporal order. Our model, by contrast, learns entire event chains, uses more sophisticated probabilistic measures, and uses temporal ordering models instead of relying on document order.

## 3 The Narrative Chain Model

### 3.1 Definition

Our model is inspired by Centering (Grosz et al., 1995) and other entity-based models of coherence (Barzilay and Lapata, 2005) in which an entity is in focus through a sequence of sentences. We propose to use this same intuition to induce narrative chains.

We assume that although a narrative has several participants, there is a central actor who characterizes a narrative chain: the **protagonist**. Narrative chains are thus structured by the protagonist’s grammatical roles in the events. In addition, narrative

<sup>1</sup>We analyzed FrameNet (Baker et al., 1998) for insight, but found that very few of the frames are event *sequences* of the type characterizing narratives and scripts.

events are ordered by some theory of time. This paper describes a partial ordering with the *before* (no overlap) relation.

Our task, therefore, is to learn events that constitute narrative chains. Formally, a **narrative chain** is a partially ordered set of narrative events that share a common actor. A **narrative event** is a tuple of an event (most simply a verb) and its participants, represented as *typed dependencies*. Since we are focusing on a single actor in this study, a narrative event is thus a tuple of the event and the typed dependency of the protagonist: (*event, dependency*). A narrative chain is a set of narrative events  $\{e_1, e_2, \dots, e_n\}$ , where  $n$  is the size of the chain, and a relation  $B(e_i, e_j)$  that is true if narrative event  $e_i$  occurs strictly before  $e_j$  in time.

### 3.2 The Protagonist

The notion of a protagonist motivates our approach to narrative learning. We make the following assumption of **narrative coherence**: *verbs sharing coreferring arguments are semantically connected by virtue of narrative discourse structure*. A single document may contain more than one narrative (or topic), but the narrative assumption states that a series of argument-sharing verbs is more likely to participate in a narrative chain than those not sharing.

In addition, the narrative approach captures grammatical constraints on *narrative coherence*. Simple distributional learning might discover that the verb *push* is related to the verb *fall*, but narrative learning can capture additional facts about the participants, specifically, that the object or patient of the *push* is the subject or agent of the *fall*.

Each focused protagonist chain offers one perspective on a narrative, similar to the multiple perspectives on a commercial transaction event offered by buy and sell.

### 3.3 Partial Ordering

A narrative chain, by definition, includes a partial ordering of events. Early work on scripts included ordering constraints with more complex preconditions and side effects on the sequence of events. This paper presents work toward a partial ordering and leaves logical constraints as future work. We focus on the *before* relation, but the model does not preclude advanced theories of temporal order.

## 4 Learning Narrative Relations

Our first model learns basic information about a narrative chain: the protagonist and the constituent subevents, although not their ordering. For this we need a metric for the relation between an event and a narrative chain.

Pairwise relations between events are first extracted unsupervised. A distributional score based on how often two events share grammatical arguments (using pointwise mutual information) is used to create this pairwise relation. Finally, a global narrative score is built such that *all* events in the chain provide feedback on the event in question (whether for inclusion or for decisions of inference).

Given a list of observed verb/dependency counts, we approximate the pointwise mutual information (PMI) by:

$$pmi(e(w, d), e(v, g)) = \log \frac{P(e(w, d), e(v, g))}{P(e(w, d))P(e(v, g))} \quad (1)$$

where  $e(w, d)$  is the verb/dependency pair  $w$  and  $d$  (e.g.  $e(\text{push}, \text{subject})$ ). The numerator is defined by:

$$P(e(w, d), e(v, g)) = \frac{C(e(w, d), e(v, g))}{\sum_{x,y} \sum_{d,f} C(e(x, d), e(y, f))} \quad (2)$$

where  $C(e(x, d), e(y, f))$  is the number of times the two events  $e(x, d)$  and  $e(y, f)$  had a coreferring entity filling the values of the dependencies  $d$  and  $f$ . We also adopt the ‘discount score’ to penalize low occurring words (Pantel and Ravichandran, 2004).

Given the debate over appropriate metrics for distributional learning, we also experimented with the t-test. Our experiments found that PMI outperforms the t-test on this task by itself and when interpolated together using various mixture weights.

Once pairwise relation scores are calculated, a global narrative score can then be built such that *all* events provide feedback on the event in question. For instance, given all narrative events in a document, we can find the next most likely event to occur by maximizing:

$$\max_{j:0 < j < m} \sum_{i=0}^n pmi(e_i, f_j) \quad (3)$$

where  $n$  is the number of events in our chain and  $e_i$  is the  $i$ th event.  $m$  is the number of events  $f$  in our training corpus. A ranked list of guesses can be built from this summation and we hypothesize that

<b>Known events:</b>			
(pleaded subj), (admits subj), (convicted obj)			
<b>Likely Events:</b>			
sentenced obj	0.89	indicted obj	0.74
paroled obj	0.76	finned obj	0.73
fired obj	0.75	denied subj	0.73

Figure 1: Three narrative events and the six most likely events to include in the same chain.

the more events in our chain, the more informed our ranked output. An example of a chain with 3 events and the top 6 ranked guesses is given in figure 1.

#### 4.1 Evaluation Metric: Narrative Cloze

The **cloze task** (Taylor, 1953) is used to evaluate a system (or human) for language proficiency by removing a random word from a sentence and having the system attempt to fill in the blank (e.g. *I forgot to \_\_\_ the waitress for the good service*). Depending on the type of word removed, the test can evaluate syntactic knowledge as well as semantic. Deyes (1984) proposed an extended task, **discourse cloze**, to evaluate discourse knowledge (removing phrases that are recoverable from knowledge of discourse relations like *contrast* and *consequence*).

We present a new cloze task that requires narrative knowledge to solve, the **narrative cloze**. The narrative cloze is a sequence of narrative events in a document from which one event has been removed. The task is to predict the missing verb and typed dependency. Take this example text about American football with McCann as the protagonist:

1. McCann threw two interceptions early.
2. Toledo pulled McCann aside and told him he'd start.
3. McCann quickly completed his first two passes.

These clauses are represented in the narrative model as five events: **(threw subject)**, **(pulled object)**, **(told object)**, **(start subject)**, **(completed subject)**. These verb/dependency events make up a narrative cloze model. We could remove **(threw subject)** and use the remaining four events to rank this missing event. Removing a single such pair to be filled in automatically allows us to evaluate a system's knowledge of narrative relations and coherence. We do not claim this cloze task to be solvable even by humans,

but rather assert it as a comparative measure to evaluate narrative knowledge.

#### 4.2 Narrative Cloze Experiment

We use years 1994-2004 (1,007,227 documents) of the Gigaword Corpus (Graff, 2002) for **training**<sup>2</sup>. We parse the text into typed dependency graphs with the Stanford Parser (de Marneffe et al., 2006)<sup>3</sup>, recording all verbs with subject, object, or prepositional typed dependencies. We use the OpenNLP<sup>4</sup> coreference engine to resolve the entity mentions. For each document, the verb pairs that share corefering entities are recorded with their dependency types. Particles are included with the verb.

We used 10 news stories from the 1994 section of the corpus for *development*. The stories were hand chosen to represent a range of topics such as business, sports, politics, and obituaries. We used 69 news stories from the 2001 (year selected randomly) section of the corpus for **testing** (also removed from training). The test set documents were randomly chosen and not preselected for a range of topics. From each document, the entity involved in the most events was selected as the protagonist. For this evaluation, we only look at verbs. All verb clauses involving the protagonist are manually extracted and translated into the narrative events (*verb,dependency*). Exceptions that are not included are verbs in headlines, quotations (typically not part of a narrative), "be" properties (e.g. *john is happy*), modifying verbs (e.g. *hurried to leave*, only *leave* is used), and multiple instances of one event.

The original test set included 100 documents, but

<sup>2</sup>The document count does not include duplicate news stories. We found up to 18% of the corpus are duplications, mostly AP reprints. We automatically found these by matching the first two paragraphs of each document, removing exact matches.

<sup>3</sup><http://nlp.stanford.edu/software/lex-parser.shtml>

<sup>4</sup><http://opennlp.sourceforge.net>

those without a narrative chain at least five events in length were removed, leaving 69 documents. Most of the removed documents were not stories, but genres such as interviews and cooking recipes. An example of an extracted chain is shown in figure 2.

We evaluate with Narrative Cloze using leave-one-out cross validation, removing one event and using the rest to generate a ranked list of guesses. The test dataset produces 740 cloze tests (69 narratives with 740 events). After generating our ranked guesses, the position of the correct event is averaged over all 740 tests for the final score. We penalize unseen events by setting their ranked position to the length of the guess list (ranging from 2k to 15k).

Figure 1 is an example of a ranked guess list for a short chain of three events. If the original document contained (*fired obj*), this cloze test would score 3.

#### 4.2.1 Baseline

We want to measure the utility of the protagonist and the *narrative coherence assumption*, so our baseline learns relatedness strictly based upon verb co-occurrence. The PMI is then defined as between all occurrences of two verbs in the same document. This baseline evaluation is verb only, as dependencies require a protagonist to fill them.

After initial evaluations, the baseline was performing very poorly due to the huge amount of data involved in counting all possible verb pairs (using a protagonist vastly reduces the number). We experimented with various count cutoffs to remove rare occurring pairs of verbs. The final results use a baseline where all pairs occurring less than 10 times in the training data are removed.

Since the verb-only baseline does not use typed dependencies, our narrative model cannot directly compare to this abstracted approach. We thus modified the narrative model to ignore typed dependencies, but still count events with shared arguments. Thus, we calculate the PMI across verbs *that share arguments*. This approach is called **Protagonist**. The full narrative model that includes the grammatical dependencies is called **Typed Deps**.

#### 4.2.2 Results

Experiments with varying sizes of training data are presented in figure 3. Each ranked list of candidate verbs for the missing event in Base-

Figure 3: Results with varying sizes of training data. Year 2003 is not explicitly shown because it has an unusually small number of documents compared to other years.

line/Protagonist contained approximately 9 thousand candidates. Of the 740 cloze tests, 714 of the removed events were present in their respective list of guesses. This is encouraging as only 3.5% of the events are unseen (or do not meet cutoff thresholds).

When all training data is used (1994-2004), the average ranked position is 1826 for **Baseline** and 1160 for **Protagonist** (1 being most confident). The Baseline performs better at first (years 1994-5), but as more data is seen, the Baseline worsens while the Protagonist improves. This verb-only narrative model shows a **36.5%** improvement over the baseline trained on all years. Results from the full **Typed Deps** model, not comparable to the baseline, parallel the Protagonist results, improving as more data is seen (average ranked position of 1908 with all the training data). We also ran the experiment without OpenNLP coreference, and instead used exact and substring matching for coreference resolution. This showed a 5.7% decrease in the verb-only results. These results show that a protagonist greatly assists in narrative judgements.

## 5 Ordering Narrative Events

The model proposed in the previous section is designed to learn the major subevents in a narrative chain, but not how these events are ordered. In this section we extend the model to learn a partial temporal ordering of the events.

There are a number of algorithms for determining the temporal relationship between two events (Mani et al., 2006; Lapata and Lascarides, 2006; Chambers et al., 2007), many of them trained on the TimeBank Corpus (Pustejovsky et al., 2003) which codes events and their temporal relationships. The currently highest performing of these on raw data is the model of temporal labeling described in our previous work (Chambers et al., 2007). Other approaches have depended on hand tagged features.

Chambers et al. (2007) shows 59.4% accuracy on the classification task for six possible relations between pairs of events: *before*, *immediately-before*, *included-by*, *simultaneous*, *begins* and *ends*. We focus on the *before* relation because the others are less relevant to our immediate task. We combine *immediately-before* with *before*, and merge the other four relations into an *other* category. At the binary task of determining if one event is *before* or *other*, we achieve 72.1% accuracy on Timebank.

The above approach is a two-stage machine learning architecture. In the **first stage**, the model uses supervised machine learning to label temporal attributes of events, including tense, grammatical aspect, and aspectual class. This first stage classifier relies on features such as neighboring part of speech tags, neighboring auxiliaries and modals, and WordNet synsets. We use SVMs (Chambers et al. (2007) uses Naive Bayes) and see minor performance boosts on Timebank. These imperfect classifications, combined with other linguistic features, are then used in a **second stage** to classify the temporal relationship between two events. Other features include event-event syntactic properties such as the syntactic dominance relations between the two events, as well as new bigram features of tense, aspect and class (e.g. “present past” if the first event is in the present, and the second past), and whether the events occur in the same or different sentences.

## 5.1 Training a Temporal Classifier

We use the entire Timebank Corpus as supervised training data, condensing the *before* and *immediately-before* relations into one *before* relation. The remaining relations are merged into *other*.

The vast majority of potential event pairs in Timebank are unlabeled. These are often *none* relations (events that have no explicit relation) or as is of-

ten the case, *overlap* relations where the two events have no Timebank-defined ordering but overlap in time. Even worse, many events do have an ordering, but they were not tagged by the human annotators. This could be due to the overwhelming task of temporal annotation, or simply because some event orderings are deemed more important than others in understanding the document. We consider all untagged relations as *other*, and experiment with including none, half, and all of them in training.

Taking a cue from Mani et al. (2006), we also increased Timebank’s size by applying transitivity rules to the hand labeled data. The following is an example of the applied transitive rule:

**if** run BEFORE fall **and** fall BEFORE injured  
**then** run BEFORE injured

This increases the number of relations from 37519 to 45619. Perhaps more importantly for our task, of all the added relations, the *before* relation is added the most. We experimented with original vs. expanded Timebank and found the expanded performed slightly worse. The decline may be due to poor transitivity additions, as several Timebank documents contain inconsistent labelings. All reported results are from training *without* transitivity.

## 5.2 Temporal Classifier in Narrative Chains

We classify the Gigaword Corpus in two stages, once for the temporal features on each event (tense, grammatical aspect, aspectual class), and once between all pairs of events that share arguments. This allows us to classify the *before/other* relations between all potential narrative events.

The first stage is trained on Timebank, and the second is trained using the approach described above, varying the size of the *none* training relations. Each pair of events in a gigaword document that share a coreferring argument is treated as a separate ordering classification task. We count the resulting number of labeled *before* relations between each verb/dependency pair. Processing the entire corpus produces a database of event pair counts where confidence of two generic events A and B can be measured by comparing how many *before* labels have been seen versus their inverted order B and A<sup>5</sup>.

<sup>5</sup>Note that we train with the *before* relation, and so transposing two events is similar to classifying the *after* relation.

### 5.3 Temporal Evaluation

We want to evaluate temporal order at the narrative level, across all events within a chain. We envision narrative chains being used for tasks of coherence, among other things, and so it is desired to evaluate temporal decisions within a coherence framework. Along these lines, our test set uses actual narrative chains from documents, hand labeled for a partial ordering. We evaluate coherence of these true chains against a random ordering. The task is thus deciding which of the two chains is most coherent, the original or the random (baseline 50%)? We generated up to 300 random orderings for each test document, averaging the accuracy across all.

Our evaluation data is the same 69 documents used in the test set for learning narrative relations. The chain from each document is hand identified and labeled for a partial ordering using only the *before* relation. Ordering was done by the authors and all attempts were made to include every before relation that exists in the document, or that could be deduced through transitivity rules. Figure 4 shows an example and its full reversal, although the evaluation uses random orderings. Each edge is a distinct before relation and is used in the judgement score.

The coherence score for a partially ordered narrative chain is the sum of all the relations that our classified corpus agrees with, weighted by how certain we are. If the gigaword classifications disagree, a weighted negative score is given. Confidence is based on a logarithm scale of the difference between the counts of before and after classifications. Formally, the score is calculated as the following:

$$\sum_{E:x,y} \begin{cases} \log(D(x,y)) & \text{if } x\beta y \text{ and } B(x,y) > B(y,x) \\ -\log(D(x,y)) & \text{if } x\beta y \text{ and } B(y,x) > B(x,y) \\ -\log(D(x,y)) & \text{if } !x\beta y \text{ \& \!}y\beta x \text{ \& } D(x,y) > 0 \\ 0 & \text{otherwise} \end{cases}$$

where  $E$  is the set of all event pairs,  $B(i, j)$  is how many times we classified events  $i$  and  $j$  as *before* in Gigaword, and  $D(i, j) = |B(i, j) - B(j, i)|$ . The relation  $i\beta j$  indicates that  $i$  is temporally before  $j$ .

### 5.4 Results

Our approach gives higher scores to orders that coincide with the pairwise orderings classified in our gigaword training data. The results are shown in figure 5. Of the 69 chains, 6 did not have any ordered events and were removed from the evaluation. We

Figure 4: A narrative chain and its reverse order.

	All	$\geq 6$	$\geq 10$
correct	8086 <b>75%</b>	7603 <b>78%</b>	6307 <b>89%</b>
incorrect	1738	1493	619
tie	931	627	160

Figure 5: Results for choosing the correct ordered chain. ( $\geq 10$ ) means there were at least 10 pairs of ordered events in the chain.

generated (up to) 300 random orderings for each of the remaining 63. We report 75.2% accuracy, but 22 of the 63 had 5 or fewer pairs of ordered events. Figure 5 therefore shows results from chains with more than 5 pairs, and also 10 or more. As we would hope, the accuracy improves the larger the ordered narrative chain. We achieve 89.0% accuracy on the 24 documents whose chains most progress through time, rather than chains that are difficult to order with just the *before* relation.

Training without *none* relations resulted in high recall for *before* decisions. Perhaps due to data sparsity, this produces our best results as reported above.

## 6 Discrete Narrative Event Chains

Up till this point, we have learned narrative relations across all possible events, including their temporal order. However, the discrete lists of events for which Schank scripts are most famous have not yet been constructed.

We intentionally did not set out to reproduce explicit self-contained *scripts* in the sense that the ‘restaurant script’ is complete and cannot include other events. The name *narrative* was chosen to imply a *likely order* of events that is common in spoken and written retelling of world events. Discrete sets have the drawback of shutting out unseen and un-

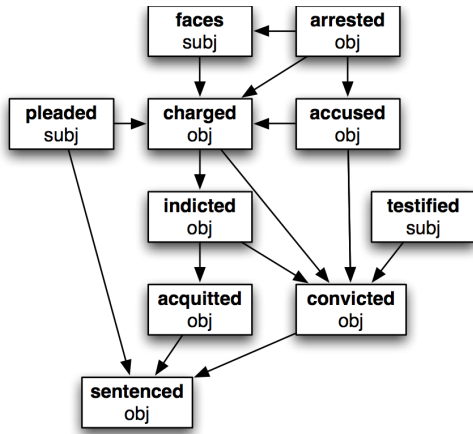

Figure 6: An automatically learned Prosecution Chain. Arrows indicate the *before* relation.

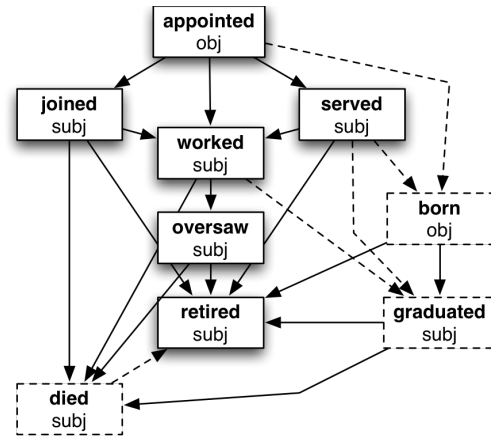

Figure 7: An Employment Chain. Dotted lines indicate incorrect *before* relations.

likely events from consideration. It is advantageous to consider a space of possible narrative events and the ordering within, not a closed list.

However, it is worthwhile to construct discrete narrative chains, if only to see whether the combination of event learning and ordering produce script-like structures. This is easily achievable by using the PMI scores from section 4 in an agglomerative clustering algorithm, and then applying the ordering relations from section 5 to produce a directed graph.

Figures 6 and 7 show two learned chains after clustering and ordering. Each arrow indicates a before relation. Duplicate arrows implied by rules of transitivity are removed. Figure 6 is remarkably accurate, and figure 7 addresses one of the chains from our introduction, the employment narrative. The core employment events are accurate, but clustering included life events (born, died, graduated) from obituaries of which some temporal information is incorrect. The Timebank corpus does not include obituaries, thus we suffer from sparsity in training data.

## 7 Discussion

We have shown that it is possible to learn narrative event chains unsupervised from raw text. Not only do our narrative relations show improvements over a baseline, but narrative chains offer hope for many other areas of NLP. Inference, coherence in summarization and generation, slot filling for question answering, and frame induction are all potential areas.

We learned a new measure of similarity, the nar-

rative relation, using the protagonist as a hook to extract a list of related events from each document. The 37% improvement over a verb-only baseline shows that we may not need presorted topics of documents to learn inferences. In addition, we applied state of the art temporal classification to show that sets of events can be partially ordered. Judgements of coherence can then be made over chains within documents. Further work in temporal classification may increase accuracy even further.

Finally, we showed how the event space of narrative relations can be clustered to create discrete sets. While it is unclear if these are better than an unconstrained distribution of events, they do offer insight into the quality of narratives.

An important area not discussed in this paper is the possibility of using narrative chains for semantic role learning. A narrative chain can be viewed as defining the semantic roles of an event, constraining it against roles of the other events in the chain. An argument's class can then be defined as the set of narrative arguments in which it appears.

We believe our model provides an important first step toward learning the rich causal, temporal and inferential structure of scripts and frames.

## Abstract

There is a widely held belief in the natural language and computational linguistics communities that Semantic Role Labeling (SRL) is a significant step toward improving important applications, e.g. question answering and information extraction. In this paper, we present an SRL system for Modern Standard Arabic that exploits many aspects of the rich morphological features of the language. The experiments on the pilot Arabic Propbank data show that our system based on Support Vector Machines and Kernel Methods yields a global SRL  $F_1$  score of 82.17%, which improves the current state-of-the-art in Arabic SRL.

## 1 Introduction

Shallow approaches to semantic processing are making large strides in the direction of efficiently and effectively deriving tacit semantic information from text. Semantic Role Labeling (SRL) is one such approach. With the advent of faster and more powerful computers, more effective machine learning algorithms, and importantly, large data resources annotated with relevant levels of semantic information, such as the FrameNet (Baker et al., 1998) and PropBank (Kingsbury and Palmer, 2003), we are seeing a surge in efficient approaches to SRL (Carreras and Màrquez, 2005).

SRL is the process by which predicates and their arguments are identified and their roles are defined in a sentence. For example, in the English sentence, ‘John likes apples.’, the predicate is ‘likes’ whereas ‘John’ and ‘apples’, bear the semantic role labels *agent* (ARG0) and *theme* (ARG1). The crucial fact about semantic roles is that regardless of the overt syntactic structure variation, the underlying predicates remain the same. Hence, for the sentence ‘John opened the door’ and ‘the door opened’, though ‘the door’ is the object of the first sentence

and the subject of the second, it is the ‘theme’ in both sentences. Same idea applies to passive constructions, for example.

There is a widely held belief in the NLP and computational linguistics communities that identifying and defining roles of predicate arguments in a sentence has a lot of potential for and is a significant step toward improving important applications such as document retrieval, machine translation, question answering and information extraction (Moschitti et al., 2007).

To date, most of the reported SRL systems are for English, and most of the data resources exist for English. We do see some headway for other languages such as German and Chinese (Erk and Pado, 2006; Sun and Jurafsky, 2004). The systems for the other languages follow the successful models devised for English, e.g. (Gildea and Jurafsky, 2002; Gildea and Palmer, 2002; Chen and Rambow, 2003; Thompson et al., 2003; Pradhan et al., 2003; Moschitti, 2004; Xue and Palmer, 2004; Haghighi et al., 2005). In the same spirit and facilitated by the release of the SemEval 2007 Task 18 data<sup>1</sup>, based on the Pilot Arabic Propbank, a preliminary SRL system exists for Arabic<sup>2</sup> (Diab and Moschitti, 2007; Diab et al., 2007a). However, it did not exploit some special characteristics of the Arabic language on the SRL task.

In this paper, we present an SRL system for MSA that exploits many aspects of the rich morphological features of the language. It is based on a supervised model that uses support vector machines (SVM) technology (Vapnik, 1998) for argument boundary detection and argument classification. It is trained and tested using the pilot Arabic Propbank data released as part of the SemEval 2007 data. Given the lack of a reliable Arabic deep syntactic parser, we

<sup>1</sup><http://nlp.cs.swarthmore.edu/semeval/>

<sup>2</sup>We use Arabic to refer to Modern Standard Arabic (MSA).

use gold standard trees from the Arabic Tree Bank (ATB) (Maamouri et al., 2004).

This paper is laid out as follows: Section 2 presents facts about the Arabic language especially in relevant contrast to English; Section 3 presents the approach and system adopted for this work; Section 4 presents the experimental setup, results and discussion. Finally, Section 5 draws our conclusions.

## 2 Arabic Language and Impact on SRL

Arabic is a very different language from English in several respects relevant to the SRL task. Arabic is a semitic language. It is known for its templatic morphology where words are made up of roots and affixes. Clitics agglutinate to words. Clitics include prepositions, conjunctions, and pronouns.

In contrast to English, Arabic exhibits rich morphology. Similar to English, Arabic verbs explicitly encode tense, voice, Number, and Person features. Additionally, Arabic encodes verbs with Gender, Mood (subjunctive, indicative and jussive) information. For nominals (nouns, adjectives, proper names), Arabic encodes syntactic Case (accusative, genitive and nominative), Number, Gender and Definiteness features. In general, many of the morphological features of the language are expressed via short vowels also known as diacritics<sup>3</sup>.

Unlike English, syntactically Arabic is a pro-drop language, where the subject of a verb may be implicitly encoded in the verb morphology. Hence, we observe sentences such as *اكل البرتقال Akl AlbrtqAl* ‘ate-[he] the-oranges’, where the verb *Akl* encodes the third Person Masculine Singular subject in the verbal morphology. It is worth noting that in the ATB 35% of all sentences are pro-dropped for subject (Maamouri et al., 2006). Unless the syntactic parse is very accurate in identifying the pro-dropped case, identifying the syntactic subject and the underlying semantic arguments are a challenge for such pro-drop cases.

Arabic syntax exhibits relative free word order. Arabic allows for both subject-verb-object (SVO) and verb-subject-object (VSO) argument orders.<sup>4</sup> In

the VSO constructions, the verb agrees with the syntactic subject in Gender only, while in the SVO constructions, the verb agrees with the subject in both Number and Gender. Even though, in the ATB, an equal distribution of both VSO and SVO is observed (each appearing 30% of the time), it is known that in general Arabic is predominantly in VSO order. Moreover, the pro-drop cases could effectively be perceived as VSO orders for the purposes of SRL. Syntactic Case is very important in the cases of VSO and pro-drop constructions as they indicate the syntactic roles of the object arguments with accusative Case. Unless the morphology of syntactic Case is explicitly present, such free word order could run the SRL system into significant confusion for many of the predicates where both arguments are semantically of the same type.

Arabic exhibits more complex noun phrases than English mainly to express possession. These constructions are known as *idafa* constructions. Modern standard Arabic does not have a special particle expressing possession. In these complex structures a surface indefinite noun (missing an explicit definite article) may be followed by a definite noun marked with genitive Case, rendering the first noun syntactically definite. For example, *رجل البيت rjl Albyt* ‘man the-house’ meaning ‘man of the house’, *رجل* becomes definite. An adjective modifying the noun *رجل* will have to agree with it in Number, Gender, Definiteness, and Case. However, without explicit morphological encoding of these agreements, the scope of the arguments would be confusing to an SRL system. In a sentence such as *رجل البيت الطويل rjlu Albyti AlTwyly* meaning ‘the tall man of the house’: ‘man’ is definite, masculine, singular, nominative, corresponding to Definiteness, Gender, Number and Case, respectively; ‘the-house’ is definite, masculine, singular, genitive; ‘the-tall’ is definite, masculine, singular, nominative. We note that ‘man’ and ‘tall’ agree in Number, Gender, Case and Definiteness. Syntactic Case is marked using short vowels *u*, and *i* at the end of the word. Hence, *rjlu* and *AlTwyly* agree in their Case ending<sup>5</sup> Without the explicit marking of the Case information,

<sup>3</sup>Diacritics encode the vocalic structure, namely the short vowels, as well as the gemination marker for consonantal doubling, among other markers.

<sup>4</sup>MSA less often allows for OSV, or OVS.

<sup>5</sup>The presence of the *Albyti* is crucial as it renders *rjlu* definite therefore allowing the agreement with *AlTwyly* to be complete.

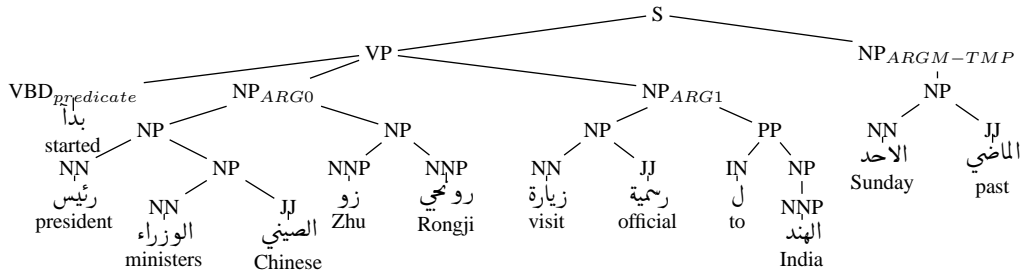

Figure 1: Annotated Arabic Tree corresponding to ‘Chinese Prime minister Zhu Rongji started an official visit to India last Sunday.’

namely in the word endings, it could be equally valid that ‘the-tall’ modifies ‘the-house’ since they agree in Number, Gender and Definiteness as explicitly marked by the Definiteness article *Al*. Hence, these *idafa* constructions could be tricky for SRL in the absence of explicit morphological features. This is compounded by the general absence of short vowels, expressed by diacritics (i.e. the *u* and *i* in *rjlu* and *Al-byti*.) in naturally occurring text. *Idafa* constructions in the ATB exhibit recursive structure, embedding other NPs, compared to English where possession is annotated with flat NPs and is designated by a possessive marker.

Arabic texts are underspecified for diacritics to different degrees depending on the genre of the text (Diab et al., 2007b). Such an underspecification of diacritics masks some of the very relevant morpho-syntactic interactions between the different categories such as agreement between nominals and their modifiers as exemplified before, or verbs and their subjects.

Having highlighted the differences, we hypothesize that the interaction between the rich morphology (if explicitly marked and present) and syntax could help with the SRL task. The presence of explicit Number and Gender agreement as well as Case information aids with identification of the syntactic subject and object even if the word order is relatively free. Gender, Number, Definiteness and Case agreement between nouns and their modifiers and other nominals, should give clues to the scope of arguments as well as their classes. The presence of such morpho-syntactic information should lead to better argument boundary detection and better classification.

### 3 An SRL system for Arabic

The previous section suggests that an optimal model should take into account specific characteristics of

Feature Name	Description
Predicate	Lemmatization of the predicate word
Path	Syntactic path linking the predicate and an argument, e.g. NN↑NP↑VP↓VBX
Partial path	<i>Path</i> feature limited to the branching of the argument
No-direction path	Like <i>Path</i> without traversal directions
Phrase type	Syntactic type of the argument node
Position	Relative position of the argument with respect to the predicate
Verb subcategorization	Production rule expanding the predicate parent node
Syntactic Frame	Position of the NPs surrounding the predicate
First and last word/POS	First and last words and POS tags of candidate argument phrases

Table 1: Standard linguistic features employed by most SRL systems.

Arabic. In this research, we go beyond the previously proposed basic SRL system for Arabic (Diab et al., 2007a; Diab and Moschitti, 2007). We exploit the full morphological potential of the language to verify our hypothesis that taking advantage of the interaction between morphology and syntax can improve on a basic SRL system for morphologically rich languages.

Similar to the previous Arabic SRL systems, our adopted SRL models use Support Vector Machines to implement a two step classification approach, i.e. boundary detection and argument classification. Such models have already been investigated in (Pradhan et al., 2005; Moschitti et al., 2005). The two step classification description is as follows.

#### 3.1 Predicate Argument Extraction

The extraction of predicative structures is based on the sentence level. Given a sentence, its predicates, as indicated by verbs, have to be identified along with their arguments. This problem is usually divided in two subtasks: (a) the detection of the target argument boundaries, i.e. the span of the argument words in the sentence, and (b) the classification of the argument type, e.g. *Arg0* or *ArgM* for Propbank

Figure 2: Fragment space generated by a tree kernel function for the sentence *Mary bought a cat*.

or *Agent* and *Goal* for the FrameNet.

The standard approach to learn both the detection and the classification of predicate arguments is summarized by the following steps:

- (a) Given a sentence from the *training-set*, generate a full syntactic parse-tree;
- (b) let  $\mathcal{P}$  and  $\mathcal{A}$  be the set of predicates and the set of parse-tree nodes (i.e. the potential arguments), respectively;
- (c) for each pair  $\langle p, a \rangle \in \mathcal{P} \times \mathcal{A}$ : extract the feature representation set,  $F_{p,a}$  and put it in  $T^+$  (positive examples) if the subtree rooted in  $a$  covers exactly the words of one argument of  $p$ , otherwise put it in  $T^-$  (negative examples).

For instance, in Figure 1, for each combination of the predicate *started* with the nodes NP, S, VP, VPD, NNP, NN, PP, JJ or IN the instances  $F_{started,a}$  are generated. In case the node  $a$  exactly covers ‘president ministers Chinese Zhu Rongji’ or ‘visit official to India’,  $F_{p,a}$  will be a positive instance otherwise it will be a negative one, e.g.  $F_{started,IN}$ .

The  $T^+$  and  $T^-$  sets are used to train the boundary classifier. To train the multi-class classifier,  $T^+$  can be reorganized as positive  $T_{arg_i}^+$  and negative  $T_{arg_i}^-$  examples for each argument  $i$ . This way, an individual ONE-vs-ALL classifier for each argument  $i$  can be trained. We adopt this solution, according to (Pradhan et al., 2005), since it is simple and effective. In the classification phase, given an unseen sentence, all its  $F_{p,a}$  are generated and classified by each individual classifier  $C_i$ . The argument associated with the maximum among the scores provided by the individual classifiers is eventually selected.

The above approach assigns labels independently, without considering the whole predicate argument structure. As a consequence, the classifier output may generate overlapping arguments. Thus, to make the annotations globally consistent, we apply a disambiguating heuristic adopted from (Diab and Moschitti, 2007) that selects only one argument among multiple overlapping arguments.

### 3.2 Features

The discovery of relevant features is, as usual, a complex task. The choice of features is further compounded for a language such as Arabic given its rich morphology and morpho-syntactic interactions.

To date, there is a common consensus on the set of basic standard features for SRL, which we will refer to as *standard*. The set of standard features, refers to unstructured information derived from parse trees. e.g. *Phrase Type*, *Predicate Word* or *Head Word*. Typically the standard features are language independent. In our experiments we employ the features listed in Table 1, defined in (Gildea and Jurafsky, 2002; Pradhan et al., 2005; Xue and Palmer, 2004). For example, the *Phrase Type* indicates the syntactic type of the phrase labeled as a predicate argument, e.g. NP for *ARG1* in Figure 1. The *Parse Tree Path* contains the path in the parse tree between the predicate and the argument phrase, expressed as a sequence of nonterminal labels linked by direction (up or down) symbols, e.g. VBD  $\uparrow$  VP  $\downarrow$  NP for *ARG1* in Figure 1. The *Predicate Word* is the surface form of the verbal predicate, e.g. *started* for all arguments. The standard features, as successful as they are, are designed primarily for English. They are not exploiting the different characteristics of the Arabic language as expressed through morphology. Hence, we explicitly encode new SRL features that capture the richness of Arabic morphology and its role in morpho-syntactic behavior. The set of morphological attributes include: inflectional morphology such as Number, Gender, Definiteness, Mood, Case, Person; derivational morphology such as the Lemma form of the words with all the diacritics explicitly marked; vowelized and fully diacritized form of the surface form; the English gloss<sup>6</sup>. It is worth noting that there exists highly accurate morphological taggers for Arabic such as the MADA system (Habash and Rambow, 2005; Roth et al., 2008). MADA tags

<sup>6</sup>The gloss is not sense disambiguated, hence they include homonyms.

Feature Name	Description
Definiteness	Applies to nominals, values are definite, indefinite or inapplicable
Number	Applies to nominals and verbs, values are singular, plural or dual or inapplicable
Gender	Applies to nominals, values are feminine, masculine or inapplicable
Case	Applies to nominals, values are accusative, genitive, nominative or inapplicable
Mood	Applies to verbs, values are subjunctive, indicative, jussive or inapplicable
Person	Applies to verbs and pronouns, values are 1st, 2nd, 3rd person or inapplicable
Lemma	The citation form of the word fully diacritized with the short vowels and gemination markers if applicable
Gloss	this is the corresponding English meaning as rendered by the underlying lexicon.
Vocalized word	The surface form of the word with all the relevant diacritics. Unlike Lemma, it includes all the inflections.
Unvowelized word	The naturally occurring form of the word in the sentence with no diacritics.

Table 2: Rich morphological features encoded in the Extended Argument Structure Tree (EAST).

modern standard Arabic with all the relevant morphological features as well as it produces highly accurate lemma and gloss information by tapping into an underlying morphological lexicon. A list of the extended features is described in Table 2.

The set of possible features and their combinations are very large leading to an intractable feature selection problem. Therefore, we exploit well known kernel methods, namely tree kernels, to robustly experiment with all the features simultaneously. Such kernel engineering, as shown in (Moschitti, 2004), allows us to experiment with many syntactic/semantic features seamlessly.

### 3.3 Engineering Arabic Features with Kernel Methods

Feature engineering via kernel methods is a useful technique that allows us to save a lot of time in the design and implementation of features. The basic idea is (a) to design a set of basic value-attribute features and apply polynomial kernels and generate all possible combinations; or (b) to design basic tree structures expressing properties related to the target linguistic objects and use tree kernels to generate all possible tree subparts, which will constitute the feature representation vectors for the learning algorithm.

Tree kernels evaluate the similarity between two trees in terms of their overlap, generally measured as the number of common substructures (Collins and Duffy, 2002). For example, Figure 2, shows a small parse tree and some of its fragments. To design a function which computes the number of common substructures between two trees  $t_1$  and  $t_2$ , let us define the set of fragments  $\mathcal{F}=\{f_1, f_2, \dots\}$  and the indicator function  $I_i(n)$ , equal to 1 if the target  $f_i$  is rooted at node  $n$  and 0 otherwise. A tree kernel function  $K_T(\cdot)$  over two trees is defined as:

Figure 3: Example of the positive AST structured feature encoding the argument ARG0 in the sentence depicted in Figure 1.

$K_T(t_1, t_2) = \sum_{n_1 \in N_{t_1}} \sum_{n_2 \in N_{t_2}} \Delta(n_1, n_2)$ , where  $N_{t_1}$  and  $N_{t_2}$  are the sets of nodes of  $t_1$  and  $t_2$ , respectively. The function  $\Delta(\cdot)$  evaluates the number of common fragments rooted in  $n_1$  and  $n_2$ , i.e.  $\Delta(n_1, n_2) = \sum_{i=1}^{|\mathcal{F}|} I_i(n_1)I_i(n_2)$ .  $\Delta$  can be efficiently computed with the algorithm proposed in (Collins and Duffy, 2002).

### 3.4 Structural Features for Arabic

In order to incorporate the characteristically rich Arabic morphology features structurally in the tree representations, we convert the features into value-attribute pairs at the leaf node level of the tree. Fig 1 illustrates the morphologically underspecified tree with some of the morphological features encoded in the POS tag such as VBD indicating past tense. This contrasts with Fig. 4 which shows an excerpt of the same tree encoding the chosen relevant morphological features.

For the sake of classification, we will be dealing with two kinds of structures: the Argument Structure Tree (AST) (Pighin and Basili, 2006) and the Extended Argument Structure Tree (EAST). The AST is defined as the minimal subtree encompassing all and only the leaf nodes encoding words belonging to the predicate or one of its arguments. An AST example is shown in Figure 3. The EAST is the corresponding structure in which all the leaf nodes have been extended with the ten morphological fea-

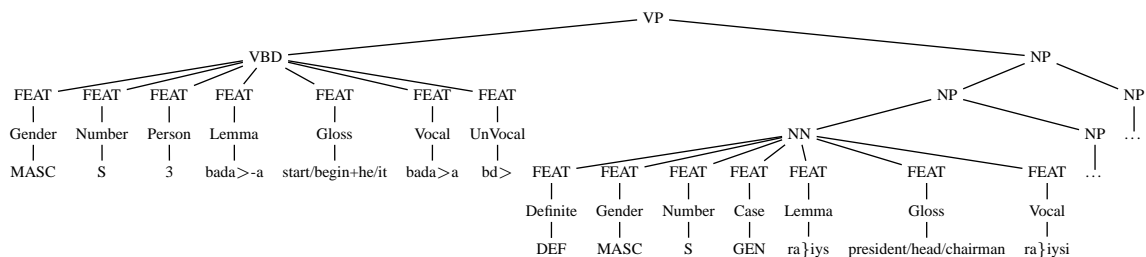

Figure 4: An excerpt of the EAST corresponding to the AST shown in Figure 3, with attribute-value extended morphological features represented as leaf nodes.

tures described in Table 2, forming a vector of 10 preterminal-terminal node pairs that replace the surface of the leaf. The resulting EAST structure is shown in Figure 4.

Not all the features are instantiated for all the leaf node words. Due to space limitations, in the figure we did not include the Features that have NULL values. For instance, Definiteness is always associated with nominals, hence the verb بدأ *bd* ‘start’ is assigned a NULL value for the Definite feature. Verbs exhibit Gender information depending on inflections. For our example, بدأ ‘started’ is inflected for masculine Gender, singular Number, third person. On the other hand, the noun الوزراء is definite and is assigned genitive Case since it is in a possessive, *idafa*, construction.

The features encoded by the EAST can provide very useful hints for boundary and role classification. Considering Figure 1, argument boundaries is not as straight forward to identify as there are several NPs. Assuming that the inner most NP ‘ministers the-Chinese’ is a valid Argument could potentially be accepted. There is ample evidence that any NN followed by a JJ would make a perfectly valid Argument. However, an AST structure would mask the fact that the JJ ‘the-Chinese’ does not modify the NN ‘ministers’ since they do not agree in Number<sup>7</sup>, and in syntactic Case, where the latter is genitive and the former is nominative. ‘the-Chinese’ in fact modifies ‘president’ as they agree on all the underlying morphological features. Conversely, the EAST in Figure 4 explicitly encodes this agreement including an agreement on Definiteness. It is worth noting that just observing the Arabic word رئيس ‘president’ in Fig 1, the system would assume that it is an indefinite word since it does not include the definite arti-

<sup>7</sup>The POS tag on this node is NN as broken plural, however, the underlying morphological feature Number is plural.

cle ال. Therefore, the system could be lead astray to conclude that ‘the-Chinese’ does not modify ‘president’ but rather ‘the-ministers’. Without knowing the Case information and the agreement features between the verb بدأ ‘started’ and the two nouns heading the two main NPs in our tree, the syntactic subject can be either زيارة ‘visit’ or رئيس ‘president’ in Figure 1. The EAST is more effective in identifying the first noun as the syntactic subject and the second as the object since the morphological information indicates that they are in nominative and accusative Case, respectively. Also the agreement in Gender and Number between the verb and the syntactic subject is identified in the enriched tree. We see that بدأ ‘started’ and رئيس ‘president’ agree in being singular and masculine. If زيارة ‘visit’ were the syntactic subject, we would have seen the verb inflected as بدأت ‘started-FEM’ with a feminine inflection to reflect the verb-subject agreement on Gender. Hence these agreement features should help with the classification task.

## 4 Experiments

In these experiments we investigate (a) if the technology proposed in previous work for automatic SRL of English texts is suitable for Arabic SRL systems, and (b) the impact of tree kernels using new tree structures on Arabic SRL. For this purpose, we test our models on the two individual phases of the traditional 2-stage SRL model (i.e. boundary detection and argument classification) and on the complete SRL task. We use three different feature spaces: a set of standard attribute-value features and the AST and the EAST structures defined in 3.4. Standard feature vectors can be combined with a polynomial kernel (Poly), which, when the degree is larger than 1, automatically generates feature conjunctions. This, as suggested in (Pradhan et al., 2005; Moschitti, 2004), can help stressing the differ-

ences between different argument types. Tree structures can be used in the learning algorithm thanks to the tree kernels described in Section 3.3. Moreover, to verify if the above feature sets are equivalent or complementary, we can join them by means of additive operation which always produces a valid kernel (Shawe-Taylor and Cristianini, 2004).

#### 4.1 Experimental setup

We use the dataset released in the SemEval 2007 Task 18 on Arabic Semantic Labeling (Diab et al., 2007a). The data covers the 95 most frequent verbs in the Arabic Treebank III ver. 2 (ATB). The ATB consists of MSA newswire data from the Annhar newspaper, spanning the months from July to November, 2002. All our experiments are carried out with gold standard trees.

An important characteristic of the dataset is the use of unvowelized Arabic in the Buckwalter transliteration scheme for deriving the basic features for the AST experimental condition. The data comprises a development set, a test set and a training set of 886, 902 and 8,402 sentences, respectively, where each set contain 1725, 1661 and 21,194 argument instances. These instances are distributed over 26 different role types. The training instances of the boundary detection task also include parse-tree nodes that do not correspond to correct boundaries (we only considered 350K examples). For the experiments, we use SVM-Light-TK toolkit<sup>8</sup> (Moschitti, 2004; Moschitti, 2006) and its SVM-Light default parameters. The system performance, i.e.  $F_1$  on single boundary and role classifier, accuracy of the role multi-classifier and the  $F_1$  of the complete SRL systems, are computed by means of the CoNLL evaluator<sup>9</sup>.

#### 4.2 Results

Figure 5 reports the  $F_1$  of the SVM boundary classifier using Polynomial Kernels with a degree from 1 to 6 (i.e. Poly $i$ ), the AST and the EAST kernels and their combinations. We note that as we introduce conjunctions, i.e. a degree larger than 2, the  $F_1$  increases by more than 3 percentage points. Thus, not only are the English features meaningful for Arabic but also their combinations are important, reveal-

<sup>8</sup><http://disi.unitn.it/~moschitti>

<sup>9</sup><http://www.lsi.upc.es/~srlconll/soft.html>

Figure 5: Impact of polynomial kernel, tree kernels and their combinations on boundary detection.

Figure 6: Impact of the polynomial kernel, tree kernels and their combinations on the accuracy in role classification (gold boundaries) and on the  $F_1$  of complete SRL task (boundary + role classification).

ing that both languages share an underlying syntax-semantic interface. Moreover, we note that the  $F_1$  of EAST is higher than the  $F_1$  of AST which in turn is higher than the linear kernel (Poly1). However, when conjunctive features (Poly2-4) are used the system accuracy exceeds those of tree kernel models alone. Further increasing the polynomial degree (Poly5-6) generates very complex hypotheses which result in very low accuracy values.

Therefore, to improve the polynomial kernel, we sum it to the contribution of AST and/or EAST, obtaining AST+Poly3 (polynomial kernel of degree 3), EAST+Poly3 and AST+EAST+Poly3, whose  $F_1$  scores are also shown in Figure 5. Such combined models improve on the best polynomial kernel. However, not much difference is shown between AST and EAST on boundary detection. This is expected since we are using gold standard trees. We hypothesize that the rich morphological features will help more with the role classification task. Therefore, we evaluate role classification with gold boundaries. The curve labeled "classification" in Figure 6 illustrates the accuracy of the SVM role multi-classifier according to different kernels.

	P3	AST	EAST	AST+ P3	EAST+ P3	AST+ EAST+ P3
P	81.73	80.33	81.7	81.73	82.46	83.08
R	78.93	75.98	77.42	80.01	80.67	81.28
F <sub>1</sub>	80.31	78.09	79.51	80.86	81.56	82.17

Table 3: F<sub>1</sub> of different models on the Arabic SRL task.

Again, we note that a degree larger than 1 yields a significant improvement of more than 3 percent points, suggesting that the design of Arabic SRL system based on SVMs requires polynomial kernels. In contrast to the boundary results, EAST highly improves over AST (by about 3 percentage points) and produces an F<sub>1</sub> comparable to the best Polynomial kernel. Moreover, AST+Poly3, EAST+Poly3 and AST+EAST+Poly3 all yield different degrees of improvement, where the latter model is both the richest in terms of features and the most accurate.

These results strongly suggest that: (a) tree kernels generate new syntactic features that are useful for the classification of Arabic semantic roles; (b) the richer morphology of Arabic language should be exploited effectively to obtain accurate SRL systems; (c) tree kernels appears to be a viable approach to effectively achieve this goal.

To illustrate the practical feasibility of our system, we investigate the complete SRL task where both the boundary detection and argument role classification are performed automatically. The curve labeled "boundary + role classification" in Figure 6 reports the F<sub>1</sub> of SRL systems based on the previous kernels. The trend of the plot is similar to the gold-standard boundaries case. The difference among the F<sub>1</sub> scores of the AST+Poly3, EAST+Poly3 and AST+EAST+Poly3 is slightly reduced. This may be attributed to the fact that they produce similar boundary detection results, which in turn, for the global SRL outcome, are summed to those of the classification phase. Table 3 details the differences among the models and shows that the best model improves the SRL system based on the polynomial kernel, i.e. the SRL state-of-the-art for Arabic, by about 2 percentage points. This is a very large improvement for SRL systems (Carreras and Màrquez, 2005). These results confirm that the new enriched structures along with tree kernels are a promising approach for Arabic SRL systems.

Finally, Table 4 reports the F<sub>1</sub> of the best model, AST+EAST+Poly3, for individual arguments in the

Role	Precision	Recall	F <sub>β=1</sub>
ARG0	96.14%	97.27%	96.70
ARG0-STR	100.00%	20.00%	33.33
ARG1	88.52%	92.70%	90.57
ARG1-STR	33.33%	15.38%	21.05
ARG2	69.35%	76.67%	72.82
ARG3	66.67%	16.67%	26.67
ARGM-ADV	66.98%	61.74%	64.25
ARGM-CAU	100.00%	9.09%	16.67
ARGM-CND	25.00%	33.33%	28.57
ARGM-LOC	67.44%	95.08%	78.91
ARGM-MNR	54.00%	49.09%	51.43
ARGM-NEG	80.85%	97.44%	88.37
ARGM-PRD	20.00%	8.33%	11.76
ARGM-PRP	85.71%	66.67%	75.00
ARGM-TMP	91.35%	88.79%	90.05

Table 4: SRL F<sub>1</sub> of the single arguments using the AST+EAST+Poly3 kernel.

SRL task. We note that, as for English SRL, ARG0 shows high values (96.70%). Conversely, ARG1 seems more difficult to be classified in Arabic. The F<sub>1</sub> for ARG1 is only 90.57% compared with 96.70% for ARG0.

This may be attributed to the different possible syntactic orders of Arabic constructions confusing the syntactic subject with the object especially where there is no clear morphological features on the arguments to decide either way.

## 5 Conclusions

We have presented a model for Arabic SRL that yields a global SRL F<sub>1</sub> score of 82.17% by combining rich structured features and traditional attribute-value features derived from English SRL systems. The resulting system significantly improves previously reported results on the same task and dataset. This outcome is very promising given that the available data is small compared to the English data sets.

For future work, we would like to explore further explicit morphological features such as aspect tense and voice as well as richer POS tag sets such as those proposed in (Diab, 2007). Finally, we would like to experiment with automatic parses and different syntactic formalisms such as dependencies and shallow parses.

## Abstract

We describe an unsupervised approach to multi-document sentence-extraction based summarization for the task of producing biographies. We utilize Wikipedia to automatically construct a corpus of biographical sentences and TDT4 to construct a corpus of non-biographical sentences. We build a biographical-sentence classifier from these corpora and an SVM regression model for sentence ordering from the Wikipedia corpus. We evaluate our work on the DUC2004 evaluation data and with human judges. Overall, our system significantly outperforms all systems that participated in DUC2004, according to the ROUGE-L metric, and is preferred by human subjects.

## 1 Introduction

Producing biographies by hand is a labor-intensive task, generally done only for famous individuals. The process is particularly difficult when persons of interest are **not** well known and when information must be gathered from a wide variety of sources. We present an automatic, unsupervised, multi-document summarization (MDS) approach based on extractive techniques to producing biographies, answering the question “Who is X?”

There is growing interest in automatic MDS in general due in part to the explosion of multilingual and multimedia data available online. The goal of MDS is to automatically produce a concise, well-organized, and fluent summary of a set of documents on the same topic. MDS strategies have been

employed to produce both generic summaries and query-focused summaries. Due to the complexity of text generation, most summarization systems employ sentence-extraction techniques, in which the most relevant sentences from one or more documents are selected to represent the summary. This approach is guaranteed to produce grammatical sentences, although they must subsequently be ordered appropriately to produce a coherent summary.

In this paper we describe a sentence-extraction based MDS procedure to produce biographies from online resources automatically. We make use of Wikipedia, the largest free multilingual encyclopedia on the internet, to build a biographical-sentence classifier and a component for ordering sentences in the output summary. Section 2 presents an overview of our system. In Section 3 we describe our corpus and in Section 4 we discuss the components of our system in more detail. In Section 5, we present an evaluation of our work on the Document Understanding Conference of 2004 (DUC2004), the biography task (task 5) test set. In Section 6 we compare our research with previous work on biography generation. We conclude in Section 7 and identify directions for future research.

## 2 System Overview

In this section, we present an overview of our biography extraction system. We assume as input a set of documents retrieved by an information retrieval engine from a query consisting of the name of the person for whom the biography is desired. We further assume that these documents have been tagged with Named Entities (NE)s with coreferences resolved

using a system such as NYU’s 2005 ACE system (Grishman et al., 2005), which we used for our experiments. Our task is to produce a concise biography from these documents.

First, we need to select the most ‘important’ biographical sentences for the target person. To do so, we first extract from the input documents all sentences that contain some reference to the target person according to the coreference assignment algorithm; this reference may be the target’s name or a coreferential full NP or pronominal referring expression, such as *the President* or *he*. We call these sentences *hypothesis sentences*. We hypothesize that most ‘biographical’ sentences will contain a reference to the target. However, some of these sentences may be irrelevant to a biography; therefore, we filter them using a binary classifier that retains only ‘biographical’ sentences. These biographical sentences may also include redundant information; therefore, we cluster them and choose one sentence from each cluster to represent the information in that cluster. Since some of these sentences have more salient biographical information than others and since manually produced biographies tend to include information in a certain order, we reorder our summary sentences using an SVM regression model trained on biographies. Finally, the first reference to the target person in the initial sentence in the reordering is rewritten using the longest coreference in our hypothesis sentences which contains the target’s full name. We then trim the output to a threshold to produce a biography of a certain length for evaluation against the DUC2004 systems.

### 3 Training Data

One of the difficulties inherent in automatic biography generation is the lack of training data. One might collect training data by manually annotating a suitable corpus containing biographical and non-biographical data about a person, as in (Zhou et al., 2004). However, such annotation is labor intensive. To avoid this problem, we adopt an unsupervised approach. We use Wikipedia biographies as our corpus of ‘biographical’ sentences. We collect our ‘non-biographical’ sentences from the English newswire documents in the TDT4 corpus.<sup>1</sup> While each corpus

<sup>1</sup><http://projects.ldc.upenn.edu/TDT4>

may contain positive and negative examples, we assume that most sentences in Wikipedia biographies are biographical and that the majority of TDT4 sentences are non-biographical.

#### 3.1 Constructing the Biographical Corpus

To automatically collect our biographical sentences, we first download the xml version of Wikipedia and extract only the documents whose authors used the Wikipedia biography template when creating their biography. There are 16,906 biographies in Wikipedia that used this template. We next apply simple text processing techniques to clean the text. We select at most the first 150 sentences from each page, to avoid sentences that are not critically important to the biography. For each of these sentences we perform the following steps:

1. We identify the biography’s subject from its title, terming this name the ‘target person.’
2. We run NYU’s 2005 ACE system (Grishman et al., 2005) to tag NEs and do coreference resolution. There are 43 unique NE tags in our corpora, including *PER\_Individual*, *ORG\_Educational*, and so on, and TIMEX tags for all dates.
3. For each sentence, we replace each NE by its tag name and type ([name-type\_subtype]) as assigned by the NYU tagger. This modified sentence we term a *class-based/lexical sentence*.
4. Each non-pronominal referring expression (e.g., *George W. Bush, the US president*) that is tagged as coreferential with the target person is replaced by our own [TARGET\_PER] tag and every pronoun *P* that refers to the target person is replaced by [TARGET\_P], where *P* is the pronoun itself. This allows us to generalize our sentences while retaining a) the essential distinction between this NE (and its role in the sentence) and all other NEs in the sentence, and b) the form of referring expressions.
5. Sentences containing no reference to the target person are assumed to be irrelevant and removed from the corpus, as are sentences with

fewer than 4 tokens; short sentences are unlikely to contain useful information beyond the target reference.

For example, given sentences from the Wikipedia biography of Martin Luther King, Jr. we produce class-based/lexical sentences as follows:

Martin Luther King, Jr., was born on January 15, 1929, in Atlanta, Georgia. He was the son of Reverend Martin Luther King, Sr. and Alberta Williams King. He had an older sister, Willie Christine (September 11, 1927) and a younger brother, Albert Daniel.

[TARGET\_PER], was born on [TIMEX], in [GPE.PopulationCenter]. [TARGET\_HE] was the son of [PER\_Individual] and [PER\_Individual]. [TARGET\_HE] had an older sister, [PER\_Individual] ([TIMEX]) and a younger brother, [PER\_Individual].

### 3.2 Constructing the Non-Biographical Corpus

We use the TDT4 corpus to identify non-biographical sentences. Again, we run NYU’s 2005 ACE system to tag NEs and do coreference resolution on each news story in TDT4. Since we have no target name for these stories, we select an NE tagged as *PER\_Individual* at random from all NEs in the story to represent the target person. We exclude any sentence with no reference to this target person and produce class-based/lexical sentences as above.

## 4 Our Biography Extraction System

### 4.1 Classifying Biographical Sentences

Using the biographical and non-biographical corpora described in Section 3, we train a binary classifier to determine whether a new sentence should be included in a biography or not. For our experiments we extracted 30,002 sentences from Wikipedia biographies and held out 2,108 sentences for testing. Similarly, we extracted 23,424 sentences from TDT4, and held out 2,108 sentences for testing. For each sentence, we then extract the frequency of three class-based/lexical features — unigram, bigram, and trigram — and two POS features — the frequency of unigram and bigram POS. To reduce the dimensionality of our feature space, we first sort the features in decreasing order of Chi-square statistics computed from the contingency tables of the observed frequencies from the training data. We then take the highest 30-80% features, where the number of features used is determined empirically for

<i>Classifier</i>	<i>Accuracy</i>	<i>F-Measure</i>
<i>SVM</i>	87.6%	0.87
<i>M. naïve Bayes</i>	84.1%	0.84
<i>C4.5</i>	81.8%	0.82

Table 1: Binary classification results: Wikipedia biography class-based/lexical sentences vs. TDT4 class-based/lexical sentences

each feature type. This process identifies features that significantly contribute to the classification task. We extract 3K class-based/lexical unigrams, 5.5K bigrams, 3K trigrams, 20 POS unigrams, and 166 POS bigrams.

Using the training data described above, we experimented with three different classification algorithms using the Weka machine learning toolkit (Witten et al., 1999): multinomial naïve Bayes, SVM with linear kernel, and C4.5. Weka also provides a classification confidence score that represents how confident the classifier is on each classified sample, which we will make use of as well.

Table 1 presents the classification results on our 4,216 held-out test-set sentences. These results are quite promising. However, we should note that they may not necessarily represent the successful classification of biographical vs. non-biographical sentences but rather the classification of Wikipedia sentences vs. TDT4 sentences. We will validate these results for our full systems in Section 5.

### 4.2 Removing Redundant Sentences

Typically, redundancy removal is a standard component in MDS systems. In sentence-extraction based summarizers, redundant sentences are defined as those which include the same information without introducing new information and identified by some form of lexically-based clustering. We use an implementation of a single-link nearest neighbor clustering technique based on stem-overlap (Blair-Goldensohn et al., 2004b) to cluster the sentences classified as biographical by our classifier, and then select the sentence from each cluster that maximizes the confidence score returned by the classifier as the representative for that cluster.

### 4.3 Sentence Reordering

It is essential for MDS systems in the extraction framework to choose the order in which sentences

should be presented in the final summary. Presenting more important information earlier in a summary is a general strategy for most domains, although importance may be difficult to determine reliably. Similar to (Barzilay and Lee, 2004), we automatically learn how to order our biographical sentences by observing the typical order of presentation of information in a particular domain. We observe that our Wikipedia biographies tend to follow a general presentation template, in which birth information is mentioned before death information, information about current professional position and affiliations usually appear early in the biography, and nuclear family members are typically mentioned before more distant relations. Learning how to order information from these biographies however would require that we learn to identify particular types of biographical information in sentences.

We directly use the position of each sentence in each Wikipedia biography as a way of determining where sentences containing similar information about different target individuals should appear in their biographies. We represent the absolute position of each sentence in its biography as an integer and train an SVM regression model with RBF kernel, from the class/lexical features of the sentence to its position. We represent each sentence by a feature vector whose elements correspond to the frequency of unigrams and bigrams of class-based items (e.g., GPE, PER) (cf. Section 3) and lexical items; for example, the unigrams *born*, *became*, and *[GPE\_State-or-Province]*, and the bigrams *was born*, *[TARGET\_PER] died* and *[TARGET\_PER] joined* would be good candidates for such features.

To minimize the dimensionality of our regression space, we constrained our feature choice to those features that are important to distinguish biographical sentences, which we term **biographical terms**. Since we want these biographical terms to impact the regression function, we define these to be phrases that consist of at least one lexical item that occurs in many biographies but rarely more than once in any given biography. We compute the biographical term score as in the following equation:

$$bio\_score(t) = \frac{|D_t|}{|D|} \cdot \frac{\sum_{d \in D_t} (1 - \frac{n(t)_d}{\max_t(n(t)_d)})}{|D|} \quad (1)$$

where  $D$  is the set of 16,906 Wikipedia biographies,

$n(t)_d$  is the number of occurrences of term  $t$  in document  $d$ , and  $D_t = \{d \in D : t \in d\}$ . The left factor represents the document frequency of term  $t$ , and the right factor calculates how infrequent the term is in each biography that contains  $t$  at least once.<sup>2</sup> We order the unigrams and bigrams in the biographies by their biographical term scores and select the highest 1K unigrams and 500 bigrams; these thresholds were determined empirically.

#### 4.4 Reference Rewriting

We observe that news articles typically mention biographical information that occurs early in Wikipedia biographies when they mention individuals for the first time in a story (e.g. *Stephen Hawking, the Cambridge University physicist*). We take advantage of the fact that the coreference resolution system we use tags full noun phrases including appositives as part of NEs. Therefore, we initially search for the sentence that contains the longest identified NE (of type PER) that includes the target person’s full name and is coreferential with the target according to the reference resolution system; we denote this NE *NE-NP*. If this sentence has already been classified as a biographical sentence by our classifier, we simply boost its rank in the summary to first. Otherwise, when we order our sentences, we replace the reference to the target person in the first sentence by *NE-NP*. For example, if the first sentence in the biography we have produced for Jimmy Carter is *He was born in 1947* and a sentence not chosen for inclusion in our biography *Jimmy Carter, former U.S. President, visited the University of California last year* contains the *NE-NP*, and *Jimmy Carter* and *He* are coreferential, then the first sentence in our biography will be rewritten as *Jimmy Carter, former U.S. President, was born in 1947*. Note that, in the evaluations presented in Section 5, sentence order was modified by this process in only eight summaries.

## 5 Evaluation

To evaluate our biography generation system, we use the document sets created for the biography evalua-

<sup>2</sup>We considered various approaches to feature selection here, such as comparing term frequency between our biographical and non-biographical corpora. However, terms such as *killed* and *died*, which are useful biographical terms, also occur frequently in our non-biographical corpus.

Figure 1: Comparing our approaches against the top performing system in DUC2004 according to ROUGE-L (diamond).

tion (task 5) of DUC2004.<sup>3</sup> The task for systems participating in this evaluation was “*Given each document cluster and a question of the form “Who is X?”, where X is the name of a person or group of people, create a short summary (no longer than 665 bytes) of the cluster that responds to the question.*” NIST assessors chose 50 clusters of TREC documents such that all the documents in a given cluster provide at least part of the answer to this question. Each cluster contained on average 10 documents. NIST had 4 human summaries written for each cluster. A baseline summary was also created for each cluster by extracting the first 665 bytes of the most recent document in the cluster. 22 systems participated in the competition, producing a total of 22 automatic summaries (restricted to 665 bytes) for each cluster. We evaluate our system against the top performing of these 22 systems, according to ROUGE-L, which we denote *top-DUC2004*.<sup>4</sup>

### 5.1 Automatic Evaluation Using ROUGE

As noted in Section 4.1, we experimented with a number of learning algorithms when building our biographical-sentence classifier. For each machine learning algorithm tested, we build a system that initially classifies the input list of sentences into biographical and non-biographical sentences and then

removes redundant sentences. Next, we produce three versions of each system: one which implements a baseline ordering procedure, in which sentences from the clusters are ordered by their appearance in their source document (e.g. any sentence which occurred first in its original document is placed first in the summary, with ties ordered randomly within the set), a second which orders the biographical sentences by the confidence score obtained from the classifier, and a third which uses the SVM regression as the reordering component. Finally, we run our reference rewriting component on each and trim the output to 665 bytes.

We evaluate first using the ROUGE-L metric (Lin and Hovy, 2003) with a 95% (ROUGE computed) confidence interval for all systems and compared these to the ROUGE-L score of the best-performing DUC2004 system.<sup>5</sup> The higher the ROUGE score, the closer the summary is to the DUC2004 human reference summaries. As shown in Figure 1, our best performing system is the multinomial naïve Bayes classifier (MNB) using the classifier confidence scores to order the sentences in the biography. This system significantly outperforms the top ranked DUC2004 system (*top-DUC2004*).<sup>6</sup> The success of this particularly learning algorithm on our task may be due to: (1) the nature of our feature space – n-gram frequencies are modeled properly by a multinomial distribution; (2) the simplicity of this classifier particularly given our large feature dimensional-

<sup>3</sup><http://duc.nist.gov/duc2004>

<sup>4</sup>Note that this system out-performed 19 of the 22 systems on ROUGE-1 and 20 of 22 on ROUGE-L and ROUGE-W-1.2 ( $p < .05$ ) (Blair-Goldensohn et al., 2004a). No ROUGE metric produced scores where this system scored significantly worse than any other system. See Figure 2 below for a comparison of all DUC2004 systems with our top system where all systems are evaluated using ROUGE-L-1.5.5.

<sup>5</sup>We used the same version (1.5.5) of the ROUGE metric to compute scores for the DUC systems and baseline also.

<sup>6</sup>Significance for each pair of systems was determined by paired t-test and calculated at the .05 significance level.

ity; and (3) the robustness of naïve Bayes with respect to noisy data: Not all sentences in Wikipedia biographies are biographical sentences and some sentences in TDT4 *are* biographical.

While the SVM regression reordering component has a slight negative impact on the performance of the MNB system, the difference between the two versions is not significant. Note however, that both the C4.5 and the SVM versions of our system *are* improved by the SVM regression sentence reordering. While neither performs better than top-DUC2004 without this component, the C4.5 system with SVM reordering is significantly better than top-DUC2004 and the performance of the SVM system with SVM regression is comparable to top-DUC2004. In fact, when we use only the SVM regression model to rank the hypothesis sentences, **without** employing any classifier, then remove redundant sentences, rewrite and trim the results, we find that, interestingly, this approach also outperforms top-DUC2004, although the difference is not statistically significant. However, we believe that this is an area worth pursuing in future, with more sophisticated features.

The following biography of Brian Jones was produced by our MNB system and then the sentences were ordered using the SVM regression model:

Born in Bristol in 1947, Brian Jones, the co-pilot on the Breitling mission, learned to fly at 16, dropping out of school a year later to join the Royal Air Force. After earning his commercial balloon flying license, Jones became a ballooning instructor in 1989 and was certified as an examiner for balloon flight licenses by the British Civil Aviation Authority. He helped organize Breitling's most recent around-the-world attempts, in 1997 and 1998. Jones, 52, replaces fellow British flight engineer Tony Brown. Jones, who is to turn 52 next week, is actually the team's third co-pilot. After 13 years of service, he joined a catering business and, in the 1980s,...

Figure 2 illustrates the performance of our MNB system with classifier confidence score sentence ordering when compared to mean ROUGE-L-1.5.5 scores of DUC2004 human-generated summaries and the 22 DUC2004 systems' summaries across all summary tasks. Human summaries are labeled A-H, DUC2004 systems 1-22, and our MNB system is marked by the rectangle. Results are sorted by mean ROUGE-L score. Note that our system performance is actually comparable in ROUGE-L score to one of the human summary generators and is signif-

icantly better than all DUC2004 systems, including top-DUC2004, which is System 1 in the figure.

## 5.2 Manual Evaluation

ROUGE evaluation is based on n-gram overlap between the automatically produced summary and the human reference summaries. Thus, it is not able to measure how fluent or coherent a summary is. Sentence ordering is one factor in determining fluency and coherence. So, we conducted two experiments to measure these qualities, one comparing our top-performing system according to ROUGE-L score (MNB) vs. the top-performing DUC2004 system (top-DUC2004) and another comparing our top system with two different ordering methods, classifier-based and SVM regression.<sup>7</sup> In each experiment, summaries were trimmed to 665 bytes.

In the first experiment, three native American English speakers were presented with the 50 questions (Who is X?). For each question they were given a pair of summaries (presented in random order): one was the output of our MNB system and the other was the summary produced by the top-DUC2004 system. Subjects were asked to decide which summary was more responsive in form and content to the question or whether both were equally responsive. 85.3% (128/150) of subject judgments preferred one summary over the other. 100/128 (78.1%) of these judgments preferred the summaries produced by our MNB system over those produced by top-DUC2004. If we compute the majority vote, there were 42/50 summaries in which at least two subjects made the same choice. 37/42 (88.1%) of these majority judgments preferred our system's summary (using binomial test,  $p = 4.4e - 7$ ). We used the weighted kappa statistic with quadratic weighting (Cohen, 1968) to determine the inter-rater agreement, obtaining a mean pairwise  $\kappa$  of 0.441.

Recall from Section 5.1 that our SVM regression reordering component slightly decreases the average ROUGE score (although not significantly) for our MNB system. For our human evaluations, we decided to evaluate the quality of the presentation of our summaries with and without this compo-

<sup>7</sup>Note that top-DUC2004 was ranked sixth in the DUC 2004 **manual** evaluation, with **no** system performing significantly better for coverage and only 1 system performing significantly better for responsiveness.

Figure 2: ROUGE-L scores for DUC2004 human summaries (A-H), our MNB system (rectangle), and the DUC2004 competing systems (1-22 anonymized), with the baseline system labeled BL.

ment to see if this reordering component affected human judgments even if it did not improve ROUGE scores. For each question, we produced two summaries from the sentences classified as biographical by the MNB classifier, one ordered by the confidence score obtained by the MNB, in decreasing order, and the other ordered by the SVM regression values, in increasing order. Note that, in three cases, the summary sentences were ordered identically by both procedures, so we used only 47 summaries for this evaluation. Three (different) native American English speakers were presented with the 47 questions for which sentence ordering differed. For each question they were given the two summaries (presented in random order) and asked to determine which biography they preferred.

We found inter-rater agreement for these judgments using Fleiss’ kappa (Fleiss, 1971) to be only moderate ( $\kappa=0.362$ ). However, when we computed the majority vote for each question, we found that 61.7% (29/47) preferred the SVM regression ordering over the MNB classifier confidence score ordering. Although this difference is not statistically significant, again we find the SVM regression ordering results encouraging enough to motivate our further research on improving such ordering procedures.

## 6 Related Work

The DUC2004 system achieving the highest overall ROUGE score, our top-DUC2004 in Section 5, was Blair-Goldensohn et al. (2004a)’s DefScriber, which treats “Who is X?” as a definition question and targets definitional themes (e.g. genus-species)

found in the input document collections which include references to the target person. Extracted sentences are then rewritten using a reference rewriting system (Nenkova and McKeown, 2003) which attempts to shorten subsequent references to the target. Sentences are ordered in the summary based on a weighted combination of topic centrality, lexical cohesion, and topic coverage scores. A similar approach is explored in Biryukov et al. (2005), which uses Topic Signatures (Lin and Hovy, 2000) constructed around the target individual’s name to identify sentences to be included in the biography.

Zhou et al. (2004)’s biography generation system, like ours, trains biographical and non-biographical sentence classifiers to select sentences to be included in the biography. Their system is trained on a hand-annotated corpus of 130 biographies of 12 people, tagged with 9 biographical elements (e.g., bio, education, nationality) and uses binary unigram and bigram lexical and unigram part-of-speech features for classification. Duboue et al. (2003) also address the problem of learning content selection rules for biography. They learn rules from two corpora, a semi-structured corpus with lists of biographical facts about show business celebrities and a corpus of free-text biographies about the same celebrities.

Filatova et al. (2005) learn text features typical of biographical descriptions by deducing biographical and occupation-related activities automatically by comparing descriptions of people with different occupations. Weischedel et al. (2004) models kernel-fact features typical for biographies using linguistic and semantic processing. Linguistic features

are derived from predicate-argument structures deduced from parse trees, and semantic features are the set of biography-related relations and events defined in the ACE guidelines (Dodgington et al., 2004). Sentences containing kernel facts are ranked using probabilities estimated from a corpus of manually created biographies, including Wikipedia, to estimate the conditional distribution of relevant material given a kernel fact and a background corpus.

The problem of ordering sentences and preserving coherence in MDS is addressed by Barzilay et al. (2001), who combine chronological ordering of events with cohesion metrics. SVM regression has recently been used by (Li et al., 2007) for sentence ranking for general MDS. The authors calculated a similarity score for each sentence to the human summaries and then regress numeric features (e.g., the centroid) from each sentence to this score. Barzilay and Lee (2004) use HMMs to capture topic shift within a particular domain; sequence of topic shifts then guides the subsequent ordering of sentences within the summary.

## 7 Discussion and Future Work

In this paper, we describe a MDS system for producing biographies, given a target name. We present an unsupervised approach using Wikipedia biography pages and a general news corpus (TDT4) to automatically construct training data for our system. We employ a NE tagger and a coreference resolution system to extract class-based and lexical features from each sentence which we use to train a binary classifier to identify biographical sentences. We also train an SVM regression model to reorder the sentences and then employ a rewriting heuristic to create the final summary.

We compare versions of our system based upon three machine learning algorithms and two sentence reordering strategies plus a baseline. Our best performing system uses the multinomial naïve Bayes (MNB) classifier with classifier confidence score reordering. However, our SVM regression reordering improves summaries produced by the other two classifiers and is preferred by human judges. We compare our MNB system on the DUC2004 biography task (task 5) to other DUC2004 systems and to human-generated summaries. Our system

out-performs all DUC2004 systems significantly, according to ROUGE-L-1.5.5. When presented with summaries produced by our system and summaries produced by the best-performing (according to ROUGE scores) of the DUC2004 systems, human judges (majority vote of 3) prefer our system’s biographies in 88.1% of cases.

In addition to its high performance, our approach has the following advantages: It employs no manual annotation but relies upon identifying appropriately different corpora to represent our training corpus. It employs class-based as well as lexical features where the classes are obtained automatically from an ACE NE tagger. It utilizes automatic coreference resolution to identify sentences containing references to the target person. Our sentence reordering approaches make use of either classifier confidence scores or ordering learned automatically from the actual ordering of sentences in Wikipedia biographies to determine the order of presentation of sentences in our summaries.

Since our task is to produce concise summaries, one focus of our future research will be to simplify the sentences we extract before classifying them as biographical or non-biographical. This procedure should also help to remove irrelevant information from sentences. Recall that our SVM regression model for sentence ordering was trained using only biographical class-based/lexical items. In future, we would also like to experiment with more linguistically-informed features. While Wikipedia does not enforce any particular ordering of information in biographies, and while different biographies may emphasize different types of information, it would appear that the success of our automatically derived ordering procedures may capture some underlying shared view of how biographies are written. The same underlying views may also apply to domains such as organization descriptions or types of historical events. In future we plan to explore such a generalization of our procedures to such domains.

## Abstract

In this paper, we present a study of a novel summarization problem, i.e., summarizing the impact of a scientific publication. Given a paper and its citation context, we study how to extract sentences that can represent the most influential content of the paper. We propose language modeling methods for solving this problem, and study how to incorporate features such as authority and proximity to accurately estimate the impact language model. Experiment results on a SIGIR publication collection show that the proposed methods are effective for generating impact-based summaries.

## 1 Introduction

The volume of scientific literature has been growing rapidly. From recent statistics, each year 400,000 new citations are added to MEDLINE, the major biomedical literature database<sup>1</sup>. This fast growth of literature makes it difficult for researchers, especially beginning researchers, to keep track of the research trends and find high impact papers on unfamiliar topics.

Impact factors (Kaplan and Nelson, 2000) are useful, but they are just numerical values, so they cannot tell researchers which aspects of a paper are influential. On the other hand, a regular content-based summary (e.g., the abstract or conclusion section of a paper or an automatically generated topical summary (Giles et al., 1998)) can help a user know

about the main content of a paper, but not necessarily the most influential content of the paper. Indeed, the abstract of a paper mostly reflects the expected impact of the paper as perceived by the author(s), which could significantly deviate from the actual impact of the paper in the research community. Moreover, the impact of a paper changes over time due to the evolution and progress of research in a field. For example, an algorithm published a decade ago may be no longer the state of the art, but the problem definition in the same paper can be still well accepted.

Although much work has been done on text summarization (See Section 6 for a detailed survey), to the best of our knowledge, the problem of impact summarization has not been studied before. In this paper, we study this novel summarization problem and propose language modeling-based approaches to solving the problem. By definition, the impact of a paper has to be judged based on the consent of research community, especially by people who cited it. Thus in order to generate an impact-based summary, we must use not only the original content, but also the descriptions of that paper provided in papers which cited it, making it a challenging task and different from a regular summarization setup such as news summarization. Indeed, unlike a regular summarization system which identifies and interprets the *topic* of a document, an impact summarization system should identify and interpret the *impact* of a paper.

We define the impact summarization problem in the framework of extraction-based text summarization (Luhn, 1958; McKeown and Radev, 1995), and cast the problem as an impact sentence retrieval

<sup>1</sup><http://www.nlm.nih.gov/bsd/history/tsld024.htm>

problem. We propose language models to exploit both the citation context and original content of a paper to generate an impact-based summary. We study how to incorporate features such as authority and proximity into the estimation of language models. We propose and evaluate several different strategies for estimating the impact language model, which is key to impact summarization. No existing test collection is available for evaluating impact summarization. We construct a test collection using 28 years of ACM SIGIR papers (1978 - 2005) to evaluate the proposed methods. Experiment results on this collection show that the proposed approaches are effective for generating impact-based summaries. The results also show that using both the original document content and the citation contexts is important and incorporating citation authority and proximity is beneficial.

An impact-based summary is not only useful for facilitating the exploration of literature, but also helpful for suggesting query terms for literature retrieval, understanding the evolution of research trends, and identifying the interactions of different research fields. The proposed methods are also applicable to summarizing the impact of documents in other domains where citation context exists, such as emails and weblogs.

The rest of the paper is organized as follows. In Section 2 and 3, we define the impact-based summarization problem and propose the general language modeling approach. In Section 4, we present different strategies and features for estimating an impact language model, a key challenge in impact summarization. We discuss our experiments and results in Section 5. Finally, the related work and conclusions are discussed in Section 6 and Section 7.

## 2 Impact Summarization

Following the existing work on topical summarization of scientific literature (Paice, 1981; Paice and Jones, 1993), we define an impact-based summary of a paper as a set of sentences extracted from a paper that can reflect the impact of the paper, where “impact” is roughly defined as the influence of the paper on research of similar or related topics as reflected in the citations of the paper. Such an extraction-based definition of summarization has

also been quite common in most existing general summarization work (Radev et al., 2002).

By definition, in order to generate an impact summary of a paper, we must look at how other papers cite the paper, use this information to infer the impact of the paper, and select sentences from the original paper that can reflect the inferred impact. Note that we do not directly use the sentences from the citation context to form a summary. This is because in citations, the discussion of the paper cited is usually mixed with the content of the paper citing it, and sometimes also with discussion about other papers cited (Siddharthan and Teufel, 2007).

Formally, let  $d = (s_0, s_1, \dots, s_n)$  be a paper to be summarized, where  $s_i$  is a sentence. We refer to a sentence (in another paper) in which there is an explicit citation of  $d$  as a *citing sentence* of  $d$ . When a paper is cited, it is often discussed consecutively in more than one sentence near the citation, thus intuitively we would like to consider a window of sentences centered at a citing sentence; the window size would be a parameter to set. We call such a window of sentences a *citation context*, and use  $C$  to denote the union of all the citation contexts of  $d$  in a collection of research papers. Thus  $C$  itself is a set (more precisely bag) of sentences. The task of **impact-based summarization** is thus to 1) construct a representation of the impact of  $d$ ,  $I$ , based on  $d$  and  $C$ ; 2) design a scoring function  $Score(.)$  to rank sentences in  $d$  based on how well a sentence reflects  $I$ . A user-defined number of top-ranked sentences can then be selected as the impact summary for  $d$ .

The formulation above immediately suggests that we can cast the impact summarization problem as a retrieval problem where each candidate sentence in  $d$  is regarded as a “document,” the impact of the paper (i.e.,  $I$ ) as a “query,” and our goal is to “retrieve” sentences that can reflect the impact of the paper as indicated by the citation context. Looking at the problem in this way, we see that there are two main challenges in impact summarization: first, we must be able to *infer* the impact based on both the citation contexts and the original document; second, we should measure how well a sentence reflects this inferred impact. To solve these challenges, in the next section, we propose to model impact with unigram language models and score sentences using

Kullback-Leibler divergence. We further propose methods for estimating the impact language model based on several features including the authority of citations, and the citation proximity.

### 3 Language Models for Impact Summarization

#### 3.1 Impact language models

From the retrieval perspective, our collection is the paper to be summarized, and each sentence is a “document” to be retrieved. However, unlike in the case of ad hoc retrieval, we do not really have a query describing the impact of the paper; instead, we have a lot of citation contexts that can be used to infer information about the query. Thus the main challenge in impact summarization is to effectively construct a “virtual impact query” based on the citation contexts.

What should such a virtual impact query look like? Intuitively, it should model the impact-reflecting content of the paper. We thus propose to represent such a virtual impact query with a unigram language model. Such a model is expected to assign high probabilities to those words that can describe the impact of paper  $d$ , just as we expect a query language model in ad hoc retrieval to assign high probabilities to words that tend to occur in relevant documents (Ponte and Croft, 1998). We call such a language model the *impact language model* of paper  $d$  (denoted as  $\theta_I$ ); it can be estimated based on both  $d$  and its citation context  $C$  as will be discussed in Section 4.

#### 3.2 KL-divergence scoring

With the impact language model in place, we can then adopt many existing probabilistic retrieval models such as the classical probabilistic retrieval models (Robertson and Sparck Jones, 1976) and the Kullback-Leibler (KL) divergence retrieval model (Lafferty and Zhai, 2001; Zhai and Lafferty, 2001a), to solve the problem of impact summarization by scoring sentences based on the estimated impact language model. In our study, we choose to use the KL-divergence scoring method to score sentences as this method has performed well for regular ad hoc retrieval tasks (Zhai and Lafferty, 2001a) and has an information theoretic interpretation.

To apply the KL-divergence scoring method, we assume that a candidate sentence  $s$  is generated from a sentence language model  $\theta_s$ . Given  $s$  in  $d$  and the citation context  $C$ , we would first estimate  $\theta_s$  based on  $s$  and estimate  $\theta_I$  based on  $C$ , and then score  $s$  with the negative KL divergence of  $\theta_s$  and  $\theta_I$ . That is,

$$\begin{aligned} \text{Score}(s) &= -D(\theta_I|\theta_s) \\ &= \sum_{w \in V} p(w|\theta_I) \log p(w|\theta_s) - \sum_{w \in V} p(w|\theta_I) \log p(w|\theta_I) \end{aligned}$$

where  $V$  is the set of words in our vocabulary and  $w$  denotes a word.

From the information theoretic perspective, the KL-divergence of  $\theta_s$  and  $\theta_I$  can be interpreted as measuring the average number of bits wasted in compressing messages generated according to  $\theta_I$  (i.e., impact descriptions) with coding non-optimally designed based on  $\theta_s$ . If  $\theta_s$  and  $\theta_I$  are very close, the KL-divergence would be small and  $\text{Score}(s)$  would be high, which intuitively makes sense. Note that the second term (entropy of  $\theta_I$ ) is independent of  $s$ , so it can be ignored for ranking  $s$ .

We see that according to the KL-divergence scoring method, our main tasks are to estimate  $\theta_s$  and  $\theta_I$ . Since  $s$  can be regarded as a short document, we can use any standard method to estimate  $\theta_s$ . In this work, we use Dirichlet prior smoothing (Zhai and Lafferty, 2001b) to estimate  $\theta_s$  as follows:

$$p(w|\theta_s) = \frac{c(w, s) + \mu_s * P(w|D)}{|s| + \mu_s} \quad (1)$$

where  $|s|$  is the length of  $s$ ,  $c(w, s)$  is the count of word  $w$  in  $s$ ,  $p(w|D)$  is a background model estimated using  $\frac{c(w, D)}{\sum_{w' \in V} c(w', D)}$  ( $D$  can be the set of all the papers available to us) and  $\mu_s$  is a smoothing parameter to be empirically set. Note that as the length of a sentence is very short, smoothing is critical for addressing the data sparseness problem.

The remaining challenge is to estimate  $\theta_I$  accurately based on  $d$  and its citation contexts.

### 4 Estimation of Impact Language Models

Intuitively, the impact of a paper is mostly reflected in the citation context. Thus the estimation of the impact language model should be primarily based on the citation context  $C$ . However, we would like

our impact model to be able to help us select impact-reflecting sentences from  $d$ , thus it is important for the impact model to explain well the paper content in general. To achieve this balance, we treat the citation context  $C$  as prior information and the current document  $d$  as the observed data, and use Bayesian estimation to estimate the impact language model.

Specifically, let  $p(w|C)$  be a citation context language model estimated based on the citation context  $C$ . We define Dirichlet prior with parameters  $\{\mu_C p(w|C)\}_{w \in V}$  for the impact model, where  $\mu_C$  encodes our confidence on this prior and effectively serves as a weighting parameter for balancing the contribution of  $C$  and  $d$  for estimating the impact model. Given the observed document  $d$ , the posterior mean estimate of the impact model would be (MacKay and Peto, 1995; Zhai and Lafferty, 2001b)

$$P(w|\theta_I) = \frac{c(w, d) + \mu_C p(w|C)}{|d| + \mu_C} \quad (2)$$

$\mu_C$  can be interpreted as the equivalent sample size of our prior. Thus setting  $\mu_C = |d|$  means that we put equal weights on the citation context and the document itself.  $\mu_C = 0$  yields  $p(w|\theta_I) = p(w|d)$ , which is to say that the impact is entirely captured by the paper itself, and our impact summarization problem would then become the standard single document (topical) summarization. Intuitively though, we would want to set  $\mu_C$  to a relatively large number to exploit the citation context in our estimation, which is confirmed in our experiments.

An alternative way is to simply interpolate  $p(w|d)$  and  $p(w|C)$  with a constant coefficient:

$$p(w|\theta_I) = (1 - \delta)p(w|d) + \delta p(w|C) \quad (3)$$

We will compare the two strategies in Section 5.

How do we estimate  $p(w|C)$ ? Intuitively, words occurring in  $C$  frequently should have high probabilities. A simple way is to pool together all the sentences in  $C$  and use the maximum likelihood estimator,

$$p(w|C) = \frac{\sum_{s \in C} c(w, s)}{\sum_{w' \in V} \sum_{s' \in C} c(w', s')} \quad (4)$$

where  $c(w, s)$  is the count of  $w$  in  $s$ .

One deficiency of this simple estimate is that we treat all the (extended) citation sentences equally.

However, there are at least two reasons why we want to assign unequal weights to different citation sentences: (1) A sentence closer to the citation label should contribute more than one far away. (2) A sentence occurring in a highly authoritative paper should contribute more than that in a less authoritative paper. To capture these two heuristics, we define a weight coefficient  $\alpha_s$  for a sentence  $s$  in  $C$  as follows:

$$\alpha_s = pg(s)pr(s)$$

where  $pg(s)$  is an authority score of the paper containing  $s$  and  $pr(s)$  is a proximity score that rewards a sentence close to the citation label.

For example,  $pg(s)$  can be the PageRank value (Brin and Page, 1998) of the document with  $s$ , which measures the authority of the document based on a citation graph, and is computed as follows: We construct a directed graph from the collection of scientific literature with each paper as a vertex and each citation as a directed edge pointing from the citing paper to the cited paper. We can then use the standard PageRank algorithm (Brin and Page, 1998) to compute a PageRank value for each document. We used this approach in our experiments.

We define  $pr(s)$  as  $pr(s) = \frac{1}{\alpha^k}$ , where  $k$  is the distance (counted in terms of the number of sentences) between sentence  $s$  and the center sentence of the window containing  $s$ ; by ‘‘center sentence’’, we mean the citing sentence containing the citation label. Thus the sentence with the citation label will have a proximity of 1 (because  $k = 0$ ), while the sentences away from the citation label will have a decaying weight controlled by parameter  $\alpha$ .

With  $\alpha_s$ , we can then use the following ‘‘weighted’’ maximum likelihood estimate for the impact language model:

$$p(w|C) = \frac{\sum_{s \in C} \alpha_s c(w, s)}{\sum_{w' \in V} \sum_{s' \in C} \alpha_{s'} c(w', s')} \quad (5)$$

As we will show in Section 5, this weighted maximum likelihood estimate performs better than the simple maximum likelihood estimate, and both  $pg(s)$  and  $pr(s)$  are useful.

## 5 Experiments and Results

### 5.1 Experiment Design

#### 5.1.1 Test set construction

Because no existing test set is available for evaluating impact summarization, we opt to create a test set based on 28 years of ACM SIGIR papers (1978 - 2005) available through the ACM Digital Library<sup>2</sup> and the SIGIR membership. Leveraging the explicit citation information provided by ACM Digital Library, for each of the 1303 papers, we recorded all other papers that cited the paper and extracted the citation context from these citing papers. Each citation context contains 5 sentences with 2 sentences before and after the citing sentence.

Since a low-impact paper would not be useful for evaluating impact summarization, we took all the 14 papers from the SIGIR collection that have no less than 20 citations by papers in the same collection as candidate papers for evaluation. An expert in Information Retrieval field read each paper and its citation context, and manually created an impact-based summary by selecting all the “impact-capturing” sentences from the paper. Specifically, the expert first attempted to understand the most influential content of a paper by reading the citation contexts. The expert then read each sentence of the paper and made a decision whether the sentence covers some “influential content” as indicated in the citation contexts. The sentences that were decided as covering some influential content were then collected as the gold standard impact summary for the paper.

We assume that the title of a paper will always be included in the summary, so we excluded the title both when constructing the gold standard and when generating a summary. The gold standard summaries have a minimum length of 5 sentences and a maximum length of 18 sentences; the median length is 9 sentences. These 14 impact-based summaries are used as gold standards for our experiments, based on which all summaries generated by the system are evaluated. This data set is available at <http://timan.cs.uiuc.edu/data/impact.html>. We must admit that using only 14 papers and only one expert for evaluation is a limitation of our work. However,

<sup>2</sup><http://www.acm.org/dl>

going beyond the 14 papers would risk reducing the reliability of impact judgment due to the sparseness of citations. How to develop a better test collection is an important future direction.

#### 5.1.2 Evaluation Metrics

Following the current practice in evaluating summarization, particularly DUC<sup>3</sup>, we use the ROUGE evaluation package (Lin and Hovy, 2003). Among ROUGE metrics, ROUGE-N (models n-gram co-occurrence,  $N = 1, 2$ ) and ROUGE-L (models longest common sequence) generally perform well in evaluating both single-document summarization and multi-document summarization (Lin and Hovy, 2003). Since they are general evaluation measures for summarization, they are also applicable to evaluating the MEAD-Doc+Cite baseline method to be described below. Thus although we evaluated our methods with all the metrics provided by ROUGE, we only report ROUGE-1 and ROUGE-L in this paper (other metrics give very similar results).

#### 5.1.3 Baseline methods

Since impact summarization has not been previously studied, there is no natural baseline method to compare with. We thus adapt some state-of-the-art conventional summarization methods implemented in the MEAD toolkit (Radev et al., 2003)<sup>4</sup> to obtain three baseline methods: (1) **LEAD**: It simply extracts sentences from the beginning of a paper, i.e., sentences in the abstract or beginning of the introduction section; we include **LEAD** to see if such “leading sentences” reflect the impact of a paper as authors presumably would expect to summarize a paper’s contributions in the abstract. (2) **MEAD-Doc**: It uses the single-document summarizer in MEAD to generate a summary based solely on the original paper; comparison with this baseline can tell us how much better we can do than a conventional topic-based summarizer that does not consider the citation context. (3) **MEAD-Doc+Cite**: Here we concatenate all the citation contexts in a paper to form a “citation document” and then use the MEAD multidocument summarizer to generate a summary from the original paper plus all its citation documents; this baseline represents a reasonable way

<sup>3</sup><http://duc.nist.gov/>

<sup>4</sup><http://www.summarization.com/mead/>

Sum. Length	Metric	Random	LEAD	MEAD-Doc	MEAD-Doc+Cite	KL-Divergence
3	ROUGE-1	0.163	0.167	0.301*	0.248	<b>0.323</b>
3	ROUGE-L	0.144	0.158	0.265	0.217	<b>0.299</b>
5	ROUGE-1	0.230	0.301	0.401	0.333	<b>0.467</b>
5	ROUGE-L	0.214	0.292	0.362	0.298	<b>0.444</b>
10	ROUGE-1	0.430	0.514	0.575	0.472	<b>0.649</b>
10	ROUGE-L	0.396	0.494	0.535	0.428	<b>0.622</b>
15	ROUGE-1	0.538	0.610	0.685	0.552	<b>0.730</b>
15	ROUGE-L	0.499	0.586	0.650	0.503	<b>0.705</b>

Table 1: Performance Comparison of Summarizers

of applying an existing summarization method to generate an impact-based summary. Note that this method may extract sentences in the citation contexts but not in the original paper.

## 5.2 Basic Results

We first show some basic results of impact summarization in Table 1. They are generated using constant coefficient interpolation for the impact language model (i.e., Equation 3) with  $\delta = 0.8$ , weighted maximum likelihood estimate for the citation context model (i.e., Equation 5) with  $\alpha = 3$ , and  $\mu_s = 1,000$  for candidate sentence smoothing (Equation 1). These results are not necessarily optimal as will be seen when we examine parameter and method variations.

From Table 1, we see clearly that our method consistently outperforms all the baselines. Among the baselines, MEAD-Doc is consistently better than both LEAD and MEAD-Doc+Cite. While MEAD-Doc’s outperforming LEAD is not surprising, it is a bit surprising that MEAD-Doc also outperforms MEAD-Doc+Cite as the latter uses both the citation context and the original document. One possible explanation may be that MEAD is not designed for impact summarization and it has been trapped by the distracting content in the citation context<sup>5</sup>. Indeed, this can also explain why MEAD-Doc+Cite tends to perform worse than LEAD by ROUGE-L since if MEAD-Doc+Cite picks up sentences from the citation context rather than the original papers, it would not match as well with the gold standard as LEAD which selects sentences from the origi-

<sup>5</sup>One anonymous reviewer suggested an interesting improvement to the MEAD-Doc+Cite baseline, in which we would first extract sentences from the citation context and then for each extracted sentence find a similar one in the original paper. Unfortunately, we did not have time to test this approach before the deadline for the camera-ready version of this paper.

nal papers. These results thus show that conventional summarization techniques are inadequate for impact summarization, and the proposed language modeling methods are more effective for generating impact-based summaries.

In Table 2, we show a sample impact-based summary and the corresponding MEAD-Doc regular summary. We see that the regular summary tends to have general sentences about the problem, background and techniques, not very informative in conveying specific contributions of the paper. None of these sentences was selected by the human expert. In contrast, the sentences in the impact summary cover several details of the impact of the paper (i.e., specific smoothing methods especially Dirichlet prior, sensitivity of performance to smoothing, and dual role of smoothing), and sentences 4 and 6 are also among the 8 sentences picked by the human expert. Interestingly, neither sentence is in the abstract of the original paper, suggesting a deviation of the actual impact of a paper and that perceived by the author(s).

## 5.3 Component analysis

We now turn to examine the effectiveness of each component in the proposed methods and different strategies for estimating  $\theta_I$ .

**Effectiveness of interpolation:** We hypothesized that we need to use both the original document and the citation context to estimate  $\theta_I$ . To test this hypothesis, we compare the results of using only  $d$ , only the citation context, and interpolation of them in Table 3. We show two different strategies of interpolation (i.e., constant coefficient with  $\delta = 0.8$  and Dirichlet with  $\mu_c = 20,000$ ) as described in Section 4.

From Table 3, we see that both strategies of interpolation indeed outperform using either the origi-

Impact-based summary:
1. Figure 5: Interpolation versus backoff for Jelinek-Mercer (top), Dirichlet smoothing (middle), and absolute discounting (bottom).
2. Second, one can de-couple the two different roles of smoothing by adopting a two stage smoothing strategy in which Dirichlet smoothing is first applied to implement the estimation role and Jelinek-Mercer smoothing is then applied to implement the role of query modeling
3. We find that the backoff performance is more sensitive to the smoothing parameter than that of interpolation, especially in Jelinek-Mercer and Dirichlet prior.
4. We then examined three popular interpolation-based smoothing methods (Jelinek-Mercer method, Dirichlet priors, and absolute discounting), as well as their backoff versions, and evaluated them using several large and small TREC retrieval testing collections.
summary 5. By rewriting the query-likelihood retrieval model using a smoothed document language model, we derived a general retrieval formula where the smoothing of the document language model can be interpreted in terms of several heuristics used intraditional models, including TF-IDF weighting and document length normalization.
6. We find that the retrieval performance is generally sensitive to the smoothing parameters, suggesting that an understanding and appropriate setting of smoothing parameters is very important in the language modeling approach.
Regular summary (generated using MEAD-Doc):
1. Language modeling approaches to information retrieval are attractive and promising because they connect the problem of retrieval with that of language model estimation, which has been studied extensively in other application areas such as speech recognition.
2. The basic idea of these approaches is to estimate a language model for each document, and then rank documents by the likelihood of the query according to the estimated language model.
3. On the one hand, theoretical studies of an underlying model have been developed; this direction is, for example, represented by the various kinds of logic models and probabilistic models (e.g., [14, 3, 15, 22]).
4. After applying the Bayes' formula and dropping a document-independent constant (since we are only interested in ranking documents), we have $p(d q) \propto (q d)p(d)$ .
5. As discussed in [1], the righthand side of the above equation has an interesting interpretation, where, $p(d)$ is our prior belief that $d$ is relevant to any query and $p(q d)$ is the query likelihood given the document, which captures how well the document "fits" the particular query $q$ .
6. The probability of an unseen word is typically taken as being proportional to the general frequency of the word, e.g., as computed using the document collection.

Table 2: Impact-based summary vs. regular summary for the paper "A study of smoothing methods for language models applied to ad hoc information retrieval".

nal document model ( $p(w|d)$ ) or the citation context model ( $p(w|C)$ ) alone, which confirms that both the original paper and the citation context are important for estimating  $\theta_I$ . We also see that using the citation context alone is better than using the original paper alone, which is expected. Between the two strategies, Dirichlet dynamic coefficient is slightly better than constant coefficient (CC), after optimizing the interpolation parameter for both strategy.

Measure	$P(w d)$	$P(w C)$	Interpolation	
			ConstCoef	Dirichlet
ROUGE-1	0.529	0.635	0.643	<b>0.647</b>
ROUGE-L	0.501	0.607	0.619	<b>0.623</b>

Table 3: Effectiveness of interpolation

**Citation authority and proximity:** These heuristics are very interesting to study as they are unique to impact summarization and not well studied in the existing summarization work.

pg(s)	pr(s) off	pr(s)=1/ $\alpha^k$		
		$\alpha = 2$	$\alpha = 3$	$\alpha = 4$
<b>Off</b>	0.685	0.711	0.714	0.700
<b>On</b>	0.708	0.712	0.706	0.703

Table 4: Authority (pg(s)) and proximity (pr(s))

In Table 4, we show the ROUGE-L values for various combinations of these two heuristics (summary length is 15). We turn off either  $pg(s)$  or  $pr(s)$  by setting it to a constant; when both are turned off, we have the unweighted MLE of  $p(w|C)$  (Equation 4). Clearly, using weighted MLE with any of the two heuristics is better than the unweighted MLE, indicating that both heuristics are effective. However, combining the two heuristics does not always improve over using a single one. Since intuitively these two heuristics are orthogonal, this may suggest that our way of combining the two scores (i.e., taking a product of them) may not be optimal; further study is needed to better understand this. The ROUGE-1 results are similar.

**Tuning of other parameters:** There are three other parameters which need to be tuned: (1)  $\mu_s$  for candidate sentence smoothing (Equation 1); (2)  $\mu_c$  in Dirichlet interpolation for impact model estimation (Equation 2); and (3)  $\delta$  in constant coefficient interpolation (Equation 3). We have examined the sensitivity of performance to these parameters. In general, for a wide range of values of these parameters, the performance is relatively stable and near optimal. Specifically, the performance is near optimal as

long as  $\mu_s$  and  $\mu_c$  are sufficiently large ( $\mu_s \geq 1000$ ,  $\mu_c \geq 20,000$ ), and the interpolation parameter  $\delta$  is between 0.4 and 0.9.

## 6 Related Work

General text summarization, including single document summarization (Luhn, 1958; Goldstein et al., 1999) and multi-document summarization (Kraaij et al., 2001; Radev et al., 2003) has been well studied; our work is under the framework of extractive summarization (Luhn, 1958; McKeown and Radev, 1995; Goldstein et al., 1999; Kraaij et al., 2001), but our problem formulation differs from any existing formulation of the summarization problem. It differs from regular single-document summarization because we utilize extra information (i.e. citation contexts) to summarize the impact of a paper. It also differs from regular multi-document summarization because the roles of original documents and citation contexts are not equivalent. Specifically, citation contexts serve as an indicator of the impact of the paper, but the summary is generated by extracting the sentences from the original paper.

Technical paper summarization has also been studied (Paice, 1981; Paice and Jones, 1993; Saggion and Lapalme, 2002; Teufel and Moens, 2002), but the previous work did not explore citation context to emphasize the impact of papers.

Citation context has been explored in several studies (Nakov et al., 2004; Ritchie et al., 2006; Schwartz et al., 2007; Siddharthan and Teufel, 2007). However, none of the previous studies has used citation context in the same way as we did, though the potential of *directly* using citation sentences (called *citances*) to summarize a paper was pointed out in (Nakov et al., 2004).

Recently, people have explored various types of auxiliary knowledge such as hyperlinks (Delort et al., 2003) and clickthrough data (Sun et al., 2005), to summarize a webpage; such work is related to ours as anchor text is similar to citation context, but it is based on a standard formulation of multi-document summarization and would contain only sentences from anchor text.

Our work is also related to work on using language models for retrieval (Ponte and Croft, 1998; Zhai and Lafferty, 2001b; Lafferty and Zhai, 2001)

and summarization (Kraaij et al., 2001). However, we do not have an explicit query and constructing the impact model is a novel exploration. We also proposed new language models to capture the impact.

## 7 Conclusions

We have defined and studied the novel problem of summarizing the impact of a research paper. We cast the problem as an impact sentence retrieval problem, and proposed new language models to model the impact of a paper based on both the original content of the paper and its citation contexts in a literature collection with consideration of citation authority and proximity.

To evaluate impact summarization, we created a test set based on ACM SIGIR papers. Experiment results on this test set show that the proposed impact summarization methods are effective and outperform several baselines that represent the existing summarization methods.

An important future work is to construct larger test sets (e.g., of biomedical literature) to facilitate evaluation of impact summarization. Our formulation of the impact summarization problem can be further improved by going beyond sentence retrieval and considering factors such as redundancy and coherency to better organize an impact summary. Finally, automatically generating impact-based summaries can not only help users access and digest influential research publications, but also facilitate other literature mining tasks such as milestone mining and research trend monitoring. It would be interesting to explore all these applications.

## Abstract

Different summarization requirements could make the writing of a good summary more difficult, or easier. Summary length and the characteristics of the input are such constraints influencing the quality of a potential summary. In this paper we report the results of a quantitative analysis on data from large-scale evaluations of multi-document summarization, empirically confirming this hypothesis. We further show that features measuring the cohesiveness of the input are highly correlated with eventual summary quality and that it is possible to use these as features to predict the difficulty of new, unseen, summarization inputs.

## 1 Introduction

In certain situations even the best automatic summarizers or professional writers can find it hard to write a good summary of a set of articles. If there is no clear topic shared across the input articles, or if they follow the development of the same event in time for a longer period, it could become difficult to decide what information is most representative and should be conveyed in a summary. Similarly, length requirements could pre-determine summary quality—a short outline of a story might be confusing and unclear but a page long discussion might give an excellent overview of the same issue.

Even systems that perform well on average produce summaries of poor quality for some inputs. For this reason, understanding what aspects of the input make it difficult for summarization becomes an interesting and important issue that has not been addressed in the summarization community until now.

In information retrieval, for example, the variable system performance has been recognized as a research challenge and numerous studies on identifying query difficulty have been carried out (most recently (Cronen-Townsend et al., 2002; Yom-Tov et al., 2005; Carmel et al., 2006)).

In this paper we present results supporting the hypotheses that input topicality cohesiveness and summary length are among the factors that determine summary quality regardless of the choice of summarization strategy (Section 2). The data used for the analyses comes from the annual Document Understanding Conference (DUC) in which various summarization approaches are evaluated on common data, with new test sets provided each year.

In later sections we define a suite of features capturing aspects of the topicality cohesiveness of the input (Section 3) and relate these to system performance, identifying reliable correlates of input difficulty (Section 4). Finally, in Section 5, we demonstrate that the features can be used to build a classifier predicting summarization input difficulty with accuracy considerably above chance level.

## 2 Preliminary analysis and distinctions: DUC 2001

Generic multi-document summarization was featured as a task at the Document Understanding Conference (DUC) in four years, 2001 through 2004. In our study we use the DUC 2001 multi-document task submissions as development data for in-depth analysis and feature selection. There were 29 input sets and 12 automatic summarizers participating in the evaluation that year. Summaries of different

lengths were produced by each system: 50, 100, 200 and 400 words. Each summary was manually evaluated to determine the extent to which its content overlapped with that of a human model, giving a *coverage score*. The content comparison was performed on a subsentence level and was based on elementary discourse units in the model summary.<sup>1</sup>

The coverage scores are taken as an indicator of difficulty of the input: systems achieve low coverage for difficult sets and higher coverage for easy sets. Since we are interested in identifying characteristics of generally difficult inputs rather than in discovering what types of inputs might be difficult for one given system, we use the average system score per set as indicator of general difficulty.

## 2.1 Analysis of variance

Before attempting to derive characteristics of inputs difficult for summarization, we first confirm that indeed expected performance is influenced by the input itself. We performed analysis of variance for DUC 2001 data, with *automatic system* coverage score as the dependent variable, to gain some insight into the factors related to summarization difficulty. The results of the ANOVA with input set, summarizer identity and summary length as factors, as well as the interaction between these, are shown in Table 1.

As expected, summarizer identity is a significant factor: some summarization strategies/systems are more effective than others and produce summaries with higher coverage score. More interestingly, the input set and summary length factors are also highly significant and explain more of the variability in coverage scores than summarizer identity does, as indicated by the larger values of the  $F$  statistic.

**Length** The average automatic summarizer coverage scores increase steadily as length requirements are relaxed, going up from 0.50 for 50-word summaries to 0.76 for 400-word summaries as shown in Table 2 (second row). The general trend we observe is that on average systems are better at producing summaries when more space is available. The dif-

<sup>1</sup>The routinely used tool for automatic evaluation ROUGE was adopted exactly because it was demonstrated it is highly correlated with the manual DUC coverage scores (Lin and Hovy, 2003a; Lin, 2004).

Type	50	100	200	400
Human	1.00	1.17	1.38	1.29
Automatic	0.50	0.55	0.70	0.76
Baseline	0.41	0.46	0.52	0.57

Table 2: Average human, system and baseline coverage scores for different summary lengths of  $N$  words.  $N = 50, 100, 200,$  and  $400$ .

ferences are statistically significant<sup>2</sup> only between 50-word and 200- and 400-word summaries and between 100-word and 400-word summaries. The fact that summary quality improves with increasing summary length has been observed in prior studies as well (Radev and Tam, 2003; Lin and Hovy, 2003b; Kolluru and Gotoh, 2005) but generally little attention has been paid to this fact in system development and no specific user studies are available to show what summary length might be most suitable for specific applications. In later editions of the DUC conference, only summaries of 100 words were produced, focusing development efforts on one of the more demanding length restrictions. The interaction between summary length and summarizer is small but significant (Table 1), with certain summarization strategies more successful at particular summary lengths than at others.

Improved performance as measured by increase in coverage scores is observed for human summarizers as well (shown in the first row of Table 2). Even the baseline systems (first  $n$  words of the most recent article in the input or first sentences from different input articles) show improvement when longer summaries are allowed (performance shown in the third row of the table). It is important to notice that the difference between automatic system and baseline performance increases as the summary length increases—the difference between systems and baselines coverage scores is around 0.1 for the shorter 50- and 100-word summaries but 0.2 for the longer summaries. This fact has favorable implications for practical system developments because it indicates that in applications where somewhat longer summaries are appropriate, automatically produced summaries will be much more informative than a baseline summary.

<sup>2</sup>One-sided t-test, 95% level of significance.

Factor	DF	Sum of squares	Expected mean squares	F stat	Pr(> F)
input	28	150.702	5.382	59.4227	0
summarizer	11	34.316	3.120	34.4429	0
length	3	16.082	5.361	59.1852	0
input:summarizer	306	65.492	0.214	2.3630	0
input:length	84	36.276	0.432	4.7680	0
summarizer:length	33	6.810	0.206	2.2784	0

Table 1: Analysis of variance for coverage scores of automatic systems with input, summarizer, and length as factors.

**Input** The input set itself is a highly significant factor that influences the coverage scores that systems obtain: some inputs are handled by the systems better than others. Moreover, the input interacts both with the summarizers and the summary length.

This is an important finding for several reasons. First, in system evaluations such as DUC the inputs for summarization are manually selected by annotators. There is no specific attempt to ensure that the inputs across different years have on average the same difficulty. Simply assuming this to be the case could be misleading: it is possible in a given year to have “easier” input test set compared to a previous year. Then system performance across years cannot be meaningfully compared, and higher system scores would not be indicative of system improvement between the evaluations.

Second, in summarization applications there is some control over the input for summarization. For example, related documents that need to be summarized could be split into smaller subsets that are more amenable to summarization or routed to an appropriate summarization system than can handle this kind of input using a different strategy, as done for instance in (McKeown et al., 2002).

Because of these important implications we investigate input characteristics and define various features distinguishing easy inputs from difficult ones.

## 2.2 Difficulty for people and machines

Before proceeding to the analysis of input difficulty in multi-document summarization, it is worth mentioning that our study is primarily motivated by system development needs and consequently the focus is on finding out what inputs are easy or difficult *for automatic systems*. Different factors might make summarization difficult *for people*. In order to see to what extent the notion of summarization input dif-

summary length	correlation
50	0.50
100	0.57*
200	0.77**
400	0.70**

Table 3: Pearson correlation between average human and system coverage scores on the DUC 2001 dataset. Significance levels: \* $p < 0.05$  and \*\* $p < 0.00001$ .

iculty is shared between machines and people, we computed the correlation between the average system and average human coverage score at a given summary length for all DUC 2001 test sets (shown in Table 3). The correlation is highest for 200-word summaries, 0.77, which is also highly significant. For shorter summaries the correlation between human and system performance is not significant.

In the remaining part of the paper we deal exclusively with difficulty as defined by system performance, which differs from difficulty for people summarizing the same material as evidenced by the correlations in Table 3. We do not attempt to draw conclusions about any cognitively relevant factors involved in summarizing.

## 2.3 Type of summary and difficulty

In DUC 2001, annotators prepared test sets from five possible predefined input categories:<sup>3</sup>.

**Single event** (3 sets) Documents describing a single event over a timeline (e.g. The Exxon Valdez oil spill).

<sup>3</sup>Participants in the evaluation were aware of the different categories of input and indeed some groups developed systems that handled different types of input employing different strategies (McKeown et al., 2001). In later years, the idea of multi-strategy summarization has been further explored by (Lacatusu et al., 2006)

**Subject** (6 sets) Documents discussing a single topic (e.g. Mad cow disease)

**Biographical** (2 sets) All documents in the input provide information about the same person (e.g. Elizabeth Taylor)

**Multiple distinct events** (12 sets) The documents discuss different events of the same type (e.g. different occasions of police misconduct).

**Opinion** (6 sets) Each document describes a different perspective to a common topic (e.g. views of the senate, congress, public, lawyers etc on the decision by the senate to count illegal aliens in the 1990 census).

Figure 1 shows the average system coverage score for the different input types. The more topically cohesive input types such as *biographical*, *single event* and *subject*, which are more focused on a single entity or news item and narrower in scope, are easier for systems. The average system coverage score for them is higher than for the non-cohesive sets such as multiple distinct events and opinion sets, regardless of summary length. The difference is even more apparently clear when the scores are plotted after grouping input types into cohesive (biographical, single event and subject) and non-cohesive (multiple events and opinion). Such grouping also gives the necessary power to perform statistical test for significance, confirming the difference in coverage scores for the two groups. This is not surprising: a summary of documents describing multiple distinct events of the same type is likely to require higher degree of generalization and abstraction. Summarizing opinions would in addition be highly subjective. A summary of a cohesive set meanwhile would contain facts directly from the input and it would be easier to determine which information is important. The example human summaries for set D32 (single event) and set D19 (opinions) shown below give an idea of the potential difficulties automatic summarizers have to deal with.

**set D32** On 24 March 1989, the oil tanker Exxon Valdez ran aground on a reef near Valdez, Alaska, spilling 8.4 million gallons of crude oil into Prince William Sound. In two days, the oil spread over 100 miles with a heavy toll on wildlife. Cleanup proceeded at a slow pace, and a plan for cleaning 364 miles of Alaskan coastline was released. In June, the tanker was refloated. By early 1990, only 5 to 9 percent of spilled oil was recovered. A federal jury indicted Exxon

on five criminal charges and the Valdez skipper was guilty of negligent discharge of oil.

**set D19** Congress is debating whether or not to count illegal aliens in the 1990 census. Congressional House seats are apportioned to the states and huge sums of federal money are allocated based on census population. California, with an estimated half of all illegal aliens, will be greatly affected. *Those arguing for inclusion say that the Constitution does not mention “citizens”, but rather, instructs that House apportionment be based on the “whole number of persons” residing in the various states. Those opposed say that the framers were unaware of this issue. “Illegal aliens” did not exist in the U.S. until restrictive immigration laws were passed in 1875.*

The manual set-type labels give an intuitive idea of what factors might be at play but it is desirable to devise more specific measures to predict difficulty. Do such measures exist? Is there a way to automatically distinguish cohesive (easy) from non-cohesive (difficult) sets? In the next section we define a number of features that aim to capture the cohesiveness of an input set and show that some of them are indeed significantly related to set difficulty.

### 3 Features

We implemented 14 features for our analysis of input set difficulty. The working hypothesis is that cohesive sets with clear topics are easier to summarize and the features we define are designed to capture aspects of input cohesiveness.

**Number of sentences** in the input, calculated over all articles in the input set. Shorter inputs should be easier as there will be less information loss between the summary and the original material.

**Vocabulary size** of the input set, equal to the number of unique words in the input. Smaller vocabularies would be characteristic of easier sets.

**Percentage of words used only once** in the input. The rationale behind this feature is that cohesive input sets contain news articles dealing with a clearly defined topic, so words will be reused across documents. Sets that cover disparate events and opinions are likely to contain more words that appear in the input only once.

**Type-token ratio** is a measure of the lexical variation in an input set and is equal to the input vocabulary size divided by the number of words in the

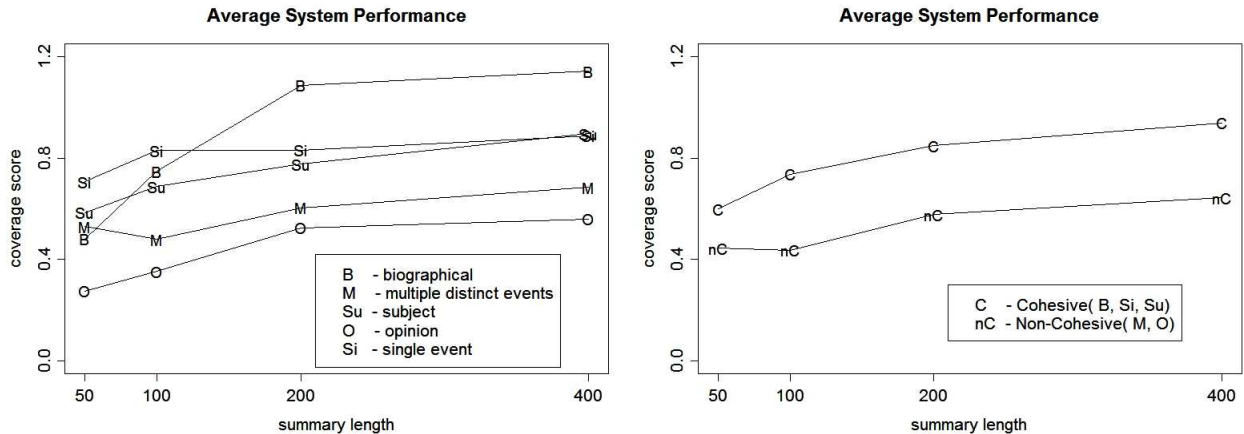

Figure 1: Average system coverage scores for summaries in a category

input. A high type-token ratio indicates there is little (lexical) repetition in the input, a possible side-effect of non-cohesiveness.

**Entropy** of the input set. Let  $X$  be a discrete random variable taking values from the finite set  $V = \{w_1, \dots, w_n\}$  where  $V$  is the vocabulary of the input set and  $w_i$  are the words that appear in the input. The probability distribution  $p(w) = Pr(X = w)$  can be easily calculated using frequency counts from the input. The entropy of the input set is equal to the entropy of  $X$ :

$$H(X) = - \sum_{i=1}^{i=n} p(w_i) \log_2 p(w_i) \quad (1)$$

**Average, minimum and maximum cosine overlap** between the news articles in the input. Repetition in the input is often exploited as an indicator of importance by different summarization approaches (Luhn, 1958; Barzilay et al., 1999; Radev et al., 2004; Nenkova et al., 2006). The more similar the different documents in the input are to each other, the more likely there is repetition across documents at various granularities.

Cosine similarity between the document vector representations is probably the easiest and most commonly used among the various similarity measures. We use tf\*idf weights in the vector representations, with term frequency (tf) normalized by the total number of words in the document in order to remove bias resulting from high frequencies by virtue of higher document length alone.

The cosine similarity between two (document representation) vectors  $v_1$  and  $v_2$  is given by  $\cos\theta = \frac{v_1 \cdot v_2}{\|v_1\| \|v_2\|}$ . A value of 0 indicates that the vectors are orthogonal and dissimilar, a value of 1 indicates perfectly similar documents in terms of the words contained in them.

To compute the cosine overlap features, we find the pairwise cosine similarity between each two documents in an input set and compute their average. The minimum and maximum overlap features are also computed as an indication of the overlap bounds. We expect cohesive inputs to be composed of similar documents, hence the cosine overlaps in these sets of documents must be higher than those in non-cohesive inputs.

**KL divergence** Another measure of relatedness of the documents comprising an input set is the difference in word distributions in the input compared to the word distribution in a large collection of diverse texts. If the input is found to be largely different from a generic collection, it is plausible to assume that the input is not a random collection of articles but rather is defined by a clear topic discussed within and across the articles. It is reasonable to expect that the higher the divergence is, the easier it is to define what is important in the article and hence the easier it is to produce a good summary.

For computing the distribution of words in a general background corpus, we used all the inputs sets from DUC years 2001 to 2006. The divergence measure we used is the Kullback Leibler divergence, or

relative entropy, between the input ( $I$ ) and collection language models. Let  $p_{inp}(w)$  be the probability of the word  $w$  in the input and  $p_{coll}(w)$  be the probability of the word occurring in the large background collection. Then the relative entropy between the input and the collection is given by

$$\text{KL divergence} = \sum_{w \in I} p_{inp}(w) \log_2 \frac{p_{inp}(w)}{p_{coll}(w)} \quad (2)$$

Low KL divergence from a random background collection may be characteristic of highly non-cohesive inputs consisting of unrelated documents.

**Number of topic signature terms** for the input set. The idea of topic signature terms was introduced by Lin and Hovy (Lin and Hovy, 2000) in the context of single document summarization, and was later used in several multi-document summarization systems (Conroy et al., 2006; Lacatusu et al., 2004; Gupta et al., 2007).

Lin and Hovy’s idea was to automatically identify words that are descriptive for a cluster of documents on the same topic, such as the input to a multi-document summarizer. We will call this cluster  $T$ . Since the goal is to find descriptive terms for the cluster, a comparison collection of documents not on the topic is also necessary (we will call this background collection  $NT$ ).

Given  $T$  and  $NT$ , the likelihood ratio statistic (Dunning, 1994) is used to identify the topic signature terms. The probabilistic model of the data allows for statistical inference in order to decide which terms  $t$  are associated with  $T$  more strongly than with  $NT$  than one would expect by chance.

More specifically, there are two possibilities for the distribution of a term  $t$ : either it is very indicative of the topic of cluster  $T$ , and appears more often in  $T$  than in documents from  $NT$ , or the term  $t$  is not topical and appears with equal frequency across both  $T$  and  $NT$ . These two alternatives can be formally written as the following hypotheses:

H1:  $P(t|T) = P(t|NT) = p$  ( $t$  is not a descriptive term for the input)

H2:  $P(t|T) = p_1$  and  $P(t|NT) = p_2$  and  $p_1 > p_2$  ( $t$  is a descriptive term)

In order to compute the likelihood of each hypothesis given the collection of the background docu-

ments and the topic cluster, we view them as a sequence of words  $w_i: w_1 w_2 \dots w_N$ . The occurrence of a given word  $t$ ,  $w_i = t$ , can thus be viewed a Bernoulli trial with probability  $p$  of success, with success occurring when  $w_i = t$  and failure otherwise.

The probability of observing the term  $t$  appearing  $k$  times in  $N$  trials is given by the binomial distribution

$$b(k, N, p) = \binom{N}{k} p^k (1-p)^{N-k} \quad (3)$$

We can now compute

$$\lambda = \frac{\text{Likelihood of the data given H1}}{\text{Likelihood of the data given H2}} \quad (4)$$

which is equal to

$$\lambda = \frac{b(c_t, N, p)}{b(c_T, N_T, p_1) * b(c_{NT}, N_{NT}, p_2)} \quad (5)$$

The maximum likelihood estimates for the probabilities can be computed directly.  $p = \frac{c_t}{N}$ , where  $c_t$  is equal to the number of times term  $t$  appeared in the entire corpus  $T+NT$ , and  $N$  is the number of words in the entire corpus. Similarly,  $p_1 = \frac{c_T}{N_T}$ , where  $c_T$  is the number of times term  $t$  occurred in  $T$  and  $N_T$  is the number of all words in  $T$ .  $p_2 = \frac{c_{NT}}{N_{NT}}$ , where  $c_{NT}$  is the number of times term  $t$  occurred in  $NT$  and  $N_{NT}$  is the total number of words in  $NT$ .

$-2 \log \lambda$  has a well-know distribution:  $\chi^2$ . Bigger values of  $-2 \log \lambda$  indicate that the likelihood of the data under H2 is higher, and the  $\chi^2$  distribution can be used to determine when it is significantly higher ( $-2 \log \lambda$  exceeding 10 gives a significance level of 0.001 and is the cut-off we used).

For terms for which the computed  $-2 \log \lambda$  is higher than 10, we can infer that they occur more often with the topic  $T$  than in a general corpus  $NT$ , and we can dub them “topic signature terms”.

#### Percentage of signature terms in vocabulary

The number of signature terms gives the total count of topic signatures over all the documents in the input. However, the number of documents in an input set and the size of the individual documents across different sets are not the same. It is therefore possible that the mere count feature is biased to the length

and number of documents in the input set. To account for this, we add the percentage of topic words in the vocabulary as a feature.

**Average, minimum and maximum topic signature overlap** between the documents in the input. Cosine similarity measures the overlap between two documents based on all the words appearing in them. A more refined document representation can be defined by assuming the document vectors contain only the topic signature words rather than all words. A high overlap of topic words across two documents is indicative of shared topicality. The average, minimum and maximum pairwise cosine overlap between the tf\*idf weighted topic signature vectors of the two documents are used as features for predicting input cohesiveness. If the overlap is large, then the topic is similar across the two documents and hence their combination will yield a cohesive input.

#### 4 Feature selection

Table 4 shows the results from a one-sided t-test comparing the values of the various features for the easy and difficult input set classes. The comparisons are for summary length of 100 words because in later years only such summaries were evaluated. The binary easy/difficult classes were assigned based on the average system coverage score for the given set, with half of the sets assigned to each class.

In addition to the t-tests we also calculated Pearson’s correlation (shown in Table 5) between the features and the average system coverage score for each set. In the correlation analysis the input sets are not classified into easy or difficult but rather the real valued coverage scores are used directly. Overall, the features that were identified by the t-test as most descriptive of the differences between easy and difficult inputs were also the ones with higher correlations with real-valued coverage scores.

Our expectations in defining the features are confirmed by the correlation results. For example, systems have low coverage scores for sets with high-entropy vocabularies as indicated by the negative and high by absolute value correlation (-0.4256). Sets with high entropy are those in which there is little repetition within and across different articles, and for which it is subsequently difficult to deter-

feature	t-stat	p-value
KL divergence*	-2.4725	0.01

\*Significant at a 95% confidence level( $p < 0.05$ )

Table 4: Comparison of non-cohesive (average system coverage score < median average system score) vs cohesive sets for summary length of 100 words

mine what is the most important content. On the other hand, sets characterized by bigger KL divergence are easier—there the distribution of words is skewed compared to a general collection of articles, with important topic words occurring more often.

Easy to summarize sets are characterized by low entropy, small vocabulary, high average cosine and average topic signature overlaps, high KL divergence and a high percentage of the vocabulary consists of topic signature terms.

#### 5 Classification results

We used the 192 sets from multi-document summarization DUC evaluations in 2002 (55 generic sets), 2003 (30 generic summary sets and 7 viewpoint sets) and 2004 (50 generic and 50 biography sets) to train and test a logistic regression classifier. The sets from all years were pooled together and evenly divided into easy and difficult inputs based on the average system coverage score for each set.

Table 6 shows the results from 10-fold cross validation. SIG is a classifier based on the six features identified as significant in distinguishing easy from difficult inputs based on a t-test comparison (Table 4). SIG+yt has two additional features: the year and the type of summarization input (generic, viewpoint and biographical). ALL is a classifier based on all 14 features defined in the previous section, and

feature	correlation
set entropy	-0.4256
KL divergence	0.3663
vocabulary size	-0.3610
% of sig. terms in vocab	0.3277
average sig. term overlap	0.2860
number of sentences	-0.2511
max topic signature overlap	0.2416
average cosine overlap	0.2244
number of signature terms	-0.1880
max cosine overlap	0.1337
min topic signature overlap	0.0401
min cosine overlap	0.0308
type-token ratio	-0.0276
% of words used only once	-0.0025

Table 5: Correlation between coverage score and feature values for the 29 DUC'01 100-word summaries.

features	accuracy	P	R	F
SIG	56.25%	0.553	0.600	0.576
SIG+yt	69.27%	0.696	0.674	0.684
ALL	61.45%	0.615	0.589	0.600
ALL+yt	65.10%	0.643	0.663	0.653

Table 6: Logistic regression classification results (accuracy, precision, recall and f-measure) for balanced data of 100-word summaries from DUC'02 through DUC'04.

ALL+yt also includes the year and task features.

Classification accuracy is considerably higher than the 50% random baseline. Using all features yields better accuracy (61%) than using solely the 6 significant features (accuracy of 56%). In both cases, adding the year and task leads to extra 3% net improvement. The best overall results are for the SIG+yt classifier with net improvement over the baseline equal to 20%. At the same time, it should be taken into consideration that the amount of training data for our experiments is small: a total of 192 sets. Despite this, the measures of input cohesiveness capture enough information to result in a classifier with above-baseline performance.

## 6 Conclusions

We have addressed the question of what makes the writing of a summary for a multi-document input difficult. Summary length is a significant factor, with all summarizers (people, machines and baselines) performing better at longer summary lengths.

An exploratory analysis of DUC 2001 indicated that systems produce better summaries for cohesive inputs dealing with a clear topic (single event, subject and biographical sets) while non-cohesive sets about multiple events and opposing opinions are consistently of lower quality. We defined a number of features aimed at capturing input cohesiveness, ranging from simple features such as input length and size to more sophisticated measures such as input set entropy, KL divergence from a background corpus and topic signature terms based on log-likelihood ratio.

Generally, easy to summarize sets are characterized by low entropy, small vocabulary, high average cosine and average topic signature overlaps, high KL divergence and a high percentage of the vocabulary consists of topic signature terms. Experiments with a logistic regression classifier based on the features further confirms that input cohesiveness is predictive of the difficulty it will pose to automatic summarizers.

Several important notes can be made. First, it is important to develop strategies that can better handle non-cohesive inputs, reducing fluctuations in system performance. Most current systems are developed with the expectation they can handle any input but this is evidently not the case and more attention should be paid to the issue. Second, the interpretations of year to year evaluations can be affected. As demonstrated, the properties of the input have a considerable influence on summarization quality. If special care is not taken to ensure that the difficulty of inputs in different evaluations is kept more or less the same, results from the evaluations are not comparable and we cannot make general claims about progress and system improvements between evaluations. Finally, the presented results are clearly just a beginning in understanding of summarization difficulty. A more complete characterization of summarization input will be necessary in the future.

# You talking to me? A Corpus and Algorithm for Conversation Disentanglement

Micha Elsner and Eugene Charniak

Brown Laboratory for Linguistic Information Processing (BLLIP)

Brown University

Providence, RI 02912

{melsner, ec}@cs.brown.edu

## Abstract

When multiple conversations occur simultaneously, a listener must decide which conversation each utterance is part of in order to interpret and respond to it appropriately. We refer to this task as disentanglement. We present a corpus of Internet Relay Chat (IRC) dialogue in which the various conversations have been manually disentangled, and evaluate annotator reliability. This is, to our knowledge, the first such corpus for internet chat. We propose a graph-theoretic model for disentanglement, using discourse-based features which have not been previously applied to this task. The model's predicted disentanglements are highly correlated with manual annotations.

## 1 Motivation

Simultaneous conversations seem to arise naturally in both informal social interactions and multi-party typed chat. Aoki et al. (2006)'s study of voice conversations among 8-10 people found an average of 1.76 conversations (floors) active at a time, and a maximum of four. In our chat corpus, the average is even higher, at 2.75. The typical conversation, therefore, is one which is interrupted— frequently.

Disentanglement is the clustering task of dividing a transcript into a set of distinct conversations. It is an essential prerequisite for any kind of higher-level dialogue analysis: for instance, consider the multi-party exchange in figure 1.

Contextually, it is clear that this corresponds to two conversations, and Felicia's<sup>1</sup> response “excel-

**(Chanel)** Felicia: google works :)  
**(Gale)** Arlie: you guys have never worked in a factory before have you

lent” is intended for Chanel and Regine. A straightforward reading of the transcript, however, might interpret it as a response to Gale's statement immediately preceding.

Humans are adept at disentanglement, even in complicated environments like crowded cocktail parties or chat rooms; in order to perform this task, they must maintain a complex mental representation of the ongoing discourse. Moreover, they adapt their utterances to some degree to make the task easier (O'Neill and Martin, 2003), which suggests that disentanglement is in some sense a “difficult” discourse task.

Disentanglement has two practical applications. One is the analysis of pre-recorded transcripts in order to extract some kind of information, such as question-answer pairs or summaries. These tasks should probably take as input each separate conversation, rather than the entire transcript. Another

identifiers for ethical reasons.

<sup>1</sup>Real user nicknames are replaced with randomly selected

application is as part of a user-interface system for active participants in the chat, in which users target a conversation of interest which is then highlighted for them. Aoki et al. (2003) created such a system for speech, which users generally preferred to a conventional system—when the disentanglement worked!

Previous attempts to solve the problem (Aoki et al., 2006; Aoki et al., 2003; Camtepe et al., 2005; Acar et al., 2005) have several flaws. They cluster speakers, not utterances, and so fail when speakers move from one conversation to another. Their features are mostly time gaps between one utterance and another, without effective use of utterance content. Moreover, there is no framework for a principled comparison of results: there are no reliable annotation schemes, no standard corpora, and no agreed-upon metrics.

We attempt to remedy these problems. We present a new corpus of manually annotated chat room data and evaluate annotator reliability. We give a set of metrics describing structural similarity both locally and globally. We propose a model which uses discourse structure and utterance contents in addition to time gaps. It partitions a chat transcript into distinct conversations, and its output is highly correlated with human annotations.

## 2 Related Work

Two threads of research are direct attempts to solve the disentanglement problem: Aoki et al. (2006), Aoki et al. (2003) for speech and Camtepe et al. (2005), Acar et al. (2005) for chat. We discuss their approaches below. However, we should emphasize that we cannot compare our results directly with theirs, because none of these studies publish results on human-annotated data. Although Aoki et al. (2006) construct an annotated speech corpus, they give no results for model performance, only user satisfaction with their conversational system. Camtepe et al. (2005) and Acar et al. (2005) do give performance results, but only on synthetic data.

All of the previous approaches treat the problem as one of clustering speakers, rather than utterances. That is, they assume that during the window over which the system operates, a particular speaker is engaging in only one conversation. Camtepe et al. (2005) assume this is true throughout the entire tran-

script; real speakers, by contrast, often participate in many conversations, sequentially or sometimes even simultaneously. Aoki et al. (2003) analyze each thirty-second segment of the transcript separately. This makes the single-conversation restriction somewhat less severe, but has the disadvantage of ignoring all events which occur outside the segment.

Acar et al. (2005) attempt to deal with this problem by using a fuzzy algorithm to cluster speakers; this assigns each speaker a distribution over conversations rather than a hard assignment. However, the algorithm still deals with speakers rather than utterances, and cannot determine which conversation any particular utterance is part of.

Another problem with these approaches is the information used for clustering. Aoki et al. (2003) and Camtepe et al. (2005) detect the arrival times of messages, and use them to construct an affinity graph between participants by detecting turn-taking behavior among pairs of speakers. (Turn-taking is typified by short pauses between utterances; speakers aim neither to interrupt nor leave long gaps.) Aoki et al. (2006) find that turn-taking on its own is inadequate. They motivate a richer feature set, which, however, does not yet appear to be implemented. Acar et al. (2005) adds word repetition to their feature set. However, their approach deals with all word repetitions on an equal basis, and so degrades quickly in the presence of *noise words* (their term for words which shared across conversations) to almost complete failure when only 1/2 of the words are shared.

To motivate our own approach, we examine some linguistic studies of discourse, especially analysis of multi-party conversation. O’Neill and Martin (2003) point out several ways in which multi-party text chat differs from typical two-party conversation. One key difference is the frequency with which participants mention each others’ names. They hypothesize that mentioning is a strategy which participants use to make disentanglement easier, compensating for the lack of cues normally present in face-to-face dialogue. Mentions (such as Gale’s comments to Arlie in figure 1) are very common in our corpus, occurring in 36% of comments, and provide a useful feature.

Another key difference is that participants may create a new conversation (floor) at any time, a process which Sacks et al. (1974) calls *schisming*. Dur-

ing a schism, a new conversation is formed, not necessarily because of a shift in the topic, but because certain participants have refocused their attention onto each other, and away from whoever held the floor in the parent conversation.

Despite these differences, there are still strong similarities between chat and other conversations such as meetings. Our feature set incorporates information which has proven useful in meeting segmentation (Galley et al., 2003) and the task of detecting addressees of a specific utterance in a meeting (Jovanovic et al., 2006). These include word repetitions, utterance topic, and *cue words* which can indicate the bounds of a segment.

### 3 Dataset

Our dataset is recorded from the IRC (Internet Relay Chat) channel `##LINUX` at *freenode.net*, using the freely-available *gaim* client. `##LINUX` is an unofficial tech support line for the Linux operating system, selected because it is one of the most active chat rooms on *freenode*, leading to many simultaneous conversations, and because its content is typically inoffensive. Although it is notionally intended only for tech support, it includes large amounts of social chat as well, such as the conversation about factory work in the example above (figure 1).

The entire dataset contains 52:18 hours of chat, but we devote most of our attention to three annotated sections: development (706 utterances; 2:06 hr) and test (800 utts.; 1:39 hr) plus a short pilot section on which we tested our annotation system (359 utts.; 0:58 hr).

#### 3.1 Annotation

Our annotators were seven university students with at least some familiarity with the Linux OS, although in some cases very slight. Annotation of the test dataset typically took them about two hours. In all, we produced six annotations of the test set<sup>2</sup>.

Our annotation scheme marks each utterance as part of a single conversation. Annotators are instructed to create as many, or as few conversations as they need to describe the data. Our instructions state that a conversation can be between any number of

---

<sup>2</sup>One additional annotation was discarded because the annotator misunderstood the task.

people, and that, “We mean conversation in the typical sense: a discussion in which the participants are all reacting and paying attention to one another. . . it should be clear that the comments inside a conversation fit together.” The annotation system itself is a simple Java program with a graphical interface, intended to appear somewhat similar to a typical chat client. Each speaker’s name is displayed in a different color, and the system displays the elapsed time between comments, marking especially long pauses in red. Annotators group sentences into conversations by clicking and dragging them onto each other.

#### 3.2 Metrics

Before discussing the annotations themselves, we will describe the metrics we use to compare different annotations; these measure both how much our annotators agree with each other, and how well our model and various baselines perform. Comparing clusterings with different numbers of clusters is a non-trivial task, and metrics for agreement on supervised classification, such as the  $\kappa$  statistic, are not applicable.

To measure global similarity between annotations, we use *one-to-one accuracy*. This measure describes how well we can extract whole conversations intact, as required for summarization or information extraction. To compute it, we pair up conversations from the two annotations to maximize the total overlap<sup>3</sup>, then report the percentage of overlap found.

If we intend to monitor or participate in the conversation as it occurs, we will care more about local judgements. The *local agreement* metric counts agreements and disagreements within a context  $k$ . We consider a particular utterance: the previous  $k$  utterances are each in either the *same* or a *different* conversation. The  $loc_k$  score between two annotators is their average agreement on these  $k$  same/different judgements, averaged over all utterances. For example,  $loc_1$  counts pairs of adjacent utterances for which two annotations agree.

	Mean	Max	Min
Conversations	81.33	128	50
Avg. Conv. Length	10.6	16.0	6.2
Avg. Conv. Density	2.75	2.92	2.53
Entropy	4.83	6.18	3.00
1-to-1	52.98	63.50	35.63
$loc_3$	81.09	86.53	74.75
M-to-1 (by entropy)	86.70	94.13	75.50

Table 1: Statistics on 6 annotations of 800 lines of chat transcript. Inter-annotator agreement metrics (below the line) are calculated between distinct pairs of annotations.

### 3.3 Discussion

A statistical examination of our data (table 1) shows that that it is eminently suitable for disentanglement: the average number of conversations active at a time is 2.75. Our annotators have high agreement on the local metric (average of 81.1%). On the 1-to-1 metric, they disagree more, with a mean overlap of 53.0% and a maximum of only 63.5%. This level of overlap does indicate a useful degree of reliability, which cannot be achieved with naive heuristics (see section 5). Thus measuring 1-to-1 overlap with our annotations is a reasonable evaluation for computational models. However, we feel that the major source of disagreement is one that can be remedied in future annotation schemes: the specificity of the individual annotations.

To measure the level of detail in an annotation, we use the information-theoretic entropy of the random variable which indicates which conversation an utterance is in. This quantity is non-negative, increasing as the number of conversations grow and their size becomes more balanced. It reaches its maximum, 9.64 bits for this dataset, when each utterance is placed in a separate conversation. In our annotations, it ranges from 3.0 to 6.2. This large variation shows that some annotators are more specific than others, but does not indicate how much they agree on the general structure. To measure this, we introduce the many-to-one accuracy. This measurement is asymmetrical, and maps each of the conversations of the *source* annotation to the single con-

<sup>3</sup>This is an example of max-weight bipartite matching, and can be computed optimally using, eg, max-flow. The widely used greedy algorithm is a two-approximation, although we have not found large differences in practice.

**(Lai)** need money

Figure 2: A schism occurring in our corpus (abridged): not all annotators agree on where the thread about charging for answers to techical questions diverges from the one about setting up Paypal accounts. Either Gale's or Azzie's first comment seems to be the schism-inducing utterance.

versation in the *target* with which it has the greatest overlap, then counts the total percentage of overlap. This is not a statistic to be optimized (indeed, optimization is trivial: simply make each utterance in the source into its own conversation), but it can give us some intuition about specificity. In particular, if one subdivides a coarse-grained annotation to make a more specific variant, the many-to-one accuracy from fine to coarse remains 1. When we map high-entropy annotations (fine) to lower ones (coarse), we find high many-to-one accuracy, with a mean of 86%, which implies that the more specific annotations have mostly the same large-scale boundaries as the coarser ones.

By examining the local metric, we can see even more: local correlations are good, at an average of 81.1%. This means that, in the three-sentence window preceding each sentence, the annotators are of-

ten in agreement. If they recognize subdivisions of a large conversation, these subdivisions tend to be contiguous, not mingled together, which is why they have little impact on the local measure.

We find reasons for the annotators’ disagreement about appropriate levels of detail in the linguistic literature. As mentioned, new conversations often break off from old ones in schisms. Aoki et al. (2006) discuss conversational features associated with schisming and the related process of *affiliation*, by which speakers attach themselves to a conversation. Schisms often branch off from asides or even normal comments (*toss-outs*) within an existing conversation. This means that there is no clear beginning to the new conversation— at the time when it begins, it is not clear that there are two separate floors, and this will not become clear until distinct sets of speakers and patterns of turn-taking are established. Speakers, meanwhile, take time to orient themselves to the new conversation. An example schism is shown in Figure 2.

Our annotation scheme requires annotators to mark each utterance as part of a single conversation, and distinct conversations are not related in any way. If a schism occurs, the annotator is faced with two options: if it seems short, they may view it as a mere digression and label it as part of the parent conversation. If it seems to deserve a place of its own, they will have to separate it from the parent, but this severs the initial comment (an otherwise unremarkable aside) from its context. One or two of the annotators actually remarked that this made the task confusing. Our annotators seem to be either “splitters” or “lumpers”— in other words, each annotator seems to aim for a consistent level of detail, but each one has their own idea of what this level should be.

As a final observation about the dataset, we test the appropriateness of the assumption (used in previous work) that each speaker takes part in only one conversation. In our data, the average speaker takes part in about 3.3 conversations (the actual number varies for each annotator). The more talkative a speaker is, the more conversations they participate in, as shown by a plot of conversations versus utterances (Figure 3). The assumption is not very accurate, especially for speakers with more than 10 utterances.

Figure 3: Utterances versus conversations participated in per speaker on development data.

## 4 Model

Our model for disentanglement fits into the general class of graph partitioning algorithms (Roth and Yih, 2004) which have been used for a variety of tasks in NLP, including the related task of meeting segmentation (Malioutov and Barzilay, 2006). These algorithms operate in two stages: first, a binary classifier marks each pair of items as alike or different, and second, a consistent partition is extracted.<sup>4</sup>

### 4.1 Classification

We use a maximum-entropy classifier (Daumé III, 2004) to decide whether a pair of utterances  $x$  and  $y$  are in *same* or *different* conversations. The most likely class is *different*, which occurs 57% of the time in development data. We describe the classifier’s performance in terms of raw accuracy (correct decisions / total), precision and recall of the *same* class, and F-score, the harmonic mean of precision and recall. Our classifier uses several types of features (table 2). The chat-specific features yield the highest accuracy and precision. Discourse and content-based features have poor accuracy on their own (worse than the baseline), since they work best on nearby pairs of utterances, and tend to fail on more distant pairs. Paired with the time gap feature, however, they boost accuracy somewhat and produce substantial gains in recall, encouraging the model to group related utterances together.

The time gap, as discussed above, is the most widely used feature in previous work. We exam-

<sup>4</sup>Our first attempt at this task used a Bayesian generative model. However, we could not define a sharp enough posterior over new sentences, which made the model unstable and overly sensitive to its prior.

**Chat-specific (Acc 73: Prec: 73 Rec: 61 F: 66)**

Time	The time between $x$ and $y$ in seconds, bucketed logarithmically.
Speaker	$x$ and $y$ have the same speaker.
Mention	$x$ mentions $y$ (or vice versa), both mention the same name, either mentions any name.

**Discourse (Acc 52: Prec: 47 Rec: 77 F: 58)**

Cue words	Either $x$ or $y$ uses a greeting (“hello” &c), an answer (“yes”, “no” &c), or thanks.
Question	Either asks a question (explicitly marked with “?”).
Long	Either is long ( $> 10$ words).

**Content (Acc 50: Prec: 45 Rec: 74 F: 56)**

Repeat( $i$ )	The number of words shared between $x$ and $y$ which have unigram probability $i$ , bucketed logarithmically.
Tech	Whether both $x$ and $y$ use technical jargon, neither do, or only one does.

**Combined (Acc 75: Prec: 73 Rec: 68 F: 71)**

Table 2: Feature functions with performance on development data.

ine the distribution of pauses between utterances in the same conversation. Our choice of a logarithmic bucketing scheme is intended to capture two characteristics of the distribution (figure 4). The curve has its maximum at 1-3 seconds, and pauses shorter than a second are less common. This reflects turn-taking behavior among participants; participants in the same conversation prefer to wait for each others’ responses before speaking again. On the other hand, the curve is quite heavy-tailed to the right, leading us to bucket long pauses fairly coarsely.

Our discourse-based features model some pair-

Figure 4: Distribution of pause length (log-scaled) between utterances in the same conversation.

wise relationships: questions followed by answers, short comments reacting to longer ones, greetings at the beginning and thanks at the end.

Word repetition is a key feature in nearly every model for segmentation or coherence, so it is no surprise that it is useful here. We bucket repeated words by their unigram probability<sup>5</sup> (measured over the entire 52 hours of transcript). The bucketing scheme allows us to deal with “noise words” which are repeated coincidentally.

The point of the repetition feature is of course to detect sentences with similar topics. We also find that sentences with technical content are more likely to be related than non-technical sentences. We label an utterance as technical if it contains a web address, a long string of digits, or a term present in a guide for novice Linux users<sup>6</sup> but not in a large news corpus (Graff, 1995)<sup>7</sup>. This is a light-weight way to capture one “semantic dimension” or cluster of related words, in a corpus which is not amenable to full LSA or similar techniques. LSA in text corpora yields a better relatedness measure than simple repetition (Foltz et al., 1998), but is ineffective in our corpus because of its wide variety of topics and lack of distinct document boundaries.

Pairs of utterances which are widely separated in the discourse are unlikely to be directly related—even if they are part of the same conversation, the link between them is probably a long chain of intervening utterances. Thus, if we run our classifier on a pair of very distant utterances, we expect it to default to the majority class, which in this case will be *different*, and this will damage our performance in case the two are really part of the same conversation. To deal with this, we run our classifier only on utterances separated by 129 seconds or less. This is the last of our logarithmic buckets in which the classifier has a significant advantage over the majority baseline. For 99.9% of utterances in an ongoing conversation, the previous utterance in that conversation is within this gap, and so the system has a

<sup>5</sup>We discard the 50 most frequent words entirely.

<sup>6</sup>“Introduction to Linux: A Hands-on Guide”. Machtelt Garrels. Edition 1.25 from <http://tldp.org/LDP/intro-linux/html/intro-linux.html>.

<sup>7</sup>Our data came from the LA times, 94-97— helpfully, it pre-dates the current wide coverage of Linux in the mainstream press.

chance of correctly linking the two.

On test data, the classifier has a mean accuracy of 68.2 (averaged over annotations). The mean precision of *same conversation* is 53.3 and the recall is 71.3, with mean F-score of 60. This error rate is high, but the partitioning procedure allows us to recover from some of the errors, since if nearby utterances are grouped correctly, the bad decisions will be outvoted by good ones.

## 4.2 Partitioning

The next step in the process is to cluster the utterances. We wish to find a set of clusters for which the weighted accuracy of the classifier would be maximal; this is an example of *correlation clustering* (Bansal et al., 2004), which is NP-complete<sup>8</sup>. Finding an exact solution proves to be difficult; the problem has a quadratic number of variables (one for each pair of utterances) and a cubic number of triangle inequality constraints (three for each triplet). With 800 utterances in our test set, even solving the linear program with CPLEX (Ilog, Inc., 2003) is too expensive to be practical.

Although there are a variety of approximations and local searches, we do not wish to investigate partitioning methods in this paper, so we simply use a greedy search. In this algorithm, we assign utterance  $j$  by examining all previous utterances  $i$  within the classifier’s window, and treating the classifier’s judgement  $p_{i,j} - .5$  as a vote for  $cluster(i)$ . If the maximum vote is greater than 0, we set  $cluster(j) = argmax_c vote_c$ . Otherwise  $j$  is put in a new cluster. Greedy clustering makes at least a reasonable starting point for further efforts, since it is a natural online algorithm— it assigns each utterance as it arrives, without reference to the future.

At any rate, we should not take our objective function too seriously. Although it is roughly correlated with performance, the high error rate of the classifier makes it unlikely that small changes in objective will mean much. In fact, the objective value of our output solutions are generally higher than those for true so-

<sup>8</sup>We set up the problem by taking the weight of edge  $i, j$  as the classifier’s decision  $p_{i,j} - .5$ . Roth and Yih (2004) use log probabilities as weights. Bansal et al. (2004) propose the log odds ratio  $log(p/(1 - p))$ . We are unsure of the relative merit of these approaches.

lutions, which implies we have already reached the limits of what our classifier can tell us.

## 5 Experiments

We annotate the 800 line test transcript using our system. The annotation obtained has 63 conversations, with mean length 12.70. The average density of conversations is 2.9, and the entropy is 3.79. This places it within the bounds of our human annotations (see table 1), toward the more general end of the spectrum.

As a standard of comparison for our system, we provide results for several baselines— trivial systems which any useful annotation should outperform.

**All different** Each utterance is a separate conversation.

**All same** The whole transcript is a single conversation.

**Blocks of  $k$**  Each consecutive group of  $k$  utterances is a conversation.

**Pause of  $k$**  Each pause of  $k$  seconds or more separates two conversations.

**Speaker** Each speaker’s utterances are treated as a monologue.

For each particular metric, we calculate the best baseline result among all of these. To find the best block size or pause length, we search over multiples of 5 between 5 and 300. This makes these baselines appear better than they really are, since their performance is optimized with respect to the test data.

Our results, in table 3, are encouraging. On average, annotators agree more with each other than with any artificial annotation, and more with our model than with the baselines. For the 1-to-1 accuracy metric, we cannot claim much beyond these general results. The range of human variation is quite wide, and there are annotators who are closer to baselines than to any other human annotator. As explained earlier, this is because some human annotations are much more specific than others. For very specific annotations, the best baselines are short blocks or pauses. For the most general, marking all utterances the same does very well (although for all other annotations, it is extremely poor).

	Other Annotators	Model	Best Baseline	All Diff	All Same
Mean 1-to-1	52.98	40.62	34.73 (Blocks of 40)	10.16	20.93
Max 1-to-1	63.50	51.12	56.00 (Pause of 65)	16.00	53.50
Min 1-to-1	35.63	33.63	28.62 (Pause of 25)	6.25	7.13
Mean $loc_3$	81.09	72.75	62.16 (Speaker)	52.93	47.07
Max $loc_3$	86.53	75.16	69.05 (Speaker)	62.15	57.47
Min $loc_3$	74.75	70.47	54.37 (Speaker)	42.53	37.85

Table 3: Metric values between proposed annotations and human annotations. Model scores typically fall between inter-annotator agreement and baseline performance.

For the local metric, the results are much clearer. There is no overlap in the ranges; for every test annotation, agreement is highest with other annotator, then our model and finally the baselines. The most competitive baseline is one conversation per speaker, which makes sense, since if a speaker makes two comments in a four-utterance window, they are very likely to be related.

The name mention features are critical for our model’s performance. Without this feature, the classifier’s development F-score drops from 71 to 56. The disentanglement system’s test performance decreases proportionally; mean 1-to-1 falls to 36.08, and mean  $loc_3$  to 63.00, essentially baseline performance. On the other hand, mentions are not sufficient; with only name mention and time gap features, mean 1-to-1 is 38.54 and  $loc_3$  is 67.14. For some utterances, of course, name mentions provide the only reasonable clue to the correct decision, which is why humans mention names in the first place. But our system is probably overly dependent on them, since they are very reliable compared to our other features.

## 6 Future Work

Although our annotators are reasonably reliable, it seems clear that they think of conversations as a hierarchy, with digressions and schisms. We are interested to see an annotation protocol which more closely follows human intuition and explicitly includes these kinds of relationships.

We are also interested to see how well this feature set performs on speech data, as in (Aoki et al., 2003). Spoken conversation is more natural than text chat, but when participants are not face-to-face, disentanglement remains a problem. On the other hand, spoken dialogue contains new sources of information,

such as prosody. Turn-taking behavior is also more distinct, which makes the task easier, but according to (Aoki et al., 2006), it is certainly not sufficient.

Improving the current model will definitely require better features for the classifier. However, we also left the issue of partitioning nearly completely unexplored. If the classifier can indeed be improved, we expect the impact of search errors to increase. Another issue is that human users may prefer more or less specific annotations than our model provides. We have observed that we can produce lower or higher-entropy annotations by changing the classifier’s bias to label more edges same or different. But we do not yet know whether this corresponds with human judgements, or merely introduces errors.

## 7 Conclusion

This work provides a corpus of annotated data for chat disentanglement, which, along with our proposed metrics, should allow future researchers to evaluate and compare their results quantitatively<sup>9</sup>. Our annotations are consistent with one another, especially with respect to local agreement. We show that features based on discourse patterns and the content of utterances are helpful in disentanglement. The model we present can outperform a variety of baselines.

## Abstract

The traditional mention-pair model for coreference resolution cannot capture information beyond mention pairs for both learning and testing. To deal with this problem, we present an expressive entity-mention model that performs coreference resolution at an entity level. The model adopts the Inductive Logic Programming (ILP) algorithm, which provides a relational way to organize different knowledge of entities and mentions. The solution can explicitly express relations between an entity and the contained mentions, and automatically learn first-order rules important for coreference decision. The evaluation on the ACE data set shows that the ILP based entity-mention model is effective for the coreference resolution task.

## 1 Introduction

Coreference resolution is the process of linking multiple mentions that refer to the same entity. Most of previous work adopts the mention-pair model, which recasts coreference resolution to a binary classification problem of determining whether or not two mentions in a document are co-referring (e.g. Aone and Bennett (1995); McCarthy and Lehnert (1995); Soon et al. (2001); Ng and Cardie (2002)). Although having achieved reasonable success, the mention-pair model has a limitation that information beyond mention pairs is ignored for training and testing. As an individual mention usually lacks adequate descriptive information of the referred entity, it is often difficult to judge whether or not two men-

tions are talking about the same entity simply from the pair alone.

An alternative learning model that can overcome this problem performs coreference resolution based on entity-mention pairs (Luo et al., 2004; Yang et al., 2004b). Compared with the traditional mention-pair counterpart, the entity-mention model aims to make coreference decision at an entity level. Classification is done to determine whether a mention is a referent of a partially found entity. A mention to be resolved (called *active mention* henceforth) is linked to an appropriate entity chain (if any), based on classification results.

One problem that arises with the entity-mention model is how to represent the knowledge related to an entity. In a document, an entity may have more than one mention. It is impractical to enumerate all the mentions in an entity and record their information in a single feature vector, as it would make the feature space too large. Even worse, the number of mentions in an entity is not fixed, which would result in variant-length feature vectors and make trouble for normal machine learning algorithms. A solution seen in previous work (Luo et al., 2004; Culotta et al., 2007) is to design a set of first-order features summarizing the information of the mentions in an entity, for example, “whether the entity has any mention that is a name alias of the active mention?” or “whether most of the mentions in the entity have the same head word as the active mention?” These features, nevertheless, are designed in an ad-hoc manner and lack the capability of describing each individual mention in an entity.

In this paper, we present a more expressive entity-

mention model for coreference resolution. The model employs Inductive Logic Programming (ILP) to represent the relational knowledge of an active mention, an entity, and the mentions in the entity. On top of this, a set of first-order rules is automatically learned, which can capture the information of each individual mention in an entity, as well as the global information of the entity, to make coreference decision. Hence, our model has a more powerful representation capability than the traditional mention-pair or entity-mention model. And our experimental results on the ACE data set shows the model is effective for coreference resolution.

## 2 Related Work

There are plenty of learning-based coreference resolution systems that employ the mention-pair model. A typical one of them is presented by Soon et al. (2001). In the system, a training or testing instance is formed for two mentions in question, with a feature vector describing their properties and relationships. At a testing time, an active mention is checked against all its preceding mentions, and is linked with the closest one that is classified as positive. The work is further enhanced by Ng and Cardie (2002) by expanding the feature set and adopting a “best-first” linking strategy.

Recent years have seen some work on the entity-mention model. Luo et al. (2004) propose a system that performs coreference resolution by doing search in a large space of entities. They train a classifier that can determine the likelihood that an active mention should belong to an entity. The entity-level features are calculated with an “Any-X” strategy: an entity-mention pair would be assigned a feature X, if any mention in the entity has the feature X with the active mention.

Culotta et al. (2007) present a system which uses an online learning approach to train a classifier to judge whether two entities are coreferential or not. The features describing the relationships between two entities are obtained based on the information of every possible pair of mentions from the two entities. Different from (Luo et al., 2004), the entity-level features are computed using a “Most-X” strategy, that is, two given entities would have a feature X, if most of the mention pairs from the two entities

have the feature X.

Yang et al. (2004b) suggest an entity-based coreference resolution system. The model adopted in the system is similar to the mention-pair model, except that the entity information (e.g., the global number/gender agreement) is considered as additional features of a mention in the entity.

McCallum and Wellner (2003) propose several graphical models for coreference analysis. These models aim to overcome the limitation that pairwise coreference decisions are made independently of each other. The simplest model conditions coreference on mention pairs, but enforces dependency by calculating the distance of a node to a partition (i.e., the probability that an active mention belongs to an entity) based on the sum of its distances to all the nodes in the partition (i.e., the sum of the probability of the active mention co-referring with the mentions in the entity).

Inductive Logic Programming (ILP) has been applied to some natural language processing tasks, including parsing (Mooney, 1997), POS disambiguation (Cussens, 1996), lexicon construction (Claveau et al., 2003), WSD (Specia et al., 2007), and so on. However, to our knowledge, our work is the first effort to adopt this technique for the coreference resolution task.

## 3 Modelling Coreference Resolution

Suppose we have a document containing  $n$  mentions  $\{m_j : 1 < j < n\}$ , in which  $m_j$  is the  $j$ th mention occurring in the document. Let  $e_i$  be the  $i$ th entity in the document. We define

$$P(L|e_i, m_j), \quad (1)$$

the probability that a mention belongs to an entity. Here the random variable  $L$  takes a binary value and is 1 if  $m_j$  is a mention of  $e_i$ .

By assuming that mentions occurring after  $m_j$  have no influence on the decision of linking  $m_j$  to an entity, we can approximate (1) as:

$$\begin{aligned} & P(L|e_i, m_j) \\ \propto & P(L|\{m_k \in e_i, 1 \leq k \leq j-1\}, m_j) \quad (2) \\ \propto & \max_{m_k \in e_i, 1 \leq k \leq j-1} P(L|m_k, m_j) \quad (3) \end{aligned}$$

(3) further assumes that an entity-mention score can be computed by using the maximum mention-

Table 1: A sample text

pair score. Both (2) and (1) can be approximated with a machine learning method, leading to the traditional mention-pair model and the entity-mention model for coreference resolution, respectively.

The two models will be described in the next subsections, with the sample text in Table 1 used for demonstration. In the table, a mention  $m$  is highlighted as  $[ m ]_{mid}^{eid}$ , where  $mid$  and  $eid$  are the IDs for the mention and the entity to which it belongs, respectively. Three entity chains can be found in the text, that is,

- e1** : *Microsoft Corp.* - *its* - *The company*
- e2** : *its new CEO* - *he*
- e3** : *yesterday*

### 3.1 Mention-Pair Model

As a baseline, we first describe a learning framework with the mention-pair model as adopted in the work by Soon et al. (2001) and Ng and Cardie (2002).

In the learning framework, a training or testing instance has the form of  $i\{m_k, m_j\}$ , in which  $m_j$  is an active mention and  $m_k$  is a preceding mention. An instance is associated with a vector of features, which is used to describe the properties of the two mentions as well as their relationships. Table 2 summarizes the features used in our study.

For training, given each encountered anaphoric mention  $m_j$  in a document, one single positive training instance is created for  $m_j$  and its closest antecedent. And a group of negative training instances is created for every intervening mentions between  $m_j$  and the antecedent. Consider the example text in Table 1, for the pronoun “*he*”, three instances are generated:  $i(\text{“The company”}, \text{“he”})$ ,  $i(\text{“yesterday”}, \text{“he”})$ , and  $i(\text{“its new CEO”}, \text{“he”})$ . Among them, the first two are labelled as negative while the last one is labelled as positive.

Based on the training instances, a binary classifier can be generated using any discriminative learning algorithm. During resolution, an input document is processed from the first mention to the last. For each

encountered mention  $m_j$ , a test instance is formed for each preceding mention,  $m_k$ . This instance is presented to the classifier to determine the coreference relationship.  $m_j$  is linked with the mention that is classified as positive (if any) with the highest confidence value.

### 3.2 Entity-Mention Model

The mention-based solution has a limitation that information beyond a mention pair cannot be captured. As an individual mention usually lacks complete description about the referred entity, the coreference relationship between two mentions may be not clear, which would affect classifier learning. Consider a document with three coreferential mentions “*Mr. Powell*”, “*he*”, and “*Powell*”, appearing in that order. The positive training instance  $i(\text{“he”}, \text{“Powell”})$  is not informative, as the pronoun “*he*” itself discloses nothing but the gender. However, if the whole entity is considered instead of only one mention, we can know that “*he*” refers to a male person named “*Powell*”. And consequently, the coreference relationships between the mentions would become more obvious.

The mention-pair model would also cause errors at a testing time. Suppose we have three mentions “*Mr. Powell*”, “*Powell*”, and “*she*” in a document. The model tends to link “*she*” with “*Powell*” because of their proximity. This error can be avoided, if we know “*Powell*” belongs to the entity starting with “*Mr. Powell*”, and therefore refers to a male person and cannot co-refer with “*she*”.

The entity-mention model based on Eq. (2) performs coreference resolution at an entity-level. For simplicity, the framework considered for the entity-mention model adopts similar training and testing procedures as for the mention-pair model. Specifically, a training or testing instance has the form of  $i\{e_i, m_j\}$ , in which  $m_j$  is an active mention and  $e_i$  is a partial entity found before  $m_j$ . During training, given each anaphoric mention  $m_j$ , one single positive training instance is created for the entity to which  $m_j$  belongs. And a group of negative training instances is created for every partial entity whose last mention occurs between  $m_j$  and the closest antecedent of  $m_j$ .

See the sample in Table 1 again. For the pronoun “*he*”, the following three instances are generated for

Features describing an active mention, $m_j$	
defNP <sub>_mj</sub>	1 if $m_j$ is a definite description; else 0
indefNP <sub>_mj</sub>	1 if $m_j$ is an indefinite NP; else 0
nameNP <sub>_mj</sub>	1 if $m_j$ is a named-entity; else 0
pron <sub>_mj</sub>	1 if $m_j$ is a pronoun; else 0
bareNP <sub>_mj</sub>	1 if $m_j$ is a bare NP (i.e., NP without determiners); else 0
Features describing a previous mention, $m_k$	
defNP <sub>_mk</sub>	1 if $m_k$ is a definite description; else 0
indefNP <sub>_mk</sub>	1 if $m_k$ is an indefinite NP; else 0
nameNP <sub>_mk</sub>	1 if $m_k$ is a named-entity; else 0
pron <sub>_mk</sub>	1 if $m_k$ is a pronoun; else 0
bareNP <sub>_mk</sub>	1 if $m_k$ is a bare NP; else 0
subject <sub>_mk</sub>	1 if $m_k$ is an NP in a subject position; else 0
Features describing the relationships between $m_k$ and $m_j$	
sentDist	sentence distance between two mentions
numAgree	1 if two mentions match in the number agreement; else 0
genderAgree	1 if two mentions match in the gender agreement; else 0
parallelStruct	1 if two mentions have an identical collocation pattern; else 0
semAgree	1 if two mentions have the same semantic category; else 0
nameAlias	1 if two mentions are an alias of the other; else 0
apposition	1 if two mentions are in an appositive structure; else 0
predicative	1 if two mentions are in a predicative structure; else 0
strMatch_Head	1 if two mentions have the same head string; else 0
strMatch_Full	1 if two mentions contain the same strings, excluding the determiners; else 0
strMatch_Contain	1 if the string of $m_j$ is fully contained in that of $m_k$ ; else 0

Table 2: Feature set for coreference resolution

entity  $e1$ ,  $e3$  and  $e2$ :

$i(\{\text{"Microsoft Corp."}, \text{"its"}, \text{"The company"}\}, \text{"he"}),$   
 $i(\{\text{"yesterday"}\}, \text{"he"}),$   
 $i(\{\text{"its new CEO"}\}, \text{"he"}).$

Among them, the first two are labelled as negative, while the last one is positive.

The resolution is done using a greedy clustering strategy. Given a test document, the mentions are processed one by one. For each encountered mention  $m_j$ , a test instance is formed for each partial entity found so far,  $e_i$ . This instance is presented to the classifier.  $m_j$  is appended to the entity that is classified as positive (if any) with the highest confidence value. If no positive entity exists, the active mention is deemed as non-anaphoric and forms a new entity. The process continues until the last mention of the document is reached.

One potential problem with the entity-mention model is how to represent the entity-level knowledge. As an entity may contain more than one candidate and the number is not fixed, it is impractical to enumerate all the mentions in an entity and put their properties into a single feature vector. As a baseline, we follow the solution proposed in (Luo et al., 2004) to design a set of first-order features. The features are similar to those for the mention-pair model as shown in Table 2, but their values are calculated at an entity level. Specifically, the lexical and grammatical features are computed by testing any mention<sup>1</sup> in the entity against the active mention, for ex-

ample, the feature *nameAlias* is assigned value 1 if at least one mention in the entity is a name alias of the active mention. The distance feature (i.e., *sentDist*) is the minimum distance between the mentions in the entity and the active mention.

The above entity-level features are designed in an ad-hoc way. They cannot capture the detailed information of each individual mention in an entity. In the next section, we will present a more expressive entity-mention model by using ILP.

## 4 Entity-mention Model with ILP

### 4.1 Motivation

The entity-mention model based on Eq. (2) requires relational knowledge that involves information of an active mention ( $m_j$ ), an entity ( $e_i$ ), and the mentions in the entity ( $\{m_k \in e_i\}$ ). However, normal machine learning algorithms work on attribute-value vectors, which only allows the representation of atomic proposition. To learn from relational knowledge, we need an algorithm that can express first-order logic. This requirement motivates our use of Inductive Logic Programming (ILP), a learning algorithm capable of inferring logic programs. The relational nature of ILP makes it possible to explicitly represent relations between an entity and its mentions, and thus provides a powerful expressiveness for the coreference resolution task.

reference relationship with antecedents in a local discourse. Hence, if an active mention is a pronoun, we only consider the mentions in its previous two sentences for feature computation.

<sup>1</sup>Linguistically, pronouns usually have the most direct coref-

ILP uses logic programming as a uniform representation for examples, background knowledge and hypotheses. Given a set of positive and negative example  $E = E^+ \cup E^-$ , and a set of background knowledge  $K$  of the domain, ILP tries to induce a set of hypotheses  $h$  that covers most of  $E^+$  with no  $E^-$ , i.e.,  $K \wedge h \models E^+$  and  $K \wedge h \not\models E^-$ .

In our study, we choose ALEPH<sup>2</sup>, an ILP implementation by Srinivasan (2000) that has been proven well suited to deal with a large amount of data in multiple domains. For its routine use, ALEPH follows a simple procedure to induce rules. It first selects an example and builds the most specific clause that entertains the example. Next, it tries to search for a clause more general than the bottom one. The best clause is added to the current theory and all the examples made redundant are removed. The procedure repeats until all examples are processed.

## 4.2 Apply ILP to coreference resolution

Given a document, we encode a mention or a partial entity with a unique constant. Specifically,  $m_j$  represents the  $j$ th mention (e.g.,  $m_6$  for the pronoun “he”).  $e_{i-j}$  represents the partial entity  $i$  before the  $j$ th mention. For example,  $e_{1-6}$  denotes the part of  $e_1$  before  $m_6$ , i.e., {“Microsoft Corp.”, “its”, “the company”}, while  $e_{1-5}$  denotes the part of  $e_1$  before  $m_5$  (“The company”), i.e., {“Microsoft Corp.”, “its”}.

Training instances are created as described in Section 3.2 for the entity-mention model. Each instance is recorded with a predicate  $link(e_{i-j}, m_j)$ , where  $m_j$  is an active mention and  $e_{i-j}$  is a partial entity. For example, the three training instances formed by the pronoun “he” are represented as follows:

$link(e_{1-6}, m_6)$ .

$link(e_{3-6}, m_6)$ .

$link(e_{2-6}, m_6)$ .

The first two predicates are put into  $E^-$ , while the last one is put to  $E^+$ .

The background knowledge for an instance  $link(e_{i-j}, m_j)$  is also represented with predicates, which are divided into the following types:

1. Predicates describing the information related to  $e_{i-j}$  and  $m_j$ . The properties of  $m_j$  are pre-

<sup>2</sup>[http://web.comlab.ox.ac.uk/oucl/research/areas/machlearn/Aleph/aleph\\_toc.html](http://web.comlab.ox.ac.uk/oucl/research/areas/machlearn/Aleph/aleph_toc.html)

sented with predicates like  $f(m, v)$ , where  $f$  corresponds to a feature in the first part of Table 2 (removing the suffix  $_mj$ ), and  $v$  is its value. For example, the pronoun “he” can be described by the following predicates:

$defNP(m_6, 0)$ .  $indefNP(m_6, 0)$ .

$nameNP(m_6, 0)$ .  $pron(m_6, 1)$ .

$bareNP(m_6, 0)$ .

The predicates for the relationships between  $e_{i-j}$  and  $m_j$  take a form of  $f(e, m, v)$ . In our study, we consider the number agreement (*entNumAgree*) and the gender agreement (*entGenderAgree*) between  $e_{i-j}$  and  $m_j$ .  $v$  is 1 if all of the mentions in  $e_{i-j}$  have consistent number/gender agreement with  $m_j$ , e.g.,  $entNumAgree(e_{1-6}, m_6, 1)$ .

2. Predicates describing the belonging relations between  $e_{i-j}$  and its mentions. A predicate  $has\_mention(e, m)$  is used for each mention in  $e$ <sup>3</sup>. For example, the partial entity  $e_{1-6}$  has three mentions,  $m_1$ ,  $m_2$  and  $m_5$ , which can be described as follows:

$has\_mention(e_{1-6}, m_1)$ .

$has\_mention(e_{1-6}, m_2)$ .

$has\_mention(e_{1-6}, m_5)$ .

3. Predicates describing the information related to  $m_j$  and each mention  $m_k$  in  $e_{i-j}$ . The predicates for the properties of  $m_k$  correspond to the features in the second part of Table 2 (removing the suffix  $_mk$ ), while the predicates for the relationships between  $m_j$  and  $m_k$  correspond to the features in the third part of Table 2. For example, given the two mentions  $m_1$  (“Microsoft Corp.”) and  $m_6$  (“he”), the following predicates can be applied:

$nameNP(m_1, 1)$ .

$pron(m_1, 0)$ .

...

$nameAlias(m_1, m_6, 0)$ .

$sentDist(m_1, m_6, 1)$ .

...

the last two predicates represent that  $m_1$  and

<sup>3</sup>If an active mention  $m_j$  is a pronoun, only the previous mentions in two sentences apart are recorded by *has\\_mention*, while the farther ones are ignored as they have less impact on the resolution of the pronoun.

$m_6$  are not name alias, and are one sentence apart.

By using the three types of predicates, the different knowledge related to entities and mentions are integrated. The predicate *has\_mention* acts as a bridge connecting the entity-mention knowledge and the mention-pair knowledge. As a result, when evaluating the coreference relationship between an active mention and an entity, we can make use of the “global” information about the entity, as well as the “local” information of each individual mention in the entity.

From the training instances and the associated background knowledge, a set of hypotheses can be automatically learned by ILP. Each hypothesis is output as a rule that may look like:

*link(A,B):-*  
*predi1, predi2, ..., has\_mention(A,C), ..., prediN.*  
 which corresponds to first-order logic  
 $\forall A, B (predi1 \wedge predi2 \wedge \dots \wedge$   
 $\exists C (has\_mention(A, C) \wedge \dots \wedge prediN)$   
 $\rightarrow link(A, B))$

Consider an example rule produced in our system:

*link(A,B) :-*  
*has\_mention(A,C), numAgree(B,C,1),*  
*strMatch\_Head(B,C,1), bareNP(C,1).*

Here, variables  $A$  and  $B$  stand for an entity and an active mention in question. The first-order logic is implemented by using non-instantiated arguments  $C$  in the predicate *has\_mention*. This rule states that a mention  $B$  should belong to an entity  $A$ , if there exists a mention  $C$  in  $A$  such that  $C$  is a bare noun phrase with the same head string as  $B$ , and matches in number with  $B$ . In this way, the detailed information of each individual mention in an entity can be captured for resolution.

A rule is applicable to an instance  $link(e, m)$ , if the background knowledge for the instance can be described by the predicates in the body of the rule. Each rule is associated with a score, which is the accuracy that the rule can produce for the training instances.

The learned rules are applied to resolution in a similar way as described in Section 3.2. Given an active mention  $m$  and a partial entity  $e$ , a test instance  $link(e, m)$  is formed and tested against every rule in the rule set. The confidence that  $m$  should

	Train		Test

belong to  $e$  is the maximal score of the applicable rules. An active mention is linked to the entity with the highest confidence value (above 0.5), if any.

## 5 Experiments and Results

### 5.1 Experimental Setup

In our study, we did evaluation on the ACE-2003 corpus, which contains two data sets, training and devtest, used for training and testing respectively. Each of these sets is further divided into three domains: newswire (NWire), newspaper (NPaper), and broadcast news (BNews). The number of entities with more than one mention, as well as the number of the contained mentions, is summarized in Table 3.

For both training and resolution, an input raw document was processed by a pipeline of NLP modules including Tokenizer, Part-of-Speech tagger, NP Chunker and Named-Entity (NE) Recognizer. Trained and tested on Penn WSJ TreeBank, the POS tagger could obtain an accuracy of 97% and the NP chunker could produce an F-measure above 94% (Zhou and Su, 2000). Evaluated for the MUC-6 and MUC-7 Named-Entity task, the NER module (Zhou and Su, 2002) could provide an F-measure of 96.6% (MUC-6) and 94.1% (MUC-7). For evaluation, Vilain et al. (1995)’s scoring algorithm was adopted to compute recall and precision rates.

By default, the ALEPH algorithm only generates rules that have 100% accuracy for the training data. And each rule contains at most three predicates. To accommodate for coreference resolution, we loosened the restrictions to allow rules that have above 50% accuracy and contain up to ten predicates. Default parameters were applied for all the other settings in ALEPH as well as other learning algorithms used in the experiments.

### 5.2 Results and Discussions

Table 4 lists the performance of different coreference resolution systems. For comparison, we first

	NWire			NPaper			BNews

Table 4: Results of different systems for coreference resolution

examined the C4.5 algorithm<sup>4</sup> which is widely used for the coreference resolution task. The first line of the table shows the baseline system that employs the traditional mention-pair model (MP) as described in Section 3.1. From the table, our baseline system achieves a recall of around 66%-68% and a precision of around 50%-60%. The overall F-measure for NWire, NPaper and BNews is 60.4%, 57.9% and 62.9% respectively. The results are comparable to those reported in (Ng, 2005) which uses similar features and gets an F-measure ranging in 50-60% for the same data set. As our system relies only on simple and knowledge-poor features, the achieved F-measure is around 2-4% lower than the state-of-the-art systems do, like (Ng, 2007) and (Yang and Su, 2007) which utilized sophisticated semantic or real-world knowledge. Since ILP has a strong capability in knowledge management, our system could be further improved if such helpful knowledge is incorporated, which will be explored in our future work.

The second line of Table 4 is for the system that employs the entity-mention model (EM) with “Any-X” based entity features, as described in Section 3.2. We can find that the EM model does not show superiority over the baseline MP model. It achieves a higher precision (up to 2.6%), but a lower recall (2.9%), than MP. As a result, we only see  $\pm 0.4\%$  difference between the F-measure. The results are consistent with the reports by Luo et al. (2004) that the entity-mention model with the “Any-X” first-order features performs worse than the normal mention-pair model. In our study, we also tested the “Most-X” strategy for the first-order features as in (Culotta et al., 2007), but got similar results without much difference ( $\pm 0.5\%$  F-measure) in perfor-

mance. Besides, as with our entity-mention predicates described in Section 4.2, we also tried the “All-X” strategy for the entity-level agreement features, that is, whether all mentions in a partial entity agree in number and gender with an active mention. However, we found this bring no improvement against the “Any-X” strategy.

As described, given an active mention  $m_j$ , the MP model only considers the mentions between  $m_j$  and its closest antecedent. By contrast, the EM model considers not only these mentions, but also their antecedents in the same entity link. We were interested in examining what if the MP model utilizes all the mentions in an entity as the EM model does. As shown in the third line of Table 4, such a solution damages the performance; while the recall is at the same level, the precision drops significantly (up to 12%) and as a result, the F-measure is even lower than the original MP model. This should be because a mention does not necessarily have direct coreference relationships with all of its antecedents. As the MP model treats each mention-pair as an independent instance, including all the antecedents would produce many less-confident positive instances, and thus adversely affect training.

The second block of the table summarizes the performance of the systems with ILP. We were first concerned with how well ILP works for the mention-pair model, compared with the normally used algorithm C4.5. From the results shown in the fourth line of Table 4, ILP exhibits the same capability in the resolution; it tends to produce a slightly higher precision but a lower recall than C4.5 does. Overall, it performs better in F-measure (1.8%) for Npaper, while slightly worse ( $< 1\%$ ) for Nwire and BNews. These results demonstrate that ILP could be used as

Figure 1: Examples of rules produced by ILP (entity-mention model)

a good classifier learner for the mention-pair model.

The fifth line of Table 4 is for the ILP based entity-mention model (described in Section 4.2). We can observe that the model leads to a better performance than all the other models. Compared with the system with the MP model (under ILP), the EM version is able to achieve a higher precision (up to 4.6% for BNews). Although the recall drops slightly (up to 1.8% for BNews), the gain in the precision could compensate it well; it beats the MP model in the overall F-measure for all three domains (2.3% for Nwire, 0.4% for Npaper, 1.4% for BNews). Especially, the improvement in NWire and BNews is statistically significant under a 2-tailed  $t$  test ( $p < 0.05$ ). Compared with the EM model with the manually designed first-order feature (the second line), the ILP-based EM solution also yields better performance in precision (with a slightly lower recall) as well as the overall F-measure (1.0% - 1.8%).

The improvement in precision against the mention-pair model confirms that the global information beyond a single mention pair, when being considered for training, can make coreference relations clearer and help classifier learning. The better performance against the EM model with heuristically designed features also suggests that ILP is able to learn effective first-order rules for the coreference resolution task.

In Figure 1, we illustrate part of the rules produced by ILP for the entity-mention model (NWire domain), which shows how the relational knowledge of entities and mentions is represented for decision making. An interesting finding, as shown in the last

rule of the table, is that multiple non-instantiated arguments (i.e.  $C$  and  $D$ ) could possibly appear in the same rule. According to this rule, a pronominal mention should be linked with a partial entity which contains a named-entity and contains an indefinite NP in a subject position. This supports the claims in (Yang et al., 2004a) that coreferential information is an important factor to evaluate a candidate antecedent in pronoun resolution. Such complex logic makes it possible to capture information of multiple mentions in an entity at the same time, which is difficult to implemented in the mention-pair model and the ordinary entity-mention model with heuristic first-order features.

## 6 Conclusions

This paper presented an expressive entity-mention model for coreference resolution by using Inductive Logic Programming. In contrast to the traditional mention-pair model, our model can capture information beyond single mention pairs for both training and testing. The relational nature of ILP enables our model to explicitly express the relations between an entity and its mentions, and to automatically learn the first-order rules effective for the coreference resolution task. The evaluation on ACE data set shows that the ILP based entity-model performs better than the mention-pair model (with up to 2.3% increase in F-measure), and also beats the entity-mention model with heuristically designed first-order features.

Our current work focuses on the learning model that calculates the probability of a mention belonging to an entity. For simplicity, we just use a greedy clustering strategy for resolution, that is, a mention is linked to the current best partial entity. In our future work, we would like to investigate more sophisticated clustering methods that would lead to global optimization, e.g., by keeping a large search space (Luo et al., 2004) or using integer programming (Denis and Baldridge, 2007).

## Abstract

This paper explores the relationship between discourse segmentation and coverbal gesture. Introducing the idea of *gestural cohesion*, we show that coherent topic segments are characterized by homogeneous gestural forms and that changes in the distribution of gestural features predict segment boundaries. Gestural features are extracted automatically from video, and are combined with lexical features in a Bayesian generative model. The resulting multimodal system outperforms text-only segmentation on both manual and automatically-recognized speech transcripts.

## 1 Introduction

When people communicate face-to-face, discourse cues are expressed simultaneously through multiple channels. Previous research has extensively studied how discourse cues correlate with lexico-syntactic and prosodic features (Hearst, 1994; Hirschberg and Nakatani, 1998; Passonneau and Litman, 1997); this work informs various text and speech processing applications, such as automatic summarization and segmentation. Gesture is another communicative modality that frequently accompanies speech, yet it has not been exploited for computational discourse analysis.

This paper empirically demonstrates that gesture correlates with discourse structure. In particular, we show that automatically-extracted visual features can be combined with lexical cues in a statistical model to predict topic segmentation, a frequently studied form of discourse structure. Our

method builds on the idea that coherent discourse segments are characterized by *gestural cohesion*; in other words, that such segments exhibit homogeneous gestural patterns. Lexical cohesion (Halliday and Hasan, 1976) forms the backbone of many verbal segmentation algorithms, on the theory that segmentation boundaries should be placed where the distribution of words changes (Hearst, 1994). With gestural cohesion, we explore whether the same idea holds for gesture features.

The motivation for this approach comes from a series of psycholinguistic studies suggesting that gesture supplements speech with meaningful and unique semantic content (McNeill, 1992; Kendon, 2004). We assume that repeated patterns in gesture are indicative of the semantic coherence that characterizes well-defined discourse segments. An advantage of this view is that gestures can be brought to bear on discourse analysis without undertaking the daunting task of recognizing and interpreting individual gestures. This is crucial because coverbal gesture – unlike formal sign language – rarely follows any predefined form or grammar, and may vary dramatically by speaker.

A key implementational challenge is automatically extracting gestural information from raw video and representing it in a way that can be applied to discourse analysis. We employ a representation of *visual codewords*, which capture clusters of low-level motion patterns. For example, one codeword may correspond to strong left-right motion in the upper part of the frame. These codewords are then treated similarly to lexical items; our model identifies changes in their distribution, and predicts topic

boundaries appropriately. The overall framework is implemented as a hierarchical Bayesian model, supporting flexible integration of multiple knowledge sources.

Experimental results support the hypothesis that gestural cohesion is indicative of discourse structure. Applying our algorithm to a dataset of face-to-face dialogues, we find that gesture communicates unique information, improving segmentation performance over lexical features alone. The positive impact of gesture is most pronounced when automatically-recognized speech transcripts are used, but gestures improve performance by a significant margin even in combination with manual transcripts.

## 2 Related Work

**Gesture and discourse** Much of the work on gesture in natural language processing has focused on multimodal dialogue systems in which the gestures and speech may be constrained, e.g. (Johnston, 1998). In contrast, we focus on improving discourse processing on unconstrained natural language between humans. This effort follows basic psychological and linguistic research on the communicative role of gesture (McNeill, 1992; Kendon, 2004), including some efforts that made use of automatically acquired visual features (Quek, 2003). We extend these empirical studies with a statistical model of the relationship between gesture and discourse segmentation.

Hand-coded descriptions of body posture shifts and eye gaze behavior have been shown to correlate with topic and turn boundaries in task-oriented dialogue (Cassell et al., 2001). These findings are exploited to generate realistic conversational “grounding” behavior in an animated agent. The semantic content of gesture was leveraged – again, for gesture generation – in (Kopp et al., 2007), which presents an animated agent that is capable of augmenting navigation directions with gestures that describe the physical properties of landmarks along the route. Both systems generate plausible and human-like gestural behavior; we address the converse problem of *interpreting* such gestures.

In this vein, hand-coded gesture features have been used to improve sentence segmentation, show-

ing that sentence boundaries are unlikely to overlap gestures that are in progress (Chen et al., 2006). Features that capture the start and end of gestures are shown to improve sentence segmentation beyond lexical and prosodic features alone. This idea of gestural features as a sort of visual punctuation has parallels in the literature on prosody, which we discuss in the next subsection.

Finally, ambiguous noun phrases can be resolved by examining the similarity of co-articulated gestures (Eisenstein and Davis, 2007). While noun phrase coreference can be viewed as a discourse processing task, we address the higher-level discourse phenomenon of topic segmentation. In addition, this prior work focused primarily on pointing gestures directed at pre-printed visual aids. The current paper presents a new domain, in which speakers do not have access to visual aids. Thus pointing gestures are less frequent than “iconic” gestures, in which the form of motion is the principle communicative feature (McNeill, 1992).

**Non-textual features for topic segmentation** Research on non-textual features for topic segmentation has primarily focused on prosody, under the assumption that a key prosodic function is to mark structure at the discourse level (Steedman, 1990; Grosz and Hirshberg, 1992; Swerts, 1997). The ultimate goal of this research is to find correlates of hierarchical discourse structure in phonetic features.

Today, research on prosody has converged on prosodic cues which correlate with discourse structure. Such markers include pause duration, fundamental frequency, and pitch range manipulations (Grosz and Hirshberg, 1992; Hirschberg and Nakatani, 1998). These studies informed the development of applications such as segmentation tools for meeting analysis, e.g. (Tur et al., 2001; Galley et al., 2003).

In comparison, the connection between gesture and discourse structure is a relatively unexplored area, at least with respect to computational approaches. One conclusion that emerges from our analysis is that gesture may signal discourse structure in a different way than prosody does: while specific prosodic markers characterize segment boundaries, gesture predicts segmentation through intra-segmental cohesion. The combination of these two

modalities is an exciting direction for future research.

### 3 Visual Features for Discourse Analysis

This section describes the process of building a representation that permits the assessment of gestural cohesion. The core signal-level features are based on *spatiotemporal interest points*, which provide a sparse representation of the motion in the video. At each interest point, visual, spatial, and kinematic characteristics are extracted and then concatenated into vectors. Principal component analysis (PCA) reduces the dimensionality to a feature vector of manageable size (Bishop, 2006). These feature vectors are then clustered, yielding a codebook of visual forms. This video processing pipeline is shown in Figure 1; the remainder of the section describes the individual steps in greater detail.

#### 3.1 Spatiotemporal Interest Points

Spatiotemporal interest points (Laptev, 2005) provide a sparse representation of motion in video. The idea is to select a few local regions that contain high information content in both the spatial and temporal dimensions. The image features at these regions should be relatively robust to lighting and perspective changes, and they should capture the relevant movement in the video. The set of spatiotemporal interest points thereby provides a highly compressed representation of the key visual features. Purely spatial interest points have been successful in a variety of image processing tasks (Lowe, 1999), and spatiotemporal interest points are beginning to show similar advantages for video processing (Laptev, 2005).

The use of spatiotemporal interest points is specifically motivated by techniques from the computer vision domain of *activity recognition* (Efros et al., 2003; Niebles et al., 2006). The goal of activity recognition is to classify video sequences into semantic categories: e.g., walking, running, jumping. As a simple example, consider the task of distinguishing videos of walking from videos of jumping. In the walking videos, the motion at most of the interest points will be horizontal, while in the jumping videos it will be vertical. Spurious vertical motion in a walking video is unlikely to confuse the

classifier, as long as the majority of interest points move horizontally. The hypothesis of this paper is that just as such low-level movement features can be applied in a supervised fashion to distinguish activities, they can be applied in an unsupervised fashion to group co-speech gestures into perceptually meaningful clusters.

The Activity Recognition Toolbox (Dollár et al., 2005)<sup>1</sup> is used to detect spatiotemporal interest points for our dataset. This toolbox ranks interest points using a difference-of-Gaussians filter in the spatial dimension, and a set of Gabor filters in the temporal dimension. The total number of interest points extracted per video is set to equal the number of frames in the video. This bounds the complexity of the representation to be linear in the length of the video; however, the system may extract many interest points in some frames and none in other frames.

Figure 2 shows the interest points extracted from a representative video frame from our corpus. Note that the system has identified high contrast regions of the gesturing hand. From manual inspection, the large majority of interest points extracted in our dataset capture motion created by hand gestures. Thus, for this dataset it is reasonable to assume that an interest point-based representation expresses the visual properties of the speakers' hand gestures. In videos containing other sources of motion, preprocessing may be required to filter out interest points that are extraneous to gestural communication.

#### 3.2 Visual Descriptors

At each interest point, the temporal and spatial brightness gradients are constructed across a small space-time volume of nearby pixels. Brightness gradients have been used for a variety of problems in computer vision (Forsyth and Ponce, 2003), and provide a fairly general way to describe the visual appearance of small image patches. However, even for a small space-time volume, the resulting dimensionality is still quite large: a 10-by-10 pixel box across 5 video frames yields a 500-dimensional feature vector for each of the three gradients. For this reason, principal component analysis (Bishop, 2006) is used to reduce the dimensionality. The spatial location of the interest point is added to the final feature vector.

<sup>1</sup>[http://vision.ucsd.edu/~pdollar/research/cuboids\\_doc/index.html](http://vision.ucsd.edu/~pdollar/research/cuboids_doc/index.html)

Figure 1: The visual processing pipeline for the extraction of gestural codewords from video.

Figure 2: Circles indicate the interest points extracted from this frame of the corpus.

This visual feature representation is substantially lower-level than the descriptions of gesture form found in both the psychology and computer science literatures. For example, when manually annotating gesture, it is common to employ a taxonomy of hand shapes and trajectories, and to describe the location with respect to the body and head (McNeill, 1992; Martell, 2005). Working with automatic hand tracking, Quek (2003) automatically computes perceptually-salient gesture features, such as symmetric motion and oscillatory repetitions.

In contrast, our feature representation takes the form of a vector of continuous values and is not easily interpretable in terms of how the gesture actually appears. However, this low-level approach offers several important advantages. Most critically, it requires no initialization and comparatively little tuning: it can be applied directly to any video with a fixed camera position and static background. Second, it is robust: while image noise may cause a few spurious interest points, the majority of interest points should still guide the system to an appropriate characterization of the gesture. In contrast, hand tracking can become irrevocably lost, requiring

manual resets (Gavrila, 1999). Finally, the success of similar low-level interest point representations at the activity-recognition task provides reason for optimism that they may also be applicable to unsupervised gesture analysis.

### 3.3 A Lexicon of Visual Forms

After extracting a set of low-dimensional feature vectors to characterize the visual appearance at each spatiotemporal interest point, it remains only to convert this into a representation amenable to a cohesion-based analysis. Using k-means clustering (Bishop, 2006), the feature vectors are grouped into *codewords*: a compact, lexicon-like representation of salient visual features in video. The number of clusters is a tunable parameter, though a systematic investigation of the role of this parameter is left for future work.

Codewords capture frequently-occurring patterns of motion and appearance at a local scale – interest points that are clustered together have a similar visual appearance. Because most of the motion in our videos is gestural, the codewords that appear during a given sentence provide a succinct representation of the ongoing gestural activity. Distributions of codewords over time can be analyzed in similar terms to the distribution of lexical features. A change in the distribution of codewords indicates new visual kinematic elements entering the discourse. Thus, the codeword representation allows gestural cohesion to be assessed in much the same way as lexical cohesion.

## 4 Bayesian Topic Segmentation

Topic segmentation is performed in a Bayesian framework, with each sentence’s segment index encoded in a hidden variable, written  $z_t$ . The hidden variables are assumed to be generated by a linear segmentation, such that  $z_t \in \{z_{t-1}, z_{t-1} + 1\}$ . Observations – the words and gesture codewords – are

generated by multinomial language models that are indexed according to the segment. In this framework, a high-likelihood segmentation will include language models that are tightly focused on a compact vocabulary. Such a segmentation maximizes the lexical cohesion of each segment. This model thus provides a principled, probabilistic framework for cohesion-based segmentation, and we will see that the Bayesian approach is particularly well-suited to the combination of multiple modalities.

Formally, our goal is to identify the best possible segmentation  $S$ , where  $S$  is a tuple:  $S = \langle \mathbf{z}, \theta, \phi \rangle$ . The segment indices for each sentence are written  $z_t$ ; for segment  $i$ ,  $\theta_i$  and  $\phi_i$  are multinomial language models over words and gesture codewords respectively. For each sentence,  $\mathbf{x}_t$  and  $\mathbf{y}_t$  indicate the words and gestures that appear. We will seek to identify the segmentation  $\hat{S} = \operatorname{argmax}_S p(S, \mathbf{x}, \mathbf{y})$ , conditioned on priors that will be defined below.

$$p(S, \mathbf{x}, \mathbf{y}) = p(\mathbf{x}, \mathbf{y} | S) p(S)$$

$$p(\mathbf{x}, \mathbf{y} | S) = \prod_i p(\{x_t : z_t = i\} | \theta_i) p(\{y_t : z_t = i\} | \phi_i)$$
(1)

$$p(S) = p(\mathbf{z}) \prod_i p(\theta_i) p(\phi_i)$$
(2)

The language models  $\theta_i$  and  $\phi_i$  are multinomial distributions, so the log-likelihood of the observations  $\mathbf{x}_t$  is  $\log p(\mathbf{x}_t | \theta_i) = \sum_j^W n(t, j) \log \theta_{i,j}$ , where  $n(t, j)$  is the count of word  $j$  in sentence  $t$ , and  $W$  is the size of the vocabulary. An analogous equation is used for the gesture codewords. Each language model is given a symmetric Dirichlet prior  $\alpha$ . As we will see shortly, the use of different priors for the verbal and gestural language models allows us to weight these modalities in a Bayesian framework. Finally, we model the probability of the segmentation  $\mathbf{z}$  by considering the durations of each segment:  $p(\mathbf{z}) = \prod_i p(\operatorname{dur}(i) | \psi)$ . A negative-binomial distribution with parameter  $\psi$  is applied to discourage extremely short or long segments.

**Inference** Crucially, both the likelihood (equation 1) and the prior (equation 2) factor into a product across the segments. This factorization enables the optimal segmentation to be found using a dynamic program, similar to those demonstrated by Utiyama and Isahara (2001) and Malioutov and

Barzilay (2006). For each set of segmentation points  $\mathbf{z}$ , the associated language models are set to their posterior expectations, e.g.,  $\theta_i = E[\theta | \{x_t : z_t = i\}, \alpha]$ .

The Dirichlet prior is conjugate to the multinomial, so this expectation can be computed in closed form:

$$\theta_{i,j} = \frac{n(i, j) + \alpha}{N(i) + W\alpha},$$
(3)

where  $n(i, j)$  is the count of word  $j$  in segment  $i$  and  $N(i)$  is the total number of words in segment  $i$  (Bernardo and Smith, 2000). The symmetric Dirichlet prior  $\alpha$  acts as a smoothing pseudo-count. In the multimodal context, the priors act to control the weight of each modality. If the prior for the verbal language model  $\theta$  is high relative to the prior for the gestural language model  $\phi$  then the verbal multinomial will be smoother, and will have a weaker impact on the final segmentation. The impact of the priors on the weights of each modality is explored in Section 6.

**Estimation of priors** The distribution over segment durations is negative-binomial, with parameters  $\psi$ . In general, the maximum likelihood estimate of the parameters of a negative-binomial distribution cannot be found in closed form (Balakrishnan and Nevzorov, 2003). For any given segmentation, the maximum-likelihood setting for  $\psi$  is found via a gradient-based search. This setting is then used to generate another segmentation, and the process is iterated until convergence, as in hard expectation-maximization. The Dirichlet priors on the language models are symmetric, and are chosen via cross-validation. Sampling or gradient-based techniques may be used to estimate these parameters, but this is left for future work.

**Relation to other segmentation models** Other cohesion-based techniques have typically focused on hand-crafted similarity metrics between sentences, such as cosine similarity (Galley et al., 2003; Malioutov and Barzilay, 2006). In contrast, the model described here is probabilistically motivated, maximizing the joint probability of the segmentation with the observed words and gestures. Our objective criterion is similar in form to that of Utiyama and Isahara (2001); however, in contrast to this prior

work, our criterion is justified by a Bayesian approach. Also, while the smoothing in our approach arises naturally from the symmetric Dirichlet prior, Utiyama and Isahara apply Laplace’s rule and add pseudo-counts of one in all cases. Such an approach would be incapable of flexibly balancing the contributions of each modality.

## 5 Evaluation Setup

**Dataset** Our dataset is composed of fifteen audio-video recordings of dialogues limited to three minutes in duration. The dataset includes nine different pairs of participants. In each video one of five subjects is discussed. The potential subjects include a “Tom and Jerry” cartoon, a “Star Wars” toy, and three mechanical devices: a latchbox, a piston, and a candy dispenser. One participant – “participant A” – was familiarized with the topic, and is tasked with explaining it to participant B, who is permitted to ask questions. Audio from both participants is used, but only video of participant A is used; we do not examine whether B’s gestures are relevant to discourse segmentation.

Video was recorded using standard camcorders, with a resolution of 720 by 480 at 30 frames per second. The video was reduced to 360 by 240 gray-scale images before visual analysis is applied. Audio was recorded using headset microphones. No manual postprocessing is applied to the video.

**Annotations and data processing** All speech was transcribed by hand, and time stamps were obtained using the SPHINX-II speech recognition system for forced alignment (Huang et al., 1993). Sentence boundaries are annotated according to (NIST, 2003), and additional sentence boundaries are automatically inserted at all turn boundaries. Commonly-occurring terms unlikely to impact segmentation are automatically removed by using a stoplist.

For automatic speech recognition, the default Microsoft speech recognizer was applied to each sentence, and the top-ranked recognition result was reported. As is sometimes the case in real-world applications, no speaker-specific training data is available. The resulting recognition quality is very poor, yielding a word error rate of 77%.

Annotators were instructed to select segment boundaries that divide the dialogue into coherent

topics. Segmentation points are required to coincide with sentence or turn boundaries. A second annotator – who is not an author on any paper connected with this research – provided an additional set of segment annotations on six documents. On this subset of documents, the  $P_k$  between annotators was .306, and the WindowDiff was .325 (these metrics are explained in the next subsection). This is similar to the interrater agreement reported by Malioutov and Barzilay (2006).

Over the fifteen dialogues, a total of 7458 words were transcribed (497 per dialogue), spread over 1440 sentences or interrupted turns (96 per dialogue). There were a total of 102 segments (6.8 per dialogue), from a minimum of four to a maximum of ten. This rate of fourteen sentences or interrupted turns per segment indicates relatively fine-grained segmentation. In the physics lecture corpus used by Malioutov and Barzilay (2006), there are roughly 100 sentences per segment. On the ICSI corpus of meeting transcripts, Galley *et al.* (2003) report 7.5 segments per meeting, with 770 “potential boundaries,” suggesting a similar rate of roughly 100 sentences or interrupted turns per segment.

The size of this multimodal dataset is orders of magnitude smaller than many other segmentation corpora. For example, the Broadcast News corpus used by Beeferman *et al.* (1999) and others contains two million words. The entire ICSI meeting corpus contains roughly 600,000 words, although only one third of this dataset was annotated for segmentation (Galley et al., 2003). The physics lecture corpus that was mentioned above contains 232,000 words (Malioutov and Barzilay, 2006). The task considered in this section is thus more difficult than much of the previous discourse segmentation work on two dimensions: there is less training data, and a finer-grained segmentation is required.

**Metrics** All experiments are evaluated in terms of the commonly-used  $P_k$  (Beeferman et al., 1999) and WindowDiff (WD) (Pevzner and Hearst, 2002) scores. These metrics are penalties, so lower values indicate better segmentations. The  $P_k$  metric expresses the probability that any randomly chosen pair of sentences is incorrectly segmented, if they are  $k$  sentences apart (Beeferman et al., 1999). Following tradition,  $k$  is set to half of the mean seg-

Method	$P_k$	WD
1. gesture only	.486	.502
2. ASR only	.462	.476
3. ASR + gesture	<b>.388</b>	<b>.401</b>
4. transcript only	.382	.397
5. transcript + gesture	<b>.332</b>	<b>.349</b>
6. random	.473	.526
7. equal-width	.508	.515

Table 1: For each method, the score of the best performing configuration is shown.  $P_k$  and WD are penalties, so lower values indicate better performance.

ment length. The WindowDiff metric is a variation of  $P_k$  (Pevzner and Hearst, 2002), applying a penalty whenever the number of segments within the  $k$ -sentence window differs for the reference and hypothesized segmentations.

**Baselines** Two naïve baselines are evaluated. Given that the annotator has divided the dialogue into  $K$  segments, the random baseline arbitrary chooses  $K$  random segmentation points. The results of this baseline are averaged over 1000 iterations. The equal-width baseline places boundaries such that all segments contain an equal number of sentences. Both the experimental systems and these naïve baselines were given the correct number of segments, and also were provided with manually annotated sentence boundaries – their task is to select the  $k$  sentence boundaries that most accurately segment the text.

## 6 Results

Table 1 shows the segmentation performance for a range of feature sets, as well as the two baselines. Given only gesture features the segmentation results are poor (line 1), barely outperforming the baselines (lines 6 and 7). However, gesture proves highly effective as a supplementary modality. The combination of gesture with ASR transcripts (line 3) yields an absolute 7.4% improvement over ASR transcripts alone (line 4). Paired t-tests show that this result is statistically significant ( $t(14) = 2.71, p < .01$  for both  $P_k$  and WindowDiff). Even when manual speech transcripts are available, gesture features yield a substantial improvement, reducing  $P_k$  and WD by roughly 5%. This result is statistically sig-

nificant for both  $P_k$  ( $t(14) = 2.00, p < .05$ ) and WD ( $t(14) = 1.94, p < .05$ ).

**Interactions of verbal and gesture features** We now consider the relative contribution of the verbal and gesture features. In a discriminative setting, the contribution of each modality would be explicitly weighted. In a Bayesian generative model, the same effect is achieved through the Dirichlet priors, which act to smooth the verbal and gestural multinomials – see equation 3. For example, when the gesture prior is high and verbal prior is low, the gesture counts are smoothed, and the verbal counts play a greater role in segmentation. When both priors are very high, the model will simply try to find equally-sized segments, satisfying the distribution over durations.

The effects of these parameters can be seen in Figure 3. The gesture model prior is held constant at its ideal value, and the segmentation performance is plotted against the logarithm of the verbal prior. Low values of the verbal prior cause it to dominate the segmentation; this can be seen at the left of both graphs, where the performance of the multimodal and verbal-only systems are nearly identical. High values of the verbal prior cause it to be over-smoothed, and performance thus approaches that of the gesture-only segmenter.

**Comparison to other models** While much of the research on topic segmentation focuses on written text, there are some comparable systems that also aim at unsupervised segmentation of spontaneous spoken language. For example, Malioutov and Barzilay (2006) segment a corpus of classroom lectures, using similar lexical cohesion-based features. With manual transcriptions, they report a .383  $P_k$  and .417 WD on artificial intelligence (AI) lectures, and .298  $P_k$  and .311 WD on physics lectures. Our results are in the range bracketed by these two extremes; the wide range of results suggests that segmentation scores are difficult to compare across domains. The segmentation of physics lectures was at a very coarse level of granularity, while the segmentation of AI lectures was more similar to our annotations.

We applied the publicly-available executable for this algorithm to our data, but performance was poor, yielding a .417  $P_k$  and .465 WD even when both verbal and gestural features were available.

Figure 3: The multimodal and verbal-only performance using the reference transcript. The x-axis shows the logarithm of the verbal prior; the gestural prior is held fixed at the optimal value.

This may be because the technique is not designed for the relatively fine-grained segmentation demanded by our dataset (Malioutov, 2006).

## 7 Conclusions

This research shows a novel relationship between gestural cohesion and discourse structure. Automatically extracted gesture features are predictive of discourse segmentation when used in isolation; when lexical information is present, segmentation performance is further improved. This suggests that gestures provide unique information not present in the lexical features alone, even when perfect transcripts are available.

There are at least two possibilities for how gesture might impact topic segmentation: “visual punctuation,” and cohesion. The visual punctuation view would attempt to identify specific gestural patterns that are characteristic of segment boundaries. This is analogous to research that identifies prosodic signatures of topic boundaries, such as (Hirschberg and Nakatani, 1998). By design, our model is incapable of exploiting such phenomena, as our goal is to investigate the notion of gestural cohesion. Thus, the performance gains demonstrated in this paper cannot be explained by such punctuation-like phenomena; we believe that they are due to the consistent gestural themes that characterize coherent topics. However, we are interested in pursuing the idea of visual punctuation in the future, so as to compare the power of visual punctuation and gestural cohesion to predict segment boundaries. In addition, the in-

teraction of gesture and prosody suggests additional possibilities for future research.

The videos in the dataset for this paper are focused on the description of physical devices and events, leading to a fairly concrete set of gestures. In other registers of conversation, gestural form may be driven more by spatial metaphors, or may consist mainly of temporal “beats.” In such cases, the importance of gestural cohesion for discourse segmentation may depend on the visual expressivity of the speaker. We plan to examine the extensibility of gesture cohesion to more naturalistic settings, such as classroom lectures.

Finally, topic segmentation provides only an outline of the discourse structure. Richer models of discourse include hierarchical structure (Grosz and Sidner, 1986) and Rhetorical Structure Theory (Mann and Thompson, 1988). The application of gestural analysis to such models may lead to fruitful areas of future research.

## Abstract

We extend the classical single-task active learning (AL) approach. In the multi-task active learning (MTAL) paradigm, we select examples for several annotation tasks rather than for a single one as usually done in the context of AL. We introduce two MTAL meta-protocols, alternating selection and rank combination, and propose a method to implement them in practice. We experiment with a two-task annotation scenario that includes named entity and syntactic parse tree annotations on three different corpora. MTAL outperforms random selection and a stronger baseline, one-sided example selection, in which one task is pursued using AL and the selected examples are provided also to the other task.

## 1 Introduction

Supervised machine learning methods have successfully been applied to many NLP tasks in the last few decades. These techniques have demonstrated their superiority over both hand-crafted rules and unsupervised learning approaches. However, they require large amounts of labeled training data for every level of linguistic processing (e.g., POS tags, parse trees, or named entities). When, when domains and text genres change (e.g., moving from common-sense newspapers to scientific biology journal articles), extensive retraining on newly supplied training material is often required, since different domains may use different syntactic structures as well as different semantic classes (entities and relations).

Consequently, with an increasing coverage of a wide variety of domains in human language technology (HLT) systems, we can expect a growing need for manual annotations to support many kinds of application-specific training data.

Creating annotated data is extremely labor-intensive. The Active Learning (AL) paradigm (Cohn et al., 1996) offers a promising solution to deal with this bottleneck, by allowing the learning algorithm to control the selection of examples to be manually annotated such that the human labeling effort be minimized. AL has been successfully applied already for a wide range of NLP tasks, including POS tagging (Engelson and Dagan, 1996), chunking (Ngai and Yarowsky, 2000), statistical parsing (Hwa, 2004), and named entity recognition (Tomanek et al., 2007).

However, AL is designed in such a way that it selects examples for manual annotation with respect to a *single* learning algorithm or classifier. Under this AL annotation policy, one has to perform a separate annotation cycle for each classifier to be trained. In the following, we will refer to the annotations supplied for a classifier as the annotations for a *single annotation task*.

Modern HLT systems often utilize annotations resulting from different tasks. For example, a machine translation system might use features extracted from parse trees and named entity annotations. For such an application, we obviously need the different annotations to reside in the same text corpus. It is not clear how to apply the single-task AL approach here, since a training example that is beneficial for one task might not be so for others. We could annotate

\* Both authors contributed equally to this work.

the same corpus independently by the two tasks and merge the resulting annotations, but that (as we show in this paper) would possibly yield sub-optimal usage of human annotation efforts.

There are two reasons why multi-task AL, and by this, a combined corpus annotated for various tasks, could be of immediate benefit. First, annotators working on *similar* annotation tasks (e.g., considering named entities and relations between them), might exploit annotation data from one subtask for the benefit of the other. If for each subtask a separate corpus is sampled by means of AL, annotators will definitely lack synergy effects and, therefore, annotation will be more laborious and is likely to suffer in terms of quality and accuracy. Second, for *dissimilar* annotation tasks – take, e.g., a comprehensive HLT pipeline incorporating morphological, syntactic and semantic data – a classifier might require features as input which constitute the output of another preceding classifier. As a consequence, training such a classifier which takes into account several annotation tasks will best be performed on a rich corpus annotated with respect to all input-relevant tasks. Both kinds of annotation tasks, similar and dissimilar ones, constitute examples of what we refer to as *multi-task* annotation problems.

Indeed, there have been efforts in creating resources annotated with respect to various annotation tasks though each of them was carried out independently of the other. In the general language UPenn annotation efforts for the WSJ sections of the Penn Treebank (Marcus et al., 1993), sentences are annotated with POS tags, parse trees, as well as discourse annotation from the Penn Discourse Treebank (Mitsakaki et al., 2008), while verbs and verb arguments are annotated with Propbank rolesets (Palmer et al., 2005). In the biomedical GENIA corpus (Ohta et al., 2002), scientific text is annotated with POS tags, parse trees, and named entities.

In this paper, we introduce *multi-task active learning* (MTAL), an active learning paradigm for multiple annotation tasks. We propose a new AL framework where the examples to be annotated are selected so that they are as informative as possible for a *set* of classifiers instead of a single classifier only. This enables the creation of a single combined corpus annotated with respect to various annotation tasks, while preserving the advantages of AL with

respect to the minimization of annotation efforts.

In a proof-of-concept scenario, we focus on two highly dissimilar tasks, syntactic parsing and named entity recognition, study the effects of multi-task AL under rather extreme conditions. We propose two MTAL meta-protocols and a method to implement them for these tasks. We run experiments on three corpora for domains and genres that are very different (WSJ: newspapers, Brown: mixed genres, and GENIA: biomedical abstracts). Our protocols outperform two baselines (random and a stronger one-sided selection baseline).

In Section 2 we introduce our MTAL framework and present two MTAL protocols. In Section 3 we discuss the evaluation of these protocols. Section 4 describes the experimental setup, and results are presented in Section 5. We discuss related work in Section 6. Finally, we point to open research issues for this new approach in Section 7.

## 2 A Framework for Multi-Task AL

In this section we introduce a sample selection framework that aims at reducing the human annotation effort in a multiple annotation scenario.

### 2.1 Task Definition

To measure the efficiency of selection methods, we define the *training quality*  $TQ$  of annotated material  $S$  as the performance  $p$  yielded with a reference learner  $X$  trained on that material:  $TQ(X, S) = p$ . A selection method can be considered better than another one if a higher TQ is yielded with the same amount of examples being annotated.

Our framework is an extension of the Active Learning (AL) framework (Cohn et al., 1996). The original AL framework is based on querying in an iterative manner those examples to be manually annotated that are most useful for the learner at hand. The TQ of an annotated corpus selected by means of AL is much higher than random selection. This AL approach can be considered as *single-task AL* because it focuses on a single learner for which the examples are to be selected. In a multiple annotation scenario, however, there are several annotation tasks to be accomplished at once and for each task typically a separate statistical model will then be trained. Thus, the goal of *multi-task AL* is to query those examples for

human annotation that are most informative for *all* learners involved.

## 2.2 One-Sided Selection vs. Multi-Task AL

The naive approach to select examples in a multiple annotation scenario would be to perform a single-task AL selection, i.e., the examples to be annotated are selected with respect to one of the learners only.<sup>1</sup> In a multiple annotation scenario we call such an approach *one-sided* selection. It is an *intrinsic* selection for the reference learner, and an *extrinsic* selection for all the other learners also trained on the annotated material. Obviously, a corpus compiled with the help of one-sided selection will have a good TQ for that learner for which the intrinsic selection has taken place. For all the other learners, however, we have no guarantee that their TQ will not be inferior than the TQ of a random selection process.

In scenarios where the different annotation tasks are highly dissimilar we can expect extrinsic selection to be rather poor. This intuition is demonstrated by experiments we conducted for named entity (NE) and parse annotation tasks<sup>2</sup> (Figure 1). In this scenario, extrinsic selection for the NE annotation task means that examples were selected with respect to the parsing task. Extrinsic selection performed about the same as random selection for the NE task, while for the parsing task extrinsic selection performed markedly worse. This shows that examples that were very informative for the NE learner were not that informative for the parse learner.

## 2.3 Protocols for Multi-Task AL

Obviously, we can expect one-sided selection to perform better for the reference learner (the one for which an intrinsic selection took place) than multi-task AL selection, because the latter would be a compromise for all learners involved in the multiple annotation scenario. However, the goal of multi-task AL is to minimize the annotation effort over all annotation tasks and not just the effort for a single annotation task.

For a multi-task AL protocol to be valuable in a specific multiple annotation scenario, the TQ for all considered learners should be

<sup>1</sup>Of course, all selected examples would be annotated w.r.t. all annotation tasks.

<sup>2</sup>See Section 4 for our experimental setup.

1. better than the TQ of random selection,
2. and better than the TQ of any extrinsic selection.

In the following, we introduce two protocols for multi-task AL. Multi-task AL protocols can be considered *meta-protocols* because they basically specify how task-specific, single-task AL approaches can be combined into one selection decision. By this, the protocols are independent of the underlying task-specific AL approaches.

### 2.3.1 Alternating Selection

The *alternating selection* protocol alternates one-sided AL selection. In  $s_j$  consecutive AL iterations, the selection is performed as one-sided selection with respect to learning algorithm  $X_j$ . After that, another learning algorithm is considered for selection for  $s_k$  consecutive iterations and so on. Depending on the specific scenario, this enables to weight the different annotation tasks by allowing them to guide the selection in more or less AL iterations. This protocol is a straight-forward compromise between the different single-task selection approaches.

In this paper we experiment with the special case of  $s_i = 1$ , where in every AL iteration the selection leadership is changed. More sophisticated calibration of the parameters  $s_i$  is beyond the scope of this paper and will be dealt with in future work.

### 2.3.2 Rank Combination

The *rank combination* protocol is more directly based on the idea to combine single-task AL selection decisions. In each AL iteration, the usefulness score  $s_{X_j}(e)$  of each unlabeled example  $e$  from the pool of examples is calculated with respect to each learner  $X_j$  and then translated into a rank  $r_{X_j}(e)$  where higher usefulness means lower rank number (examples with identical scores get the same rank number). Then, for each example, we sum the rank numbers of each annotation task to get the overall rank  $r(e) = \sum_{j=1}^n r_{X_j}(e)$ . All examples are sorted by this combined rank and  $b$  examples with lowest rank numbers are selected for manual annotation.<sup>3</sup>

<sup>3</sup>As the number of ranks might differ between the single annotation tasks, we normalize them to the coarsest scale. Then we can sum up the ranks as explained above.

Figure 1: Learning curves for random and extrinsic selection on both tasks: named entity annotation (left) and syntactic parse annotation (right), using the WSJ corpus scenario

This protocol favors examples which are good for all learning algorithms. Examples that are highly informative for one task but rather uninformative for another task will not be selected.

### 3 Evaluation of Multi-Task AL

The notion of training quality (TQ) can be used to quantify the effectiveness of a protocol, and by this, annotation costs in a single-task AL scenario. To actually quantify the overall training quality in a multiple annotation scenario one would have to sum over all the single task’s TQs. Of course, depending on the specific annotation task, one would not want to quantify the number of examples being annotated but different task-specific units of annotation. While for entity annotations one does typically count the number of tokens being annotated, in the parsing scenario the number of constituents being annotated is a generally accepted measure. As, however, the actual time needed for the annotation of one example usually differs for different annotation tasks, normalizing exchange rates have to be specified which can then be used as weighting factors. In this paper, we do not define such weighting factors<sup>4</sup>, and leave this challenging question to be discussed in the context of psycholinguistic research.

We could quantify the overall efficiency score  $E$  of a MTAL protocol  $P$  by

$$E(P) = \sum_{j=1}^n \alpha_j \cdot TQ(X_j, u_j)$$

where  $u_j$  denotes the individual annotation task’s

<sup>4</sup>Such weighting factors not only depend on the annotation level or task but also on the domain, and especially on the cognitive load of the annotation task.

number of units being annotated (e.g., constituents for parsing) and the task-specific weights are defined by  $\alpha_j$ . Given weights are properly defined, such a score can be applied to directly compare different protocols and quantify their differences.

In practice, such task-specific weights might also be considered in the MTAL protocols. In the alternating selection protocol, the numbers of consecutive iterations  $s_i$  each single task protocol can be tuned according to the  $\alpha$  parameters. As for the rank combination protocol, the weights can be considered when calculating the overall rank:  $r(e) = \sum_{j=1}^n \beta_j \cdot r_{X_j}(e)$  where the parameters  $\beta_1 \dots \beta_n$  reflect the values of  $\alpha_1 \dots \alpha_n$  (though they need not necessarily be the same).

In our experiments, we assumed the same weight for all annotation schemata, thus simply setting  $s_i = 1, \beta_i = 1$ . This was done for the sake of a clear framework presentation. Finding proper weights for the single tasks and tuning the protocols accordingly is a subject for further research.

## 4 Experiments

### 4.1 Scenario and Task-Specific Selection Protocols

The tasks in our scenario comprise one semantic task (annotation with named entities (NE)) and one syntactic task (annotation with PCFG parse trees). The tasks are highly dissimilar, thus increasing the potential value of MTAL. Both tasks are subject to intensive research by the NLP community.

The MTAL protocols proposed are meta-protocols that combine the selection decisions of the underlying, task-specific AL protocols. In our scenario, the task-specific AL protocols are

committee-based (Freund et al., 1997) selection protocols. In committee-based AL, a committee consists of  $k$  classifiers of the same type trained on different subsets of the training data.<sup>5</sup> Each committee member then makes its predictions on the unlabeled examples, and those examples on which the committee members disagree most are considered most informative for learning and are thus selected for manual annotation. In our scenario the example grain-size is the sentence level.

For the NE task, we apply the AL approach of Tomanek et al. (2007). The committee consists of  $k_1 = 3$  classifiers and the vote entropy (VE) (Engelson and Dagan, 1996) is employed as disagreement metric. It is calculated on the token-level as

$$VE_{tok}(t) = -\frac{1}{\log k} \sum_{i=0}^c \frac{V(l_i, t)}{k} \log \frac{V(l_i, t)}{k} \quad (1)$$

where  $\frac{V(l_i, t)}{k}$  is the ratio of  $k$  classifiers where the label  $l_i$  is assigned to a token  $t$ . The sentence level vote entropy  $VE_{sent}$  is then the average over all tokens  $t_j$  of sentence  $s$ .

For the parsing task, the disagreement score is based on a committee of  $k_2 = 10$  instances of Dan Bikel’s reimplementation of Collins’ parser (Bickel, 2005; Collins, 1999). For each sentence in the unlabeled pool, the agreement between the committee members was calculated using the function reported by Reichart and Rappoport (2007):

$$AF(s) = \frac{1}{N} \sum_{i, l \in [1 \dots N], i \neq l} f_{score}(m_i, m_l) \quad (2)$$

Where  $m_i$  and  $m_l$  are the committee members and  $N = \frac{k_2 \cdot (k_2 - 1)}{2}$  is the number of pairs of different committee members. This function calculates the agreement between the members of each pair by calculating their relative f-score and then averages the pairs’ scores. The disagreement of the committee on a sentence is simply  $1 - AF(s)$ .

## 4.2 Experimental settings

For the NE task we employed the classifier described by Tomanek et al. (2007): The NE tagger is based on Conditional Random Fields (Lafferty et al., 2001)

<sup>5</sup>We randomly sampled  $L = \frac{3}{4}$  of the training data to create each committee member.

and has a rich feature set including orthographical, lexical, morphological, POS, and contextual features. For parsing, Dan Bikel’s reimplementation of Collins’ parser is employed, using gold POS tags.

In each AL iteration we select 100 sentences for manual annotation.<sup>6</sup> We start with a randomly chosen seed set of 200 sentences. Within a corpus we used the same seed set in all selection scenarios. We compare the following five selection scenarios: Random selection (*RS*), which serves as our baseline; one-sided AL selection for both tasks (called *NE-AL* and *PARSE-AL*); and multi-task AL selection with the alternating selection protocol (*alter-MTAL*) and the rank combination protocol (*ranks-MTAL*).

We performed our experiments on three different corpora, namely one from the newspaper genre (*WSJ*), a mixed-genre corpus (*Brown*), and a biomedical corpus (*Bio*). Our simulation corpora contain both entity annotations and (constituent) parse annotations. For each corpus we have a pool set (from which we select the examples for annotation) and an evaluation set (used for generating the learning curves). The *WSJ* corpus is based on the *WSJ* part of the *PENN TREEBANK* (Marcus et al., 1993); we used the first 10,000 sentences of section 2-21 as the pool set, and section 00 as evaluation set (1,921 sentences). The *Brown* corpus is also based on the respective part of the *PENN TREEBANK*. We created a sample consisting of 8 of any 10 consecutive sentences in the corpus. This was done as *Brown* contains text from various English text genres, and we did that to create a representative sample of the corpus domains. We finally selected the first 10,000 sentences from this sample as pool set. Every 9th from every 10 consecutive sentences package went into the evaluation set which consists of 2,424 sentences. For both *WSJ* and *Brown* only parse annotations though no entity annotations were available. Thus, we enriched both corpora with entity annotations (three entities: person, location, and organization) by means of a tagger trained on the English data set of the *CoNLL-2003* shared task (Tjong Kim Sang and De Meulder, 2003).<sup>7</sup> The *Bio* corpus

<sup>6</sup>Manual annotation is simulated by just unveiling the annotations already contained in our corpora.

<sup>7</sup>We employed a tagger similar to the one presented by Settles (2004). Our tagger has a performance of  $\approx 84\%$  f-score on the *CoNLL-2003* data; inspection of the predicted entities on

is based on the parsed section of the GENIA corpus (Ohta et al., 2002). We performed the same divisions as for Brown, resulting in 2,213 sentences in our pool set and 276 sentences for the evaluation set. This part of the GENIA corpus comes with entity annotations. We have collapsed the entity classes annotated in GENIA (cell line, cell type, DNA, RNA, protein) into a single, biological entity class.

## 5 Results

In this section we present and discuss our results when applying the five selection strategies (RS, NE-AL, PARSE-AL, alter-MTAL, and ranks-MTAL) to our scenario on the three corpora. We refrain from calculating the overall efficiency score (Section 3) here due to the lack of generally accepted weights for the considered annotation tasks. However, we require from a good selection protocol to exceed the performance of random selection and extrinsic selection. In addition, recall from Section 3 that we set the alternate selection and rank combination parameters to  $s_i = 1, \beta_i = 1$ , respectively to reflect a tradeoff between the annotation efforts of both tasks.

Figures 2 and 3 depict the learning curves for the NE tagger and the parser on WSJ and Brown, respectively. Each figure shows the five selection strategies. As expected, on both corpora and both tasks intrinsic selection performs best, i.e., for the NE tagger NE-AL and for the parser PARSE-AL. Further, random selection and extrinsic selection perform worst. Most importantly, both MTAL protocols clearly outperform extrinsic and random selection in all our experiments. This is in contrast to NE-AL which performs worse than random selection for all corpora when used as extrinsic selection, and for PARSE-AL that outperforms the random baseline only for Brown when used as extrinsic selection. That is, the MTAL protocols suggest a tradeoff between the annotation efforts of the different tasks, here.

On WSJ, both for the NE and the parse annotation tasks, the performance of the MTAL protocols is very similar, though ranks-MTAL performs slightly better. For the parser task, up to 30,000 constituents MTAL performs almost as good as does PARSE-AL. This is different for the NE task where NE-AL

clearly outperforms MTAL. On Brown, in general we see the same results, with some minor differences. On the NE task, extrinsic selection (PARSE-AL) performs better than random selection, but it is still much worse than intrinsic AL or MTAL. Here, ranks-MTAL significantly outperforms alter-MTAL and almost performs as good as intrinsic selection. For the parser task, we see that extrinsic and random selection are equally bad. Both MTAL protocols perform equally well, again being quite similar to the intrinsic selection. On the BIO corpus<sup>8</sup> we observed the same tendencies as in the other two corpora, i.e., MTAL clearly outperforms extrinsic and random selection and supplies a better tradeoff between annotation efforts of the task at hand than one-sided selection.

Overall, we can say that in all scenarios MTAL performs much better than random selection and extrinsic selection, and in most cases the performance of MTAL (especially but not exclusively, ranks-MTAL) is even close to intrinsic selection. This is promising evidence that MTAL selection can be a better choice than one-sided selection in multiple annotation scenarios. Thus, considering all annotation tasks in the selection process (even if the selection protocol is as simple as the alternating selection protocol) is better than selecting only with respect to one task. Further, it should be noted that overall the more sophisticated rank combination protocol does not perform much better than the simpler alternating selection protocol in all scenarios.

Finally, Figure 4 shows the disagreement curves for the two tasks on the WSJ corpus. As has already been discussed by Tomanek and Hahn (2008), disagreement curves can be used as a stopping criterion and to monitor the progress of AL-driven annotation. This is especially valuable when no annotated validation set is available (which is needed for plotting learning curves). We can see that the disagreement curves significantly flatten approximately at the same time as the learning curves do. In the context of MTAL, disagreement curves might not only be interesting as a stopping criterion but rather as a switching criterion, i.e., to identify when MTAL could be turned into one-sided selection. This would be the case if in an MTAL scenario, the disagree-

WSJ and Brown revealed a good tagging performance.

<sup>8</sup>The plots for the Bio are omitted due to space restrictions.

Figure 2: Learning curves for NE task on WSJ (left) and Brown (right)

Figure 3: Learning curves for parse task on WSJ (left) and Brown (right)

ment curve of one task has a slope of (close to) zero. Future work will focus on issues related to this.

## 6 Related Work

There is a large body of work on single-task AL approaches for many NLP tasks where the focus is mainly on better, task-specific selection protocols and methods to quantify the usefulness score in different scenarios. As to the tasks involved in our scenario, several papers address AL for NER (Shen et al., 2004; Hachey et al., 2005; Tomanek et al., 2007) and syntactic parsing (Tang et al., 2001; Hwa, 2004; Baldridge and Osborne, 2004; Becker and Osborne, 2005). Further, there is some work on questions arising when AL is to be used in real-life annotation scenarios, including impaired inter-annotator agreement, stopping criteria for AL-driven annotation, and issues of reusability (Baldridge and Osborne, 2004; Hachey et al., 2005; Zhu and Hovy, 2007; Tomanek et al., 2007).

Multi-task AL is methodologically related to approaches of decision combination, especially in the context of classifier combination (Ho et al., 1994) and ensemble methods (Breiman, 1996). Those approaches focus on the combination of classifiers in

order to improve the classification error rate for one specific classification task. In contrast, the focus of multi-task AL is on strategies to select training material for multi classifier systems where all classifiers cover different classification tasks.

## 7 Discussion

Our treatment of MTAL within the context of the orthogonal two-task scenario leads to further interesting research questions. First, future investigations will have to focus on the question whether the positive results observed in our orthogonal (i.e., highly dissimilar) two-task scenario will also hold for a more realistic (and maybe more complex) multiple annotation scenario where tasks are more similar and more than two annotation tasks might be involved. Furthermore, several forms of *interdependencies* may arise between the single annotation tasks. As a first example, consider the (functional) interdependencies (i.e., task similarity) in higher-level semantic NLP tasks of relation or event recognition. In such a scenario, several tasks including entity annotations and relation/event annotations, as well as syntactic parse data, have to be incorporated at the same time. Another type of (data flow) inter-

Figure 4: Disagreement curves for NE task (left) and parse task (right) on WSJ

dependency occurs in a second scenario where material for several classifiers that are data-dependent on each other – one takes the output of another classifier as input features – has to be efficiently annotated. Whether the proposed protocols are beneficial in the context of such highly interdependent tasks is an open issue. Even more challenging is the idea to provide methodologies helping to predict in an arbitrary application scenario whether the choice of MTAL is truly advantageous.

Another open question is how to measure and quantify the overall *annotation costs* in multiple annotation scenarios. Exchange rates are inherently tied to the specific task and domain. In practice, one might just want to measure the time needed for the annotations. However, in a simulation scenario, a common metric is necessary to compare the performance of different selection strategies with respect to the overall annotation costs. This requires studies on how to quantify, with a comparable cost function, the efforts needed for the annotation of a textual unit of choice (e.g., tokens, sentences) with respect to different annotation tasks.

Finally, the question of *reusability* of the annotated material is an important issue. Reusability in the context of AL means to which degree corpora assembled with the help of any AL technique can be (re)used as a general resource, i.e., whether they are well suited for the training of classifiers other than the ones used during the selection process. This is especially interesting as the details of the classifiers that should be trained in a later stage are typically not known at the resource building time. Thus, we want to select samples valuable to a *family* of classifiers using the various annotation layers. This, of course, is only possible if data annotated with the

help of AL is reusable by modified though similar classifiers (e.g., with respect to the features being used) – compared to the classifiers employed for the selection procedure.

The issue of reusability has already been raised but not yet conclusively answered in the context of single-task AL (see Section 6). Evidence was found that reusability up to a certain, though not well-specified, level is possible. Of course, reusability has to be analyzed separately in the context of various MTAL scenarios. We feel that these scenarios might both be more challenging and more relevant to the reusability issue than the single-task AL scenario, since resources annotated with multiple layers can be used to the design of a larger number of a (possibly more complex) learning algorithms.

## 8 Conclusions

We proposed an extension to the single-task AL approach such that it can be used to select examples for annotation with respect to several annotation tasks. To the best of our knowledge this is the first paper on this issue, with a focus on NLP tasks. We outlined a problem definition and described a framework for multi-task AL. We presented and tested two protocols for multi-task AL. Our results are promising as they give evidence that in a multiple annotation scenario, multi-task AL outperforms naive one-sided and random selection.

## Abstract

This paper presents a semi-supervised training method for linear-chain conditional random fields that makes use of labeled features rather than labeled instances. This is accomplished by using *generalized expectation* criteria to express a preference for parameter settings in which the model's distribution on unlabeled data matches a target distribution. We induce target conditional probability distributions of labels given features from both annotated feature occurrences in context and ad-hoc feature majority label assignment. The use of generalized expectation criteria allows for a dramatic reduction in annotation time by shifting from traditional instance-labeling to feature-labeling, and the methods presented outperform traditional CRF training and other semi-supervised methods when limited human effort is available.

## 1 Introduction

A significant barrier to applying machine learning to new real world domains is the cost of obtaining the necessary training data. To address this problem, work over the past several years has explored semi-supervised or unsupervised approaches to the same problems, seeking to improve accuracy with the addition of lower cost unlabeled data. Traditional approaches to semi-supervised learning are applied to cases in which there is a small amount of fully labeled data and a much larger amount of unlabeled data, presumably from the same data source. For example, EM (Nigam et al., 1998), transductive SVMs (Joachims, 1999), entropy regularization (Grandvalet and Bengio, 2004), and graph-based

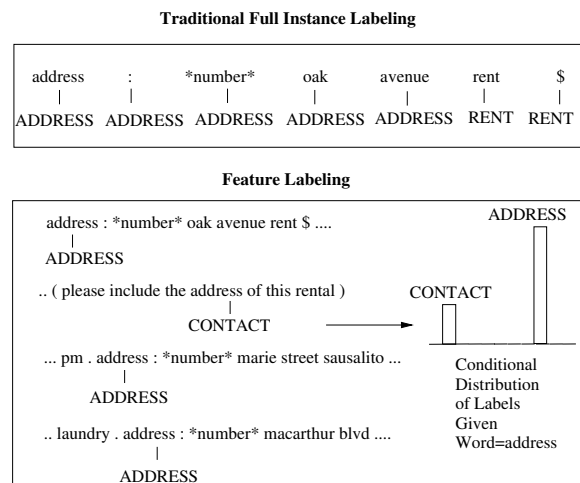

Figure 1: Top: Traditional instance-labeling in which sequences of contiguous tokens are annotated as to their correct label. Bottom: Feature-labeling in which non-contiguous feature occurrences in context are labeled for the purpose of deriving a conditional probability distribution of labels given a particular feature.

methods (Zhu and Ghahramani, 2002; Szummer and Jaakkola, 2002) have all been applied to a limited amount of fully labeled data in conjunction with unlabeled data to improve the accuracy of a classifier.

In this paper, we explore an alternative approach in which, instead of fully labeled instances, the learner has access to *labeled features*. These features can often be labeled at a lower-cost to the human annotator than labeling entire instances, which may require annotating the multiple sub-parts of a sequence structure or tree. Features can be labeled either by specifying the majority label for a particular feature or by annotating a few occurrences of a particular feature in context with the correct label (Figure 1).

To train models using this information we use

generalized expectation (GE) criteria. GE criteria are terms in a training objective function that assign scores to values of a model expectation. In particular we use a version of GE that prefers parameter settings in which certain model expectations are close to target distributions. Previous work has shown how to apply GE criteria to maximum entropy classifiers. In section 4, we extend GE criteria to semi-supervised learning of linear-chain conditional random fields, using conditional probability distributions of labels given features.

To empirically evaluate this method we compare it with several competing methods for CRF training, including entropy regularization and expected gradient, showing that GE provides significant improvements. We achieve competitive performance in comparison to alternate model families, in particular generative models such as MRFs trained with EM (Haghighi and Klein, 2006) and HMMs trained with soft constraints (Chang et al., 2007). Finally, in Section 5.3 we show that feature-labeling can lead to dramatic reductions in the annotation time that is required in order to achieve the same level of accuracy as traditional instance-labeling.

## 2 Related Work

There has been a significant amount of work on semi-supervised learning with small amounts of *fully labeled* data (see Zhu (2005)). However there has been comparatively less work on learning from alternative forms of labeled resources. One example is Schapire et al. (2002) who present a method in which features are annotated with their associated majority labels and this information is used to bootstrap a parameterized text classification model. Unlike the model presented in this paper, they require some labeled data in order to train their model.

This type of input information (features + majority label) is a powerful and flexible model for specifying alternative inputs to a classifier, and has been additionally used by Haghighi and Klein (2006). In that work, “prototype” features—words with their associated labels—are used to train a generative MRF sequence model. Their probability model can be formally described as:

$$p_{\theta}(\mathbf{x}, \mathbf{y}) = \frac{1}{Z(\theta)} \exp \left( \sum_k \theta_k F_k(\mathbf{x}, \mathbf{y}) \right).$$

Although the partition function must be computed over all  $(\mathbf{x}, \mathbf{y})$  tuples, learning via EM in this model is possible because of approximations made in computing the partition function.

Another way to gather supervision is by means of prior label distributions. Mann and McCallum (2007) introduce a special case of GE, *label regularization*, and demonstrate its effectiveness for training maximum entropy classifiers. In label regularization, the model prefers parameter settings in which the model’s predicted label distribution on the unsupervised data match a target distribution. Note that supervision here consists of the the full distribution over labels (i.e. conditioned on the maximum entropy “default feature”), instead of simply the majority label. Druck et al. (2007) also use GE with full distributions for semi-supervised learning of maximum entropy models, except here the distributions are on labels *conditioned on features*. In Section 4 we describe how GE criteria can be applied to CRFs given conditional probability distributions of labels given features.

Another recent method that has been proposed for training sequence models with constraints is Chang et al. (2007). They use constraints for approximate EM training of an HMM, incorporating the constraints by looking only at the top  $K$  most-likely sequences from a joint model of likelihood and the constraints. This model can be applied to the combination of labeled and unlabeled instances, but cannot be applied in situations where only labeled features are available. Additionally, our model can be easily combined with other semi-supervised criteria, such as entropy regularization. Finally, their model is a generative HMM which cannot handle the rich, non-independent feature sets that are available to a CRF.

There have been relatively few different approaches to CRF semi-supervised training. One approach has been that proposed in both Miller et al. (2004) and Freitag (2004), uses distributional clustering to induce features from a large corpus, and then uses these features to augment the feature space of the labeled data. Since this is an orthogonal method for improving accuracy it can be combined with many of the other methods discussed above, and indeed we have obtained positive preliminary experimental results with GE criteria (not reported on here).

Another method for semi-supervised CRF training is entropy regularization, initially proposed by Grandvalet and Bengio (2004) and extended to linear-chain CRFs by Jiao et al. (2006). In this formulation, the traditional label likelihood (on supervised data) is augmented with an additional term that encourages the model to predict low-entropy label distributions on the unlabeled data:

$$\mathcal{O}(\theta; D, U) = \sum_d \log p_\theta(\mathbf{y}^{(d)} | \mathbf{x}^{(d)}) - \lambda H(\mathbf{y} | \mathbf{x}).$$

This method can be quite brittle, since the minimal entropy solution assigns all of the tokens the same label.<sup>1</sup> In general, entropy regularization is fragile, and accuracy gains can come only with precise settings of  $\lambda$ . High values of  $\lambda$  fall into the minimal entropy trap, while low values of  $\lambda$  have no effect on the model (see (Jiao et al., 2006) for an example).

When some instances have partial labelings (i.e. labels for some of their tokens), it is possible to train CRFs via expected gradient methods (Salakhutdinov et al., 2003). Here a reformulation is presented in which the gradient is computed for a probability distribution with a marginalized hidden variable,  $z$ , and observed training labels  $y$ :

$$\begin{aligned} \nabla_L(\theta) &= \frac{\partial}{\partial \theta} \sum_z \log p(x, y, z; \theta) \\ &= \sum_z p(z|y, x) f_k(x, y, z) \\ &\quad - \sum_{z, y'} p(z, y' | x; \theta) f_k(x, y, z). \end{aligned}$$

In essence, this resembles the standard gradient for the CRF, except that there is an additional marginalization in the first term over the hidden variable  $z$ . This type of training has been applied by Quattoni et al. (2007) for hidden-state conditional random fields, and can be equally applied to semi-supervised conditional random fields. Note, however, that labeling variables of a structured instance (e.g. tokens) is different than labeling features—being both more coarse-grained and applying supervision narrowly only to the individual subpart, not to all places in the data where the feature occurs.

<sup>1</sup>In the experiments in this paper, we use  $\lambda = 0.001$ , which we tuned for best performance on the test set, giving an unfair advantage to our competitor.

Finally, there are some methods that use auxiliary tasks for training sequence models, though they do not train linear-chain CRFs per se. Ando and Zhang (2005) include a cluster discovery step into the supervised training. Smith and Eisner (2005) use neighborhoods of related instances to figure out what makes found instances “good”. Although these methods can often find good solutions, both are quite sensitive to the selection of auxiliary information, and making good selections requires significant insight.<sup>2</sup>

### 3 Conditional Random Fields

Linear-chain conditional random fields (CRFs) are a discriminative probabilistic model over sequences  $\mathbf{x}$  of feature vectors and label sequences  $\mathbf{y} = \langle y_1..y_n \rangle$ , where  $|\mathbf{x}| = |\mathbf{y}| = n$ , and each label  $y_i$  has  $s$  different possible discrete values. This model is analogous to maximum entropy models for structured outputs, where expectations can be efficiently calculated by dynamic programming. For a linear-chain CRF of Markov order one:

$$p_\theta(\mathbf{y} | \mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp \left( \sum_k \theta_k F_k(\mathbf{x}, \mathbf{y}) \right),$$

where  $F_k(\mathbf{x}, \mathbf{y}) = \sum_i f_k(\mathbf{x}, y_i, y_{i+1}, i)$ , and the partition function  $Z(\mathbf{x}) = \sum_{\mathbf{y}} \exp(\sum_k \theta_k F_k(\mathbf{x}, \mathbf{y}))$ . Given training data  $D = \langle (\mathbf{x}^{(1)}, \mathbf{y}^{(1)})..(\mathbf{x}^{(n)}, \mathbf{y}^{(n)}) \rangle$ , the model is traditionally trained by maximizing the log-likelihood  $\mathcal{O}(\theta; D) = \sum_d \log p_\theta(\mathbf{y}^{(d)} | \mathbf{x}^{(d)})$  by gradient ascent where the gradient of the likelihood is:

$$\begin{aligned} \frac{\partial}{\partial \theta_k} \mathcal{O}(\theta; D) &= \sum_d F_k(\mathbf{x}^{(d)}, \mathbf{y}^{(d)}) \\ &\quad - \sum_d \sum_{\mathbf{y}} p_\theta(\mathbf{y} | \mathbf{x}^{(d)}) F_k(\mathbf{x}^{(d)}, \mathbf{y}). \end{aligned}$$

The second term (the expected counts of the features given the model) can be computed in a tractable amount of time, since according to the Markov as-

<sup>2</sup>Often these are more complicated than picking informative features as proposed in this paper. One example of the kind of operator used is the transposition operator proposed by Smith and Eisner (2005).

sumption, the feature expectations can be rewritten:

$$\sum_{\mathbf{y}} p_{\theta}(\mathbf{y}|\mathbf{x}) F_k(\mathbf{x}, \mathbf{y}) = \sum_i \sum_{y_i, y_{i+1}} p_{\theta}(y_i, y_{i+1}|\mathbf{x}) f_k(\mathbf{x}, y_i, y_{i+1}, i).$$

A dynamic program (the forward/backward algorithm) then computes in time  $O(ns^2)$  all the needed probabilities  $p_{\theta}(y_i, y_{i+1})$ , where  $n$  is the sequence length, and  $s$  is the number of labels.

#### 4 Generalized Expectation Criteria for Conditional Random Fields

Prior semi-supervised learning methods have augmented a limited amount of fully labeled data with either unlabeled data or with constraints (e.g. features marked with their majority label). GE criteria can use more information than these previous methods. In particular GE criteria can take advantage of conditional probability distributions of labels given a feature ( $p(y|f_k(x) = 1)$ ). This information provides richer constraints to the model while remaining easily interpretable. People have good intuitions about the relative predictive strength of different features. For example, it is clear that the probability of label PERSON given the feature WORD=JOHN is high, perhaps around 0.95, where as for WORD=BROWN it would be lower, perhaps 0.4. These distributions need not be not estimated with great precision—it is far better to have the freedom to express shades of gray than to be force into a binary supervision signal. Another advantage of using conditional probability distributions as probabilistic constraints is that they can be easily estimated from data. For the feature INITIAL-CAPITAL, we identify all tokens with the feature, and then count the labels with which the feature co-occurs.

GE criteria attempt to match these conditional probability distributions by model expectations on unlabeled data, encouraging, for example, the model to predict that the proportion of the label PERSON given the word “john” should be .95 over all of the unlabeled data.

In general, a GE (generalized expectation) criterion (McCallum et al., 2007) expresses a preference on the value of a model expectation. One kind of preference may be expressed by a distance function

$\Delta$ , a target expectation  $\hat{f}$ , data  $D$ , a function  $f$ , and a model distribution  $p_{\theta}$ , the GE criterion objective function term is  $\Delta(\hat{f}, E[f(x)])$ . For the purposes of this paper, we set the functions to be conditional probability distributions and set  $\Delta(p, q) = D(p||q)$ , the KL-divergence between two distributions.<sup>3</sup> For semi-supervised training of CRFs, we augment the objective function with the regularization term:

$$\mathcal{O}(\theta; D, U) = \sum_d \log p_{\theta}(\mathbf{y}^{(d)}|\mathbf{x}^{(d)}) - \frac{\sum_k \theta_k}{2\sigma^2} - \lambda D(\hat{p}||\tilde{p}_{\theta}),$$

where  $\hat{p}$  is given as a target distribution and

$$\begin{aligned} \tilde{p}_{\theta} &= \tilde{p}_{\theta}(y_j|f_m(\mathbf{x}, j) = 1) \\ &= \frac{1}{U_m} \sum_{\mathbf{x} \in U_m} \sum_{j^*} p_{\theta}(y_{j^*}^*|\mathbf{x}), \end{aligned}$$

with the unnormalized potential

$$\tilde{q}_{\theta} = \tilde{q}_{\theta}(y_j|f_m(\mathbf{x}, j) = 1) = \sum_{\mathbf{x} \in U_m} \sum_{j^*} p_{\theta}(y_{j^*}^*|\mathbf{x}),$$

where  $f_m(\mathbf{x}, j)$  is a feature that depends only on the observation sequence  $\mathbf{x}$ , and  $j^*$  is defined as  $\{j : f_m(\mathbf{x}, j) = 1\}$ , and  $U_m$  is the set of sequences where  $f_m(\mathbf{x}, j)$  is present for some  $j$ .<sup>4</sup>

#### Computing the Gradient

To compute the gradient of the GE criteria,  $D(\hat{p}||\tilde{p}_{\theta})$ , first we drop terms that are constant with respect to the partial derivative, and we derive the gradient as follows:

$$\begin{aligned} \frac{\partial}{\partial \theta_k} \sum_l \hat{p} \log \tilde{q}_{\theta} &= \sum_l \frac{\hat{p}}{\tilde{q}_{\theta}} \frac{\partial}{\partial \theta_k} \tilde{q}_{\theta} \\ &= \sum_l \frac{\hat{p}}{\tilde{q}_{\theta}} \sum_{\mathbf{x} \in U} \sum_{j^*} \frac{\partial}{\partial \theta_k} p_{\theta}(y_{j^*} = l|\mathbf{x}) \\ &= \sum_l \frac{\hat{p}}{\tilde{q}_{\theta}} \sum_{\mathbf{x} \in U} \sum_{j^*} \sum_{y_{-j^*}} \frac{\partial}{\partial \theta_k} p_{\theta}(y_{j^*} = l, \mathbf{y}_{-j^*}|\mathbf{x}), \end{aligned}$$

where  $\mathbf{y}_{-j} = \langle \mathbf{y}_{1..(j-1)} \mathbf{y}_{(j+1)..n} \rangle$ . The last step follows from the definition of the marginal probability

<sup>3</sup>We are actively investigating different choices of distance functions which may have different generalization properties.

<sup>4</sup>This formulation assumes binary features.

$P(y_j|\mathbf{x})$ . Now that we have a familiar form in which we are taking the gradient of a particular label sequence, we can continue:

$$\begin{aligned}
&= \sum_l \frac{\hat{p}}{\tilde{q}_\theta} \sum_{\mathbf{x} \in \mathbf{U}} \sum_{j^*} \sum_{\mathbf{y}_{-j^*}} p_\theta(y_{j^*} = l, \mathbf{y}_{-j^*} | \mathbf{x}) F_k(\mathbf{x}, \mathbf{y}) \\
&\quad - \sum_l \frac{\hat{p}}{\tilde{q}_\theta} \sum_{\mathbf{x} \in \mathbf{U}} \sum_{j^*} \sum_{\mathbf{y}_{-j^*}} p_\theta(y_{j^*} = l, \mathbf{y}_{-j^*} | \mathbf{x}) \\
&\quad \quad \sum_{\mathbf{y}'} p_\theta(\mathbf{y}' | \mathbf{x}) F_k(\mathbf{x}, \mathbf{y}') \\
&= \sum_l \frac{\hat{p}}{\tilde{q}_\theta} \sum_{\mathbf{x} \in \mathbf{U}} \sum_i \sum_{y_i, y_{i+1}} f_k(\mathbf{x}, y_i, y_{i+1}, i) \\
&\quad \quad \sum_{j^*} p_\theta(y_i, y_{i+1}, y_{j^*} = l | \mathbf{x}) \\
&\quad - \sum_l \frac{\hat{p}}{\tilde{q}_\theta} \sum_{\mathbf{x} \in \mathbf{U}} \sum_i \sum_{y_i, y_{i+1}} f_k(\mathbf{x}, y_i, y_{i+1}, i) \\
&\quad \quad p_\theta(y_i, y_{i+1} | \mathbf{x}) \sum_{j^*} p_\theta(y_{j^*} = l | \mathbf{x}).
\end{aligned}$$

After combining terms and rearranging we arrive at the final form of the gradient:

$$\begin{aligned}
&= \sum_{\mathbf{x} \in \mathbf{U}} \sum_i \sum_{y_i, y_{i+1}} f_k(\mathbf{x}, y_i, y_{i+1}, i) \sum_l \frac{\hat{p}}{\tilde{q}_\theta} \times \\
&\quad \left( \sum_{j^*} p_\theta(y_i, y_{i+1}, y_{j^*} = l | \mathbf{x}) - \right. \\
&\quad \quad \left. p_\theta(y_i, y_{i+1} | \mathbf{x}) \sum_{j^*} p_\theta(y_{j^*} = l | \mathbf{x}) \right).
\end{aligned}$$

Here, the second term is easily gathered from forward/backward, but obtaining the first term is somewhat more complicated. Computing this term naively would require multiple runs of constrained forward/backward. Here we present a more efficient method that requires only one run of forward/backward.<sup>5</sup> First we decompose the probability into two parts:  $\sum_{j^*} p_\theta(y_i, y_{i+1}, y_{j^*} = l | \mathbf{x}) = \sum_{j=1}^i p_\theta(y_i, y_{i+1}, y_j = l | \mathbf{x}) I(j \in j^*) + \sum_{j=i+1}^J p_\theta(y_i, y_{i+1}, y_j = l | \mathbf{x}) I(j \in j^*)$ . Next, we show how to compute these terms efficiently. Similar to forward/backward, we build a lattice of intermediate results that then can be used to calculate the

<sup>5</sup>(Kakade et al., 2002) propose a related method that computes  $p(y_{1..i} = l_{1..i} | y_{i+1} = l)$ .

quantity of interest:

$$\begin{aligned}
&\sum_{j=1}^i p_\theta(y_i, y_{i+1}, y_j = l | \mathbf{x}) I(j \in j^*) \\
&= p(y_i, y_{i+1} | \mathbf{x}) \delta(y_i, l) I(i \in j^*) \\
&\quad + \sum_{j=1}^{i-1} p_\theta(y_i, y_{i+1}, y_j = l | \mathbf{x}) I(j \in j^*) \\
&= p(y_i, y_{i+1} | \mathbf{x}) \delta(y_i, l) I(i \in j^*) \\
&\quad + \left( \sum_{y_{i-1}} \sum_{j=1}^{i-1} p_\theta(y_{i-1}, y_i, y_j = l | \mathbf{x}) I(j \in j^*) \right) \\
&\quad \quad p_\theta(y_{i+1} | y_i, \mathbf{x}).
\end{aligned}$$

For efficiency,  $\sum_{y_{i-1}} \sum_{j=1}^{i-1} p_\theta(y_{i-1}, y_i, y_j = l | \mathbf{x}) I(j \in j^*)$  is saved at each stage in the lattice.  $\sum_{j=i+1}^J p_\theta(y_{i-1}, y_i, y_j = l | \mathbf{x}) I(j \in j^*)$  can be computed in the same fashion. To compute the lattices it takes time  $O(ns^2)$ , and one lattice must be computed for each label so the total time is  $O(ns^3)$ .

## 5 Experimental Results

We use the CLASSIFIEDS data provided by Grenager et al. (2005) and compare with results reported by HK06 (Haghighi and Klein, 2006) and CRR07 (Chang et al., 2007). HK06 introduced a set of 33 features along with their majority labels, these are the primary set of additional constraints (Table 1). As HK06 notes, these features are selected using statistics of the labeled data, and here we used similar features here in order to compare with previous results. Though in practice we have found that feature selection is often intuitive, recent work has experimented with automatic feature selection using LDA (Druck et al., 2008). For some of the experiments we also use two sets of 33 additional features that we chose by the same method as HK06, the first 33 of which are also shown in Table 1. We use the same tokenization of the dataset as HK06, and training/test/unsupervised sets of 100 instances each. This data differs slightly from the tokenization used by CRR07. In particular it lacks the newline breaks which might be a useful piece of information.

There are three types of supervised/semi-supervised data used in the experiments. **Labeled instances** are the traditional or conventionally

Label	HK06: 33 Features	33 Added Features

Table 1: Features and their associated majority label. Features for each label were chosen by the method described in HK06 – top frequency for that label and not higher frequency for any other label.

		+ SVD features
HK06	53.7%	<b>71.5%</b>
CRF + GE/Heuristic	<b>66.9%</b>	68.3%

Table 2: Accuracy of semi-supervised learning methods with majority labeled features alone. GE outperforms HK06 when neither model has access to SVD features. When SVD features are included, HK06 has an edge in accuracy.

labeled instances used for estimation in traditional CRF training. **Majority labeled features** are features annotated with their majority label.<sup>6</sup> **Labeled features** are features  $m$  where the distribution  $p(y_i|f_m(\mathbf{x}, i))$  has been specified. In Section 5.3 we estimate these distributions from isolated labeled tokens.

We evaluate the system in two scenarios: (1) with feature constraints alone and (2) feature constraints in conjunction with a minimal amount of labeled instances. There is little prior work that demonstrates the use of both scenarios; CRR07 can only be applied when there is some labeled data, while HK06 could be applied in both scenarios though there are no such published experiments.

## 5.1 Majority Labeled Features Only

When using majority labeled features alone, it can be seen in Table 2 that GE is the best performing method. This is important, as it demonstrates that GE out of the box can be used effectively, without tuning and extra modifications.

<sup>6</sup>While HK06 and CRR07 require only majority labeled features, GE criteria use conditional probability distributions of labels given features, and so in order to apply GE we must decide on a particular distribution for each feature constraint. In sections 5.1 and 5.2 we use a simple heuristic to derive distributions from majority label information: we assign .99 probability to the majority label of the feature and divide the remaining probability uniformly among the remainder of the labels.

	Labeled Instances		
	10	25	100
supervised HMM	61.6%	70.0%	76.3%
supervised CRF	64.6%	72.9%	79.4%
CRF+ Entropy Reg.	67.3%	73.7%	79.5%
CRR07	70.9%	74.8%	78.6%
+ inference constraints	<b>74.7%</b>	<b>78.5%</b>	<b>81.7%</b>
CRF+GE/Heuristic	72.6%	76.3%	80.1%

Table 3: Accuracy of semi-supervised learning methods with constraints and limited amounts of training data. Even though CRR07 uses more constraints and requires additional development data for estimating mixture weights, GE still outperforms CRR07 when that system is run without applying constraints during inference. When these constraints are applied during test-time inference, CRR07 has an edge over the CRF trained with GE criteria.

In their original work, HK06 propose a method for generating additional features given a set of “prototype” features (the feature constraints in Table 1), which they demonstrate to be highly effective. In their method, they collect contexts around all words in the corpus, then perform a SVD decomposition. They take the first 50 singular values for all words, and then if a word is within a thresholded distance to a prototype feature, they assign that word a new feature which indicates close similarity to a prototype feature. When SVD features such as these are made available to the systems, HK06 has a higher accuracy.<sup>7</sup> For the remainder of the experiments we use the SVD feature enhanced data sets.<sup>8</sup>

We ran additional experiments with expected gradient methods but found them to be ineffective, reaching around 50% accuracy on the experiments with the additional SVD features, around 20% less than the competing methods.

## 5.2 Majority Labeled Features and Labeled Instances

Labeled instances are available, the technique described in CRR07 can be used. While CRR07 is run on the same data set as used by HK06, a direct comparison is problematic. First, they use additional constraints beyond those used in this paper and those

<sup>7</sup>We generated our own set of SVD features, so they might not match exactly the SVD features described in HK06.

<sup>8</sup>One further experiment HK06 performs which we do not duplicate here is post-processing the label assignments to better handle field boundaries. With this addition they realize another 2.5% improvement.

used by HK06 (e.g. each contiguous label sequence must be at least 3 labels long)—so their results cannot be directly compared. Second, they require additional training data to estimate weights for their soft constraints, and do not measure how much of this additional data is needed. Third, they use a slightly different tokenization procedure. Fourth, CRR07 uses different subsets of labeled training instances than used here. For these reasons, the comparison between the method presented here and CRR07 cannot be exact.

The technique described in CRR07 can be applied in two ways: constraints can be applied during learning, and they can also be applied during inference. We present comparisons with both of these systems in Table 3. CRFs trained with GE criteria consistently outperform CRR07 when no constraints are applied during inference time, even though CRR07 has additional constraints. When the method in CRR07 is applied with constraints in inference time, it is able to outperform CRFs trained with GE. We tried adding the additional constraints described in CRR07 during test-time inference in our system, but found no accuracy improvement. After doing error inspection, those additional constraints weren’t frequently violated by the GE trained method, which also suggests that adding them wouldn’t have a significant effect during training either. It is possible that for GE training there are alternative inference-time constraints that would improve performance, but we didn’t pursue this line of investigation as there are benefits to operating within a formal probabilistic model, and eschewing constraints applied during inference time. Without these constraints, probabilistic models can be combined easily with one another in order to arrive at a joint model, and adding in these constraints at inference time complicates the nature of the combination.

### 5.3 Labeled Features vs. Labeled Instances

In the previous section, the supervision signal was the majority label of each feature.<sup>9</sup> Given a feature of interest, a human can gather a set of tokens that have this feature and label them to discover the cor-

<sup>9</sup>It is not clear how these features would be tagged with majority label in a real use case. Tagging data to discover the majority label could potentially require a large number of tagged instances before the majority label was definitively identified.

Figure 2: Accuracy of supervised and semi-supervised learning methods for fixed numbers of labeled tokens. Training a GE model with only labeled features significantly outperforms traditional log-likelihood training with labeled instances for comparable numbers of labeled tokens. When training on less than 1500 annotated tokens, it also outperforms CRR07 + inference time constraints, which uses not only labeled tokens but additional constraints and development data for estimating mixture weights.

	Labeled Instances			
	0	10	25	100
HK06	71.5%	-	-	-
GE/Heuristic	68.3%	72.6%	76.3%	80.1%
GE/Sampled	<b>73.0%</b>	<b>74.6%</b>	<b>77.2%</b>	<b>80.5%</b>

Table 4: Accuracy of semi-supervised learning methods comparing the effects of (1) a heuristic for setting conditional distributions of labels given features and (2) estimating this distributions via human annotation. When GE is given feature distributions are better than the simple heuristic it is able to realize considerable gains.

relation between the feature and the labels.<sup>10</sup> While the resulting label distribution information could not be fully utilized by previous methods (HK06 and CRR07 use only the majority label of the word), it can, however, be integrated into the GE criteria by using the distribution from the relative proportions of labels rather than a the previous heuristic distribution. We present a series of experiments that test the advantages of this annotation paradigm.

To simulate a human labeler, we randomly sample (without replacement) tokens with the particular feature in question, and generate a label using the human annotations provided in the data. Then we normalize and smooth the raw counts to obtain a

<sup>10</sup>In this paper we observe a 10x speed-up by using isolated labeled tokens instead of a wholly labeled instances—so even if it takes slightly longer to label isolated tokens, there will still be a substantial gain.

conditional probability distribution over labels given feature. We experiment with samples of 1, 2, 5, 10, 100 tokens per feature, as well as with all available labeled data. We sample instances for labeling exclusively from the training and development data, not from the testing data. We train a model using GE with these estimated conditional probability distributions and compare them with corresponding numbers of tokens of traditionally labeled instances.

Training from labeled features significantly outperforms training from traditional labeled instances for equivalent numbers of labeled tokens (Figure 2). With 1000 labeled tokens, instance-labeling achieves accuracy around 65%, while labeling 33 features reaches 72% accuracy.<sup>11</sup> To achieve the same level of performance as traditional instance-labeling, it can require as much as a factor of ten-fold fewer annotations of feature occurrences. For example, the accuracy achieved after labeling 257 tokens of 33 features is 71% – the same accuracy achieved only after labeling more than 2000 tokens in traditional instance-labeling.<sup>12</sup>

Assuming that labeling one token in isolation takes the same time as labeling one token in a sequence, these results strongly support a new paradigm of labeling in which instead of annotating entire sentences, the human instead selects some key features of interest and labels tokens that have this feature. Particularly intriguing is the flexibility our scenario provides for the selection of “features of interest” to be driven by error analysis.

Table 4 compares the heuristic method described above against sampled conditional probability distributions of labels given features<sup>13</sup>. Sampled distributions yield consistent improvements over the heuristic method. The accuracy with no labeled instances (73.0%) is better than HK06 (71.5%), which demonstrates that the precisely estimated feature distributions are helpful for improving accuracy.

Though accuracy begins to level off with distri-

<sup>11</sup>Labeling 99 features with 1000 tokens reaches nearly 76%.

<sup>12</sup>Accuracy at one labeled token per feature is much worse than accuracy with majority label information. This due to the noise introduced by sampling, as there is the potential for a relatively rare label be sampled and labeled, and thereby train the system on a non-canonical supervision signal.

<sup>13</sup>Where the tokens labeled is the total available number in the data, roughly 2500 tokens.

Figure 3: From left to right: distributions (with standard error) for the feature WORD=ADDRESS obtained from sampling, using 1 sample per feature and 10 samples per feature. Labels 1, 2, 3, and 9 are (respectively) FEATURES, CONTACT, SIZE, and ADDRESS. Instead of more precisely estimating these distributions, it is more beneficial to label a larger set of features.

butions over the original set of 33 labeled features, we ran additional experiments with 66 and 99 labeled features, whose results are also shown in Figure 2.<sup>14</sup> The graph shows that with an increased number of labeled features, for the same numbers of labeled tokens, accuracy can be improved. The reason behind this is clear—while there is some gain from increased precision of probability estimates (as they asymptotically approach their “true” values as shown in Figure 3), there is more information to be gained from rougher estimates of a larger set of features. One final point about these additional features is that their distributions are less peaked than the original feature set. Where the original feature set distribution has entropy of 8.8, the first 33 added features have an entropy of 22.95. Surprisingly, even *ambiguous* feature constraints are able to improve accuracy.

## 6 Conclusion

We have presented generalized expectation criteria for linear-chain conditional random fields, a new semi-supervised training method that makes use of labeled features rather than labeled instances. Previous semi-supervised methods have typically used ad-hoc feature majority label assignments as constraints. Our new method uses conditional probability distributions of labels given features and can dramatically reduce annotation time. When these distributions are estimated by means of annotated feature occurrences in context, there is as much as a ten-fold reduction in the annotation time that is required in order to achieve the same level of accuracy over traditional instance-labeling.

<sup>14</sup>Also note that for less than 1500 tokens of labeling, the 99 labeled features outperform CRR07 with inference time constraints.

# Analyzing the Errors of Unsupervised Learning

Percy Liang     Dan Klein

University of California at Berkeley  
Berkeley, CA 94720  
{pliang,klein}@cs.berkeley.edu

## Abstract

We identify four types of errors that unsupervised induction systems make and study each one in turn. Our contributions include (1) using a *meta-model* to analyze the incorrect biases of a model in a systematic way, (2) providing an efficient and robust method of measuring distance between two parameter settings of a model, and (3) showing that local optima issues which typically plague EM can be somewhat alleviated by increasing the number of training examples. We conduct our analyses on three models: the HMM, the PCFG, and a simple dependency model.

## 1 Introduction

The unsupervised induction of linguistic structure from raw text is an important problem both for understanding language acquisition and for building language processing systems such as parsers from limited resources. Early work on inducing grammars via EM encountered two serious obstacles: the inappropriateness of the likelihood objective and the tendency of EM to get stuck in local optima. Without additional constraints on bracketing (Pereira and Shabes, 1992) or on allowable rewrite rules (Carroll and Charniak, 1992), unsupervised grammar learning was ineffective.

Since then, there has been a large body of work addressing the flaws of the EM-based approach. Syntactic models empirically more learnable than PCFGs have been developed (Clark, 2001; Klein and Manning, 2004). Smith and Eisner (2005) proposed a new objective function; Smith and Eisner (2006) introduced a new training procedure. Bayesian approaches can also improve performance (Goldwater and Griffiths, 2007; Johnson, 2007; Kurihara and Sato, 2006).

Though these methods have improved induction accuracy, at the core they all still involve optimizing non-convex objective functions related to the likelihood of some model, and thus are not completely immune to the difficulties associated with early approaches. It is therefore important to better understand the behavior of unsupervised induction systems in general.

In this paper, we take a step back and present a more statistical view of unsupervised learning in the context of grammar induction. We identify four types of error that a system can make: *approximation*, *identifiability*, *estimation*, and *optimization* errors (see Figure 1). We try to isolate each one in turn and study its properties.

Approximation error is caused by a mis-match between the likelihood objective optimized by EM and the true relationship between sentences and their syntactic structures. Our key idea for understanding this mis-match is to “cheat” and initialize EM with the true relationship and then study the ways in which EM repurposes our desired syntactic structures to increase likelihood. We present a *meta-model* of the changes that EM makes and show how this tool can shed some light on the undesired biases of the HMM, the PCFG, and the dependency model with valence (Klein and Manning, 2004).

Identifiability error can be incurred when two distinct parameter settings yield the same probability distribution over sentences. One type of non-identifiability present in HMMs and PCFGs is label symmetry, which even makes computing a meaningful distance between parameters NP-hard. We present a method to obtain lower and upper bounds on such a distance.

Estimation error arises from having too few training examples, and optimization error stems from

EM getting stuck in local optima. While it is to be expected that estimation error should decrease as the amount of data increases, we show that optimization error can also decrease. We present striking experiments showing that if our data actually comes from the model family we are learning with, we can sometimes recover the true parameters by simply running EM without clever initialization. This result runs counter to the conventional attitude that EM is doomed to local optima; it suggests that increasing the amount of data might be an effective way to partially combat local optima.

## 2 Unsupervised models

Let  $\mathbf{x}$  denote an input sentence and  $\mathbf{y}$  denote the unobserved desired output (e.g., a parse tree). We consider a model family  $\mathcal{P} = \{p_\theta(\mathbf{x}, \mathbf{y}) : \theta \in \Theta\}$ . For example, if  $\mathcal{P}$  is the set of all PCFGs, then the parameters  $\theta$  would specify all the rule probabilities of a particular grammar. We sometimes use  $\theta$  and  $p_\theta$  interchangeably to simplify notation. In this paper, we analyze the following three model families:

In the **HMM**, the input  $\mathbf{x}$  is a sequence of words and the output  $\mathbf{y}$  is the corresponding sequence of part-of-speech tags.

In the **PCFG**, the input  $\mathbf{x}$  is a sequence of POS tags and the output  $\mathbf{y}$  is a binary parse tree with yield  $\mathbf{x}$ . We represent  $\mathbf{y}$  as a multiset of binary rewrites of the form  $(y \rightarrow y_1 y_2)$ , where  $y$  is a nonterminal and  $y_1, y_2$  can be either nonterminals or terminals.

In the dependency model with valence (**DMV**) (Klein and Manning, 2004), the input  $\mathbf{x} = (x_1, \dots, x_m)$  is a sequence of POS tags and the output  $\mathbf{y}$  specifies the directed links of a projective dependency tree. The generative model is as follows: for each head  $x_i$ , we generate an independent sequence of arguments to the left and to the right from a direction-dependent distribution over tags. At each point, we stop with a probability parametrized by the direction and whether any arguments have already been generated in that direction. See Klein and Manning (2004) for a formal description.

In all our experiments, we used the Wall Street Journal (WSJ) portion of the Penn Treebank. We binarized the PCFG trees and created gold dependency trees according to the Collins head rules. We trained 45-state HMMs on all 49208 sentences, 11-state

PCFGs on WSJ-10 (7424 sentences) and DMVs on WSJ-20 (25523 sentences) (Klein and Manning, 2004). We ran EM for 100 iterations with the parameters initialized uniformly (always plus a small amount of random noise). We evaluated the HMM and PCFG by mapping model states to Treebank tags to maximize accuracy.

## 3 Decomposition of errors

Now we will describe the four types of errors (Figure 1) more formally. Let  $p^*(\mathbf{x}, \mathbf{y})$  denote the distribution which governs the true relationship between the input  $\mathbf{x}$  and output  $\mathbf{y}$ . In general,  $p^*$  does not live in our model family  $\mathcal{P}$ . We are presented with a set of  $n$  unlabeled examples  $\mathbf{x}^{(1)}, \dots, \mathbf{x}^{(n)}$  drawn i.i.d. from the true  $p^*$ . In unsupervised induction, our goal is to approximate  $p^*$  by some model  $p_\theta \in \mathcal{P}$  in terms of strong generative capacity. A standard approach is to use the EM algorithm to optimize the empirical likelihood  $\hat{\mathbb{E}} \log p_\theta(\mathbf{x})$ .<sup>1</sup> However, EM only finds a local maximum, which we denote  $\hat{\theta}_{\text{EM}}$ , so there is a *discrepancy* between what we get ( $p_{\hat{\theta}_{\text{EM}}}$ ) and what we want ( $p^*$ ).

We will define this discrepancy later, but for now, it suffices to remark that the discrepancy depends on the distribution over  $\mathbf{y}$  whereas learning depends only on the distribution over  $\mathbf{x}$ . This is an important property that distinguishes unsupervised induction from more standard supervised learning or density estimation scenarios.

Now let us walk through the four types of error bottom up. First,  $\hat{\theta}_{\text{EM}}$ , the local maximum found by EM, is in general different from  $\hat{\theta} \in \operatorname{argmax}_\theta \hat{\mathbb{E}} \log p_\theta(\mathbf{x})$ , any global maximum, which we could find given unlimited computational resources. *Optimization error* refers to the discrepancy between  $\hat{\theta}$  and  $\hat{\theta}_{\text{EM}}$ .

Second, our training data is only a noisy sample from the true  $p^*$ . If we had infinite data, we would choose an optimal parameter setting under the model,  $\theta_2^* \in \operatorname{argmax}_\theta \mathbb{E} \log p_\theta(\mathbf{x})$ , where now the expectation  $\mathbb{E}$  is taken with respect to the true  $p^*$  instead of the training data. The discrepancy between  $\theta_2^*$  and  $\hat{\theta}$  is the *estimation error*.

Note that  $\theta_2^*$  might not be unique. Let  $\theta_1^*$  denote

<sup>1</sup>Here, the expectation  $\hat{\mathbb{E}} f(\mathbf{x}) \stackrel{\text{def}}{=} \frac{1}{n} \sum_{i=1}^n f(\mathbf{x}^{(i)})$  denotes averaging some function  $f$  over the training data.

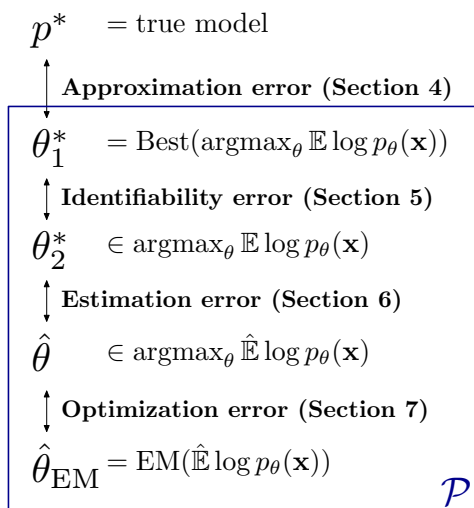

Figure 1: The discrepancy between what we get ( $\hat{\theta}_{\text{EM}}$ ) and what we want ( $p^*$ ) can be decomposed into four types of errors. The box represents our model family  $\mathcal{P}$ , which is the set of possible parametrized distributions we can represent. Best( $S$ ) returns the  $\theta \in S$  which has the smallest discrepancy with  $p^*$ .

the maximizer of  $\mathbb{E} \log p_\theta(\mathbf{x})$  that has the smallest discrepancy with  $p^*$ . Since  $\theta_1^*$  and  $\theta_2^*$  have the same value under the objective function, we would not be able to choose  $\theta_1^*$  over  $\theta_2^*$ , even with infinite data or unlimited computation. Identifiability error refers to the discrepancy between  $\theta_1^*$  and  $\theta_2^*$ .

Finally, the model family  $\mathcal{P}$  has fundamental limitations. *Approximation error* refers to the discrepancy between  $p^*$  and  $p_{\theta_1^*}$ . Note that  $\theta_1^*$  is not necessarily the best in  $\mathcal{P}$ . If we had labeled data, we could find a parameter setting in  $\mathcal{P}$  which is closer to  $p^*$  by optimizing joint likelihood  $\mathbb{E} \log p_\theta(\mathbf{x}, \mathbf{y})$  (generative training) or even conditional likelihood  $\mathbb{E} \log p_\theta(\mathbf{y} | \mathbf{x})$  (discriminative training).

In the remaining sections, we try to study each of the four errors in isolation. In practice, since it is difficult to work with some of the parameter settings that participate in the error decomposition, we use computationally feasible surrogates so that the error under study remains the dominant effect.

## 4 Approximation error

We start by analyzing approximation error, the discrepancy between  $p^*$  and  $p_{\theta_1^*}$  (the model found by optimizing likelihood), a point which has been dis-

Figure 2: For the PCFG, when we initialize EM with the supervised estimate  $\hat{\theta}_{\text{gen}}$ , the likelihood increases but the accuracy decreases.

cussed by many authors (Merialdo, 1994; Smith and Eisner, 2005; Haghghi and Klein, 2006).<sup>2</sup>

To confront the question of specifically how the likelihood diverges from prediction accuracy, we perform the following experiment: we initialize EM with the supervised estimate<sup>3</sup>  $\hat{\theta}_{\text{gen}} = \operatorname{argmax}_\theta \hat{\mathbb{E}} \log p_\theta(\mathbf{x}, \mathbf{y})$ , which acts as a surrogate for  $p^*$ . As we run EM, the likelihood increases but the accuracy decreases (Figure 2 shows this trend for the PCFG; the HMM and DMV models behave similarly). We believe that the initial iterations of EM contain valuable information about the incorrect biases of these models. However, EM is changing hundreds of thousands of parameters at once in a non-trivial way, so we need a way of characterizing the important changes.

One broad observation we can make is that the first iteration of EM reinforces the systematic mistakes of the supervised initializer. In the first E-step, the posterior counts that are computed summarize the predictions of the supervised system. If these match the empirical counts, then the M-step does not change the parameters. But if the supervised system predicts too many JJs, for example, then the M-step will update the parameters to reinforce this bias.

### 4.1 A meta-model for analyzing EM

We would like to go further and characterize the specific changes EM makes. An initial approach is to find the parameters that changed the most during the first iteration (weighted by the correspond-

<sup>2</sup>Here, we think of discrepancy between  $p$  and  $p'$  as the error incurred when using  $p'$  for prediction on examples generated from  $p$ ; in symbols,  $\mathbb{E}_{(\mathbf{x}, \mathbf{y}) \sim p} \text{loss}(\mathbf{y}, \operatorname{argmax}_{\mathbf{y}'} p'(\mathbf{y}' | \mathbf{x}))$ .

<sup>3</sup>For all our models, the supervised estimate is solved in closed form by taking ratios of counts.

ing expected counts computed in the E-step). For the HMM, the three most changed parameters are the transitions 2:DT→8:JJ, START→0:NNP, and 8:JJ→3:NN.<sup>4</sup> If we delve deeper, we can see that 2:DT→3:NN (the parameter with the 10th largest change) fell and 2:DT→8:JJ rose. After checking with a few examples, we can then deduce that some nouns were retagged as adjectives. Unfortunately, this type of ad-hoc reasoning requires considerable manual effort and is rather subjective.

Instead, we propose using a general *meta-model* to analyze the changes EM makes in an automatic and objective way. Instead of treating parameters as the primary object of study, we look at predictions made by the model and study how they change over time. While a model is a distribution over sentences, a meta-model is a distribution over how the predictions of the model change.

Let  $R(\mathbf{y})$  denote the set of *parts* of a prediction  $\mathbf{y}$  that we are interested in tracking. Each part  $(c, l) \in R(\mathbf{y})$  consists of a *configuration*  $c$  and a *location*  $l$ . For a PCFG, we define a configuration to be a rewrite rule (e.g.,  $c = \text{PP} \rightarrow \text{IN NP}$ ), and a location  $l = [i, k, j]$  to be a span  $[i, j]$  split at  $k$ , where the rewrite  $c$  is applied.

In this work, each configuration is associated with a parameter of the model, but in general, a configuration could be a larger unit such as a subtree, allowing one to track more complex changes. The size of a configuration governs how much the meta-model generalizes from individual examples.

Let  $\mathbf{y}^{(i,t)}$  denote the model prediction on the  $i$ -th training example after  $t$  iterations of EM. To simplify notation, we write  $R_t = R(\mathbf{y}^{(i,t)})$ . The meta-model explains how  $R_t$  became  $R_{t+1}$ .<sup>5</sup>

In general, we expect a part in  $R_{t+1}$  to be explained by a part in  $R_t$  that has a similar location and furthermore, we expect the locations of the two parts to be related in some consistent way. The meta-model uses two notions to formalize this idea: a *distance*  $d(l, l')$  and a *relation*  $r(l, l')$ . For the PCFG,  $d(l, l')$  is the number of positions among  $i, j, k$  that are the same as the corresponding ones in  $l'$ , and  $r((i, k, j), (i', k', j')) = (\text{sign}(i - i'), \text{sign}(j -$

$j'), \text{sign}(k - k'))$  is one of  $3^3$  values. We define a *migration* as a triple  $(c, c', r(l, l'))$ ; this is the unit of change we want to extract from the meta-model.

Our meta-model provides the following generative story of how  $R_t$  becomes  $R_{t+1}$ : each new part  $(c', l') \in R_{t+1}$  chooses an old part  $(c, l) \in R_t$  with some probability that depends on (1) the distance between the locations  $l$  and  $l'$  and (2) the likelihood of the particular migration. Formally:

$$p^{\text{meta}}(R_{t+1} | R_t) = \prod_{(c', l') \in R_{t+1}} \sum_{(c, l) \in R_t} Z_l^{-1} e^{-\alpha d(l, l')} p(c' | c, r(l, l')),$$

where  $Z_l = \sum_{(c, l) \in R_t} e^{-\alpha d(l, l')}$  is a normalization constant, and  $\alpha$  is a hyperparameter controlling the possibility of distant migrations (set to 3 in our experiments).

We learn the parameters of the meta-model with an EM algorithm similar to the one for IBM model 1. Fortunately, the likelihood objective is convex, so we need not worry about local optima.

## 4.2 Results of the meta-model

We used our meta-model to analyze the approximation errors of the HMM, DMV, and PCFG. For these models, we initialized EM with the supervised estimate  $\hat{\theta}_{\text{gen}}$  and collected the model predictions as EM ran. We then trained the meta-model on the predictions between successive iterations. The meta-model gives us an expected count for each migration. Figure 3 lists the migrations with the highest expected counts.

From these migrations, we can see that EM tries to explain  $\mathbf{x}$  better by making the corresponding  $\mathbf{y}$  more *regular*. In fact, many of the HMM migrations on the first iteration attempt to resolve inconsistencies in gold tags. For example, noun adjuncts (e.g., *stock-index*), tagged as both nouns and adjectives in the Treebank, tend to become consolidated under adjectives, as captured by migration (B). EM also re-purposes under-utilized states to better capture distributional similarities. For example, state 24 has migrated to state 40 (N), both of which are now dominated by proper nouns. State 40 initially contained only #, but was quickly overrun with distributionally similar proper nouns such as *Oct.* and *Chap-ter*, which also precede numbers, just as # does.

<sup>4</sup>Here 2:DT means state 2 of the HMM, which was greedily mapped to DT.

<sup>5</sup>If the same part appears in both  $R_t$  and  $R_{t+1}$ , we remove it from both sets.

Iteration 0→1	Iteration 1→2	Iteration 2→3	Iteration 3→4	Iteration 4→5

(c) Top PCFG migrations. Example: migration (D) means a NP→NNP NP rewrite is replaced by NP→NNP NNP, where the new NNP right child spans less than the old NP right child.

Figure 3: We show the prominent migrations that occur during the first 5 iterations of EM for the HMM, DMV, and PCFG, as recovered by our meta-model. We sort the migrations across each iteration by their expected counts under the meta-model and show the top 3. Iteration 0 corresponds to the correct outputs. Blue indicates the new iteration, red indicates the old.

DMV migrations also try to regularize model predictions, but in a different way—in terms of the number of arguments. Because the stop probability is different for adjacent and non-adjacent arguments, it is statistically much cheaper to generate one argument rather than two or more. For example, if we train a DMV on only DT JJ NN, it can fit the data perfectly by using a chain of single arguments, but perfect fit is not possible if NN generates both DT and JJ (which is the desired structure); this explains migration (J). Indeed, we observed that the variance of the number of arguments decreases with more EM iterations (for NN, from 1.38 to 0.41).

In general, low-entropy conditional distributions are preferred. Migration (H) explains how adverbs now consistently attach to verbs rather than modals. After a few iterations, the modal has committed itself to generating exactly one verb to the right,

which is statistically advantageous because there must be a verb after a modal, while the adverb is optional. This leaves the verb to generate the adverb.

The PCFG migrations regularize categories in a manner similar to the HMM, but with the added complexity of changing bracketing structures. For example, sentential adverbs are re-analyzed as VP adverbs (A). Sometimes, multiple migrations explain the same phenomenon.<sup>6</sup> For example, migrations (B) and (C) indicate that PPs that previously attached to NPs are now raised to the verbal level. Tree rotation is another common phenomenon, leading to many left-branching structures (D,G,H). The migrations that happen during one iteration can also trigger additional migrations in the next. For example, the raising of the PP (B,C) inspires more of the

<sup>6</sup>We could consolidate these migrations by using larger configurations, but at the risk of decreased generalization.

same raising (E). As another example, migration (I) regularizes TO VB infinitival clauses into PPs, and this momentum carries over to the next iteration with even greater force (J).

In summary, the meta-model facilitates our analyses by automatically identifying the broad trends. We believe that the central idea of modeling the errors of a system is a powerful one which can be used to analyze a wide range of models, both supervised and unsupervised.

## 5 Identifiability error

While approximation error is incurred when likelihood diverges from accuracy, identifiability error is concerned with the case where likelihood is indifferent to accuracy.

We say a set of parameters  $S$  is *identifiable* (in terms of  $\mathbf{x}$ ) if  $p_\theta(\mathbf{x}) \neq p_{\theta'}(\mathbf{x})$  for every  $\theta, \theta' \in S$  where  $\theta \neq \theta'$ .<sup>7</sup> In general, identifiability error is incurred when the set of maximizers of  $\mathbb{E} \log p_\theta(\mathbf{x})$  is non-identifiable.<sup>8</sup>

Label symmetry is perhaps the most familiar example of non-identifiability and is intrinsic to models with hidden labels (HMM and PCFG, but not DMV). We can permute the hidden labels without changing the objective function or even the nature of the solution, so there is no reason to prefer one permutation over another. While seemingly benign, this symmetry actually presents a serious challenge in measuring discrepancy (Section 5.1).

Grenager et al. (2005) augments an HMM to allow emission from a generic stopword distribution at any position with probability  $q$ . Their model would definitely not be identifiable if  $q$  were a free parameter, since we can set  $q$  to 0 and just mix in the stopword distribution with each of the other emission distributions to obtain a different parameter setting yielding the same overall distribution. This is a case where our notion of desired structure is absent in the likelihood, and a prior over parameters could help break ties.

<sup>7</sup>For our three model families,  $\theta$  is identifiable in terms of  $(\mathbf{x}, \mathbf{y})$ , but not in terms of  $\mathbf{x}$  alone.

<sup>8</sup>We emphasize that non-identifiability is in terms of  $\mathbf{x}$ , so two parameter settings could still induce the same marginal distribution on  $\mathbf{x}$  (weak generative capacity) while having different joint distributions on  $(\mathbf{x}, \mathbf{y})$  (strong generative capacity). Recall that discrepancy depends on the latter.

The above non-identifiabilities apply to all parameter settings, but another type of non-identifiability concerns only the maximizers of  $\mathbb{E} \log p_\theta(\mathbf{x})$ . Suppose the true data comes from a  $K$ -state HMM. If we attempt to fit an HMM with  $K + 1$  states, we can split any one of the  $K$  states and maintain the same distribution on  $\mathbf{x}$ . Or, if we learn a PCFG on the same HMM data, then we can choose either the left- or right-branching chain structures, which both mimic the true HMM equally well.

### 5.1 Permutation-invariant distance

KL-divergence is a natural measure of discrepancy between two distributions, but it is somewhat non-trivial to compute—for our three recursive models, it requires solving fixed point equations, and becomes completely intractable in face of label symmetry. Thus we propose a more manageable alternative:

$$d_\mu(\theta \parallel \theta') \stackrel{\text{def}}{=} \frac{\sum_j \mu_j |\theta_j - \theta'_j|}{\sum_j \mu_j}, \quad (1)$$

where we weight the difference between the  $j$ -th component of the parameter vectors by  $\mu_j$ , the  $j$ -th expected sufficient statistic with respect to  $p_\theta$  (the expected counts computed in the E-step).<sup>9</sup> Unlike KL, our distance  $d_\mu$  is only defined on distributions in the model family and is not invariant to reparametrization. Like KL,  $d_\mu$  is asymmetric, with the first argument holding the status of being the “true” parameter setting. In our case, the parameters are conditional probabilities, so  $0 \leq d_\mu(\theta \parallel \theta') \leq 1$ , so we can interpret  $d_\mu$  as an expected difference between these probabilities.

Unfortunately, label symmetry can wreak havoc on our distance measure  $d_\mu$ . Suppose we want to measure the distance between  $\theta$  and  $\theta'$ . If  $\theta'$  is simply  $\theta$  with the labels permuted, then  $d_\mu(\theta \parallel \theta')$  would be substantial even though the distance ought to be zero. We define a revised distance to correct for this by taking the minimum distance over all label permutations:

$$D_\mu(\theta \parallel \theta') = \min_\pi d_\mu(\theta \parallel \pi(\theta')), \quad (2)$$

<sup>9</sup>Without this factor, rarely used components could contribute to the sum as much as frequently used ones, thus, making the distance overly pessimistic.

where  $\pi(\theta')$  denotes the parameter setting resulting from permuting the labels according to  $\pi$ . (The DMV has no label symmetries, so just  $d_\mu$  works.)

For mixture models, we can compute  $D_\mu(\theta \parallel \theta')$  efficiently as follows. Note that each term in the summation of (1) is associated with one of the  $K$  labels. We can form a  $K \times K$  matrix  $M$ , where each entry  $M_{ij}$  is the distance between the parameters involving label  $i$  of  $\theta$  and label  $j$  of  $\theta'$ .  $D_\mu(\theta \parallel \theta')$  can then be computed by finding a maximum weighted bipartite matching on  $M$  using the  $O(K^3)$  Hungarian algorithm (Kuhn, 1955).

For models such as the HMM and PCFG, computing  $D_\mu$  is NP-hard, since the summation in  $d_\mu$  (1) contains both first-order terms which depend on one label (e.g., emission parameters) and higher-order terms which depend on more than one label (e.g., transitions or rewrites). We cannot capture these problematic higher-order dependencies in  $M$ .

However, we can bound  $D_\mu(\theta \parallel \theta')$  as follows. We create  $M$  using only first-order terms and find the best matching (permutation) to obtain a lower bound  $\underline{D}_\mu$  and an associated permutation  $\pi_0$  achieving it. Since  $D_\mu(\theta \parallel \theta')$  takes the minimum over all permutations,  $d_\mu(\theta \parallel \pi(\theta'))$  is an upper bound for any  $\pi$ , in particular for  $\pi = \pi_0$ . We then use a local search procedure that changes  $\pi$  to further tighten the upper bound. Let  $\overline{D}_\mu$  denote the final value.

## 6 Estimation error

Thus far, we have considered approximation and identifiability errors, which have to do with flaws of the model. The remaining errors have to do with how well we can fit the model. To focus on these errors, we consider the case where the true model is in our family ( $p^* \in \mathcal{P}$ ). To keep the setting as realistic as possible, we do supervised learning on real labeled data to obtain  $\theta^* = \operatorname{argmax}_\theta \mathbb{E} \log p(\mathbf{x}, \mathbf{y})$ . We then throw away our real data and let  $p^* = p_{\theta^*}$ . Now we start anew: sample new artificial data from  $\theta^*$ , learn a model using this artificial data, and see how close we get to recovering  $\theta^*$ .

In order to compute estimation error, we need to compare  $\theta^*$  with  $\hat{\theta}$ , the global maximizer of the likelihood on our generated data. However, we cannot compute  $\hat{\theta}$  exactly. Let us therefore first consider the simpler supervised scenario. Here,  $\hat{\theta}_{\text{gen}}$  has a closed

form solution, so there is no optimization error. Using our distance  $D_\mu$  (defined in Section 5.1) to quantify estimation error, we see that, for the HMM,  $\hat{\theta}_{\text{gen}}$  quickly approaches  $\theta^*$  as we increase the amount of data (Table 1).

# examples	500	5K	50K	500K
$\underline{D}_\mu(\theta^* \parallel \hat{\theta}_{\text{gen}})$	0.003	6.3e-4	2.7e-4	8.5e-5
$\overline{D}_\mu(\theta^* \parallel \hat{\theta}_{\text{gen}})$	0.005	0.001	5.2e-4	1.7e-4
$\underline{D}_\mu(\theta^* \parallel \hat{\theta}_{\text{gen-EM}})$	0.022	0.018	0.008	0.002
$\overline{D}_\mu(\theta^* \parallel \hat{\theta}_{\text{gen-EM}})$	0.049	0.039	0.016	0.004

Table 1: Lower and upper bounds on the distance from the true  $\theta^*$  for the HMM as we increase the number of examples.

In the unsupervised case, we use the following procedure to obtain a surrogate for  $\hat{\theta}$ : initialize EM with the supervised estimate  $\hat{\theta}_{\text{gen}}$  and run EM for 100 iterations. Let  $\hat{\theta}_{\text{gen-EM}}$  denote the final parameters, which should be representative of  $\hat{\theta}$ . Table 1 shows that the estimation error of  $\hat{\theta}_{\text{gen-EM}}$  is an order of magnitude higher than that of  $\hat{\theta}_{\text{gen}}$ , which is to be expected since  $\hat{\theta}_{\text{gen-EM}}$  does not have access to labeled data. However, this error can also be driven down given a moderate number of examples.

## 7 Optimization error

Finally, we study optimization error, which is the discrepancy between the global maximizer  $\hat{\theta}$  and  $\hat{\theta}_{\text{EM}}$ , the result of running EM starting from a uniform initialization (plus some small noise). As before, we cannot compute  $\hat{\theta}$ , so we use  $\hat{\theta}_{\text{gen-EM}}$  as a surrogate. Also, instead of comparing  $\hat{\theta}_{\text{gen-EM}}$  and  $\hat{\theta}$  with each other, we compare each of their discrepancies with respect to  $\theta^*$ .

Let us first consider optimization error in terms of prediction error. The first observation is that there is a gap between the prediction accuracies of  $\hat{\theta}_{\text{gen-EM}}$  and  $\hat{\theta}_{\text{EM}}$ , but this gap shrinks considerably as we increase the number of examples. Figures 4(a,b,c) support this for all three model families: for the HMM, both  $\hat{\theta}_{\text{gen-EM}}$  and  $\hat{\theta}_{\text{EM}}$  eventually achieve around 90% accuracy; for the DMV, 85%. For the PCFG,  $\hat{\theta}_{\text{EM}}$  still lags  $\hat{\theta}_{\text{gen-EM}}$  by 10%, but we believe that more data can further reduce this gap.

Figure 4(d) shows that these trends are not particular to artificial data. On real WSJ data, the gap

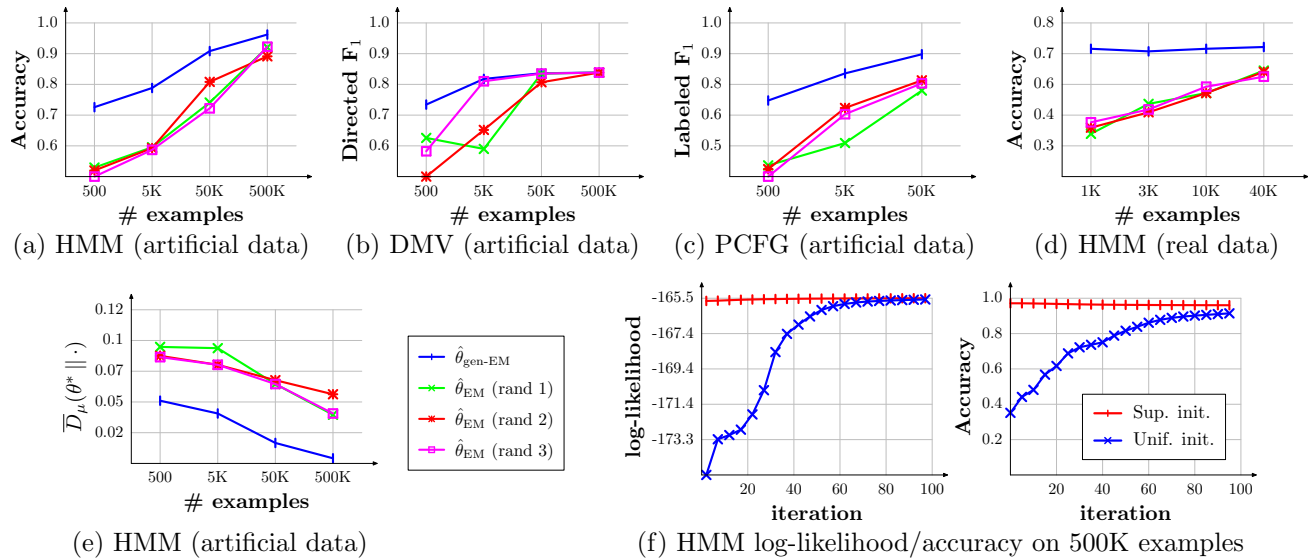

Figure 4: Compares the performance of  $\hat{\theta}_{EM}$  (EM with a uniform initialization) against  $\hat{\theta}_{gen-EM}$  (EM initialized with the supervised estimate) on (a–c) various models, (d) real data. (e) measures distance instead of accuracy and (f) shows a sample EM run.

between  $\hat{\theta}_{gen-EM}$  and  $\hat{\theta}_{EM}$  also diminishes for the HMM. To reaffirm the trends, we also measure distance  $D_\mu$ . Figure 4(e) shows that the distance from  $\hat{\theta}_{EM}$  to the true parameters  $\theta^*$  decreases, but the gap between  $\hat{\theta}_{gen-EM}$  and  $\hat{\theta}_{EM}$  does not close as decisively as it did for prediction error.

It is quite surprising that by simply running EM with a neutral initialization, we can accurately learn a complex model with thousands of parameters. Figures 4(f,g) show how both likelihood and accuracy, which both start quite low, improve substantially over time for the HMM on artificial data.

Carroll and Charniak (1992) report that EM fared poorly with local optima. We do not claim that there are no local optima, but only that the likelihood surface that EM is optimizing can become smoother with more examples. With more examples, there is less noise in the aggregate statistics, so it might be easier for EM to pick out the salient patterns.

Srebro et al. (2006) made a similar observation in the context of learning Gaussian mixtures. They characterized three regimes: one where EM was successful in recovering the true clusters (given lots of data), another where EM failed but the global optimum was successful, and the last where both failed (without much data).

There is also a rich body of theoretical work on

learning latent-variable models. Specialized algorithms can provably learn certain constrained discrete hidden-variable models, some in terms of weak generative capacity (Ron et al., 1998; Clark and Thollard, 2005; Adriaans, 1999), others in term of strong generative capacity (Dasgupta, 1999; Feldman et al., 2005). But with the exception of Dasgupta and Schulman (2007), there is little theoretical understanding of EM, let alone on complex model families such as the HMM, PCFG, and DMV.

## 8 Conclusion

In recent years, many methods have improved unsupervised induction, but these methods must still deal with the four types of errors we have identified in this paper. One of our main contributions of this paper is the idea of using the meta-model to diagnose the approximation error. Using this tool, we can better understand model biases and hopefully correct for them. We also introduced a method for measuring distances in face of label symmetry and ran experiments exploring the effectiveness of EM as a function of the amount of data. Finally, we hope that setting up the general framework to understand the errors of unsupervised induction systems will aid the development of better methods and further analyses.

## Abstract

For Chinese POS tagging, word segmentation is a preliminary step. To avoid error propagation and improve segmentation by utilizing POS information, segmentation and tagging can be performed simultaneously. A challenge for this joint approach is the large combined search space, which makes efficient decoding very hard. Recent research has explored the integration of segmentation and POS tagging, by decoding under restricted versions of the full combined search space. In this paper, we propose a joint segmentation and POS tagging model that does not impose any hard constraints on the interaction between word and POS information. Fast decoding is achieved by using a novel multiple-beam search algorithm. The system uses a discriminative statistical model, trained using the generalized perceptron algorithm. The joint model gives an error reduction in segmentation accuracy of 14.6% and an error reduction in tagging accuracy of 12.2%, compared to the traditional pipeline approach.

## 1 Introduction

Since Chinese sentences do not contain explicitly marked word boundaries, word segmentation is a necessary step before POS tagging can be performed. Typically, a Chinese POS tagger takes segmented inputs, which are produced by a separate word segmentor. This two-step approach, however, has an obvious flaw of error propagation, since word segmentation errors cannot be corrected by the POS tagger. A better approach would be to utilize POS in-

formation to improve word segmentation. For example, the POS-word pattern “number word” + “个 (a common measure word)” can help in segmenting the character sequence “一个人” into the word sequence “一 (one) 个 (measure word) 人 (person)” instead of “一 (one) 个人 (personal; adj)”. Moreover, the comparatively rare POS pattern “number word” + “number word” can help to prevent segmenting a long number word into two words.

In order to avoid error propagation and make use of POS information for word segmentation, segmentation and POS tagging can be viewed as a single task: given a raw Chinese input sentence, the joint POS tagger considers all possible segmented and tagged sequences, and chooses the overall best output. A major challenge for such a joint system is the large search space faced by the decoder. For a sentence with  $n$  characters, the number of possible output sequences is  $O(2^{n-1} \cdot T^n)$ , where  $T$  is the size of the tag set. Due to the nature of the combined candidate items, decoding can be inefficient even with dynamic programming.

Recent research on Chinese POS tagging has started to investigate joint segmentation and tagging, reporting accuracy improvements over the pipeline approach. Various decoding approaches have been used to reduce the combined search space. Ng and Low (2004) mapped the joint segmentation and POS tagging task into a single character sequence tagging problem. Two types of tags are assigned to each character to represent its segmentation and POS. For example, the tag “b\_NN” indicates a character at the beginning of a noun. Using this method, POS features are allowed to interact with segmentation.

Since tagging is restricted to characters, the search space is reduced to  $O((4T)^n)$ , and beam search decoding is effective with a small beam size. However, the disadvantage of this model is the difficulty in incorporating whole word information into POS tagging. For example, the standard “word + POS tag” feature is not explicitly applicable. Shi and Wang (2007) introduced POS information to segmentation by reranking.  $N$ -best segmentation outputs are passed to a separately-trained POS tagger, and the best output is selected using the overall POS-segmentation probability score. In this system, the decoding for word segmentation and POS tagging are still performed separately, and exact inference for both is possible. However, the interaction between POS and segmentation is restricted by reranking: POS information is used to improve segmentation only for the  $N$  segmentor outputs.

In this paper, we propose a novel joint model for Chinese word segmentation and POS tagging, which does not limiting the interaction between segmentation and POS information in reducing the combined search space. Instead, a novel multiple beam search algorithm is used to do decoding efficiently. Candidate ranking is based on a discriminative joint model, with features being extracted from segmented words and POS tags simultaneously. The training is performed by a single generalized perceptron (Collins, 2002). In experiments with the Chinese Treebank data, the joint model gave an error reduction of 14.6% in segmentation accuracy and 12.2% in the overall segmentation and tagging accuracy, compared to the traditional pipeline approach. In addition, the overall results are comparable to the best systems in the literature, which exploit knowledge outside the training data, even though our system is fully data-driven.

Different methods have been proposed to reduce error propagation between pipelined tasks, both in general (Sutton et al., 2004; Daumé III and Marcu, 2005; Finkel et al., 2006) and for specific problems such as language modeling and utterance classification (Saraclar and Roark, 2005) and labeling and chunking (Shimizu and Haas, 2006). Though our model is built specifically for Chinese word segmentation and POS tagging, the idea of using the perceptron model to solve multiple tasks simultaneously can be generalized to other tasks.

1	word $w$
2	word bigram $w_1w_2$
3	single-character word $w$
4	a word of length $l$ with starting character $c$
5	a word of length $l$ with ending character $c$
6	space-separated characters $c_1$ and $c_2$
7	character bigram $c_1c_2$ in any word
8	the first / last characters $c_1 / c_2$ of any word
9	word $w$ immediately before character $c$
10	character $c$ immediately before word $w$
11	the starting characters $c_1$ and $c_2$ of two consecutive words
12	the ending characters $c_1$ and $c_2$ of two consecutive words
13	a word of length $l$ with previous word $w$
14	a word of length $l$ with next word $w$

## 2 The Baseline System

We built a two-stage baseline system, using the perceptron segmentation model from our previous work (Zhang and Clark, 2007) and the perceptron POS tagging model from Collins (2002). We use *baseline system* to refer to the system which performs segmentation first, followed by POS tagging (using the single-best segmentation); *baseline segmentor* to refer to the segmentor from (Zhang and Clark, 2007) which performs segmentation only; and *baseline POS tagger* to refer to the Collins tagger which performs POS tagging only (given segmentation). The features used by the baseline segmentor are shown in Table 1. The features used by the POS tagger, some of which are different to those from Collins (2002) and are specific to Chinese, are shown in Table 2.

The word segmentation features are extracted from word bigrams, capturing word, word length and character information in the context. The word length features are normalized, with those more than 15 being treated as 15.

The POS tagging features are based on contextual information from the tag trigram, as well as the neighboring three-word window. To reduce overfitting and increase the decoding speed, templates 4, 5, 6 and 7 only include words with less than 3 characters. Like the baseline segmentor, the baseline tagger also normalizes word length features.

1	tag $t$ with word $w$
2	tag bigram $t_1t_2$
3	tag trigram $t_1t_2t_3$
4	tag $t$ followed by word $w$
5	word $w$ followed by tag $t$
6	word $w$ with tag $t$ and previous character $c$
7	word $w$ with tag $t$ and next character $c$
8	tag $t$ on single-character word $w$ in character trigram $c_1wc_2$
9	tag $t$ on a word starting with char $c$
10	tag $t$ on a word ending with char $c$
11	tag $t$ on a word containing char $c$ (not the starting or ending character)
12	tag $t$ on a word starting with char $c_0$ and containing char $c$
13	tag $t$ on a word ending with char $c_0$ and containing char $c$
14	tag $t$ on a word containing repeated char $cc$
15	tag $t$ on a word starting with character category $g$
16	tag $t$ on a word ending with character category $g$

Table 2: Feature templates for the baseline POS tagger

Templates 15 and 16 in Table 2 are inspired by the CTBMorph feature templates in Tseng et al. (2005), which gave the most accuracy improvement in their experiments. Here the category of a character is the set of tags seen on the character during training. Other morphological features from Tseng et al. (2005) are not used because they require extra web corpora besides the training data.

During training, the baseline POS tagger stores special word-tag pairs into a *tag dictionary* (Ratnaparkhi, 1996). Such information is used by the decoder to prune unlikely tags. For each word occurring more than  $N$  times in the training data, the decoder can only assign a tag the word has been seen with in the training data. This method led to improvement in the decoding speed as well as the output accuracy for English POS tagging (Ratnaparkhi, 1996). Besides tags for frequent words, our baseline POS tagger also uses the tag dictionary to store closed-set tags (Xia, 2000) – those associated only with a limited number of Chinese words.

### 3 Joint Segmentation and Tagging Model

In this section, we build a joint word segmentation and POS tagging model that uses exactly the same source of information as the baseline system, by applying the feature templates from the baseline word segmentor and POS tagger. No extra knowledge is used by the joint model. However, because word segmentation and POS tagging are performed simultaneously, POS information participates in word segmentation.

#### 3.1 Formulation of the joint model

We formulate joint word segmentation and POS tagging as a single problem, which maps a raw Chinese sentence to a segmented and POS tagged output. Given an input sentence  $x$ , the output  $F(x)$  satisfies:

$$F(x) = \arg \max_{y \in \text{GEN}(x)} \text{Score}(y)$$

where  $\text{GEN}(x)$  represents the set of possible outputs for  $x$ .

$\text{Score}(y)$  is computed by a feature-based linear model. Denoting the global feature vector for the tagged sentence  $y$  with  $\Phi(y)$ , we have:

$$\text{Score}(y) = \Phi(y) \cdot \vec{w}$$

where  $\vec{w}$  is the parameter vector in the model. Each element in  $\vec{w}$  gives a weight to its corresponding element in  $\Phi(y)$ , which is the count of a particular feature over the whole sentence  $y$ . We calculate the  $\vec{w}$  value by supervised learning, using the averaged perceptron algorithm (Collins, 2002), given in Figure 1.<sup>1</sup>

We take the union of feature templates from the baseline segmentor (Table 1) and POS tagger (Table 2) as the feature templates for the joint system. All features are treated equally and processed together according to the linear model, regardless of whether they are from the baseline segmentor or tagger. In fact, most features from the baseline POS tagger, when used in the joint model, represent segmentation patterns as well. For example, the aforementioned pattern “number word” + “↑”, which is

<sup>1</sup>In order to provide a comparison for the perceptron algorithm we also tried  $\text{svm}^{\text{struct}}$  (Tsochantaridis et al., 2004) for parameter estimation, but this training method was prohibitively slow.

**Inputs:** training examples  $(x_i, y_i)$   
**Initialization:** set  $\vec{w} = 0$   
**Algorithm:**  
 for  $t = 1..T, i = 1..N$   
   calculate  $z_i = \arg \max_{y \in \text{GEN}(x_i)} \Phi(y) \cdot \vec{w}$   
   if  $z_i \neq y_i$   
      $\vec{w} = \vec{w} + \Phi(y_i) - \Phi(z_i)$   
**Outputs:**  $\vec{w}$

Figure 1: The perceptron learning algorithm

useful only for the POS “number word” in the baseline tagger, is also an effective indicator of the segmentation of the two words (especially “ $\uparrow$ ”) in the joint model.

### 3.2 The decoding algorithm

One of the main challenges for the joint segmentation and POS tagging system is the decoding algorithm. The speed and accuracy of the decoder is important for the perceptron learning algorithm, but the system faces a very large search space of combined candidates. Given the linear model and feature templates, exact inference is very hard even with dynamic programming.

Experiments with the standard beam-search decoder described in (Zhang and Clark, 2007) resulted in low accuracy. This beam search algorithm processes an input sentence incrementally. At each stage, the incoming character is combined with existing partial candidates in all possible ways to generate new partial candidates. An agenda is used to control the search space, keeping only the  $B$  best partial candidates ending with the current character. The algorithm is simple and efficient, with a linear time complexity of  $O(BTn)$ , where  $n$  is the size of input sentence, and  $T$  is the size of the tag set ( $T = 1$  for pure word segmentation). It worked well for word segmentation alone (Zhang and Clark, 2007), even with an agenda size as small as 8, and a simple beam search algorithm also works well for POS tagging (Ratnaparkhi, 1996). However, when applied to the joint model, it resulted in a reduction in segmentation accuracy (compared to the baseline segmentor) even with  $B$  as large as 1024.

One possible cause of the poor performance of the standard beam search method is the combined nature of the candidates in the search space. In the base-

**Input:** raw sentence  $sent$  – a list of characters  
**Variables:** candidate sentence  $item$  – a list of (word, tag) pairs;  
 maximum word-length record  $maxlen$  for each tag;  
 the agenda list  $agendas$ ;  
 the tag dictionary  $tagdict$ ;  
 $start\_index$  for current word;  
 $end\_index$  for current word  
**Initialization:**  $agendas[0] = [“”]$ ,  
 $agendas[i] = []$  ( $i! = 0$ )

**Algorithm:**  
 for  $end\_index = 1$  to  $sent.length$ :  
   foreach  $tag$ :  
     for  $start\_index =$   
        $\max(1, end\_index - maxlen[tag] + 1)$   
     to  $end\_index$ :  
        $word = sent[start\_index..end\_index]$   
       if  $(word, tag)$  consistent with  $tagdict$ :  
         for  $item \in agendas[start\_index - 1]$ :  
            $item_1 = item$   
            $item_1.append((word, tag))$   
            $agendas[end\_index].insert(item_1)$   
**Outputs:**  $agendas[sent.length].best\_item$

Figure 2: The decoding algorithm for the joint word segmentor and POS tagger

line POS tagger, candidates in the beam are tagged sequences ending with the current word, which can be compared directly with each other. However, for the joint problem, candidates in the beam are segmented and tagged sequences up to the current character, where the last word can be a complete word or a partial word. A problem arises in whether to give POS tags to incomplete words. If partial words are given POS tags, it is likely that some partial words are “justified” as complete words by the current POS information. On the other hand, if partial words are not given POS tag features, the correct segmentation for long words can be lost during partial candidate comparison (since many short completed words with POS tags are likely to be preferred to a long incomplete word with no POS tag features).<sup>2</sup>

<sup>2</sup>We experimented with both assigning POS features to partial words and omitting them; the latter method performed better but both performed significantly worse than the multiple beam search method described below.

Another possible cause is the exponential growth in the number of possible candidates with increasing sentence size. The number increases from  $O(T^n)$  for the baseline POS tagger to  $O(2^{n-1}T^n)$  for the joint system. As a result, for an incremental decoding algorithm, the number of possible candidates increases exponentially with the current word or character index. In the POS tagging problem, a new incoming word enlarges the number of possible candidates by a factor of  $T$  (the size of the tag set). For the joint problem, however, the enlarging factor becomes  $2T$  with each incoming character. The speed of search space expansion is much faster, but the number of candidates is still controlled by a single, fixed-size beam at any stage. If we assume that the beam is not large enough for all the candidates at each stage, then, from the newly generated candidates, the baseline POS tagger can keep  $1/T$  for the next processing stage, while the joint model can keep only  $1/2T$ , and has to discard the rest. Therefore, even when the candidate comparison standard is ignored, we can still see that the chance for the overall best candidate to fall out of the beam is largely increased. Since the search space growth is exponential, increasing the fixed beam size is not effective in solving the problem.

To solve the above problems, we developed a multiple beam search algorithm, which compares candidates only with complete tagged words, and enables the size of the search space to scale with the input size. The algorithm is shown in Figure 2. In this decoder, an agenda is assigned to each character in the input sentence, recording the  $B$  best segmented and tagged partial candidates ending with the character. The input sentence is still processed incrementally. However, now when a character is processed, existing partial candidates ending with any previous characters are available. Therefore, the decoder enumerates all possible tagged words ending with the current character, and combines each word with the partial candidates ending with its previous character. All input characters are processed in the same way, and the final output is the best candidate in the final agenda. The time complexity of the algorithm is  $O(WTBn)$ , with  $W$  being the maximum word size,  $T$  being the total number of POS tags and  $n$  the number of characters in the input. It is also linear in the input size. Moreover, the decoding algorithm

gives competent accuracy with a small agenda size of  $B = 16$ .

To further limit the search space, two optimizations are used. First, the maximum word length for each tag is recorded and used by the decoder to prune unlikely candidates. Because the majority of tags only apply to words with length 1 or 2, this method has a strong effect. Development tests showed that it improves the speed significantly, while having a very small negative influence on the accuracy. Second, like the baseline POS tagger, the tag dictionary is used for Chinese closed set tags and the tags for frequent words. To words outside the tag dictionary, the decoder still tries to assign every possible tag.

### 3.3 Online learning

Apart from features, the decoder maintains other types of information, including the tag dictionary, the word frequency counts used when building the tag dictionary, the maximum word lengths by tag, and the character categories. The above data can be collected by scanning the corpus before training starts. However, in both the baseline tagger and the joint POS tagger, they are updated incrementally during the perceptron training process, consistent with online learning.<sup>3</sup>

The online updating of word frequencies, maximum word lengths and character categories is straightforward. For the online updating of the tag dictionary, however, the decision for frequent words must be made dynamically because the word frequencies keep changing. This is done by caching the number of occurrences of the current most frequent word  $M$ , and taking all words currently above the threshold  $M/5000 + 5$  as frequent words. 5000 is a rough figure to control the number of frequent words, set according to Zipf’s law. The parameter 5 is used to force all tags to be enumerated before a word is seen more than 5 times.

## 4 Related Work

Ng and Low (2004) and Shi and Wang (2007) were described in the Introduction. Both models reduced

<sup>3</sup>We took this approach because we wanted the whole training process to be online. However, for comparison purposes, we also tried precomputing the above information before training and the difference in performance was negligible.

the large search space by imposing strong restrictions on the form of search candidates. In particular, Ng and Low (2004) used character-based POS tagging, which prevents some important POS tagging features such as word + POS tag; Shi and Wang (2007) used an  $N$ -best reranking approach, which limits the influence of POS tagging on segmentation to the  $N$ -best list. In comparison, our joint model does not impose any hard limitations on the interaction between segmentation and POS information.<sup>4</sup> Fast decoding speed is achieved by using a novel multiple-beam search algorithm.

Nakagawa and Uchimoto (2007) proposed a hybrid model for word segmentation and POS tagging using an HMM-based approach. Word information is used to process known-words, and character information is used for unknown words in a similar way to Ng and Low (2004). In comparison, our model handles character and word information simultaneously in a single perceptron model.

## 5 Experiments

The Chinese Treebank (CTB) 4 is used for the experiments. It is separated into two parts: CTB 3 (420K characters in 150K words / 10364 sentences) is used for the final 10-fold cross validation, and the rest (240K characters in 150K words / 4798 sentences) is used as training and test data for development.

The standard F-scores are used to measure both the word segmentation accuracy and the overall segmentation and tagging accuracy, where the overall accuracy is  $TF = 2pr / (p + r)$ , with the precision  $p$  being the percentage of correctly segmented and tagged words in the decoder output, and the recall  $r$  being the percentage of gold-standard tagged words that are correctly identified by the decoder. For direct comparison with Ng and Low (2004), the POS tagging accuracy is also calculated by the percentage of correct tags on each character.

### 5.1 Development experiments

The learning curves of the baseline and joint models are shown in Figure 3, Figure 4 and Figure 5, respectively. These curves are used to show the conver-

<sup>4</sup>Apart from the beam search algorithm, we do impose some minor limitations on the search space by methods such as the tag dictionary, but these can be seen as optional pruning methods for optimization.

Figure 3: The learning curve of the baseline segmentor

JJ	3.09	0.93	0.15	0.26	0.26	–	0.04
CD	1.08	0.04	0	0	0.07	0	–

Table 3: Error analysis for the joint model

for the baseline segmentor, POS tagger, and the joint system are set to 8, 6, and 7, respectively for the remaining experiments.

There are many factors which can influence the accuracy of the joint model. Here we consider the special character category features and the effect of the tag dictionary. The character category features (templates 15 and 16 in Table 2) represent a Chinese character by all the tags associated with the character in the training data. They have been shown to improve the accuracy of a Chinese POS tagger (Tseng et al., 2005). In the joint model, these features also represent segmentation information, since they concern the starting and ending characters of a word. Development tests showed that the overall tagging F-score of the joint model increased from 84.54% to 84.93% using the character category features. In the development test, the use of the tag dictionary improves the decoding speed of the joint model, reducing the decoding time from 416 seconds to 256 seconds. The overall tagging accuracy also increased slightly, consistent with observations from the pure POS tagger.

The error analysis for the development test is shown in Table 3. Here an error is counted when a word in the standard output is not produced by the decoder, due to incorrect segmentation or tag assignment. Statistics about the six most frequently mistaken tags are shown in the table, where each row presents the analysis of one tag from the standard output, and each column gives a wrongly assigned value. The column “Seg” represents segmentation errors. Each figure in the table shows the percentage of the corresponding error from all the errors.

It can be seen from the table that the NN-VV and VV-NN mistakes were the most commonly made by the decoder, while the NR-NN mistakes are also fre-

quent. These three types of errors significantly outnumber the rest, together contributing 14.92% of all the errors. Moreover, the most commonly mistaken tags are NN and VV, while among the most frequent tags in the corpus, PU, DEG and M had comparatively less errors. Lastly, segmentation errors contribute around half (51.47%) of all the errors.

## 5.2 Test results

10-fold cross validation is performed to test the accuracy of the joint word segmentor and POS tagger, and to make comparisons with existing models in the literature. Following Ng and Low (2004), we partition the sentences in CTB 3, ordered by sentence ID, into 10 groups evenly. In the  $n$ th test, the  $n$ th group is used as the testing data.

Table 4 shows the detailed results for the cross validation tests, each row representing one test. As can be seen from the table, the joint model outperforms the baseline system in each test.

Table 5 shows the overall accuracies of the baseline and joint systems, and compares them to the relevant models in the literature. The accuracy of each model is shown in a row, where “Ng” represents the models from Ng and Low (2004) and “Shi” represents the models from Shi and Wang (2007). Each accuracy measure is shown in a column, including the segmentation F-score (*SF*), the overall tagging

Joint (ours)	95.90	91.34	93.02

Table 5: The comparison of overall accuracies by 10-fold cross validation using CTB

- + – knowledge about special characters,
- \* – knowledge from semantic net outside CTB.

F-score (*TF*) and the tagging accuracy by characters (*TA*). As can be seen from the table, our joint model achieved the largest improvement over the baseline, reducing the segmentation error by 14.58% and the overall tagging error by 12.18%.

The overall tagging accuracy of our joint model was comparable to but less than the joint model of Shi and Wang (2007). Despite the higher accuracy improvement from the baseline, the joint system did not give higher overall accuracy. One likely reason is that Shi and Wang (2007) included knowledge about special characters and semantic knowledge from web corpora (which may explain the higher baseline accuracy), while our system is completely data-driven. However, the comparison is indirect because our partitions of the CTB corpus are different. Shi and Wang (2007) also chunked the sentences before doing 10-fold cross validation, but used an uneven split. We chose to follow Ng and Low (2004) and split the sentences evenly to facilitate further comparison.

Compared with Ng and Low (2004), our baseline model gave slightly better accuracy, consistent with our previous observations about the word segmentors (Zhang and Clark, 2007). Due to the large accuracy gain from the baseline, our joint model performed much better.

In summary, when compared with existing joint word segmentation and POS tagging systems in the literature, our proposed model achieved the best accuracy boost from the cascaded baseline, and competent overall accuracy.

## 6 Conclusion and Future Work

We proposed a joint Chinese word segmentation and POS tagging model, which achieved a considerable reduction in error rate compared to a baseline two-stage system.

We used a single linear model for combined word segmentation and POS tagging, and chose the generalized perceptron algorithm for joint training. and beam search for efficient decoding. However, the application of beam search was far from trivial because of the size of the combined search space. Motivated by the question of what are the comparable partial hypotheses in the space, we developed a novel multiple beam search decoder which effectively explores the large search space. Similar techniques can potentially be applied to other problems involving joint inference in NLP.

Other choices are available for the decoding of a joint linear model, such as exact inference with dynamic programming, provided that the range of features allows efficient processing. The baseline feature templates for Chinese segmentation and POS tagging, when added together, makes exact inference for the proposed joint model very hard. However, the accuracy loss from the beam decoder, as well as alternative decoding algorithms, are worth further exploration.

The joint system takes features only from the baseline segmentor and the baseline POS tagger to allow a fair comparison. There may be additional features that are particularly useful to the joint system. Open features, such as knowledge of numbers and European letters, and relationships from semantic networks (Shi and Wang, 2007), have been reported to improve the accuracy of segmentation and POS tagging. Therefore, given the flexibility of the feature-based linear model, an obvious next step is the study of open features in the joint segmentor and POS tagger.

## Abstract

We propose a cascaded linear model for joint Chinese word segmentation and part-of-speech tagging. With a character-based perceptron as the core, combined with real-valued features such as language models, the cascaded model is able to efficiently utilize knowledge sources that are inconvenient to incorporate into the perceptron directly. Experiments show that the cascaded model achieves improved accuracies on both segmentation only and joint segmentation and part-of-speech tagging. On the Penn Chinese Treebank 5.0, we obtain an error reduction of 18.5% on segmentation and 12% on joint segmentation and part-of-speech tagging over the perceptron-only baseline.

## 1 Introduction

Word segmentation and part-of-speech (POS) tagging are important tasks in computer processing of Chinese and other Asian languages. Several models were introduced for these problems, for example, the Hidden Markov Model (HMM) (Rabiner, 1989), Maximum Entropy Model (ME) (Ratnaparkhi and Adwait, 1996), and Conditional Random Fields (CRFs) (Lafferty et al., 2001). CRFs have the advantage of flexibility in representing features compared to generative ones such as HMM, and usually behaves the best in the two tasks. Another widely used discriminative method is the perceptron algorithm (Collins, 2002), which achieves comparable performance to CRFs with much faster training, so we base this work on the perceptron.

To segment and tag a character sequence, there are two strategies to choose: performing POS tagging following segmentation; or joint segmentation and POS tagging (Joint S&T). Since the typical approach of discriminative models treats segmentation as a labelling problem by assigning each character a boundary tag (Xue and Shen, 2003), Joint S&T can be conducted in a labelling fashion by expanding boundary tags to include POS information (Ng and Low, 2004). Compared to performing segmentation and POS tagging one at a time, Joint S&T can achieve higher accuracy not only on segmentation but also on POS tagging (Ng and Low, 2004). Besides the usual character-based features, additional features dependent on POS's or words can also be employed to improve the performance. However, as such features are generated dynamically during the decoding procedure, two limitations arise: on the one hand, the amount of parameters increases rapidly, which is apt to overfit on training corpus; on the other hand, exact inference by dynamic programming is intractable because the current predication relies on the results of prior predications. As a result, many theoretically useful features such as higher-order word or POS  $n$ -grams are difficult to be incorporated in the model efficiently.

To cope with this problem, we propose a cascaded linear model inspired by the log-linear model (Och and Ney, 2004) widely used in statistical machine translation to incorporate different kinds of knowledge sources. Shown in Figure 1, the cascaded model has a two-layer architecture, with a character-based perceptron as the core combined with other real-valued features such as language models. We

Figure 1: Structure of Cascaded Linear Model.  $|R|$  denotes the scale of the feature space of the core perceptron.

will describe it in detail in Section 4. In this architecture, knowledge sources that are intractable to incorporate into the perceptron, can be easily incorporated into the outside linear model. In addition, as these knowledge sources are regarded as separate features, we can train their corresponding models independently with each other. This is an interesting approach when the training corpus is large as it reduces the time and space consumption. Experiments show that our cascaded model can utilize different knowledge sources effectively and obtain accuracy improvements on both segmentation and Joint S&T.

## 2 Segmentation and POS Tagging

Given a Chinese character sequence:

$$C_{1:n} = C_1 C_2 \dots C_n$$

the segmentation result can be depicted as:

$$C_{1:e_1} C_{e_1+1:e_2} \dots C_{e_{m-1}+1:e_m}$$

while the segmentation and POS tagging result can be depicted as:

$$C_{1:e_1}/t_1 C_{e_1+1:e_2}/t_2 \dots C_{e_{m-1}+1:e_m}/t_m$$

Here,  $C_i$  ( $i = 1..n$ ) denotes Chinese character,  $t_i$  ( $i = 1..m$ ) denotes POS tag, and  $C_{l:r}$  ( $l \leq r$ ) denotes character sequence ranges from  $C_l$  to  $C_r$ . We can see that segmentation and POS tagging task is to divide a character sequence into several subsequences and label each of them a POS tag.

It is a better idea to perform segmentation and POS tagging jointly in a uniform framework. According to Ng and Low (2004), the segmentation

task can be transformed to a tagging problem by assigning each character a boundary tag of the following four types:

- $b$ : the begin of the word
- $m$ : the middle of the word
- $e$ : the end of the word
- $s$ : a single-character word

We can extract segmentation result by splitting the labelled result into subsequences of pattern  $s$  or  $bm^*e$  which denote single-character word and multi-character word respectively. In order to perform POS tagging at the same time, we expand boundary tags to include POS information by attaching a POS to the tail of a boundary tag as a postfix following Ng and Low (2004). As each tag is now composed of a boundary part and a POS part, the joint S&T problem is transformed to a uniform boundary-POS labelling problem. A subsequence of boundary-POS labelling result indicates a word with POS  $t$  only if the boundary tag sequence composed of its boundary part conforms to  $s$  or  $bm^*e$  style, and all POS tags in its POS part equal to  $t$ . For example, a tag sequence  $b\_NN m\_NN e\_NN$  represents a three-character word with POS tag  $NN$ .

## 3 The Perceptron

The perceptron algorithm introduced into NLP by Collins (2002), is a simple but effective discriminative training method. It has comparable performance

Non-lexical-target	Instances
$C_n (n = -2..2)$	$C_{-2}=\text{下}, C_{-1}=\text{雨}, C_0=\text{天}, C_1=\text{地}, C_2=\text{面}$

to CRFs, while with much faster training. The perceptron has been used in many NLP tasks, such as POS tagging (Collins, 2002), Chinese word segmentation (Ng and Low, 2004; Zhang and Clark, 2007) and so on. We trained a character-based perceptron for Chinese Joint S&T, and found that the perceptron itself could achieve considerably high accuracy on segmentation and Joint S&T. In following subsections, we describe the feature templates and the perceptron training algorithm.

### 3.1 Feature Templates

The feature templates we adopted are selected from those of Ng and Low (2004). To compare with others conveniently, we excluded the ones forbidden by the close test regulation of SIGHAN, for example,  $Pu(C_0)$ , indicating whether character  $C_0$  is a punctuation.

All feature templates and their instances are shown in Table 1.  $C$  represents a Chinese character while the subscript of  $C$  indicates its position in the sentence relative to the current character (it has the subscript 0). Templates immediately borrowed from Ng and Low (2004) are listed in the upper column named *non-lexical-target*. We called them *non-lexical-target* because predications derived from them can predicate without considering the current character  $C_0$ . Templates in the column below are expanded from the upper ones. We add a field  $C_0$  to each template in the upper column, so that it can carry out predication according to not only the context but also the current character itself. As predications generated from such templates depend on the current character, we name these templates *lexical-target*. Note that the templates of Ng and Low (2004) have already contained some *lexical-target* ones. With the two kinds

of predications, the perceptron model will do exact predicating to the best of its ability, and can back off to approximately predicating if exact predicating fails.

### 3.2 Training Algorithm

We adopt the perceptron training algorithm of Collins (2002) to learn a discriminative model mapping from inputs  $x \in X$  to outputs  $y \in Y$ , where  $X$  is the set of sentences in the training corpus and  $Y$  is the set of corresponding labelled results. Following Collins, we use a function  $\text{GEN}(x)$  generating all candidate results of an input  $x$ , a representation  $\Phi$  mapping each training example  $(x, y) \in X \times Y$  to a feature vector  $\Phi(x, y) \in R^d$ , and a parameter vector  $\vec{\alpha} \in R^d$  corresponding to the feature vector.  $d$  means the dimension of the vector space, it equals to the amount of features in the model. For an input character sequence  $x$ , we aim to find an output  $F(x)$  satisfying:

$$F(x) = \operatorname{argmax}_{y \in \text{GEN}(x)} \Phi(x, y) \cdot \vec{\alpha} \quad (1)$$

$\Phi(x, y) \cdot \vec{\alpha}$  represents the inner product of feature vector  $\Phi(x, y)$  and the parameter vector  $\vec{\alpha}$ . We used the algorithm depicted in Algorithm 1 to tune the parameter vector  $\vec{\alpha}$ .

To alleviate overfitting on the training examples, we use the refinement strategy called “averaged parameters” (Collins, 2002) to the algorithm in Algorithm 1.

## 4 Cascaded Linear Model

In theory, any useful knowledge can be incorporated into the perceptron directly, besides the character-based features already adopted. Additional features most widely used are related to word or POS  $n$ -grams. However, such features are generated dynamically during the decoding procedure so that the feature space enlarges much more rapidly. Figure 2 shows the growing tendency of feature space with the introduction of these features as well as the character-based ones. We noticed that the templates related to word unigrams and bigrams bring to the feature space an enlargement much rapider than the character-base ones, not to mention the higher-order grams such as trigrams or 4-grams. In addition, even though these higher grams were managed to be used, there still remains another problem: as the current predication relies on the results of prior ones, the decoding procedure has to resort to approximate inference by maintaining a list of  $N$ -best candidates at each predication position, which evokes a potential risk to depress the training.

To alleviate the drawbacks, we propose a cascaded linear model. It has a two-layer architecture, with a perceptron as the core and another linear model as the outside-layer. Instead of incorporating all features into the perceptron directly, we first trained the perceptron using character-based features, and several other sub-models using additional ones such as word or POS  $n$ -grams, then trained the outside-layer linear model using the outputs of these sub-models, including the perceptron. Since the perceptron is fixed during the second training step, the whole training procedure need relative small time and memory cost.

The outside-layer linear model, similar to those in SMT, can synthetically utilize different knowledge sources to conduct more accurate comparison between candidates. In this layer, each knowledge source is treated as a feature with a corresponding weight denoting its relative importance. Suppose we have  $n$  features  $g_j$  ( $j = 1..n$ ) coupled with  $n$  corre-

Figure 2: Feature space growing curve. The horizontal scope  $X[i:j]$  denotes the introduction of different templates.  $X[0:5]$ :  $C_n$  ( $n = -2..2$ );  $X[5:9]$ :  $C_n C_{n+1}$  ( $n = -2..1$ );  $X[9:10]$ :  $C_{-1} C_1$ ;  $X[10:15]$ :  $C_0 C_n$  ( $n = -2..2$ );  $X[15:19]$ :  $C_0 C_n C_{n+1}$  ( $n = -2..1$ );  $X[19:20]$ :  $C_0 C_{-1} C_1$ ;  $X[20:21]$ :  $W_0$ ;  $X[21:22]$ :  $W_{-1} W_0$ .  $W_0$  denotes the current considering word, while  $W_{-1}$  denotes the word in front of  $W_0$ . All the data are collected from the training procedure on MSR corpus of SIGHAN bake-off 2.

sponding weights  $w_j$  ( $j = 1..n$ ), each feature  $g_j$  gives a score  $g_j(r)$  to a candidate  $r$ , then the total score of  $r$  is given by:

$$S(r) = \sum_{j=1..n} w_j \times g_j(r) \quad (2)$$

The decoding procedure aims to find the candidate  $r^*$  with the highest score:

$$r^* = \underset{r}{\operatorname{argmax}} S(r) \quad (3)$$

While the mission of the training procedure is to tune the weights  $w_j$  ( $j = 1..n$ ) to guarantee that the candidate  $r$  with the highest score happens to be the best result with a high probability.

As all the sub-models, including the perceptron, are regarded as separate features of the outside-layer linear model, we can train them respectively with special algorithms. In our experiments we trained a 3-gram word language model measuring the fluency of the segmentation result, a 4-gram POS language model functioning as the product of state-transition probabilities in HMM, and a word-POS co-occurrence model describing how much probably a word sequence coexists with a POS sequence. As shown in Figure 1, the character-based perceptron is used as the inside-layer linear model and sends its output to the outside-layer. Besides the output of the perceptron, the outside-layer also receive the outputs

of the word LM, the POS LM, the co-occurrence model and a word count penalty which is similar to the translation length penalty in SMT.

#### 4.1 Language Model

Language model (LM) provides linguistic probabilities of a word sequence. It is an important measure of fluency of the translation in SMT. Formally, an  $n$ -gram word LM approximates the probability of a word sequence  $W = w_{1:m}$  with the following product:

$$P_{wlm}(W) = \prod_{i=1}^m \Pr(w_i | w_{\max(0, i-n+1):i-1}) \quad (4)$$

Similarly, the  $n$ -gram POS LM of a POS sequence  $T = t_{1:m}$  is:

$$P_{tlm}(T) = \prod_{i=1}^m \Pr(t_i | t_{\max(0, i-n+1):i-1}) \quad (5)$$

Notice that a bi-gram POS LM functions as the product of transition probabilities in HMM.

#### 4.2 Word-POS Co-occurrence Model

Given a training corpus with POS tags, we can train a word-POS co-occurrence model to approximate the probability that the word sequence of the labelled result co-exists with its corresponding POS sequence. Using  $W = w_{1:m}$  to denote the word sequence,  $T = t_{1:m}$  to denote the corresponding POS sequence,  $P(T|W)$  to denote the probability that  $W$  is labelled as  $T$ , and  $P(W|T)$  to denote the probability that  $T$  generates  $W$ , we can define the co-occurrence model as follows:

$$Co(W, T) = P(T|W)^{\lambda_{wt}} \times P(W|T)^{\lambda_{tw}} \quad (6)$$

$\lambda_{wt}$  and  $\lambda_{tw}$  denote the corresponding weights of the two components.

Suppose the conditional probability  $Pr(t|w)$  describes the probability that the word  $w$  is labelled as the POS  $t$ , while  $Pr(w|t)$  describes the probability that the POS  $t$  generates the word  $w$ , then  $P(T|W)$  can be approximated by:

$$P(T|W) \simeq \prod_{k=1}^m \Pr(t_k | w_k) \quad (7)$$

And  $P(W|T)$  can be approximated by:

$$P(W|T) \simeq \prod_{k=1}^m \Pr(w_k | t_k) \quad (8)$$

$Pr(w|t)$  and  $Pr(t|w)$  can be easily acquired by Maximum Likelihood Estimates (MLE) over the corpus. For instance, if the word  $w$  appears  $N$  times in training corpus and is labelled as POS  $t$  for  $n$  times, the probability  $Pr(t|w)$  can be estimated by the formula below:

$$Pr(t|w) \simeq \frac{n}{N} \quad (9)$$

The probability  $Pr(w|t)$  could be estimated through the same approach.

To facilitate tuning the weights, we use two components of the co-occurrence model  $Co(W, T)$  to represent the co-occurrence probability of  $W$  and  $T$ , rather than use  $Co(W, T)$  itself. In the rest of the paper, we will call them labelling model and generating model respectively.

### 5 Decoder

Sequence segmentation and labelling problem can be solved through a viterbi style decoding procedure. In Chinese Joint S&T, the mission of the decoder is to find the boundary-POS labelled sequence with the highest score. Given a Chinese character sequence  $C_{1:n}$ , the decoding procedure can proceed in a left-right fashion with a dynamic programming approach. By maintaining a stack of size  $N$  at each position  $i$  of the sequence, we can preserve the top  $N$  best candidate labelled results of subsequence  $C_{1:i}$  during decoding. At each position  $i$ , we enumerate all possible word-POS pairs by assigning each POS to each possible word formed from the character subsequence spanning length  $l = 1.. \min(i, K)$  ( $K$  is assigned 20 in all our experiments) and ending at position  $i$ , then we derive all candidate results by attaching each word-POS pair  $p$  (of length  $l$ ) to the tail of each candidate result at the prior position of  $p$  (position  $i-l$ ), and select for position  $i$  a  $N$ -best list of candidate results from all these candidates. When we derive a candidate result from a word-POS pair  $p$  and a candidate  $q$  at prior position of  $p$ , we calculate the scores of the word LM, the POS LM, the labelling probability and the generating probability,

---

**Algorithm 2** Decoding algorithm.

12: Output: n-best results  $\mathcal{V}[n]$ 
```

---

as well as the score of the perceptron model. In addition, we add the score of the word count penalty as another feature to alleviate the tendency of LMs to favor shorter candidates. By equation 2, we can synthetically evaluate all these scores to perform more accurately comparing between candidates.

Algorithm 2 shows the decoding algorithm. Lines 3 – 11 generate a  $N$ -best list for each character position  $i$ . Line 4 scans words of all possible lengths  $l$  ( $l = 1.. \min(i, K)$ , where  $i$  points to the current considering character). Line 6 enumerates all POS's for the word  $w$  spanning length  $l$  and ending at position  $i$ . Line 8 considers each candidate result in  $N$ -best list at prior position of the current word. Function  $D$  derives the candidate result from the word-POS pair  $p$  and the candidate  $q$  at prior position of  $p$ .

## 6 Experiments

We reported results from two set of experiments. The first was conducted to test the performance of the perceptron on segmentation on the corpus from SIGHAN Bakeoff 2, including the Academia Sinica Corpus (AS), the Hong Kong City University Corpus (CityU), the Peking University Corpus (PKU) and the Microsoft Research Corpus (MSR). The second was conducted on the Penn Chinese Treebank 5.0 (CTB5.0) to test the performance of the cascaded model on segmentation and Joint S&T. In all experiments, we use the averaged parameters for the perceptrons, and F-measure as the accuracy measure. With precision  $P$  and recall  $R$ , the balance F-measure is defined as:  $F = 2PR/(P + R)$ .

Figure 3: Averaged perceptron learning curves with Non-lexical-target and Lexical-target feature templates.

	AS	CityU	PKU	MSR
SIGHAN best	0.952	0.943	0.950	0.964
Zhang & Clark	0.946	0.951	0.945	0.972
our model	0.954	0.958	0.940	0.975

Table 2: F-measure on SIGHAN bakeoff 2. SIGHAN best: best scores SIGHAN reported on the four corpus, cited from Zhang and Clark (2007).

### 6.1 Experiments on SIGHAN Bakeoff

For convenience of comparing with others, we focus only on the close test, which means that any extra resource is forbidden except the designated training corpus. In order to test the performance of the *lexical-target* templates and meanwhile determine the best iterations over the training corpus, we randomly chosen 2,000 shorter sentences (less than 50 words) as the development set and the rest as the training set (84,294 sentences), then trained a perceptron model named NON-LEX using only *non-lexical-target* features and another named LEX using both the two kinds of features. Figure 3 shows their learning curves depicting the F-measure on the development set after 1 to 10 training iterations. We found that LEX outperforms NON-LEX with a margin of about 0.002 at each iteration, and its learning curve reaches a tableland at iteration 7. Then we trained LEX on each of the four corpora for 7 iterations. Test results listed in Table 2 shows that this model obtains higher accuracy than the best of SIGHAN Bakeoff 2 in three corpora (AS, CityU and MSR). On the three corpora, it also outperformed the word-based perceptron model of Zhang and Clark (2007). However, the accuracy on PKU corpus is obvious lower than the best score SIGHAN

Training setting	Test task	F-measure
POS-	Segmentation	0.971
POS+	Segmentation	0.973
POS+	Joint S&T	0.925

Table 3: F-measure on segmentation and Joint S&T of perceptrons. POS-: perceptron trained without POS, POS+: perceptron trained with POS.

reported, we need to conduct further research on this problem.

## 6.2 Experiments on CTB5.0

We turned to experiments on CTB 5.0 to test the performance of the cascaded model. According to the usual practice in syntactic analysis, we choose chapters 1 – 260 (18074 sentences) as training set, chapter 271 – 300 (348 sentences) as test set and chapter 301 – 325 (350 sentences) as development set.

At the first step, we conducted a group of contrasting experiments on the core perceptron, the first concentrated on the segmentation regardless of the POS information and reported the F-measure on segmentation only, while the second performed Joint S&T using POS information and reported the F-measure both on segmentation and on Joint S&T. Note that the accuracy of Joint S&T means that a word-POS pair is recognized only if both the boundary tags and the POS’s are correctly labelled.

The evaluation results are shown in Table 3. We find that Joint S&T can also improve the segmentation accuracy. However, the F-measure on Joint S&T is obvious lower, about a rate of 95% to the F-measure on segmentation. Similar trend appeared in experiments of Ng and Low (2004), where they conducted experiments on CTB 3.0 and achieved F-measure 0.919 on Joint S&T, a ratio of 96% to the F-measure 0.952 on segmentation.

As the next step, a group of experiments were conducted to investigate how well the cascaded linear model performs. Here the core perceptron was just the POS+ model in experiments above. Besides this perceptron, other sub-models are trained and used as additional features of the outside-layer linear model. We used SRI Language Modelling Toolkit (Stolcke and Andreas, 2002) to train a 3-gram word LM with modified Kneser-Ney smoothing (Chen and Goodman, 1998), and a 4-gram POS

Features	Segmentation F1	Joint S&T F1
All	0.9785	0.9341
All - PER	0.9049	0.8432
All - WLM	0.9785	0.9340
All - PLM	0.9752	0.9270
All - GPR	0.9774	0.9329
All - LPR	0.9765	0.9321
All - LEN	0.9772	0.9325

Table 4: Contribution of each feature. ALL: all features, PER: perceptron model, WLM: word language model, PLM: POS language model, GPR: generating model, LPR: labelling model, LEN: word count penalty.

LM with Witten-Bell smoothing, and we trained a word-POS co-occurrence model simply by MLE without smoothing. To obtain their corresponding weights, we adapted the minimum-error-rate training algorithm (Och, 2003) to train the outside-layer model. In order to inspect how much improvement each feature brings into the cascaded model, every time we removed a feature while retaining others, then retrained the model and tested its performance on the test set.

Table 4 shows experiments results. We find that the cascaded model achieves a F-measure increment of about 0.5 points on segmentation and about 0.9 points on Joint S&T, over the perceptron-only model POS+. We also find that the perceptron model functions as the kernel of the outside-layer linear model. Without the perceptron, the cascaded model (if we can still call it “cascaded”) performs poorly on both segmentation and Joint S&T. Among other features, the 4-gram POS LM plays the most important role, removing this feature causes F-measure decrement of 0.33 points on segmentation and 0.71 points on Joint S&T. Another important feature is the labelling model. Without it, the F-measure on segmentation and Joint S&T both suffer a decrement of 0.2 points. The generating model, which functions as that in HMM, brings an improvement of about 0.1 points to each test item. However unlike the three features, the word LM brings very tiny improvement. We suppose that the character-based features used in the perceptron play a similar role as the lower-order word LM, and it would be helpful if we train a higher-order word LM on a larger scale corpus. Finally, the word count penalty gives improvement to the cascaded model, 0.13 points on segmentation

and 0.16 points on Joint S&T.

In summary, the cascaded model can utilize these knowledge sources effectively, without causing the feature space of the perceptron becoming even larger. Experimental results show that, it achieves obvious improvement over the perceptron-only model, about from 0.973 to 0.978 on segmentation, and from 0.925 to 0.934 on Joint S&T, with error reductions of 18.5% and 12% respectively.

## 7 Conclusions

We proposed a cascaded linear model for Chinese Joint S&T. Under this model, many knowledge sources that may be intractable to be incorporated into the perceptron directly, can be utilized effectively in the outside-layer linear model. This is a substitute method to use both local and non-local features, and it would be especially useful when the training corpus is very large.

However, can the perceptron incorporate all the knowledge used in the outside-layer linear model? If this cascaded linear model were chosen, could more accurate generative models (LMs, word-POS co-occurrence model) be obtained by training on large scale corpus even if the corpus is not correctly labelled entirely, or by self-training on raw corpus in a similar approach to that of McClosky (2006)? In addition, all knowledge sources we used in the core perceptron and the outside-layer linear model come from the training corpus, whereas many open knowledge sources (lexicon etc.) can be used to improve performance (Ng and Low, 2004). How can we utilize these knowledge sources effectively? We will investigate these problems in the following work.

## Abstract

We present a discriminative structure-prediction model for the letter-to-phoneme task, a crucial step in text-to-speech processing. Our method encompasses three tasks that have been previously handled separately: input segmentation, phoneme prediction, and sequence modeling. The key idea is online discriminative training, which updates parameters according to a comparison of the current system output to the desired output, allowing us to train all of our components together. By folding the three steps of a pipeline approach into a unified dynamic programming framework, we are able to achieve substantial performance gains. Our results surpass the current state-of-the-art on six publicly available data sets representing four different languages.

## 1 Introduction

Letter-to-phoneme (L2P) conversion is the task of predicting the pronunciation of a word, represented as a sequence of phonemes, from its orthographic form, represented as a sequence of letters. The L2P task plays a crucial role in speech synthesis systems (Schroeter et al., 2002), and is an important part of other applications, including spelling correction (Toutanova and Moore, 2001) and speech-to-speech machine translation (Engelbrecht and Schultz, 2005).

Converting a word into its phoneme representation is not a trivial task. Dictionary-based approaches cannot achieve this goal reliably, due to unseen words and proper names. Furthermore, the

construction of even a modestly-sized pronunciation dictionary requires substantial human effort for each new language. Effective rule-based approaches can be designed for some languages such as Spanish. However, Kominek and Black (2006) show that in languages with a less transparent relationship between spelling and pronunciation, such as English, Dutch, or German, the number of letter-to-sound rules grows almost linearly with the lexicon size. Therefore, most recent work in this area has focused on machine-learning approaches.

In this paper, we present a joint framework for letter-to-phoneme conversion, powered by online discriminative training. By updating our model parameters online, considering only the current system output and its feature representation, we are able to not only incorporate overlapping features, but also to use the same learning framework with increasingly complex search techniques. We investigate two online updates: averaged perceptron and Margin Infused Relaxed Algorithm (MIRA). We evaluate our system on L2P data sets covering English, French, Dutch and German. In all cases, our system outperforms the current state of the art, reducing the best observed error rate by as much as 46%.

## 2 Previous work

Letter-to-phoneme conversion is a complex task, for which a number of diverse solutions have been proposed. It is a structure prediction task; both the input and output are structured, consisting of sequences of letters and phonemes, respectively. This makes L2P a poor fit for many machine-learning techniques that are formulated for binary classification.

The L2P task is also characterized by the existence of a hidden structure connecting input to output. The training data consists of letter strings paired with phoneme strings, without explicit links connecting individual letters to phonemes. The subtask of inserting these links, called letter-to-phoneme alignment, is not always straightforward. For example, consider the word “phoenix” and its corresponding phoneme sequence [f i n i k s], where we encounter cases of two letters generating a single phoneme (ph→f), and a single letter generating two phonemes (x→k s). Fortunately, alignments between letters and phonemes can be discovered reliably with unsupervised generative models. Originally, L2P systems assumed one-to-one alignment (Black et al., 1998; Damper et al., 2005), but recently many-to-many alignment has been shown to perform better (Bisani and Ney, 2002; Jiampojarn et al., 2007). Given such an alignment, L2P can be viewed either as a sequence of classification problems, or as a sequence modeling problem.

In the classification approach, each phoneme is predicted independently using a multi-class classifier such as decision trees (Daelemans and Bosch, 1997; Black et al., 1998) or instance-based learning (Bosch and Daelemans, 1998). These systems predict a phoneme for each input letter, using the letter and its context as features. They leverage the structure of the input but ignore any structure in the output.

L2P can also be viewed as a sequence modeling, or tagging problem. These approaches model the structure of the output, allowing previously predicted phonemes to inform future decisions. The supervised Hidden Markov Model (HMM) applied by Taylor (2005) achieved poor results, mostly because its maximum-likelihood emission probabilities cannot be informed by the emitted letter’s context. Other approaches, such as those of Bisani and Ney (2002) and Marchand and Damper (2000), have shown that better performance can be achieved by pairing letter substrings with phoneme substrings, allowing context to be captured implicitly by these groupings.

Recently, two hybrid methods have attempted to capture the flexible context handling of classification-based methods, while also modeling the sequential nature of the output. The

constraint satisfaction inference (CSInf) approach (Bosch and Canisius, 2006) improves the performance of instance-based classification (Bosch and Daelemans, 1998) by predicting for each letter a trigram of phonemes consisting of the previous, current and next phonemes in the sequence. The final output sequence is the sequence of predicted phonemes that satisfies the most unigram, bigram and trigram agreement constraints. The second hybrid approach (Jiampojarn et al., 2007) also extends instance-based classification. It employs a many-to-many letter-to-phoneme alignment model, allowing substrings of letters to be classified into substrings of phonemes, and introducing an input segmentation step before prediction begins. The method accounts for sequence information with post-processing: the numerical scores of possible outputs from an instance-based phoneme predictor are combined with phoneme transition probabilities in order to identify the most likely phoneme sequence.

### 3 A joint approach

By observing the strengths and weaknesses of previous approaches, we can create the following prioritized desiderata for any L2P system:

1. The phoneme predicted for a letter should be informed by the letter’s context in the input word.
2. In addition to single letters, letter substrings should also be able to generate phonemes.
3. Phoneme sequence information should be included in the model.

Each of the previous approaches focuses on one or more of these items. Classification-based approaches such as the decision tree system (Black et al., 1998) and instance-based learning system (Bosch and Daelemans, 1998) take into account the letter’s context (#1). By pairing letter substrings with phoneme substrings, the joint n-gram approach (Bisani and Ney, 2002) accounts for all three desiderata, but each operation is informed only by a limited amount of left context. The many-to-many classifier of Jiampojarn et al. (2007) also attempts to account for all three, but it adheres

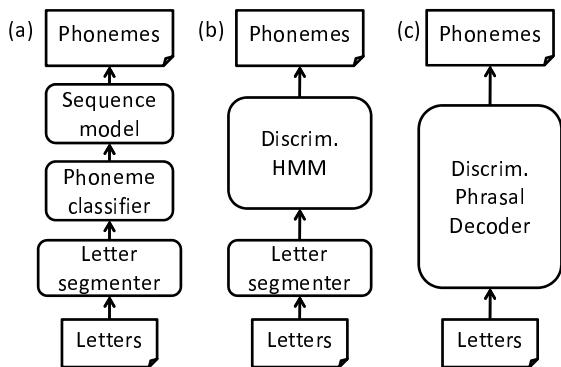

Figure 1: Collapsing the pipeline.

strictly to the pipeline approach illustrated in Figure 1a. It applies in succession three separately trained modules for input segmentation, phoneme prediction, and sequence modeling. Similarly, the CSInf approach modifies independent phoneme predictions (#1) in order to assemble them into a cohesive sequence (#3) in post-processing.

The pipeline approaches are undesirable for two reasons. First, when decisions are made in sequence, errors made early in the sequence can propagate forward and throw off later processing. Second, each module is trained independently, and the training methods are not aware of the tasks performed later in the pipeline. For example, optimal parameters for a phoneme prediction module may vary depending on whether or not the module will be used in conjunction with a phoneme sequence model.

We propose a joint approach to L2P conversion, grounded in dynamic programming and online discriminative training. We view L2P as a tagging task that can be performed with a discriminative learning method, such as the Perceptron HMM (Collins, 2002). The Perceptron HMM naturally handles phoneme prediction (#1) and sequence modeling (#3) simultaneously, as shown in Figure 1b. Furthermore, unlike a generative HMM, it can incorporate many overlapping source  $n$ -gram features to represent context. In order to complete the conversion from a pipeline approach to a joint approach, we fold our input segmentation step into the exact search framework by replacing a separate segmentation module (#2) with a monotone phrasal decoder (Zens and Ney, 2004). At this point all three of our desiderata are incorporated into a single module,

---

**Algorithm 1** Online discriminative training.

---

```

1:  $\alpha = \vec{0}$ 
2: for  $K$  iterations over training set do
3:   for all letter-phoneme sequence pairs  $(x, y)$ 
     in the training set do
4:      $\hat{y} = \arg \max_{y' \in Y} [\alpha \cdot \Phi(x, y')]$ 
5:     update weights  $\alpha$  according to  $\hat{y}$  and  $y$ 
6:   end for
7: end for
8: return  $\alpha$ 

```

---

as shown in Figure 1c.

Our joint approach to L2P lends itself to several refinements. We address an underfitting problem of the perceptron by replacing it with a more robust Margin Infused Relaxed Algorithm (MIRA), which adds an explicit notion of margin and takes into account the system’s current  $n$ -best outputs. In addition, with all of our features collected under a unified framework, we are free to conjoin context features with sequence features to create a powerful linear-chain model (Sutton and McCallum, 2006).

## 4 Online discriminative training

In this section, we describe our entire L2P system. An outline of our discriminative training process is presented in Algorithm 1. An online process repeatedly finds the best output(s) given the current weights, and then updates those weights to make the model favor the correct answer over the incorrect ones.

The system consists of the following three main components, which we describe in detail in Sections 4.1, 4.2 and 4.3, respectively.

1. A scoring model, represented by a weighted linear combination of features ( $\alpha \cdot \Phi(x, y)$ ).
2. A search for the highest scoring phoneme sequence for a given input word (Step 4).
3. An online update equation to move the model away from incorrect outputs and toward the correct output (Step 5).

### 4.1 Model

Given an input word  $x$  and an output phoneme sequence  $y$ , we define  $\Phi(x, y)$  to be a feature vector

representing the evidence for the sequence  $y$  found in  $x$ , and  $\alpha$  to be a feature weight vector providing a weight for each component of  $\Phi(x, y)$ . We assume that both the input and output consist of  $m$  substrings, such that  $x_i$  generates  $y_i$ ,  $0 \leq i < m$ . At training time, these substrings are taken from a many-to-many letter-to-phoneme alignment. At test time, input segmentation is handled by either a segmentation module or a phrasal decoder.

Table 1 shows our feature template that we include in  $\Phi(x, y)$ . We use only indicator features; each feature takes on a binary value indicating whether or not it is present in the current  $(x, y)$  pair. The context features express letter evidence found in the input string  $x$ , centered around the generator  $x_i$  of each  $y_i$ . The parameter  $c$  establishes the size of the context window. Note that we consider not only letter unigrams but all  $n$ -grams that fit within the window, which enables the model to assign phoneme preferences to contexts containing specific sequences, such as *ing* and *tion*. The transition features are HMM-like sequence features, which enforce cohesion on the output side. We include only first-order transition features, which look back to the previous phoneme substring generated by the system, because our early development experiments indicated that larger histories had little impact on performance; however, the number of previous substrings that are taken into account could be extended at a polynomial cost. Finally, the linear-chain features (Sutton and McCallum, 2006) associate the phoneme transitions between  $y_{i-1}$  and  $y_i$  with each  $n$ -gram surrounding  $x_i$ . This combination of sequence and context data provides the model with an additional degree of control.

## 4.2 Search

Given the current feature weight vector  $\alpha$ , we are interested in finding the highest-scoring phoneme sequence  $\hat{y}$  in the set  $Y$  of all possible phoneme sequences. In the pipeline approach (Figure 1b), the input word is segmented into letter substrings by an instance-based classifier (Aha et al., 1991), which learns a letter segmentation model from many-to-many alignments (Jiampoamarn et al., 2007). The search for the best output sequence is then effectively a substring tagging problem, and we can compute the  $\arg \max$  operation in line 4 of Algorithm 1

context	$x_{i-c}, y_i$
	...
	$x_{i+c}, y_i$
	$x_{i-c}x_{i-c+1}, y_i$
	...
	$x_{i+c-1}x_{i+c}, y_i$
.....	
	$x_{i-c} \dots x_{i+c}, y_i$
transition	$y_{i-1}, y_i$
linear chain	$x_{i-c}, y_{i-1}, y_i$
	...
	$x_{i+c}, y_{i-1}, y_i$
	$x_{i-c}x_{i-c+1}, y_{i-1}, y_i$
	...
	$x_{i+c-1}x_{i+c}, y_{i-1}, y_i$
	.....
	$x_{i-c} \dots x_{i+c}, y_{i-1}, y_i$

Table 1: Feature template.

with the standard HMM Viterbi search algorithm.

In the joint approach (Figure 1c), we perform segmentation and L2P prediction simultaneously by applying the monotone search algorithm developed for statistical machine translation (Zens and Ney, 2004). Thanks to its ability to translate phrases (in our case, letter substrings), we can accomplish the  $\arg \max$  operation without specifying an input segmentation in advance; the search enumerates all possible segmentations. Furthermore, the language model functionality of the decoder allows us to keep benefiting from the transition and linear-chain features, which are explicit in the previous HMM approach.

The search can be efficiently performed by the dynamic programming recurrence shown below. We define  $Q(j, p)$  as the maximum score of the phoneme sequence ending with the phoneme  $p$  generated by the letter sequence  $x_1 \dots x_j$ . Since we are no longer provided an input segmentation in advance, in this framework we view  $x$  as a sequence of  $J$  letters, as opposed to substrings. The phoneme  $p'$  is the phoneme produced in the previous step. The expression  $\phi(x_{j'+1}^j, p', p)$  is a convenient way to express the subvector of our complete feature vector  $\Phi(x, y)$  that describes the substring pair  $(x_i, y_{i-1}^i)$ , where  $x_i = x_{j'+1}^j$ ,  $y_{i-1} = p'$  and  $y_i = p$ . The value  $N$  limits the size of the dynamically created

substrings. We use  $N = 2$ , which reflects a similar limit in our many-to-many aligner. The special symbol  $\$$  represents a starting phoneme or ending phoneme. The value in  $Q(I + 1, \$)$  is the score of highest scoring phoneme sequence corresponding to the input word. The actual sequence can be retrieved by backtracking through the table  $Q$ .

$$Q(0, \$) = 0$$

$$Q(j, p) = \max_{\substack{p', p, \\ j-N \leq j' < j}} \{\alpha \cdot \phi(x_{j'+1}^j, p', p) + Q(j', p')\}$$

$$Q(J + 1, \$) = \max_{p'} \{\alpha \cdot \phi(\$, p', \$) + Q(J, p')\}$$

### 4.3 Online update

We investigate two model updates to drive our online discriminative learning. The simple perceptron update requires only the system’s current output, while MIRA allows us to take advantage of the system’s current  $n$ -best outputs.

#### Perceptron

Learning a discriminative structure prediction model with a perceptron update was first proposed by Collins (2002). The perceptron update process is relatively simple, involving only vector addition. In line 5 of Algorithm 1, the weight vector  $\alpha$  is updated according to the best output  $\hat{y}$  under the current weights and the true output  $y$  in the training data. If  $\hat{y} = y$ , there is no update to the weights; otherwise, the weights are updated as follows:

$$\alpha = \alpha + \Phi(x, y) - \Phi(x, \hat{y}) \quad (1)$$

We iterate through the training data until the system performance drops on a held-out set. In a separable case, the perceptron will find an  $\alpha$  such that:

$$\forall \hat{y} \in Y - \{y\} : \alpha \cdot \Phi(x, y) > \alpha \cdot \Phi(x, \hat{y}) \quad (2)$$

Since real-world data is not often separable, the average of all  $\alpha$  values seen throughout training is used in place of the final  $\alpha$ , as the average generalizes better to unseen data.

#### MIRA

In the perceptron training algorithm, no update is derived from a particular training example so long as the system is predicting the correct phoneme sequence. The perceptron has no notion of margin: a

slim preference for the correct sequence is just as good as a clear preference. During development, we observed that this lead to underfitting the training examples; useful and consistent evidence was ignored because of the presence of stronger evidence in the same example. The MIRA update provides a principled method to resolve this problem.

The Margin Infused Relaxed Algorithm or MIRA (Crammer and Singer, 2003) updates the model based on the system’s  $n$ -best output. It employs a margin update which can induce an update even when the 1-best answer is correct. It does so by finding a weight vector that separates incorrect sequences in the  $n$ -best list from the correct sequence by a variable width margin.

The update process finds the smallest change in the current weights so that the new weights will separate the correct answer from each incorrect answer by a margin determined by a structured loss function. The loss function describes the distance between an incorrect prediction and the correct one; that is, it quantifies just how wrong the proposed sequence is. This update process can be described as an optimization problem:

$$\begin{aligned} \min_{\alpha_n} \quad & \|\alpha_n - \alpha_o\| \\ \text{subject to } & \forall \hat{y} \in Y_n : \\ & \alpha_n \cdot (\Phi(x, y) - \Phi(x, \hat{y})) \geq \ell(y, \hat{y}) \end{aligned} \quad (3)$$

where  $Y_n$  is a set of  $n$ -best outputs found under the current model,  $y$  is the correct answer,  $\alpha_o$  is the current weight vector,  $\alpha_n$  is the new weight vector, and  $\ell(y, \hat{y})$  is the loss function.

Since our direct objective is to produce the correct phoneme sequence for a given word, the most intuitive way to define the loss function  $\ell(y, \hat{y})$  is binary: 0 if  $\hat{y} = y$ , and 1 otherwise. We refer to this as 0-1 loss. Another possibility is to base the loss function on the phoneme error rate, calculated as the Levenshtein distance between  $y$  and  $\hat{y}$ . We can also compute a combined loss function as an equally-weighted linear combination of the 0-1 and phoneme loss functions.

MIRA training is similar to averaged perceptron training, but instead of finding the single best answer, we find the  $n$ -best answers ( $Y_n$ ) and update weights according to Equation 3. To find the  $n$ -best answers, we modify the HMM and monotone search algorithms to keep track of the  $n$ -best phonemes at

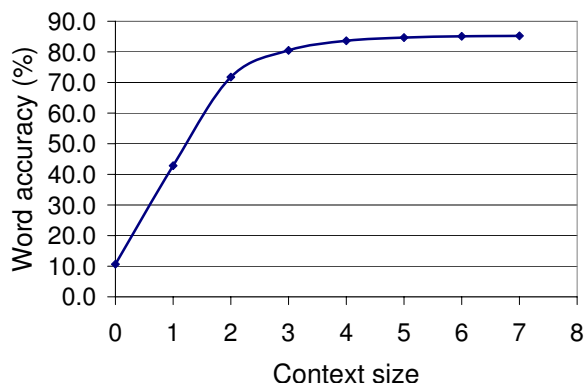

Figure 2: Perceptron update with different context size.

Figure 3: MIRA update with different size of  $n$ -best list.

each cell of the dynamic programming matrix. The optimization in Equation 3 is a standard quadratic programming problem that can be solved by using Hildreth’s algorithm (Censor and Zenios, 1997). The details of our implementation of MIRA within the SVM<sup>light</sup> framework (Joachims, 1999) are given in the Appendix A. Like the perceptron algorithm, MIRA returns the average of all weight vectors produced during learning.

## 5 Evaluation

We evaluated our approach on English, German and Dutch CELEX (Baayen et al., 1996), French Brulex, English Nttalk and English CMUDict data sets. Except for English CELEX, we used the data sets from the PRONALSYL letter-to-phoneme conversion challenge<sup>1</sup>. Each data set is divided into 10 folds: we used the first one for testing, and the rest for training. In all cases, we hold out 5% of our training data to determine when to stop perceptron or MIRA training. We ignored one-to-one alignments included in the PRONALSYL data sets, and instead induced many-to-many alignments using the method of Jiampoamarn et al. (2007).

Our English CELEX data set was extracted directly from the CELEX database. After removing duplicate words, phrases, and abbreviations, the data set contained 66,189 word-phoneme pairs, of which 10% was designated as the final test set, and the rest as the training set. We performed our development experiments on the latter part, and then used the final

test set to compare the performance of our system to other results reported in the literature.

We report the system performance in terms of word accuracy, which rewards only completely correct phoneme sequences. Word accuracy is more demanding than phoneme accuracy, which considers the number of correct phonemes. We feel that word accuracy is a more appropriate error metric, given the quality of current L2P systems. Phoneme accuracy is not sensitive enough to detect improvements in highly accurate L2P systems: Black et al. (1998) report 90% phoneme accuracy is equivalent to approximately 60% word accuracy, while 99% phoneme accuracy corresponds to only 90% word accuracy.

### 5.1 Development Experiments

We began development with a zero-order Perceptron HMM with an external segmenter, which uses only the context features from Table 1. The zero-order Perceptron HMM is equivalent to training a multi-class perceptron to make independent substring-to-phoneme predictions; however, this framework allows us to easily extend to structured models. We investigate the effect of augmenting this baseline system in turn with larger context sizes, the MIRA update, joint segmentation, and finally sequence features. We report the impact of each contribution on our English CELEX development set.

Figure 2 shows the performance of our baseline L2P system with different context size values ( $c$ ). Increasing the context size has a dramatic effect on accuracy, but the effect begins to level off for context sizes greater than 5. Henceforth, we report the

<sup>1</sup>Available at <http://www.pascal-network.org/Challenges/PRONALSYL/>. The results have not been announced.

	Perceptron	MIRA
Separate segmentation	84.5%	85.8%
Phrasal decoding	<b>86.6%</b>	<b>88.0%</b>

Table 2: Separate segmentation versus phrasal decoding in terms of word accuracy.

results with context size  $c = 5$ .

Figure 3 illustrates the effect of varying the size of  $n$ -best list in the MIRA update.  $n = 1$  is equivalent to taking into account only the best answer, which does not address the underfitting problem. A large  $n$ -best list makes it difficult for the optimizer to separate the correct and incorrect answers, resulting in large updates at each step. We settle on  $n = 10$  for the subsequent experiments.

The choice of MIRA’s loss function has a minimal impact on performance, probably because our baseline system already has a very high phoneme accuracy. We employ the loss function that combines  $0-1$  and phoneme error rate, due to its marginal improvement over  $0-1$  loss on the development set.

Looking across columns in Table 2, we observe over 8% reduction in word error rate when the perceptron update is replaced with the MIRA update. Since the perceptron is a considerably simpler algorithm, we continue to report the results of both variants throughout this section.

Table 2 also shows the word accuracy of our system after adding the option to conduct joint segmentation through phrasal decoding. The 15% relative reduction in error rate in the second row demonstrates the utility of folding the segmentation step into the search. It also shows that the joint framework enables the system to reduce and compensate for errors that occur in a pipeline. This is particularly interesting because our separate instance-based segmenter is highly accurate, achieving 98% segmentation accuracy. Our experiments indicate that the application of joint segmentation recovers more than 60% of the available improvements, according to an upper bound determined by utilizing perfect segmentation.<sup>2</sup>

Table 3 illustrates the effect of our sequence features on both the perceptron and MIRA systems.

<sup>2</sup>Perfect with respect to our many-to-many alignment (Jiampojarn et al., 2007), but not necessarily in any linguistic sense.

Feature	Perceptron	MIRA
zero order	86.6%	88.0%
+ 1 <sup>st</sup> order HMM	87.1%	88.3%
+ linear-chain	87.5%	89.3%
All features	<b>87.8%</b>	<b>89.4%</b>

Table 3: The effect of sequence features on the joint system in terms of word accuracy.

Replacing the zero-order HMM with the first-order HMM makes little difference by itself, but combined with the more powerful linear-chain features, it results in a relative error reduction of about 12%. In general, the linear-chain features make a much larger difference than the relatively simple transition features, which underscores the importance of using source-side context when assessing sequences of phonemes.

The results reported in Tables 2 and 3 were calculated using cross validation on the training part of the CELEX data set. With the exception of adding the 1<sup>st</sup> order HMM, the differences between versions are statistically significant according to McNemar’s test at 95% confidence level. On one CPU of AMD Opteron 2.2GHz with 6GB of installed memory, it takes approximately 32 hours to train the MIRA model with all features, compared to 12 hours for the zero-order model.

## 5.2 System Comparison

Table 4 shows the comparison between our approach and other systems on the evaluation data sets. We trained our system using  $n$ -gram context, transition, and linear-chain features. All parameters, including the size of  $n$ -best list, size of letter context, and the choice of loss functions, were established on the English CELEX development set, as presented in our previous experiments. With the exception of the system described in (Jiampojarn et al., 2007), which we re-ran on our current test sets, the results of other systems are taken from the original papers. Although these comparisons are necessarily indirect due to different experimental settings, they strongly suggest that our system outperforms all previous published results on all data sets, in some case by large margins. When compared to the current state-of-the-art performance of each data set, the relative reductions in error rate range from 7% to 46%.

Corpus	MIRA	Perceptron	M-M HMM	Joint n-gram*	CSInf*	PbA*	CART*
Eng. CELEX	<b>90.51%</b>	88.44%	<u>84.81%</u>	76.3%	84.5%	-	-
Dutch CELEX	<b>95.32%</b>	95.13%	91.69%	-	<u>94.5%</u>	-	-

Table 4: Word accuracy on the evaluated data sets. **MIRA**, **Perceptron**: our systems. **M-M HMM**: Many-to-Many HMM system (Jiampojamarn et al., 2007). **Joint n-gram**: Joint n-gram model (Demberg et al., 2007). **CSInf**: Constraint satisfaction inference (Bosch and Canisius, 2006). **PbA**: Pronunciation by Analogy (Marchand and Dampier, 2006). **CART**: CART decision tree system (Black et al., 1998). The columns marked with \* contain results reported in the literature. “-” indicates no reported results. We have underlined the best previously reported results.

## 6 Conclusion

We have presented a joint framework for letter-to-phoneme conversion, powered by online discriminative training. We introduced two methods to convert multi-letter substrings into phonemes: one relying on a separate segmenter, and the other incorporating a unified search that finds the best input segmentation while generating the output sequence. We investigated two online update algorithms: the perceptron, which is straightforward to implement, and MIRA, which boosts performance by avoiding underfitting. Our systems employ source  $n$ -gram features and linear-chain features, which substantially increase L2P accuracy. Our experimental results demonstrate the power of a joint approach based on online discriminative training with large feature sets. In all cases, our MIRA-based system advances the current state of the art by reducing the best reported error rate.

### Appendix A. MIRA Implementation

We optimize the objective shown in Equation 3 using the SVM<sup>light</sup> framework (Joachims, 1999), which provides the quadratic program solver shown in Equation 4.

$$\begin{aligned}
 & \min_{w, \xi} \frac{1}{2} \|w\|^2 + C \sum_i \xi_i \\
 & \text{subject to } \forall i, \\
 & w \cdot t_i \geq rhs_i - \xi_i
 \end{aligned} \tag{4}$$

In order to approximate a hard margin using the soft-margin optimizer of SVM<sup>light</sup>, we assign a very large penalty value to  $C$ , thus making the use of any slack variables ( $\xi_i$ ) prohibitively expensive. We define the vector  $w$  as the difference between the new

and previous weights:  $w = \alpha_n - \alpha_o$ . We constrain  $w$  to mirror the constraints in Equation 3. Since each  $\hat{y}$  in the  $n$ -best list ( $Y_n$ ) needs a constraint based on its feature difference vector, we define a  $t_i$  for each:

$$\forall \hat{y} \in Y_n : t_i = \Phi(x, y) - \Phi(x, \hat{y})$$

Substituting that equation along with the inferred equation  $a_n = a_o + w$  into our original MIRA constraints yields:

$$(\alpha_o + w) \cdot t_i \geq \ell(y, \hat{y})$$

Moving  $\alpha_o$  to the right-hand-side to isolate  $w \cdot t_i$  on the left, we get a set of mappings that implement MIRA in SVM<sup>light</sup>'s optimizer:

$w$	$\alpha_n - \alpha_o$
$t_i$	$\Phi(x, y) - \Phi(x, \hat{y})$
$rhs_i$	$\ell(y, \hat{y}) - \alpha_o \cdot t_i$

The output of the SVM<sup>light</sup> optimizer is an update vector  $w$  to be added to the current  $\alpha_o$ .

## Abstract

Expert search, in which given a query a ranked list of experts instead of documents is returned, has been intensively studied recently due to its importance in facilitating the needs of both information access and knowledge discovery. Many approaches have been proposed, including metadata extraction, expert profile building, and formal model generation. However, all of them conduct expert search with a coarse-grained approach. With these, further improvements on expert search are hard to achieve. In this paper, we propose conducting expert search with a fine-grained approach. Specifically, we utilize more specific evidences existing in the documents. An evidence-oriented probabilistic model for expert search and a method for the implementation are proposed. Experimental results show that the proposed model and the implementation are highly effective.

## 1 Introduction

Nowadays, team work plays a more important role than ever in problem solving. For instance, within an enterprise, people handle new problems usually by leveraging the knowledge of experienced colleagues. Similarly, within research communities, novices step into a new research area often by learning from well-established researchers in the research area. All these scenarios involve asking the questions like “who is an expert on X?” or “who knows about X?” Such questions, which cannot be answered easily through traditional document search, raise a new requirement of searching people with certain expertise.

To meet that requirement, a new task, called *expert search*, has been proposed and studied intensively. For example, TREC 2005, 2006, and 2007

provide the task of *expert search* within the enterprise track. In the TREC setting, *expert search* is defined as: given a query, a ranked list of experts is returned. In this paper, we engage our study in the same setting.

Many approaches to expert search have been proposed by the participants of TREC and other researchers. These approaches include metadata extraction (Cao et al., 2005), expert profile building (Craswell, 2001, Fu et al., 2007), data fusion (Macdonald and Ounis, 2006), query expansion (Macdonald and Ounis, 2007), hierarchical language model (Petkova and Croft, 2006), and formal model generation (Balog et al., 2006; Fang et al., 2006). However, all of them conduct expert search with what we call a coarse-grained approach. The discovering and use of evidence for expert locating is carried out under a grain of document. With it, further improvements on expert search are hard to achieve. This is because different blocks (or segments) of electronic documents usually present different functions and qualities and thus different impacts for expert locating.

In contrast, this paper is concerned with proposing a probabilistic model for fine-grained expert search. In fine-grained expert search, we are to extract and use evidence of expert search (usually blocks of documents) directly. Thus, the proposed probabilistic model incorporates evidence of expert search explicitly as a part of it. A piece of *fine-grained evidence* is formally defined as a quadruple,  $\langle \textit{topic}, \textit{person}, \textit{relation}, \textit{document} \rangle$ , which denotes the fact that a *topic* and a *person*, with a certain *relation* between them, are found in a specific *document*. The intuition behind the quadruple is that a query may be matched with phrases in various forms (denoted as *topic* here) and an *expert candidate* may appear with various name masks (denoted as *person* here), e.g., full name, email, or abbreviated names. Given a *topic* and *person, relation* type is used to measure their closeness and

*document* serves as a context indicating whether it is good *evidence*.

Our proposed model for fine-grained expert search results in an implementation of two stages.

1) Evidence Extraction: document segments in various granularities are identified and evidences are extracted from them. For example, we can have segments in which an expert candidate and a queried topic co-occur within a same section of *document-001*: "...later, *Berners-Lee* describes a *semantic web search engine* experience..." As the result, we can extract an evidence by using same-section relation, i.e., *<semantic web search engine, Berners-Lee, same-section, document-001>*.

2) Evidence Quality Evaluation: the quality (or reliability) of evidence is evaluated. The quality of a quadruple of evidence consists of four aspects, namely *topic-matching quality*, *person-name-matching quality*, *relation quality*, and *document quality*. If we regard evidence as link of expert candidate and queried topic, the four aspects will correspond to the strength of the link to query, the strength of the link to expert candidate, the type of the link, and the document context of the link respectively.

All the *evidences* with their scores of *quality* are merged together to generate a single score for each expert candidate with regard to a given query. We empirically evaluate our proposed model and implementation on the W3C corpus which is used in the expert search task at TREC 2005 and 2006. Experimental results show that both explored evidences and evaluation of evidence quality can improve the expert search significantly. Compared with existing state-of-the-art expert search methods, the probabilistic model for fine-grained expert search shows promising improvement.

The rest of the paper is organized as follows. Section 2 surveys existing studies on expert search. Section 3 and Section 4 present the proposed probabilistic model and its implementation, respectively. Section 5 gives the empirical evaluation. Finally, Section 6 concludes the work.

## 2 Related Work

### 2.1 Expert Search Systems

One setting for automatic expert search is to assume that data from specific resources are available. For example, Expertise Recommender (Kautz

et al., 1996), Expertise Browser (Mockus and Herbsleb, 2002) and the system in (McDonald and Ackerman, 1998) make use of log data in software development systems to find experts. Yet another approach is to mine expert and expertise from email communications (Campbell et al., 2003; Dom et al. 2003; Sihn and Heeren, 2001).

Searching expert from general documents has also been studied (Davenport and Prusak, 1998; Mattox et al., 1999; Hertzum and Pejtersen, 2000). P@NOPTIC employs what is referred to as the 'profile-based' approach in searching for experts (Craswell et al., 2001). Expert/Expert-Locating (EEL) system (Steer and Lochbaum, 1988) uses the same approach in searching for expert groups. DEMOIR (Yimam, 1996) enhances the profile-based approach by separating co-occurrences into different types. In essence, the profile-based approach utilizes the co-occurrences between query words and people within documents.

### 2.2 Expert Search at TREC

A task on expert search was organized within the enterprise track at TREC 2005, 2006 and 2007 (Craswell et al., 2005; Soboroff et al., 2006; Bailey et al., 2007).

Many approaches have been proposed for tackling the expert search task within the TREC track. Cao et al. (2005) propose a two-stage model with a set of extracted metadata. Balog et al. (2006) compare two generative models for expert search. Fang et al. (2006) further extend their generative model by introducing the prior of expert distribution and relevance feedback. Petkova and Croft (2006) further extend the profile based method by using a hierarchical language model. Macdonald and Ounis (2006) investigate the effectiveness of the voting approach and the associated data fusion techniques. However, such models are conducted in a coarse-grain scope of document as discussed before. In contrast, our study focuses on proposing a model for conducting expert search in a fine-grain scope of evidence (local context).

## 3 Fine-grained Expert Search

Our research is to investigate a direct use of the local contexts for expert search. We call each local context of such kind as *fine-grained evidence*.

In this work, a fine-grained evidence is formally defined as a quadruple, *<topic, person, relation,*

*document*>. Such a quadruple denotes that a *topic* and a *person* occurrence, with a certain *relation* between them, are found in a specific *document*.

Recall that *topic* is different from *query*. For example, given a query “*semantic web coordination*”, the corresponding *topic* may be either “*semantic web*” or “*web coordination*”. Similarly, *person* here is different from *expert candidate*. E.g, given an *expert candidate* “*Ritu Raj Tiwari*”, the matched *person* may be “*Ritu Raj Tiwari*”, “*Tiwari*”, or “*RRT*” etc. Although both the topics and persons may not match the query and expert candidate exactly, they do have certain indication on the connection of query “*semantic web coordination*” and expert “*Ritu Raj Tiwari*”.

### 3.1 Evidence-Oriented Expert Search Model

We conduct fine-grained expert search by incorporating evidence of local context *explicitly* in a probabilistic model which we call an *evidence-oriented expert search model*. Given a query  $q$ , the probability of a candidate  $c$  being an expert (or knowing something about  $q$ ) is estimated as

$$\begin{aligned} P(c|q) &= \sum_e P(c, e|q) \\ &= \sum_e P(c|e, q)P(e|q) \end{aligned} \quad (1)$$

where  $e$  denotes a quadruple of *evidence*.

Using the relaxation that the probability of  $c$  is independent of a query  $q$  given an evidence  $e$ , we can reduce Equation (1) as,

$$P(c|q) = \sum_e P(c|e)P(e|q). \quad (2)$$

Compared to previous work, our model conducts expert search with a new way in which local contexts of *evidence* are used to bridge a query  $q$  and an expert candidate  $c$ . The new way enables the expert search system to explore various local contexts in a precise manner.

In the following sub-sections, we will detail two sub-models: the *expert matching model*  $P(c|e)$  and the *evidence matching model*  $P(e|q)$ .

### 3.2 Expert Matching Model

We expand the evidence  $e$  as quadruple  $\langle \textit{topic}, \textit{people}, \textit{relation}, \textit{document} \rangle$  ( $\langle t, p, r, d \rangle$  for short) for expert matching. Given a set of related evidences, we assume that the generation of an expert candidate  $c$  is independent with topic  $t$  and omit it

in expert matching. Therefore, we simplify the expert matching formula as below:

$$P(c|e) = P(c|p, r, d) = P(c|p)P(p|r, d), \quad (3)$$

where  $P(c|p)$  depends on how an expert candidate  $c$  matches to a person occurrence  $p$  (e.g. full name or email of a person). The different ways of matching an expert candidate  $c$  with a person occurrence  $p$  results in varied qualities.  $P(c|p)$  represents the quality.  $P(p|r, d)$  expresses the probability of an occurrence  $p$  given a relation  $r$  and a document  $d$ .  $P(p|r, d)$  is estimated in MLE as,

$$P(p|r, d) = \frac{\textit{freq}(p, r, d)}{L(r, d)}, \quad (4)$$

where  $\textit{freq}(p, r, d)$  is the frequency of person  $p$  matched by relation  $r$  in document  $d$ , and  $L(r, d)$  is the frequency of all the persons matched by relation  $r$  in  $d$ . This estimation can further be smoothed by using the evidence collection as follows:

$$P_3(p|r, d) = \mu P(p|r, d) + (1 - \mu) \sum_{d' \in D} \frac{P(p|r, d')}{|D|}, \quad (5)$$

where  $D$  denotes the whole document collection.  $|D|$  is the total number of documents.

We use Dirichlet prior in smoothing of parameter  $\mu$ :

$$\mu = \frac{L(r, d)}{L(r, d) + K}, \quad (6)$$

where  $K$  is the average frequency of all the experts in the collection.

### 3.3 Evidence Matching Model

By expanding the evidence  $e$  and employing independence assumption, we have the following formula for evidence matching:

$$\begin{aligned} P(e|q) &= P(t, p, r, d|q) \\ &= P(t|q)P(p|q)P(r|q)P(d|q) \end{aligned} \quad (7)$$

In the following, we are to explain what these four terms represent and how they can be estimated.

The first term  $P(t|q)$  represents the probability that a query  $q$  matches to a topic  $t$  in evidence. Recall that a query  $q$  may match a topic  $t$  in various ways, not necessarily being identical to  $t$ . For example, both topic “*semantic web*” and “*semantic web search engine*” can match the query “*semantic web search engine*”. The probability is defined as

$$P(t|q) \propto P(\text{type}(t,q)), \quad (8)$$

where  $\text{type}(t, q)$  represents the way that  $q$  matches to  $t$ , e.g., *phrase matching*. Different matching methods are associated with different probabilities.

The second term  $P(p|q)$  represents the probability that a person  $p$  is generated from a query  $q$ . The probability is further approximated by the prior probability of  $p$ ,

$$P(p|q) \propto P(p). \quad (9)$$

The prior probability can be estimated by MLE, i.e., the ratio of total occurrences of person  $p$  in the collection.

The third term represents the probability that a relation  $r$  is generated from a query  $q$ . Here, we approximate the probability as

$$P(r|q) \propto P(\text{type}(r)), \quad (10)$$

where  $\text{type}(r)$  represents the way  $r$  connecting query and expert.  $P(\text{type}(r))$  represents the reliability of relation type of  $r$ .

Following the Bayes rule, the last term can be transformed as

$$P(d|q) = \frac{P(q|d)P(d)}{P(q)} \propto P(q|d)P(d), \quad (11)$$

where priority distribution  $P(d)$  can be estimated based on static rank, e.g., PageRank (Brin and Page, 1998).  $P(q|d)$  can be estimated by using a standard language model for IR (Ponte and Croft, 1998).

In summary, Equation (7) is converted to

$$P(e|q) \propto P(\text{type}(t,q))P(p)P(\text{type}(r))P(q|d)P(d). \quad (12)$$

### 3.4 Evidence Merging

We assume that the ranking score of an expert can be acquired by summing up together all scores of the supporting evidences. Thus we calculate experts' scores by aggregating the scores from all evidences as in Equation (1).

## 4 Implementation

The implementation of the proposed model consists of two stages, namely *evidence extraction* and *evidence quality evaluation*.

### 4.1 Evidence Extraction

Recall that we define an evidence for expert search as a quadruple  $\langle \text{topic}, \text{person}, \text{relation}, \text{document} \rangle$ . The evidence extraction covers the extraction of the first three elements, namely *person identification*, *topic discovering* and *relation extraction*.

#### 4.1.1 Person Identification

The occurrences of an expert can be in various forms, such as name and email address. We call each type of form an *expert mask*. Table 1 provides a statistic on various *masks* on the basis of W3C corpus. In Table 1, *rate* is the proportion of the person occurrences with relevant masks to the person occurrences with any of the masks, and *ambiguity* is defined as the probability that a mask is shared by more than one expert.

Mask	Rate/Ambiguity	Sample
Full Name( $N_F$ )	48.2% / 0.0000	Ritu Raj Tiwari
Email Name( $N_E$ )	20.1% / 0.0000	rtiwari@nuance.com
Combined Name ( $N_C$ )	4.2% / 0.3992	Tiwari, Ritu R; R R Tiwari
Abbr. Name( $N_A$ )	21.2% / 0.4890	Ritu Raj ; Ritu
Short Name( $N_S$ )	0.7% / 0.6396	RRT
Alias, new email ( $N_{AE}$ )	7% / 0.4600	Ritiwari rti- wari@hotmail.com

Table 1. Various masks and their ambiguity

1)	Every occurrence of a candidate's <i>email address</i> is normalized to the appropriate <i>candidate id</i> .
2)	Every occurrence of a candidate's <i>full_name</i> is normalized to the appropriate <i>candidate id</i> if there is no ambiguity; otherwise, the occurrence is normalized to the <i>candidate id</i> of the most frequent candidate with that <i>full_name</i> .
3)	Every occurrence of <i>combined name</i> , <i>abbreviated name</i> , and <i>email alias</i> is normalized to the appropriate <i>candidate id</i> if there is no ambiguity; otherwise, the occurrence may be normalized to the <i>candidate id</i> of a candidate whose full name also appears in the document.
4)	All the personal occurrences other than those covered by Heuristic 1) ~ 3) are ignored.

Table 2. Heuristic rules for expert extraction

As Table 1 demonstrates, it is not an easy task to identify all the *masks* with regards to an expert. On one hand, the extraction of *full name* and *email address* is straightforward but suffers from low coverage. On the other hand, the extraction of

*combined name* and *abbreviated name* can complement the coverage, while needs handling of ambiguity.

Table 2 provides the heuristic rules that we use for expert identification. In the step 2) and 3), the rules use *frequency* and *context discourse* for resolving ambiguities respectively. With *frequency*, each expert candidate actually is assigned a prior probability. With *context discourse*, we utilize the intuition that person names appearing similar in a document usually refers to the same person.

#### 4.1.2 Topic Discovering

A queried topic can occur within documents in various forms, too. We use a set of query processing techniques to handle the issue. After the processing, a set of topics transformed from an original query will be obtained and then be used in the search for experts. Table 3 shows five forms of topic discovering from a given query.

Forms	Description	Sample
Phrase Match( $Q_P$ )	The exact match with original query given by users	“ <i>semantic web search engine</i> ”
Bi-gram Match( $Q_B$ )	A set of matches formed by extracting bi-gram of words in the original query	“ <i>semantic web search engine</i> ”
Proximity Match( $Q_{PR}$ )	Each query term appears as a neighborhood within a window of specified size	“ <i>semantic web enhanced search engine</i> ”
Fuzzy Match( $Q_F$ )	A set of matches, each of which resembles the original query in appearance.	“ <i>sementic web seerch engine</i> ”
Stemmed Match( $Q_S$ )	A match formed by stemming the original query.	“ <i>sementic web seerch engin</i> ”

Table 3. Discovered topics from query “semantic web search engine”

#### 4.1.3 Relation Extraction

We focus on extracting relations between topics and expert candidates within a span of a document. To make the extraction easier, we partition a document into a pre-defined layout. Figure 1 provides a template in Backus–Naur form. Figure 2 provides a practical use of the template.

Note that we are not restricting the use of the template only for certain corpus. Actually the template can be applied to many kinds of documents. For example, for web pages, we can construct the <Title> from either the ‘title’ metadata or the con-

tent of web pages (Hu et al., 2006). As for e-mail, we can use the ‘subject’ field as the <Title>.

```

<Document> ::= {<Title>| <Author> |<Body>}
<Title> ::= {<Element>}
<Author> ::= {<Expert>}
<Body> ::= {<Section>}
<Section> ::= {<Section Title><Section Body>}
<SectionTitle> ::= {<Element>}
<SectionBody> ::= {<Section>}|{<Element >}
<Element> ::= <Term>| <Expert>

```

Figure 1. A template of document layout

```

<Title> RDF Primer
<Author> Editors: Frank Manola, fmanola@acm.org
Eric Miller, W3C, em@w3.org
<Body>
  <Section>
    <Section Title>
      2. Making Statements About Resources
    <Section Body>
      RDF is intended to provide a simple way to make state
      These capabilities (the normative specification describe)
      2.1 Basic Concepts
      Imagine trying to state that someone named John Smith
      The form of a simple statement such as:
      ...
  ...

```

Figure 2. An example use of the layout template

With the layout of partitioned documents, we can then explore many types of relations among different blocks. In this paper, we demonstrate the use of five types of relations by extending the study in (Cao et al., 2005).

**Section Relation ( $R_S$ ):** The queried topic and the expert candidate occur in the same <Section>.

**Windowed Section Relation ( $R_{WS}$ ):** The queried topic and the expert candidate occur within a fixed window of a <Section>. In our experiment, we used a window of 200 words.

**Reference Section Relation ( $R_{RS}$ ):** Some <Section>s should be treated specially. For example, the <Section> consisting of reference information like a list of <book, author> can serve as a reliable source connecting a topic and an expert candidate. We call the relation appearing in a special type of <Section> a special reference section relation. It might be argued whether the use of special sections can be generalized. According to our survey, the special <Section>s can be found in various sites such as Wikipedia as well as W3C.

**Title-Author Relation ( $R_{TA}$ ):** The queried topic appears in the <Title> and the expert candidate appears in the <Author>.

**Section Title-Body Relation ( $R_{STB}$ ):** The queried topic and the expert candidate appear in the <Section Title> and <Section Body> of the same <Section>, respectively. Reversely, the queried topic and the expert candidate can appear in the <Section Body> and <Section Title> of a <Section>. The latter case is used to characterize the documents introducing certain expert or the expert introducing certain document.

Note that our model is not restricted to use these five relations. We use them only for the aim of demonstrating the flexibility and effectiveness of fine-grained expert search.

## 4.2 Evidence Quality Evaluation

In this section, we elaborate the mechanism used for evaluating the quality of evidence.

### 4.2.1 Topic-Matching Quality

In Section 4.1.2, we use five techniques in processing query matches, which yield five sets of match types for a given query. Obviously, the different query matches should be associated with different weights because they represent different qualities.

We further note that different bi-grams generated from the same query with the *bi-gram matching* method might also present different qualities. For example, both topic “*css test*” and “*test suite*” are the bi-gram matching for query “*css test suite*”; however, the former might be more informative. To model that, we use the number of returned documents to refine the query weight. The intuition behind that is similar to the thought of IDF popularly used in IR as we prefer to the distinctive bi-grams.

Taking into consideration the above two factors, we calculate the topic-matching quality  $Q_t$  (corresponding to  $P(\text{type}(t,q))$  in Equation (12)) for the given query  $q$  as

$$Q_t = W(\text{type}(t,q)) \frac{\text{MIN}_r(df_r)}{df_t}, \quad (13)$$

where  $t$  means the discovered topic from a document and  $\text{type}(t,q)$  is the matching type between topic  $t$  and query  $q$ .  $W(\text{type}(t,q))$  is the weight for a certain query type,  $df_t$  is the number of returned documents matched by topic  $t$ . In our experiment, we use the 10 training topics of TREC2005 as our training data, and the best quality scores for *phrase match*, *bi-gram match*, *proximity match*, *fuzzy*

*match*, and *stemmed match* are 1, 0.01, 0.05,  $10^{-8}$ , and  $10^{-4}$ , respectively.

### 4.2.2 Person-Matching Quality

An expert candidate can occur in the documents in various ways. The most confident occurrence should be the ones in full name or email address. Others can include last name only, last name plus initial of first name, etc. Thus, the action of rejecting or accepting a person from his/her mask (the surface expression of a person in the text) is not simply a Boolean decision, but a probabilistic one with a reliability weight  $Q_p$  (corresponding to  $P(c|p)$  in Equation (3)). Similarly, the best trained weights for *full name*, *email name*, *combined name*, *abbreviated name*, *short name*, and *alias email* are set to 1, 1, 0.8, 0.2, 0.2, and 0.1, respectively.

### 4.2.3 Relation Type Quality

The relation quality consists of two factors. One factor is about the type of the relation. Different types of relations indicate different strength of the connection between expert candidates and queried topics. In our system, the *section title-body relation* is given the highest confidence. The other factor is about the degree of proximity between a query and an expert candidate. The intuition is that, the more distant are a query and an expert candidate within a relation, the looser the connection between them is. To include these two factors, the quality score  $Q_r$  (corresponding to  $P(\text{type}(r))$  in Equation (12)) of a relation  $r$  is defined as:

$$Q_r = W_r \frac{C_r}{\text{dis}(p,t) + 1}, \quad (14)$$

where  $W_r$  is the weight of relation type  $r$ ,  $\text{dis}(p, t)$  is the distance from the person occurrence  $p$  to the queried topic  $t$  and  $C_r$  is a constant for normalization. Again, we optimize the  $W_r$  based on the training topics, the best weights for *section relation*, *windowed section relation*, *reference section relation*, *title-author relation*, and *section title-body relation* are 1, 4, 10, 45, and 1000 respectively.

### 4.2.4 Document Quality

The quality of evidence also depends on the quality of the document, the context in which it is found. The *document context* can affect the credibility of the evidence in two ways:

**Static quality:** indicating the authority of a document. In our experiment, the static quality  $Q_d$  (corresponding to  $P(d)$  in Equation (12) ) is estimated by the PageRank, which is calculated using a standard iterative algorithm with a damping factor of 0.85 (Brin and Page, 1998).

**Dynamic quality:** by “dynamic”, we mean the quality score varies for different queries  $q$ . We denote the dynamic quality as  $Q_{Dy}(d,q)$  (corresponding to  $P(q|d)$  in Equation (12) ), which is actually the document relevance score returned by a standard language model for IR(Ponte and Croft, 1998).

## 5 Experimental Results

### 5.1 The Evaluation Data

In our experiment, we used the data set in the expert search task of enterprise search track at TREC 2005 and 2006. The document collection is a crawl of the public W3C sites in June 2004. The crawl comprises in total 331,307 web pages. In the following experiments, we used the training set of 10 topics of TREC 2005 for tuning the parameters aforementioned in Section 4.2, and used the test set of 50 topics of TREC 2005 and 49 topics of TREC 2006 as the evaluation data sets.

### 5.2 Evaluation Metrics

We used three measures in evaluation: *Mean average precision (MAP)*, *R-precision (R-P)*, and *Top N precision (P@N)*. They are also the standard measures used in the expert search task of TREC.

### 5.3 Evidence Extraction

In the following experiments, we constructed the baseline by using the query matching methods of *phrase matching*, the expert matching methods of *full name matching and email matching*, and the relation of *section relation*. To show the contribution of each individual method for evidence extraction, we incrementally add the methods to the baseline method. In the following description, we will use ‘+’ to denote applying new method on the previous setting.

#### 5.3.1 Query Matching

Table 4 shows the results of expert search achieved by applying different methods of query matching.

$Q_B$ ,  $Q_{PR}$ ,  $Q_F$ , and  $Q_S$  denote bi-gram match, proximity match, fuzzy match, and stemmed match, respectively. The performance of the proposed model increases stably on MAP when new query matches are added incrementally. We also find that the introduction of  $Q_F$  and  $Q_S$  bring some drop on R-Precision and P@10. It is reasonable because both  $Q_F$  and  $Q_S$  bring high recall while affect the precision a bit. The overall relative improvement of using query matching compared to the baseline is presented in the row “Improv.”. We performed t-tests on MAP. The p-values ( $< 0.05$ ) are presented in the “T-test” row, which shows that the improvement is statistically significant.

	TREC 2005			TREC 2006		
	MAP	R-P	P@10	MAP	R-P	P@10
Baseline	0.1840	0.2136	0.3060	0.3752	0.4585	0.5604
+ $Q_B$	0.1957	0.2438	0.3320	0.4140	0.4910	0.5799
+ $Q_{PR}$	0.2024	<b>0.2501</b>	<b>0.3360</b>	0.4530	<b>0.5137</b>	<b>0.5922</b>
+ $Q_F, Q_S$	<b>0.2030</b>	<b>0.2501</b>	<b>0.3360</b>	<b>0.4580</b>	0.5112	0.5901
Improv.	10.33%	17.09%	9.80%	22.07%	11.49%	5.30%
T-test	0.0084			0.0000		

Table 4. The effects of query matching

#### 5.3.2 Person Matching

For person matching, we considered four types of masks, namely *combined name ( $N_C$ )*, *abbreviated name ( $N_A$ )*, *short name ( $N_S$ )* and *alias and new email ( $N_{AE}$ )*. Table 5 provides the results on person matching at TREC 2005 and 2006. The baseline is the best model achieved in previous section. It seems that there is little improvement on P@10 while an improvement of 6.21% and 14.00% is observed on MAP. This might be due to the fact that the matching method such as  $N_C$  has a higher recall but lower precision.

	TREC 2005			TREC 2006		
	MAP	R-P	P@10	MAP	R-P	P@10
Baseline	0.2030	0.2501	0.3360	0.4580	0.5112	0.5901
+ $N_C$	0.2056	0.2539	<b>0.3463</b>	0.4709	0.5152	0.5931
+ $N_A$	0.2106	0.2545	0.3400	0.5010	0.5181	<b>0.6000</b>
+ $N_S$	0.2111	0.2578	0.3400	0.5121	0.5192	<b>0.6000</b>
+ $N_{AE}$	<b>0.2156</b>	<b>0.2591</b>	0.3400	<b>0.5221</b>	<b>0.5212</b>	<b>0.6000</b>
Improv.	6.21%	3.60%	1.19%	14.00%	1.96%	1.68%
T-test	0.0064			0.0057		

Table 5. The effects of person matching

### 5.3.3 Multiple Relations

For relation extraction, we experimentally demonstrated the use of each of the five relations proposed in Section 4.1.3, i.e., section relation ( $R_S$ ), windowed section relation ( $R_{WS}$ ), reference section relation ( $R_{RS}$ ), title-author relation ( $R_{TA}$ ), and section title-body relation ( $R_{STB}$ ). We used the best model achieved in previous section as the baseline. From Table 6, we can see that the section title-body relation contributes the most to the improvement of the performance. By using all the discovered relations, a significant improvement of 19.94% and 8.35% is achieved.

	TREC 2005			TREC 2006		
	MAP	R-P	P@10	MAP	R-P	P@10
Baseline	0.2156	0.2591	0.3400	0.5221	0.5212	0.6000
+ $R_{WS}$	0.2158	0.2633	0.3380	0.5255	0.5311	0.6082
+ $R_{RS}$	0.2160	0.2630	0.3380	0.5272	0.5314	0.6061
+ $R_{TA}$	0.2234	0.2634	0.3580	0.5354	0.5355	0.6245
+ $R_{STB}$	<b>0.2586</b>	<b>0.3107</b>	<b>0.3740</b>	<b>0.5657</b>	<b>0.5669</b>	<b>0.6510</b>
Improv.	19.94%	19.91%	10.00%	8.35%	8.77%	8.50%
T-test	0.0013			0.0043		

Table 6. The effects of relation extraction

### 5.4 Evidence Quality

The performance of expert search can be further improved by considering the evidence quality. Table 7 shows the results by considering the differences in quality.

We evaluated two kinds of evidence quality: *context static quality* ( $Q_d$ ) and *context dynamic quality* ( $Q_{DY}$ ). Each of the evidence quality contributes about 1%-2% improvement for MAP. The improvement from the PageRank that we calculated from the corpus implies that the web scaled rank technique is also effective in the corpus of documents. Finally, we find a significant relative improvement of 6.13% and 2.86% on MAP by using evidence qualities.

	TREC 2005			TREC 2006		
	MAP	R-P	P@10	MAP	R-P	P@10
Baseline	0.2586	0.3107	0.3740	0.5657	0.5669	0.6510
+ $Q_d$	0.2711	0.3188	0.3720	0.5900	0.5813	0.6796
+ $Q_{DY}$	<b>0.2755</b>	<b>0.3252</b>	<b>0.3880</b>	<b>0.5943</b>	<b>0.5877</b>	<b>0.7061</b>
Improv.	6.13%	4.67%	3.74%	2.86%	3.67%	8.61%
T-test	0.0360			0.0252		

Table 7. The effects of using evidence quality

### 5.5 Comparison with Other Systems

In Table 8, we juxtapose the results of our probabilistic model for fine-grained expert search with automatic expert search systems from the TREC evaluation. The performance of our proposed model is rather encouraging, which achieved comparable results to the best automatic systems on the TREC 2005 and 2006.

		MAP	R-prec	Prec@10
Rank-1 System	TREC2005	0.2749	0.3330	0.4520
	TREC2006 <sup>1</sup>	0.5947	0.5783	0.7041
Our System	TREC2005	0.2755	0.3252	0.3880
	TREC2006	0.5943	0.5877	0.7061

Table 8. Comparison with other systems

## 6 Conclusions

This paper proposed to conduct expert search using a fine-grained level of evidence. Specifically, quadruple evidence was formally defined and served as the basis of the proposed model. Different implementations of evidence extraction and evidence quality evaluation were also comprehensively studied. The main contributions are:

1. The proposal of fine-grained expert search, which we believe to be a promising direction for exploring subtle aspects of evidence.
2. The proposal of probabilistic model for fine-grained expert search. The model facilitates investigating the subtle aspects of evidence.
3. The extensive evaluation of the proposed probabilistic model and its implementation on the TREC data set. The evaluation shows promising expert search results.

In future, we are to explore more domain independent evidences and evaluate the proposed model on the basis of the data from other domains.

## Acknowledgments

The authors would like to thank the three anonymous reviewers for their elaborate and helpful comments. The authors also appreciate the valuable suggestions of Hang Li, Nick Craswell, Yangbo Zhu and Linyun Fu.

<sup>1</sup> This system, where cluster-based re-ranking is used, is a variation of the fine-grained model proposed in this paper.

mdr@science.uva.nl

## Abstract

Topical blog post retrieval is the task of ranking blog posts with respect to their relevance for a given topic. To improve topical blog post retrieval we incorporate textual credibility indicators in the retrieval process. We consider two groups of indicators: *post level* (determined using information about individual blog posts only) and *blog level* (determined using information from the underlying blogs). We describe how to estimate these indicators and how to integrate them into a retrieval approach based on language models. Experiments on the TREC Blog track test set show that both groups of credibility indicators significantly improve retrieval effectiveness; the best performance is achieved when combining them.

## 1 Introduction

The growing amount of user generated content available online creates new challenges for the information retrieval (IR) community, in terms of search and analysis tasks for this type of content. The introduction of a blog retrieval track at TREC (Ounis et al., 2007) has created a platform where we can begin to address these challenges. During the 2006 edition of the track, two types of blog post retrieval were considered: *topical* (retrieve posts about a topic) and *opinionated* (retrieve opinionated posts about a topic). Here, we consider the former task.

Blogs and blog posts offer unique features that may be exploited for retrieval purposes. E.g., Mishne (2007b) incorporates time in a blog post retrieval model to account for the fact that many blog queries and posts are a response to a news event (Mishne and de Rijke, 2006). Data quality is an issue with blogs—the quality of posts ranges from low to edited news article-like. Some approaches to post retrieval use indirect quality mea-

asures (e.g., elaborate spam filtering (Java et al., 2007) or counting inlinks (Mishne, 2007a)).

Few systems turn the *credibility* (Metzger, 2007) of blog posts into an aspect that can benefit the retrieval process. Our hypothesis is that more credible blog posts are preferred by searchers. The idea of using credibility in the blogosphere is not new: Rubin and Liddy (2006) define a framework for assessing blog credibility, consisting of four main categories: blogger’s expertise and offline identity disclosure; blogger’s trustworthiness and value system; information quality; and appeals and triggers of a personal nature. Under these four categories the authors list a large number of indicators, some of which can be determined from textual sources (e.g., literary appeal), and some of which typically need non-textual evidence (e.g., curiosity trigger); see Section 2.

We give concrete form to Rubin and Liddy (2006)’s indicators and test their impact on blog post retrieval effectiveness. We do not consider all indicators: we only consider indicators that are textual in nature, and to ensure reproducibility of our results, we only consider indicators that can be derived from the TRECBlog06 corpus (and that do not need additional resources such as bloggers’ profiles that may be hard to obtain for technical or legal reasons).

We detail and implement two groups of credibility indicators: *post level* (these use information about individual posts) and *blog level* (these use information from the underlying blogs). Within the post level group, we distinguish between topic dependent and independent indicators. To make matters concrete, consider Figure 1: both posts are relevant to the query “tennis,” but based on obvious surface level features of the posts we quickly determine *Post 2* to be more *credible* than *Post 1*. The most obvious features are spelling errors, the lack of leading capitals, and the large number of exclamation marks and

### Post 1

as for today (monday) we had no school! yaay labor day. but we had tennis from 9-11 at the highschool. after that me suzi melis & ashley had a picnic at cecil park and then played tennis. i just got home right now. it was a very very fun afternoon. (...) we will have a short week. mine will be even shorter b/c i wont be there all day on friday cuz we have the Big 7 Tournament at like keystone oaks or sumthin. so i will miss school the whole day.

### Post 2

Wimbledon champion Venus Williams has pulled out of next week's Kremlin Cup with a knee injury, tournament organisers said on Friday. The American has not played since pulling out injured of last month's China Open. The former world number one has been troubled by various injuries (...) Williams's withdrawal is the latest blow for organisers after Australian Open champion and home favorite Marat Safin withdrew (...).

Figure 1: Two blog posts relevant to the query “tennis.”

personal pronouns—i.e., topic independent ones—and the fact that the language usage in the second post is more easily associated with credible information about tennis than the language usage in the first post—i.e., a topic dependent feature.

Our main finding is that topical blog post retrieval can benefit from using credibility indicators in the retrieval process. Both post and blog level indicator groups each show a significant improvement over the baseline. When we combine all features we obtain the best retrieval performance, and this performance is comparable to the best performing TREC 2006 and 2007 Blog track participants. The improvement over the baseline is stable across most topics, although topic shift occurs in a few cases.

The rest of the paper is organized as follows. In Section 2 we provide information on determining credibility; we also relate previous work to the credibility indicators that we consider. Section 3 specifies our retrieval model, a method for incorporating credibility indicators in our retrieval model, and estimations of credibility indicators. Section 4 gives the results of our experiments aimed at assessing the contribution of credibility towards blog post retrieval effectiveness. We conclude in Section 5.

## 2 Credibility Indicators

In our choice of credibility indicators we use (Rubin and Liddy, 2006)'s work as a reference point. We recall the main points of their framework and relate our indicators to it. We briefly discuss other credibility-related indicators found in the literature.

### 2.1 Rubin and Liddy (2006)'s work

Rubin and Liddy (2006) proposed a four factor analytical framework for blog-readers' credibility assessment of blog sites, based in part on evidentiality theory (Chafe, 1986), website credibility assessment surveys (Stanford et al., 2002), and Van House (2004)'s observations on blog credibility. The four factors—plus indicators for each of them—are:

1. *blogger's expertise and offline identity disclosure* (*a*: name and geographic location; *b*: credentials; *c*: affiliations; *d*: hyperlinks to others; *e*: stated competencies; *f*: mode of knowing);
2. *blogger's trustworthiness and value system* (*a*: biases; *b*: beliefs; *c*: opinions; *d*: honesty; *e*: preferences; *f*: habits; *g*: slogans)
3. *information quality* (*a*: completeness; *b*: accuracy; *c*: appropriateness; *d*: timeliness; *e*: organization (by categories or chronology); *f*: match to prior expectations; *g*: match to information need); and
4. *appeals and triggers of a personal nature* (*a*: aesthetic appeal; *b*: literary appeal (i.e., writing style); *c*: curiosity trigger; *d*: memory trigger; *e*: personal connection).

### 2.2 Our credibility indicators

We only consider credibility indicators that avoid making use of the searcher's or blogger's identity (i.e., excluding 1a, 1c, 1e, 1f, 2e from Rubin and Liddy's list), that can be estimated automatically from available test collections only so as to facilitate repeatability of our experiments (ruling out 3e, 4a, 4c, 4d, 4e), that are textual in nature (ruling out 2d), and that can be reliably estimated with state-of-the-art language technology (ruling out 2a, 2b, 2c, 2g). For reasons that we explain below, we also ignore the “hyperlinks to others” indicator (1d).

The indicators that we do consider—1b, 2f, 3a, 3b, 3c, 3d, 3f, 3g, 4b—are organized in two groups,

depending on the information source that we use to estimate them, *post level* and *blog level*, and the former is further subdivided into *topic independent* and *topic dependent*. Table 1 lists the indicators we consider, together with the corresponding Rubin and Liddy indicator(s).

Let us quickly explain our indicators. First, we consider the use of *capitalization* to be an indicator of good writing style, which in turn contributes to a sense of credibility. Second, we identify Western style *emoticons* (e.g., :-)) and :-D) in blog posts, and assume that excessive use indicates a less credible blog post. Third, words written in all caps are considered *shouting* in a web environment; we consider shouting to be indicative for non-credible posts. Fourth, a credible author should be able to write without (a lot of) *spelling* errors; the more spelling errors occur in a blog post, the less credible we consider it to be. Fifth, we assume that credible texts have a reasonable *length*; the text should supply enough information to convince the reader of the author’s credibility. Sixth, assuming that much of what goes on in the blogosphere is inspired by events in the news (Mishne and de Rijke, 2006), we believe that, for news related topics, a blog post is more credible if it is published around the time of the triggering news event (*timeliness*). Seventh, our *semantic* indicator also exploits the news-related nature of many blog posts, and “prefers” posts whose language usage is similar to news stories on the topic. Eighth, blogs are a popular place for spammers; *spam* blogs are not considered credible and we want to demote them in the search results. Ninth, *comments* are a notable blog feature: readers of a blog post often have the possibility of leaving a comment for other readers or the author. When people comment on a blog post they apparently find the post worth putting effort in, which can be seen as an indicator of credibility (Mishne and Glance, 2006). Tenth, blogs consist of multiple posts in (reverse) chronological order. The temporal aspect of blogs may indicate credibility: we assume that bloggers with an irregular posting behavior are less credible than bloggers who post *regularly*. And, finally, we consider the topical fluctuation of a blogger’s posts. When looking for credible information we would like to retrieve posts from bloggers that have a certain level of (topical) *consistency*: not the fluctuating

indicator	topic dependent?	post level/ blog level	related Rubin & Liddy indicator
capitalization	no	post	4b
emoticons	no	post	4b
shouting	no	post	4b
spelling	no	post	4b
post length	no	post	3a
timeliness	yes	post	3d
semantic	yes	post	3b, 3c
spam	no	blog	3b, 3c, 3f, 3g
comments	no	blog	1b
regularity	no	blog	2f
consistency	no	blog	2f

Table 1: Credibility indicators

behavior of a (personal) blogger, but a solid interest.

### 2.3 Other work

In a web setting, credibility is often couched in terms of authoritativeness and estimated by exploiting the hyperlink structure. Two well-known examples are the PageRank and HITS algorithms (Liu, 2007), that use the link structure in a topic independent or topic dependent way, respectively. Zhou and Croft (2005) propose collection-document distance and signal-to-noise ratio as priors for the indication of quality in web ad hoc retrieval. The idea of using link structure for improving blog post retrieval has been researched, but results do not show improvements. E.g., Mishne (2007a) finds that retrieval performance decreased. This confirms lessons from the TREC web tracks, where participants found no conclusive benefit from the use of link information for ad hoc retrieval tasks (Hawking and Craswell, 2002). Hence, we restrict ourselves to the use of content-based features for blog post retrieval, thus ignoring indicator 1d (hyperlinks to others).

Related to credibility in blogs is the automatic assessment of forum post quality discussed by Weimer et al. (2007). The authors use surface, lexical, syntactic and forum-specific features to classify forum posts as bad posts or good posts. The use of forum-specific features (such as whether or not the post contains HTML, and the fraction of characters that are inside quotes of other posts), gives the highest benefits to the classification. Working in the community question/answering domain, Agichtein et al. (2008) use a content features, as well non-content information available, such as links between items and

explicit quality ratings from members of the community to identify high-quality content.

As we argued above, spam identification may be part of estimating a blog (or blog post’s) credibility. Spam identification has been successfully applied in the blogosphere to improve retrieval effectiveness; see, e.g., (Mishne, 2007b; Java et al., 2007).

### 3 Modeling

In this section we detail the retrieval model that we use, incorporating ranking by relevance and by credibility. We also describe how we estimate the credibility indicators listed in Section 2.

#### 3.1 Baseline retrieval model

We address the baseline retrieval task using a language modeling approach (Croft and Lafferty, 2003), where we rank documents given a query:  $p(d|q) = p(d)p(q|d)p(q)^{-1}$ . Using Bayes’ Theorem we rewrite this, ignoring expressions that do not influence the ranking, obtaining

$$p(d|q) \propto p(d)p(q|d), \quad (1)$$

and, assuming that query terms are independent,

$$p(d|q) \propto p(d) \prod_{t \in q} p(t|\theta_d)^{n(t,q)}, \quad (2)$$

where  $\theta_d$  is the blog post model, and  $n(t, q)$  denotes the number of times term  $t$  occurs in query  $q$ . To prevent numerical underflows, we perform this computation in the log domain:

$$\log p(d|q) \propto \log p(d) + \sum_{t \in q} n(t, q) \log p(t|\theta_d) \quad (3)$$

In our final formula for ranking posts based on relevance only we substitute  $n(t, q)$  by the probability of the term given the query. This allows us to assign different weights to query terms and yields:

$$\log p(d|q) \propto \log p(d) + \sum_{t \in q} p(t|q) \log p(t|\theta_d). \quad (4)$$

For our baseline experiments we assume that all query terms are equally important and set  $p(t|q)$  set to be  $n(t, q) \cdot |q|^{-1}$ . The component  $p(d)$  is the topic independent (“prior”) probability that the document is relevant; in the baseline model, priors are ignored.

#### 3.2 Incorporating credibility

Next, we extend Eq. 4 by incorporating estimations of the credibility indicators listed in Table 1. Recall that our credibility indicators come in two kinds—post level and blog level—and that the post level indicators can be topic independent or topic dependent, while all blog level indicators are topic independent. Now, modeling topic independent indicators is easy—they can simply be incorporated in Eq. 4 as a weighted sum of two priors:

$$p(d) = \lambda \cdot p_{pl}(d) + (1 - \lambda) \cdot p_{bl}(d), \quad (5)$$

where  $p_{pl}(d)$  and  $p_{bl}(d)$  are the post level and blog level prior probability of  $d$ , respectively. The priors  $p_{pl}$  and  $p_{bl}$  are defined as equally weighted sums:

$$\begin{aligned} p_{pl}(d) &= \sum_i \frac{1}{5} \cdot p_i(d) \\ p_{bl}(d) &= \sum_j \frac{1}{4} \cdot p_j(d), \end{aligned}$$

where  $i \in \{\textit{capitalization}, \textit{emoticons}, \textit{shouting}, \textit{spelling}, \textit{post\_length}\}$  and  $j \in \{\textit{spam}, \textit{comments}, \textit{regularity}, \textit{consistency}\}$ . Estimations of the priors  $p_i$  and  $p_j$  are given below; the weighting parameter  $\lambda$  is determined experimentally.

Modeling topic dependent indicators is slightly more involved. Given a query  $q$ , we create a query model  $\theta_q$  that is a mixture of a temporal query model  $\theta_{temporal}$  and a semantic query model  $\theta_{semantic}$ :

$$p(t|\theta_q) = \mu \cdot p(t|\theta_{temporal}) + (1 - \mu) \cdot p(t|\theta_{semantic}). \quad (6)$$

The component models  $\theta_{temporal}$  and  $\theta_{semantic}$  will be estimated below; the parameter  $\mu$  will be estimated experimentally.

Our final ranking formula, then, is obtained by plugging in Eq. 5 and 6 in Eq. 4:

$$\begin{aligned} \log p(d|q) \propto & \log p(d) \\ & + \beta (\sum_t p(t|q) \cdot \log p(t|\theta_d)) \\ & + (1 - \beta) (\sum_t p(t|\theta_q) \cdot \log p(t|\theta_d)). \end{aligned} \quad (7)$$

#### 3.3 Estimating credibility indicators

Next, we specify how each of the credibility indicators is estimated; we do so in two groups: post level and blog level.

### 3.3.1 Post level credibility indicators

**Capitalization** We estimate the capitalization prior as follows:

$$p_{capitalization}(d) = n(c, s) \cdot |s|^{-1}, \quad (8)$$

where  $n(c, s)$  is the number of sentences starting with a capital and  $|s|$  is the number of sentences; we only consider sentences with five or more words.

**Emoticons** The emoticons prior is estimated as

$$p_{emoticons}(d) = 1 - n(e, d) \cdot |d|^{-1}, \quad (9)$$

where  $n(e, d)$  is the number of emoticons in the post and  $|d|$  is the length of the post in words.

**Shouting** We use the following equation to estimate the shouting prior:

$$p_{shouting}(d) = 1 - n(a, d) \cdot |d|^{-1}, \quad (10)$$

where  $n(a, d)$  is the number of all caps words in blog post  $d$  and  $|d|$  is the post length in words.

**Spelling** The spelling prior is estimated as

$$p_{spelling}(d) = 1 - n(m, d) \cdot |d|^{-1}, \quad (11)$$

where  $n(m, d)$  is the number of misspelled (or unknown) words and  $|d|$  is the post length in words.

**Post length** The post length prior is estimated using  $|d|$ , the post length in words:

$$p_{length}(d) = \log(|d|). \quad (12)$$

**Timeliness** We estimate timeliness using the time-based language models  $\theta_{temporal}$  proposed in (Li and Croft, 2003; Mishne, 2007b). I.e., we use a news corpus from the same period as the blog corpus that we use for evaluation purposes (see Section 4.2). We assign a timeliness score per post based on:

$$p(d|\theta_{temporal}) = k^{-1} \cdot (n(date(d), k) + 1), \quad (13)$$

where  $k$  is the number of top results from the initial result list,  $date(d)$  is the date associated with document  $d$ , and  $n(date(d), k)$  is the number of documents in  $k$  with the same date as  $d$ . For our initial result list we perform retrieval on both the blog and the news corpus and take  $k = 50$  for both corpora.

**Semantic** A semantic query model  $\theta_{semantic}$  is obtained using ideas due to Diaz and Metzler (2006). Again, we use a news corpus from the same period as the evaluation blog corpus and estimate  $\theta_{semantic}$ . We issue the query to the external news corpus, retrieve the top 10 documents and extract the top 10 distinctive terms from these documents. These terms are added to the original query terms to capture the language usage around the topic.

### 3.3.2 Blog level credibility indicators

**Spam filtering** To estimate the spaminess of a blog, we take a simple approach. We train an SVM classifier on a labeled splog blog dataset (Kolari et al., 2006) using the top 1500 words for both spam and non-spam blogs as features. For each classified blog  $d$  we have a confidence value  $s(d)$ . If the classifier cannot make a decision ( $s(d) = 0$ ) we set  $p_{spam}(d)$  to 0, otherwise we use the following to transform  $s(d)$  into a spam prior  $p_{spam}(d)$ :

$$p_{spam}(d) = \frac{s(d)}{2|s(d)|} + \frac{-1 \cdot s(d)}{2s(d)^2 + 2|s(d)|} + \frac{1}{2}. \quad (14)$$

**Comments** We estimate the comment prior as

$$p_{comment}(d) = \log(n(r, d)), \quad (15)$$

where  $n(r, d)$  is the number of comments on post  $d$ .

**Regularity** To estimate the regularity prior we use

$$p_{regularity}(d) = \log(\sigma_{interval}), \quad (16)$$

where  $\sigma_{interval}$  expresses the standard deviation of the temporal intervals between two successive posts.

**Topical consistency** Here we use an approach similar to query clarity (Cronen-Townsend and Croft, 2002): based on the list of posts from the same blog we compare the topic distribution of blog  $B$  to the topic distribution in the collection  $C$  and assign a ‘clarity’ value to  $B$ ; a score further away from zero indicates a higher topical consistency. We estimate the topical consistency prior as

$$p_{topic}(d) = \log(clarity(d)), \quad (17)$$

where  $clarity(d)$  is estimated by

$$clarity(d) = \frac{\sum_w p(w|B) \cdot \log\left(\frac{p(w|B)}{p(w)}\right)}{\sum_w p(w|B)} \quad (18)$$

with  $p(w) = \frac{count(w, C)}{|C|}$  and  $p(w|B) = \frac{count(w, B)}{|B|}$ .

### 3.3.3 Efficiency

All estimators discussed above can be implemented efficiently: most are document priors and can therefore be calculated offline. The only topic dependent estimators are *timeliness* and *language usage*; both can be implemented efficiently as specific forms of query expansion.

## 4 Evaluation

In this section we describe the experiments we conducted to answer our research questions about the impact of credibility on blog post retrieval.

### 4.1 Research questions

Our research revolves around the contribution of credibility to the effectiveness of topical blog post retrieval: what is the contribution of individual indicators, of the post level indicators (topic dependent or independent), of the blog level indicators, and of all indicators combined? And do different topics benefit from different indicators? To answer our research question we compared the performance of the baseline retrieval system (as detailed in Section 3.1) with extensions of the baseline system with a single indicator, a set of indicators, or all indicators.

### 4.2 Setup

We apply our models to the TREC Blog06 corpus (Macdonald and Ounis, 2006). This corpus has been constructed by monitoring around 100,000 blog feeds for a period of 11 weeks in early 2006, downloading all posts created in this period. For each permalink (HTML page containing one blog post) the feed id is registered. We can use this id to aggregate post level features to the blog level. In our experiments we use only the HTML documents, 3.2M permalinks, which add up to around 88 GB.

The TREC 2006 and 2007 Blog tracks each offer 50 topics and assessments (Ounis et al., 2007; Macdonald et al., 2007). For topical relevancy, assessment was done using a standard two-level scale: the content of the post was judged to be topically relevant or not. The evaluation metrics that we use are standard ones: mean average precision (MAP) and precision@10 (p@10) (Baeza-Yates and Ribeiro-Neto, 1999). For all our retrieval tasks we use the title field (T) of the topic statement as query.

To estimate the timeliness and semantic credibility indicators, we use AQUAINT-2, a set of newswire articles (2.5 GB, about 907K documents) that are roughly contemporaneous with the TREC Blog06 collection (AQUAINT-2, 2007). Articles are in English and come from a variety of sources.

Statistical significance is tested using a two-tailed paired t-test. Significant improvements over the baseline are marked with  $\Delta$  ( $\alpha = 0.05$ ) or  $\blacktriangle$  ( $\alpha = 0.01$ ). We use  $\nabla$  and  $\blacktriangledown$  for a drop in performance (for  $\alpha = 0.05$  and  $\alpha = 0.01$ , respectively).

### 4.3 Parameter estimation

The models proposed in Section 3.2 contain parameters  $\beta$ ,  $\lambda$  and  $\mu$ . These parameters need to be estimated and, hence, require a training and test set. We use a two-fold parameter estimation process: in the first cycle we estimate the parameters on the TREC 2006 Blog topic set and test these settings on the topics of the TREC 2007 Blog track. The second cycle goes the other way around and trains on the 2007 set, while testing on the 2006 set.

Figure 2 shows the optimum values for  $\lambda$ ,  $\beta$ , and  $\mu$  on the 2006 and the 2007 topic sets for both MAP (bottom lines) and p@10 (top lines). When looking at the MAP scores, the optimal setting for  $\lambda$  is almost identical for the two topic sets: 0.4 for the 2006 set and 0.3 for the 2007 set, and also the optimal setting for  $\beta$  is very similar for both sets: 0.4 for the 2006 set and 0.5 for the 2007 set. As to  $\mu$ , it is clear that timeliness does not improve the performance over using the semantic feature alone and the optimal setting for  $\mu$  is therefore 0.0. Both  $\mu$  and  $\beta$  show similar behavior on p@10 as on MAP, but for  $\lambda$  we see a different trend. If early precision is required, the value of  $\lambda$  should be increased, giving more weight to the topic-independent post level features compared to the blog level features.

### 4.4 Retrieval performance

Table 2 lists the retrieval results for the baseline, for each of the credibility indicators (on top of the baseline), for four subsets of indicators, and for all indicators combined. The baseline performs similar to the median scores at the TREC 2006 Blog track (MAP: 0.2203; p@10: 0.564) and somewhat below the median MAP score at 2007 Blog track (MAP: 0.3340) but above the median p@10 score: 0.3805.

Figure 2: Parameter estimation on the TREC 2006 and 2007 Blog topics. (Left):  $\lambda$ . (Center):  $\beta$ . (Right):  $\mu$ .

	2006		2007	
	map	p@10	map	p@10
baseline	0.2156	0.4360	0.2820	0.5160
capitalization	0.2155	0.4500	0.2824	0.5160
emoticons	0.2156	0.4360	0.2820	0.5200
shouting	0.2159	0.4320	0.2833	0.5100
spelling	0.2179 $\Delta$	0.4480 $\Delta$	0.2839 $\blacktriangle$	0.5220
post length	0.2502 $\blacktriangle$	0.4960 $\blacktriangle$	0.3112 $\blacktriangle$	0.5700 $\blacktriangle$
timeliness	0.1865 $\nabla$	0.4520	0.2660	0.4860
semantic	0.2840 $\blacktriangle$	0.6240 $\blacktriangle$	0.3379 $\blacktriangle$	0.6640 $\blacktriangle$
spam filtering	0.2093	0.4700	0.2814	0.5760 $\blacktriangle$
comments	0.2497 $\blacktriangle$	0.5000 $\blacktriangle$	0.3099 $\blacktriangle$	0.5600 $\blacktriangle$
regularity	0.1658 $\nabla$	0.4940 $\Delta$	0.2353 $\nabla$	0.5640 $\Delta$
consistency	0.2141 $\nabla$	0.4220	0.2785 $\nabla$	0.5040
post level (topic indep.)	0.2374 $\blacktriangle$	0.4920 $\blacktriangle$	0.2990 $\blacktriangle$	0.5660 $\blacktriangle$
post level (topic dep.)	0.2840 $\blacktriangle$	0.6240 $\blacktriangle$	0.3379 $\blacktriangle$	0.6640 $\blacktriangle$
post level (all)	0.2911 $\blacktriangle$	0.6380 $\blacktriangle$	0.3369 $\blacktriangle$	0.6620 $\blacktriangle$
blog level	0.2391 $\blacktriangle$	0.4500	0.3023 $\blacktriangle$	0.5580 $\blacktriangle$
all	0.3051 $\blacktriangle$	0.6880 $\blacktriangle$	0.3530 $\blacktriangle$	0.6900 $\blacktriangle$

Table 2: Retrieval performance on 2006 and 2007 topics, using  $\lambda = 0.3$ ,  $\beta = 0.4$ , and  $\mu = 0.0$ .

Some (topic independent) post level indicators hurt the MAP score, while others help (for both years, and both measures). Combined, the topic independent post level indicators perform less well than the use of one of them (*post length*). As to the topic dependent post level indicators, *timeliness* hurts performance on MAP for both years, while the semantic indicator provides significant improvements across the board (resulting in a top 2 score in terms of MAP and a top 5 score in terms of p@10, when compared to the TREC 2006 Blog track participants that only used the T field).

Some of the blog level features hurt more than they help (*regularity*, *consistency*), while the *comments* feature helps, on all measures, and for both years. Combined, the blog level features help less

than the use of one of them (*comments*).

As a group, the combined post level features help more than either of the two post level sub groups alone. The blog level features show similar results to the topic-independent post level features, obtaining a significant increase on both MAP and p@10, but lower than the topic-dependent post level features.

The grand combination of all credibility indicators leads to a significant improvement over any of the single indicators and over any of the four subsets considered in Table 2. The MAP score of this run is higher than the best performing run in the TREC 2006 Blog track and has a top 3 performance on p@10; its 2007 performance is just within the top half on both MAP and p@10.

#### 4.5 Analysis

Next we examine the differences in average precision (per topic) between the baseline and subsets of indicators (post and blog level) and the grand combination. We limit ourselves to an analysis of the MAP scores. Figure 3 displays the per topic average precision scores, where topics are sorted by absolute gain of the grand combination over the baseline.

In 2006, 7 (out of 50) topics were negatively affected by the use of credibility indicators; in 2007, 15 (out of 50) were negatively affected. Table 3 lists the topics that displayed extreme behavior (in terms of relative performance gain or drop in AP score). While the extreme drops for both years are in the same range, the gains for 2006 are more extreme than for 2007.

The topic that is hurt most (in absolute terms) by the credibility indicators is the 2007 topic 910: *aperto network* (AP -0.2781). The semantic indicator is to blame for this decrease is: the terms included in the expanded query shift the topic from a wireless broadband provider to television networks.

Figure 3: Per-topic AP differences between baseline run and runs with blog level features (triangles), post level features (circles) and all feature (squares) on the 2006 (left) en 2007 (right) topics.

Table 3: Extreme performance gains/drops of the grand combination over the baseline (MAP).

2006		
id	topic	% gain/loss
900	mcdonalds	+525.9%
866	foods	+446.2%
865	basque	+308.6%
862	blackberry	-21.5%
870	barry bonds	-35.2%
898	business intelligence resources	-78.8%
2007		
id	topic	% gain/loss
923	challenger	+162.1%
926	hawthorne heights	+160.7%
945	bolivia	+125.5%
943	censure	-49.4%
928	big love	-80.0%
904	alterman	-84.2%

Topics that gain most (in absolute terms) are 947 (*sasha cohen*; AP +0.3809) and 923 (*challenger*; AP +0.3622) from the 2007 topic set.

Finally, the combination of all credibility indicators hurts 7 (2006) plus 15 (2007) equals 22 topics; for the post level indicators get a performance drop in AP for 28 topics (10 plus 18, respectively) and for the blog level indicators we get a drop for 15 topics (4 plus 11, respectively). Hence, the combination of all indicators strikes a good balance between overall performance gain and per topic risk.

## 5 Conclusions

We provided efficient estimations for 11 credibility indicators and assessed their impact on topical blog post retrieval, on top of a content-based retrieval

baseline. We compared the contribution of these indicators, both individually and in groups, and found that (combined) they have a significant positive impact on topical blog post retrieval effectiveness. Certain single indicators, like *post length* and *comments*, make good credibility indicators on their own; the best performing credibility indicator group consists of topic dependent post level ones. Other future work concerns indicator selection: instead of taking all indicators on board, consider selected indicators only, in a topic dependent fashion.

Our choice of credibility indicators was based on a framework proposed by Rubin and Liddy (2006): the estimators we used are natural implementations of the selected indicators, but by no means the only possible ones. In future work we intend to extend the set of indicators considered so as to include, e.g., stated competencies (1e), by harvesting and analyzing bloggers' profiles, and to extend the set of estimators for indicators that we already consider such as reading level measures (e.g., Flesch-Kincaid) for the literary appeal indicator (4b).

# Linguistically Motivated Features for Enhanced Back-of-the-Book Indexing

Andras Csomai and Rada Mihalcea

Department of Computer Science

University of North Texas

csomaia@unt.edu, rada@cs.unt.edu

## Abstract

In this paper we present a supervised method for back-of-the-book index construction. We introduce a novel set of features that goes beyond the typical frequency-based analysis, including features based on discourse comprehension, syntactic patterns, and information drawn from an online encyclopedia. In experiments carried out on a book collection, the method was found to lead to an improvement of roughly 140% as compared to an existing state-of-the-art supervised method.

## 1 Introduction

Books represent one of the oldest forms of written communication and have been used since thousands of years ago as a means to store and transmit information. Despite this fact, given that a large fraction of the electronic documents available online and elsewhere consist of short texts such as Web pages, news articles, scientific reports, and others, the focus of natural language processing techniques to date has been on the automation of methods targeting short documents. We are witnessing however a change: more and more books are becoming available in electronic format, in projects such as the Million Books project (<http://www.archive.org/details/millionbooks>), the Gutenberg project (<http://www.gutenberg.org>), or Google Book Search (<http://books.google.com>). Similarly, a large number of the books published in recent years are often available – for purchase or through libraries – in electronic format. This means that the need for language processing techniques able to handle very large documents such as books is becoming increasingly important.

This paper addresses the problem of automatic back-of-the-book index construction. A back-of-the-book index typically consists of the most important keywords addressed in a book, with pointers to the relevant pages inside the book. The construction of such indexes is one of the few tasks related to publishing that still requires extensive human labor. Although there is a certain degree of computer assistance, consisting of tools that help the professional indexer to organize and edit the index, there are no methods that would allow for a complete or nearly-complete automation.

In addition to helping professional indexers in their task, an automatically generated back-of-the-book index can also be useful for the automatic storage and retrieval of a document; as a quick reference to the content of a book for potential readers, researchers, or students (Schutze, 1998); or as a starting point for generating ontologies tailored to the content of the book (Feng et al., 2006).

In this paper, we introduce a supervised method for back-of-the-book index construction, using a novel set of linguistically motivated features. The algorithm learns to automatically identify important keywords in a book based on an ensemble of syntactic, discourse-based and information-theoretic properties of the candidate concepts. In experiments performed on a collection of books and their indexes, the method was found to exceed by a large margin the performance of a previously proposed state-of-the-art supervised system for keyword extraction.

## 2 Supervised Back-of-the-Book Indexing

We formulate the problem of back-of-the-book indexing as a supervised keyword extraction task, by making a binary yes/no classification decision at the

level of each candidate index entry. Starting with a set of candidate entries, the algorithm automatically decides which entries should be added to the back-of-the-book index, based on a set of linguistic and information theoretic features. We begin by identifying the set of candidate index entries, followed by the construction of a feature vector for each such candidate entry. In the training data set, these feature vectors are also assigned with a correct label, based on the presence/absence of the entry in the gold standard back-of-the-book index provided with the data. Finally, a machine learning algorithm is applied, which automatically classifies the candidate entries in the test data for their likelihood to belong to the back-of-the-book index.

The application of a supervised algorithm requires three components: a data set, which is described next; a set of features, which are described in Section 3; and a machine learning algorithm, which is presented in Section 4.

## 2.1 Data

We use a collection of books and monographs from the eScholarship Editions collection of the University of California Press (*UC Press*),<sup>1</sup> consisting of 289 books, each with a manually constructed back-of-the-book index. The average length of the books in this collection is 86053 words, and the average length of the indexes is 820 entries. A collection of 56 books was previously introduced in (Csomai and Mihalcea, 2006); however, that collection is too small to be split in training and test data to support supervised keyword extraction experiments.

The UC Press collection was provided in a standardized XML format, following the Text Encoding Initiative (TEI) recommendations, and thus it was relatively easy to process the collection and separate the index from the body of the text.

In order to use this corpus as a gold standard collection for automatic index construction, we had to eliminate the *inversions*, which are typical in human-built indexes. *Inversion* is a method used by professional indexers by which they break the ordering of the words in each index entry, and list the head first, thereby making it easier to find entries in an alphabetically ordered index. As an example, consider the entry *indexing of illustrations*, which, following inversion, becomes *illustrations, indexing of*. To eliminate inversion, we use an approach that gen-

erates each permutation of the composing words for each index entry, looks up the frequency of that permutation in the book, and then chooses the one with the highest frequency as the correct reconstruction of the entry. In this way, we identify the form of the index entries as appearing in the book, which is the form required for the evaluation of extraction methods. Entries that cannot be found in the book, which were most likely generated by the human indexers, are preserved in their original ordering.

For training and evaluation purposes, we used a random split of the collection into 90% training and 10% test. This yields a training corpus of 259 documents and a test data set of 30 documents.

## 2.2 Candidate Index Entries

Every sequence of words in a book represents a potential candidate for an entry in the back-of-the-book index. Thus, we extract from the training and the test data sets all the n-grams (up to the length of four), not crossing sentence boundaries. These represent the candidate index entries that will be used in the classification algorithm. The training candidate entries are then labeled as positive or negative, depending on whether the given n-gram was found in the back-of-the-book index associated with the book.

Using a n-gram-based method to extract candidate entries has the advantage of providing high coverage, but the unwanted effect of producing an extremely large number of entries. In fact, the resulting set is unmanageably large for any machine learning algorithm. Moreover, the set is extremely unbalanced, with a ratio of positive and negative examples of 1:675, which makes it unsuitable for most machine learning algorithms. In order to address this problem, we had to find ways to reduce the size of the data set, possibly eliminating the training instances that will have the least negative effect on the usability of the data set.

The first step to reduce the size of the data set was to use the candidate filtering techniques for unsupervised back-of-the-book index construction that we proposed in (Csomai and Mihalcea, 2007). Namely, we use the commonword and comma filters, which are applied to both the training and the test collections. These filters work by eliminating all the n-grams that begin or end with a common word (we use a list of 300 most frequent English words), as well as those n-grams that cross a comma. This results in a significant reduction in the number of neg-

Table 1: Number of training and test instances generated from the UC Press data set

ative examples, from 48 to 11 million instances, with a loss in terms of positive examples of only 7.6%.

The second step is to use a technique for balancing the distribution of the positive and the negative examples in the data sets. There are several methods proposed in the existing literature, focusing on two main solutions: undersampling and oversampling (Weiss and Provost, 2001). Undersampling (Kubat and Matwin, 1997) means the elimination of instances from the majority class (in our case negative examples), while oversampling focuses on increasing the number of instances of the minority class. Aside from the fact that oversampling has hard to predict effects on classifier performance, it also has the additional drawback of increasing the size of the data set, which in our case is undesirable. We thus adopted an undersampling solution, where we randomly select 10% of the negative examples. Evidently, the undersampling is applied only to the training set.

Table 1 shows the number of positive and negative entries in the data set, for the different pre-processing and balancing phases.

### 3 Features

An important step in the development of a supervised system is the choice of features used in the learning process. Ideally, any property of a word or a phrase indicating that it could be a good keyword should be represented as a feature and included in the training and test examples. We use a number of features, including information-theoretic features previously used in unsupervised keyword extraction, as well as a novel set of features based on syntactic and discourse properties of the text, or on information extracted from external knowledge repositories.

#### 3.1 Phraseness and Informativeness

We use the phraseness and informativeness features that we previously proposed in (Csomai and Mihalcea, 2007). Phraseness refers to the degree to which

a sequence of words can be considered a phrase. We use it as a measure of lexical cohesion of the component terms and treat it as a collocation discovery problem. Informativeness represents the degree to which the keyphrase is representative for the document at hand, and it correlates to the amount of information conveyed to the user.

To measure the **informativeness** of a keyphrase, various methods can be used, some of which were previously proposed in the keyword extraction literature:

- *tf.idf*, which is the traditional information retrieval metric (Salton and Buckley, 1997), employed in most existing keyword extraction applications. We measure inverse document frequency using the article collection of the online encyclopedia Wikipedia.
- $\chi^2$  *independence test*, which measures the degree to which two events happen together more often than by chance. In our work, we use the  $\chi^2$  in a novel way. We measure the informativeness of a keyphrase by finding if a phrase occurs in the document more frequently than it would by chance. The information required for the  $\chi^2$  independence test can be typically summed up in a contingency table (Manning and Schutze, 1999):

count(phrase in document)	count(all other phrases in document)
count(phrase in other documents)	count(all other phrases in all other documents)

The independence score is calculated based on the observed ( $O$ ) and expected ( $E$ ) counts:

$$\chi^2 = \sum_{i,j} \frac{(O_{i,j} - E_{i,j})^2}{E_{i,j}}$$

where  $i, j$  are the row and column indices of the

contingency table. The  $O$  counts are the cells of the table. The  $E$  counts are calculated from the marginal probabilities (the sum of the values of a column or a row) converted into proportions by dividing them with the total number of observed events ( $N$ ):

$$N = O_{1,1} + O_{1,2} + O_{2,1} + O_{2,2}$$

Then the expected count for seeing the phrase in the document is:

$$E_{1,1} = \frac{O_{1,1} + O_{1,2}}{N} \times \frac{O_{1,1} + O_{2,1}}{N} \times N$$

To measure the **phraseness** of a candidate phrase we use a technique based on the  $\chi^2$  independence test. We measure the independence of the events of seeing the components of the phrase in the text. This method was found to be one of the best performing models in collocation discovery (Pecina and Schlesinger, 2006). For n-grams where  $N > 2$  we apply the  $\chi^2$  independence test by splitting the phrase in two (e.g. for a 4-gram, we measure the independence of the composing bigrams).

### 3.2 Discourse Comprehension Features

Very few existing keyword extraction methods look beyond word frequency. Except for (Turney and Littman, 2003), who uses pointwise mutual information to improve the coherence of the keyword set, we are not aware of any other work that attempts to use the semantics of the text to extract keywords. The fact that most systems rely heavily on term frequency properties poses serious difficulties, since many index entries appear only once in the document, and thus cannot be identified by features based solely on word counts. For instance, as many as 52% of the index entries in our training data set appeared only once in the books they belong to. Moreover, another aspect not typically covered by current keyword extraction methods is the coherence of the keyword set, which can also be addressed by discourse-based properties.

In this section, we propose a novel feature for keyword extraction inspired by work on discourse comprehension. We use a construction integration framework, which is the backbone used by many discourse comprehension theories.

#### 3.2.1 Discourse Comprehension

Discourse comprehension is a field in cognitive science focusing on the modeling of mental pro-

cesses associated with reading and understanding text. The most widely accepted theory for discourse comprehension is the construction integration theory (Kintsch, 1998). According to this theory, the elementary units of comprehension are propositions, which are defined as instances of a predicate-argument schema. As an example, consider the sentence *The hemoglobin carries oxygen*, which generates the predicate CARRY[HEMOGLOBIN,OXIGEN]. The processing cycle of the construction integration model processes one proposition at a time, and builds a local representation of the text in the working memory, called the propositional network.

During the *construction* phase, propositions are extracted from a segment of the input text (typically a single sentence) using linguistic features. The propositional network is represented as a graph, with nodes consisting of propositions, and weighted edges representing the semantic relations between them. All the propositions generated from the input text are inserted into the graph, as well as all the propositions stored in the short term memory. The short term memory contains the propositions that compose the representation of the previous few sentences. The second phase of the construction step is the addition of past experiences (or background knowledge), which is stored in the long term memory. This is accomplished by adding new elements to the graph, usually consisting of the set of closely related propositions from the long term memory.

After processing a sentence, the *integration* step establishes the role of each proposition in the meaning representation of the current sentence, through a spreading activation applied on the propositions derived from the original sentence. Once the weights are stabilized, the set of propositions with the highest activation values give the mental representation of the processed sentence. The propositions with the highest activation values are added to the short term memory, the working memory is cleared and the process moves to the next sentence. Figure 3.2.1 shows the memory types used in the construction integration process and the main stages of the process.

#### 3.2.2 Keyword Extraction using Discourse Comprehension

The main purpose of the short term memory is to ensure the coherence of the meaning representation across sentences. By keeping the most important propositions in the short term memory, the spreading activation process transfers additional weight to se-

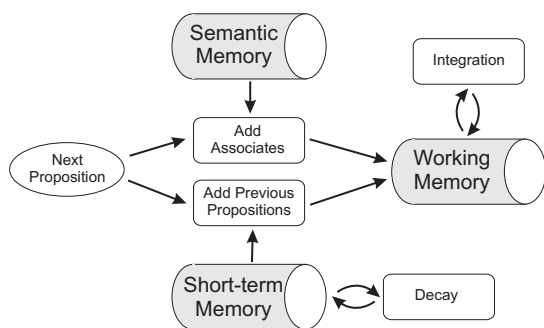

Figure 1: The construction integration process

manically related propositions in the sentences that follow. This also represents a way of alleviating one of the main problems of statistical keyword extraction, namely the sole dependence on term frequency. Even if a phrase appears only once, the construction integration process ensures the presence of the phrase in the short term memory as long as it is relevant to the current topic, thus being a good indicator of the phrase importance.

The construction integration model is not directly applicable to keyword extraction due to a number of practical difficulties. The first implementation problem was the lack of a propositional parser. We solve this problem by using a shallow parser to extract noun phrase chunks from the original text (Munoz et al., 1999). Second, since spreading activation is a process difficult to control, with several parameters that require fine tuning, we use instead a different graph centrality measure, namely PageRank (Brin and Page, 1998).

Finally, to represent the relations inside the long term semantic memory, we use a variant of latent semantic analysis (LSA) (Landauer et al., 1998) as implemented in the InfoMap package,<sup>2</sup> trained on a corpus consisting of the British National Corpus, the English Wikipedia, and the books in our collection. To alleviate the data sparsity problem, we also use the pointwise mutual information (PMI) to calculate the relatedness of the phrases based on the book being processed.

The final system works by iterating the following steps: (1) Read the text sentence by sentence. For each new sentence, a graph is constructed, consisting of the noun phrase chunks extracted from the original text. This set of nodes is augmented with all the phrases from the short term memory. (2) A

weighted edge is added between all the nodes, based on the semantic relatedness measured between the phrases by using LSA and PMI. We use a weighted combination of these two measures, with a weight of 0.9 assigned to LSA and 0.1 to PMI. For the nodes from the short term memory, we adjust the connection weights to account for memory decay, which is a function of the distance from the last occurrence. We implement decay by decreasing the weight of both the outgoing and the incoming edges by  $n * \alpha$ , where  $n$  is the number of sentences since we last saw the phrase and  $\alpha = 0.1$ . (3) Apply PageRank on the resulting graph. (4) Select the 10 highest ranked phrases and place them in the short term memory. (5) Read the next sentence and go back to step (1).

Three different features are derived based on the construction integration model:

- **CI short term memory frequency** (*CI short-term*), which measures the number of iterations that the phrase remains in the short term memory, which is seen as an indication of the phrase importance.
- **CI normalized short term memory frequency** (*CI normalized*), which is the same as *CI short-term*, except that it is normalized by the frequency of the phrase. Through this normalization, we hope to enhance the effect of the semantic relatedness of the phrase to subsequent sentences.
- **CI maximum score** (*CI maxscore*), which measures the maximum centrality score the phrase achieves across the entire book. This can be thought of as a measure of the importance of the phrase in a smaller coherent segment of the document.

### 3.3 Syntactic Features

Previous work has pointed out the importance of syntactic features for supervised keyword extraction (Hulth, 2003). The construction integration model described before is already making use of syntactic patterns to some extent, through the use of a shallow parser to identify noun phrases. However, that approach does not cover patterns other than noun phrases. To address this limitation, we introduce a new feature that captures the part-of-speech of the words composing a candidate phrase.

<sup>2</sup><http://infomap.stanford.edu/>

There are multiple ways to represent such a feature. The simplest is to create a string feature consisting of the concatenation of the part-of-speech tags. However, this representation imposes limitations on the machine learning algorithms that can be used, since many learning systems cannot handle string features. The second solution is to introduce a binary feature for each part-of-speech tag pattern found in the training and the test data sets. In our case this is again unacceptable, given the size of the documents we work with and the large number of syntactic patterns that can be extracted. Instead, we decided on a novel solution which, rather than using the part-of-speech pattern directly, determines the probability of a phrase with a certain tag pattern to be selected as a keyphrase. Formally:

$$P(\text{pattern}) = \frac{C(\text{pattern}, \text{positive})}{C(\text{pattern})}$$

where  $C(\text{pattern}, \text{positive})$  is the number of distinct phrases having the tag pattern  $\text{pattern}$  and being selected as keyword, and  $C(\text{pattern})$  represents the number of distinct phrases having the tag pattern  $\text{pattern}$ . This probability is estimated based on the training collection, and is used as a numeric feature. We refer to this feature as *part-of-speech pattern*.

### 3.4 Encyclopedic Features

Recent work has suggested the use of domain knowledge to improve the accuracy of keyword extraction. This is typically done by consulting a vocabulary of plausible keyphrases, usually in the form of a list of subject headings or a domain specific thesaurus. The use of a vocabulary has the additional benefit of eliminating the extraction of incomplete phrases (e.g. "States of America"). In fact, (Medelyan and Witten, 2006) reported an 110% F-measure improvement in keyword extraction when using a domain-specific thesaurus.

In our case, since the books can cover several domains, the construction and use of domain-specific thesauruses is not plausible, as the advantage of such resources is offset by the time it usually takes to build them. Instead, we decided to use encyclopedic information, as a way to ensure high coverage in terms of domains and concepts.

We use Wikipedia, which is the largest and the fastest growing encyclopedia available today, and whose structure has the additional benefit of being particularly useful for the task of keyword extrac-

tion. Wikipedia includes a rich set of links that connect important phrases in an article to their corresponding articles. These links are added manually by the Wikipedia contributors, and follow the general guidelines of annotation provided by Wikipedia. The guidelines coincide with the goals of keyword extraction, and thus the Wikipedia articles and their link annotations can be treated as a vast keyword annotated corpus.

We make use of the Wikipedia annotations in two ways. First, if a phrase is used as the title of a Wikipedia article, or as the anchor text in a link, this is a good indicator that the given phrase is well formed. Second, we can also estimate the probability of a term  $W$  to be selected as a keyword in a new document by counting the number of documents where the term was already selected as a keyword ( $\text{count}(D_{\text{key}})$ ) divided by the total number of documents where the term appeared ( $\text{count}(D_W)$ ). These counts are collected from the entire set of Wikipedia articles.

$$P(\text{keyword}|W) \approx \frac{\text{count}(D_{\text{key}})}{\text{count}(D_W)} \quad (1)$$

This probability can be interpreted as "the more often a term was selected as a keyword among its total number of occurrences, the more likely it is that it will be selected again." In the following, we will refer to this feature as *Wikipedia keyphraseness*.

### 3.5 Other Features

In addition to the features described before, we add several other features frequently used in keyword extraction: the frequency of the phrase inside the book (*term frequency (tf)*); the number of documents that include the phrase (*document frequency (df)*); a combination of the two (*tf.idf*); the within-document frequency, which divides a book into ten equally-sized segments, and counts the number of segments that include the phrase (*within document frequency*); the length of the phrase (*length of phrase*); and finally a binary feature indicating whether the given phrase is a named entity, according to a simple heuristic based on word capitalization.

## 4 Experiments and Evaluation

We integrate the features described in the previous section in a machine learning framework. The system is evaluated on the data set described in Section 2.1, consisting of 289 books, randomly split into

90% training (259 books) and 10% test (30 books). We experiment with three learning algorithms, selected for the diversity of their learning strategy: multilayer perceptron, SVM, and decision trees. For all three algorithms, we use their implementation as available in the Weka package.

For evaluation, we use the standard information retrieval metrics: precision, recall, and F-measure. We use two different mechanisms for selecting the number of entries in the index. In the first evaluation (*ratio-based*), we use a fixed ratio of 0.45% from the number of words in the text; for instance, if a book has 100,000 words, the index will consist of 450 entries. This number was estimated based on previous observations regarding the typical size of a back-of-the-book index (Csomai and Mihalcea, 2006). In order to match the required number of entries, we sort all the candidates in reversed order of the confidence score assigned by the machine learning algorithm, and consequently select the top entries in this ranking. In the second evaluation (*decision-based*), we allow the machine learning algorithm to decide on the number of keywords to extract. Thus, in this evaluation, all the candidates labeled as keywords by the learning algorithm will be added to the index. Note that all the evaluations are run using a training data set with 10% undersampling of the negative examples, as described before.

Table 2 shows the results of the evaluation. As seen in the table, the multilayer perceptron and the decision tree provide the best results, for an overall average F-measure of 27%. Interestingly, the results obtained when the number of keywords is automatically selected by the learning method (decision-based) are comparable to those when the number of keywords is selected a-priori (ratio-based), indicating the ability of the machine learning algorithm to correctly identify the correct keywords.

Additionally, we also ran an experiment to determine the amount of training data required by the system. While the learning curve continues to grow with additional amounts of data, the steepest part of the curve is observed for up to 10% of the training data, which indicates that a relatively small amount of data (about 25 books) is enough to sustain the system.

It is worth noting that the task of creating back-of-the-book indexes is highly subjective. In order to put the performance figures in perspective, one should also look at the inter-annotator agreement be-

tween human indexers as an upper bound of performance. Although we are not aware of any comprehensive studies for inter-annotator agreement on back-of-the-book indexing, we can look at the consistency studies that have been carried out on the MEDLINE corpus (Funk and Reid, 1983), where an inter-annotator agreement of 48% was found on an indexing task using a domain-specific controlled vocabulary of subject headings.

#### 4.1 Comparison with Other Systems

We compare the performance of our system with two other methods for keyword extraction. One is the *tf.idf* method, traditionally used in information retrieval as a mechanism to assign words in a text with a weight reflecting their importance. This *tf.idf* baseline system uses the same candidate extraction and filtering techniques as our supervised systems. The other baseline is the KEA keyword extraction system (Frank et al., 1999), a state-of-the-art algorithm for supervised keyword extraction. Very briefly, KEA is a supervised system that uses a Naïve Bayes learning algorithm and several features, including information theoretic features such as *tf.idf* and positional features reflecting the position of the words with respect to the beginning of the text. The KEA system was trained on the same training data set as used in our experiments.

Table 3 shows the performance obtained by these methods on the test data set. Since none of these methods have the ability to automatically determine the number of keywords to be extracted, the evaluation of these methods is done under the ratio-based setting, and thus for each method the top 0.45% ranked keywords are extracted.

Algorithm	P	R	F
<i>tf.idf</i>	8.09	8.63	8.35
KEA	11.18	11.48	11.32

Table 3: Baseline systems

#### 4.2 Performance of Individual Features

We also carried out experiments to determine the role played by each feature, by using the information gain weight as assigned by the learning algorithm. Note that ablation studies are not appropriate in our case, since the features are not orthogonal (e.g., there is high redundancy between the construction integration and the informativeness features), and thus we cannot entirely eliminate a feature from the system.

Algorithm	ratio-based			decision-based		
	P	R	F	P	R	F
Multilayer perceptron	27.98	27.77	27.87	23.93	31.98	27.38
Decision tree	27.06	27.13	27.09	22.75	34.12	27.30
SVM	20.94	20.35	20.64	21.76	30.27	25.32

Table 2: Evaluation results

Feature	Weight
part-of-speech pattern	0.1935
CI shortterm	0.1744
Wikipedia keyphraseness	0.1731
CI maxscore	0.1689
CI shortterm normalized	0.1379
ChiInformativeness	0.1122
document frequency (df)	0.1031
tf.idf	0.0870
ChiPhraseness	0.0660
length of phrase	0.0416
named entity heuristic	0.0279
within document frequency	0.0227
term frequency (tf)	0.0209

Table 4: Information gain feature weight

Table 4 shows the weight associated with each feature. Perhaps not surprisingly, the features with the highest weight are the linguistically motivated features, including syntactic patterns and the construction integration features. The Wikipedia keyphraseness also has a high score. The smallest weights belong to the information theoretic features, including term and document frequency.

## 5 Related Work

With a few exceptions (Schutze, 1998; Csomai and Mihalcea, 2007), very little work has been carried out to date on methods for *automatic* back-of-the-book index construction.

The task that is closest to ours is perhaps keyword extraction, which targets the identification of the most important words or phrases inside a document. The state-of-the-art in keyword extraction is currently represented by supervised learning methods, where a system is trained to recognize keywords in a text, based on lexical and syntactic features. This approach was first suggested in (Turney, 1999), where parameterized heuristic rules are combined with a genetic algorithm into a system for keyphrase extraction (GenEx) that automatically identifies keywords in a document. A different learning algorithm was used in (Frank et al., 1999), where a Naive Bayes learning scheme is applied on the document

collection, with improved results observed on the same data set as used in (Turney, 1999). Neither Turney nor Frank report on the recall of their systems, but only on precision: a 29.0% precision is achieved with GenEx (Turney, 1999) for five keyphrases extracted per document, and 18.3% precision achieved with Kea (Frank et al., 1999) for fifteen keyphrases per document. Finally, in recent work, (Hulth, 2003) proposes a system for keyword extraction from abstracts that uses supervised learning with lexical and syntactic features, which proved to improve significantly over previously published results.

## 6 Conclusions and Future Work

In this paper, we introduced a supervised method for back-of-the-book indexing which relies on a novel set of features, including features based on discourse comprehension, syntactic patterns, and information drawn from an online encyclopedia. According to an information gain measure of feature importance, the new features performed significantly better than the traditional frequency-based techniques, leading to a system with an F-measure of 27%. This represents an improvement of 140% with respect to a state-of-the-art supervised method for keyword extraction. Our system proved to be successful both in ranking the phrases in terms of their suitability as index entries, as well as in determining the optimal number of entries to be included in the index. Future work will focus on developing methodologies for computer-assisted back-of-the-book indexing, as well as on the use of the automatically extracted indexes in improving the browsing of digital libraries.

## Abstract

This paper describes a computational approach to resolving the true referent of a named mention of a person in the body of an email. A generative model of mention generation is used to guide mention resolution. Results on three relatively small collections indicate that the accuracy of this approach compares favorably to the best known techniques, and results on the full CMU Enron collection indicate that it scales well to larger collections.

## 1 Introduction

The increasing prevalence of informal text from which a dialog structure can be reconstructed (e.g., email or instant messaging), raises new challenges if we are to help users make sense of this cacophony. Large collections offer greater scope for assembling evidence to help with that task, but they pose additional challenges as well. With well over 100,000 unique email addresses in the CMU version of the Enron collection (Klimt and Yang, 2004), common names (e.g., John) might easily refer to any one of several hundred people. In this paper, we associate named mentions in unstructured text (i.e., the body of an email and/or the subject line) to modeled identities. We see at least two direct applications for this work: (1) helping searchers who are unfamiliar with the contents of an email collection (e.g., historians or lawyers) better understand the context of emails that they find, and (2) augmenting more typical social networks (based on senders and recipients) with additional links based on references found in unstructured text.

Most approaches to resolving identity can be decomposed into four sub-problems: (1) finding a reference that requires resolution, (2) identifying candidates, (3) assembling evidence, and (4) choosing

among the candidates based on the evidence. For the work reported in this paper, we rely on the user to designate references requiring resolution (which we model as a predetermined set of mention-queries for which the correct referent is known). Candidate identification is a computational expedient that permits the evidence assembly effort to be efficiently focused; we use only simple techniques for that task. Our principal contributions are the approaches we take to evidence generation (leveraging three ways of linking to other emails where evidence might be found: reply chains, social interaction, and topical similarity) and our approach to choosing among candidates (based on a generative model of reference production). We evaluate the effectiveness of our approach on four collections, three of which have previously reported results for comparison, and one that is considerably larger than the others.

The remainder of this paper is as follows. Section 2 surveys prior work. Section 3 then describes our approach to modeling identity and ranking candidates. Section 4 presents results, and Section 5 concludes.

## 2 Related Work

The problem of identity resolution in email is a special case of the more general problem referred to as “Entity Resolution.” Entity resolution is generically defined as a process of determining the mapping from references (e.g., names, phrases) observed in data to real-world entities (e.g., persons, locations). In our case, the problem is to map *mentions* in emails to the *identities* of the individuals being referred to.

Various approaches have been proposed for entity resolution. In structured data (e.g., databases), approaches have included minimizing the number of “matching” and “merging” operations (Benjelloun et al., 2006), using global relational information (Malin, 2005; Bhattacharya and Getoor, 2007; Reuther, 2006) and using a probabilistic generative

\*Department of Computer Science

<sup>†</sup>College of Information Studies

model (Bhattacharya and Getoor, 2006). None of these approaches, however, both make use of conversational, topical, and time aspects, shown important in resolving personal names (Reuther, 2006), and take into account global relational information. Similarly, approaches in unstructured data (e.g., text) have involved using clustering techniques over biographical facts (Mann and Yarowsky, 2003), within-document resolution (Blume, 2005), and discriminative unsupervised generative models (Li et al., 2005). These too are insufficient for our problem since they suffer from inability scale or to handle early negotiation.

Specific to the problem of resolving mentions in email collections, Abadi (Abadi, 2003) used email orders from an online retailer to resolve product mentions in orders and Holzer et al. (Holzer et al., 2005) used the Web to acquire information about individuals mentioned in headers of an email collection. Our work is focused on resolving personal name references in the full email including the message body; a problem first explored by Diehl et al. (Diehl et al., 2006) using header-based traffic analysis techniques. Minkov et al. (Minkov et al., 2006) studied the same problem using a lazy graph walk based on both headers and content. Those two recent studies reported results on different test collections, however, making direct comparisons difficult. We have therefore adopted their test collections in order to establish a common point of reference.

### 3 Mention Resolution Approach

The problem we are interested in is the resolution of a personal-name mention (i.e., a named reference to a person)  $m$ , in a specific email  $e^m$  in the given collection of emails  $E$ , to its true referent. We assume that the user will designate such mention. This can be formulated as a *known-item* retrieval problem (Allen, 1989) since there is always only one right answer. Our goal is to develop a system that provides a list of potential candidates, ranked according to how strongly the system believes that a candidate is the true referent meant by the email author. In this paper, we propose a probabilistic approach that ranks the candidates based on the estimated probability of having been mentioned. Formally, we seek to estimate the probability  $p(c|m)$  that a potential candi-

date  $c$  is the one referred to by the given mention  $m$ , over all candidates  $C$ .

We define a mention  $m$  as a tuple  $\langle l^m, e^m \rangle$ , where  $l^m$  is the “literal” string of characters that represents  $m$  and  $e^m$  is the email where  $m$  is observed.<sup>1</sup> We assume that  $m$  can be resolved to a distinguishable participant for whom at least one email address is present in the collection.<sup>2</sup>

The probabilistic approach we propose is motivated by a generative scenario of mentioning people in email. The scenario begins with the author of the email  $e^m$ , intending to refer to a person in that email. To do that s/he will:

1. Select a person  $c$  to whom s/he will refer
2. Select an appropriate context  $x_k$  to mention  $c$
3. Select a specific lexical reference  $l^m$  to refer to  $c$  given the context  $x_k$ .

For example, suppose “John” is sending an email to “Steve” and wants to mention a common friend “Edward.” “John” knows that he and Steve know 2 people named Edward, one is a friend of both known by “Ed” and the other is his soccer trainer. If “John” would like to talk about the former, he would use “Ed” but he would likely use “Edward” plus some terms (e.g., “soccer”, “team”, etc) for the latter. “John” relies on the social context, or the topical context, for “Steve” to disambiguate the mention.

The steps of this scenario impose a certain structure to our solution. First, we need to have a representational model for each candidate identity. Second, we need to reconstruct the context of the queried mention. Third, it requires a computational model of identity that supports reasoning about identities. Finally, it requires a resolution technique that leverages both the identity models and the context to rank the potential candidates. In this section, we will present our resolution approach within that structure. We first discuss how to build both representational and computational models of identity in section 3.1. Next, we introduce a definition of the contextual space and how we can reconstruct it in

<sup>1</sup>The exact position in  $e^m$  where  $l^m$  is observed should also be included in the definition, but we ignore it assuming that all matched literal mentions in one email refer to the same identity.

<sup>2</sup>Resolving mentions that refer to non-participants is outside the scope of this paper.

section 3.2. Finally, we link those pieces together by the resolution algorithm in section 3.3.

### 3.1 Computational Model of Identity

**Representation:** In a collection of emails, individuals often use different email addresses, multiple forms of their proper names, and different nicknames. In order to track references to a person over a large collection, we need to capture as many as possible of these *referential* attributes in one representation. We extend our simple representation of identity proposed in (Elsayed and Oard, 2006) where an identity is represented by a set of pairwise co-occurrence of referential attributes (i.e., co-occurrence “associations”), and each extracted association has a frequency of occurrence. The attributes are extracted from the headers and salutation and signature lines. For example, an “address-nickname” association  $\langle a, n \rangle$  is inferred whenever a nickname  $n$  is usually observed in signature lines of emails sent from email address  $a$ . Three types of referential attributes were identified in the original representation: email addresses, names, and nicknames. We add usernames as well to account for the absence of any other type of names. Names, nicknames, and usernames are distinguishable based on where each is extracted: email addresses and names from headers, nicknames from salutation and signature lines, and usernames from email addresses. Since (except in rare cases) an email address is bound to one personal identity, the model leverages email addresses as the basis by mandating that at least one email address must appear in any observed association. As an off-line preprocessing step, we extract the referential attributes from the whole collection and build the identity models. The first step in the resolution process is to determine the list of identity models that are viable candidates as the true referent. For the experiments reported in this paper, any identity model with a first name or nickname that exactly matches the mention is considered a candidate.

**Labeling Observed Names:** For the purpose of resolving name mentions, it is necessary to compute the probability  $p(l|c)$  that a person  $c$  is referred to by a given “literal” mention  $l$ . Intuitively, that probability can be estimated based on the observed “name-type” of  $l$  and how often that association occurs in

the represented model. We define  $T$  as the set of 3 different types of single-token name-types: first, last, and nickname. We did not handle middle names and initials, just for simplicity. Names that are extracted from salutation and signature lines are labeled as nicknames whereas full names extracted from headers are first normalized to “First Last” form and then each single token is labeled based on its relative position as being the first or last name. Usernames are treated similarly to full names if they have more than one token, otherwise they are ignored. Note that the same single-token name may appear as a first name and a nickname.

Figure 1: A computational model of identity.

**Reasoning:** Having tokenized and labeled all names, we propose to model the association of a single-token name  $l$  of type  $t$  to an identity  $c$  by a simple 3-node Bayesian network illustrated in Figure 1. In the network, the observed mention  $l$  is distributed conditionally on both the identity  $c$  and the name-type  $t$ .  $p(c)$  is the prior probability of observing the identity  $c$  in the collection.  $p(t|c)$  is the probability that a name-type  $t$  is used to refer to  $c$ .  $p(l|t, c)$  is the probability of referring to  $c$  by  $l$  of type  $t$ . These probabilities can be inferred from the representational model as follows:

$$p(c) = \frac{|assoc(c)|}{\sum_{c' \in C} |assoc(c')|}$$

$$p(t|c) = \frac{freq(t, c)}{\sum_{t' \in T} freq(t', c)}$$

$$p(l|t, c) = \frac{freq(l, t, c)}{\sum_{l' \in assoc(c)} freq(l', t, c)}$$

where  $assoc(c)$  is the set of observed associations of referential attributes in the represented model  $c$ .

The probability of observing a mention  $l$  given that it belongs to an identity  $c$ , without assuming a specific token type, can then be inferred as follows:

$$p(l|c) = \sum_{t \in T} p(t|c) p(l|t, c)$$

In the case of a multi-token names (e.g., John Smith), we assume that the first is either a first name

or nickname and the last is a last name, and compute it accordingly as follows:

$$p(l_1 l_2 | c) = \left\{ \sum_{t \in \{f, n\}} p(t | c) p(l_1 | t, c) \right\} \cdot p(l_2 | last, c)$$

where  $f$  and  $n$  above denotes first name and nickname respectively.

Email addresses are also handled, but in a different way. Since we assume each of them uniquely identifies the identity, all email addresses for one identity are mapped to just one of them, which then has half of the probability mass (because it appears in every extracted co-occurrence association).

Our computational model of identity can be thought of as a language model over a set of personal references and thus it is important to account for unobserved references. If we know that a specific first name often has a common nickname (by a dictionary of commonly used first to nickname mappings (e.g., Robert to Bob)), but this nickname was not observed in the corpus, we will need to apply smoothing. We achieve that by assuming the nickname would have been observed  $n$  times where  $n$  is some fraction (0.75 in our experiments) of the frequency of the observed name. We repeat that for each unobserved nickname and then treat them as if they were actually observed.

## 3.2 Contextual Space

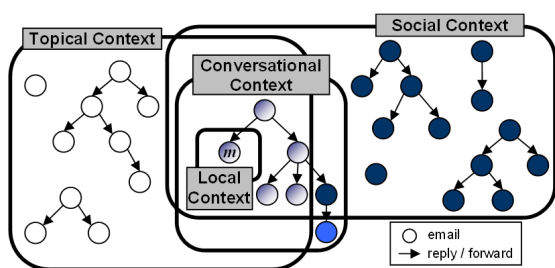

Figure 2: Contextual Space

It is obvious that understanding the context of an ambiguous mention will help with resolving it.

Fortunately, the nature of email as a conversational medium and the link-relationships between emails and people over time can reveal clues that can be exploited to partially reconstruct that context.

We define the contextual space  $X(m)$  of a mention  $m$  as a *mixture* of 4 types of contexts with  $\lambda_k$  as the mixing coefficient of context  $x_k$ . The four contexts (illustrated in Figure 2) are:

(1) **Local Context:** the email  $e^m$  where the named person is mentioned.

(2) **Conversational Context:** emails in the broader discussion that includes  $e^m$ , typically the thread that contains it.

(3) **Social Context:** discussions that some or all of the participants (sender and receivers) of  $e^m$  joined or initiated at around the time of the mention-email. These might bear some otherwise-undetected relationship to the mention-email.

(4) **Topical Context:** discussions that are topically similar to the mention-discussion that took place at around the time of  $e^m$ , regardless of whether the discussions share any common participants.

These generally represent a growing (although not strictly nested) contextual space around the queried mention. We assume that all mentions in an email share the same contextual space. Therefore, we can treat the context of a mention as the context of its email. However, each email in the collection has its own contextual space that could overlap with another email's space.

### 3.2.1 Formal Definition

We define  $K$  as the set of the 4 types of contexts. A context  $x_k$  is represented by a probability distribution over all emails in the collection. An email  $e_j$  belongs to the  $k^{\text{th}}$  context of another email  $e_i$  with probability  $p(e_j | x_k(e_i))$ . How we actually represent each context and estimate the distribution depends upon the type of the context. We explain that in detail in section 3.2.2.

### 3.2.2 Context Reconstruction

In this section, we describe how each context is constructed.

**Local Context:** Since this is simply  $e^m$ , all of the probability mass is assigned to it.

**Conversational Context:** Threads (i.e., reply chains) are imperfect approximations of focused discussions, since people sometimes switch topics within a thread (and indeed sometimes within the same email). We nonetheless expect threads to exhibit a useful degree of focus and we have therefore adopted them as a computational representation of a discussion in our experiments. To reconstruct threads in the collection, we adopted the technique introduced in (Lewis and Knowles, 1997). Thread

reconstruction results in a unique tree containing the mention-email. Although we can distinguish between different paths or subtrees of that tree, we elected to have a uniform distribution over all emails in the same thread. This also applies to threads retrieved in the social and topical contexts as well.

**Social Context:** Discussions that share common participants may also be useful, though we expect their utility to decay somewhat with time. To reconstruct that context, we temporally rank emails that share at least one participant with  $e^m$  in a time period around  $e^m$  and then expand each by its thread (with duplicate removal). Emails in each thread are then each assigned a weight that equals the reciprocal of its thread rank. We do that separately for emails that temporally precede or follow  $e^m$ . Finally, weights are normalized to produce one distribution for the whole social context.

**Topical Context:** Identifying topically-similar content is a traditional query-by-example problem that has been well researched in, for example, the TREC routing task (Lewis, 1996) and the Topic Detection and Tracking evaluations (Allan, 2002). Individual emails may be quite terse, but we can exploit the conversational structure to obtain topically related text. In our experiments, we tracked back to the root of the thread in which  $e^m$  was found and used the subject line and the body text of that root email as a query to Lucene<sup>3</sup> to identify topically-similar emails. Terms found in the subject line are doubled in the query to emphasize what is sometimes a concise description of the original topic. Subsequent processing is then similar to that used for the social context, except that the emails are first ranked by their topical, rather than temporal, similarity.

The approaches we adopted to reconstruct the social and topical contexts were chosen for their relative simplicity, but there are clearly more sophisticated alternatives. For example, topic modeling techniques (McCallum et al., 2005) could be leveraged in the reconstruction of the topical context.

### 3.3 Mention Resolution

Given a specific mention  $m$  and the set of identity models  $C$ , our goal now is to compute  $p(c|m)$  for each candidate  $c$  and rank them accordingly.

<sup>3</sup><http://lucene.apache.org>

#### 3.3.1 Context-Free Mention Resolution

If we resolve  $m$  out of its context, then we can compute  $p(c|m)$  by applying Bayes' rule as follows:

$$p(c|m) \approx p(c|l^m) = \frac{p(l^m|c) p(c)}{\sum_{c' \in C} p(l^m|c') p(c')}$$

All the terms above are estimated as discussed earlier in section 3.1. We call this approach "backoff" since it can be used as a fall-back strategy. It is considered the baseline approach in our experiments.

#### 3.3.2 Contextual Mention Resolution

We now discuss the more realistic situation in which we use the context to resolve  $m$ . By expanding the mention with its context, we get

$$p(c|m) = p(c|l^m, X(e^m))$$

We then apply Bayes' rule to get

$$p(c|l^m, X(e^m)) = \frac{p(c, l^m, X(e^m))}{p(l^m, X(e^m))}$$

where  $p(l^m, X(e^m))$  is the probability of observing  $l^m$  in the context. We can ignore this probability since it is constant across all candidates in our ranking. We now restrict our focus to the numerator  $p(c, l^m, X(e^m))$ , that is the probability that the sender chose to refer to  $c$  by  $l^m$  in the contextual space. As we discussed in section 3.2,  $X$  is defined as a mixture of contexts therefore we can further expand it as follows:

$$p(c, l^m, X(e^m)) = \sum_k \lambda_k p(c, l^m, x_k(e^m))$$

Following the intuitive generative scenario we introduced earlier, the context-specific probability can be decomposed as follows:

$$\begin{aligned} p(c, l^m, x_k(e^m)) &= p(c) \\ &\quad * p(x_k(e^m)|c) \\ &\quad * p(l^m|x_k(e^m), c) \end{aligned}$$

where  $p(c)$  is the probability of selecting a candidate  $c$ ,  $p(x_k(e^m)|c)$  is the probability of selecting  $x_k$  as an appropriate context to mention  $c$ , and  $p(l^m|x_k(e^m), c)$  is the probability of choosing to mention  $c$  by  $l^m$  given that  $x_k$  is the appropriate context.

**Choosing person to mention:**  $p(c)$  can be estimated as discussed in section 3.1.

**Choosing appropriate context:** By applying Bayes' rule to compute  $p(x_k(e^m)|c)$  we get

$$p(x_k(e^m)|c) = \frac{p(c|x_k(e^m)) p(x_k(e^m))}{p(c)}$$

$p(x_k(e^m))$  is the probability of choosing  $x_k$  to generally mention people. In our experiments, we assumed a uniform distribution over all contexts.  $p(c|x_k(e^m))$  is the probability of mentioning  $c$  in  $x_k(e^m)$ . Given that the context is defined as a distribution over emails, this can be expanded to

$$p(c|x_k(e^m)) = \sum_{e_i \in E} p(e_i|x_k(e^m)) p(c|e_i)$$

where  $p(c|e_i)$  is the probability that  $c$  is mentioned in the email  $e_i$ . This, in turn, can be estimated using the probability of referring to  $c$  by at least one unique reference observed in that email. By assuming that all lexical matches in the same email refer to the same person, and that all lexically-unique references are statistically independent, we can compute that probability as follows:

$$\begin{aligned} p(c|e_i) &= 1 - p(c \text{ is not mentioned in } e_i) \\ &= 1 - \prod_{m' \in M(e_i)} (1 - p(c|m')) \end{aligned}$$

where  $p(c|m')$  is the probability that  $c$  is the true referent of  $m'$ . This is the same general problem of resolving mentions, but now concerning a related mention  $m'$  found in the context of  $m$ . To handle this, there are two alternative solutions: (1) break the cycle and compute context-free resolution probabilities for those related mentions, or (2) jointly resolve all mentions. In this paper, we will only consider the first, leaving joint resolution for future work.

**Choosing a name-mention:** To estimate  $p(l^m|x_k(e^m), c)$ , we suggest that the email author would choose either to select a reference (or a modified version of a reference) that was previously mentioned in the context or just ignore the context. Hence, we estimate that probability as follows:

$$\begin{aligned} p(l^m|x_k(e^m), c) &= \alpha p(l^m \in x_k(e^m)|c) \\ &\quad + (1 - \alpha) p(l^m|c) \end{aligned}$$

where  $\alpha \in [0, 1]$  is a mixing parameter (set at 0.9 in our experiments), and  $p(l^m|c)$  is estimated as in section 3.1.  $p(l^m \in x_k(e^m)|c)$  can be estimated as follows:

$$\begin{aligned} p(l^m \in x_k(e^m)|c) &= \\ \sum_{m' \in x_k} p(l^m|l^{m'}) p(l^{m'}|x_k) p(c|l^{m'}) \end{aligned}$$

where  $p(l^m|l^{m'})$  is the probability of modifying  $l^{m'}$  into  $l^m$ . We assume all possible mentions of  $c$

are equally similar to  $m$  and estimate  $p(l^m|l^{m'})$  by  $\frac{1}{|\text{possible mentions of } c|} \cdot p(l^{m'}|x_k)$  is the probability of observing  $l^{m'}$  in  $x_k$ , which we estimate by its relative frequency in that context. Finally,  $p(c|l^{m'})$  is again a mention resolution problem concerning the reference  $r_i$  which can be resolved as shown earlier.

The Aho-Corasick linear-time algorithm (Aho and Corasick, 1975) is used to find mentions of names, using a corpus-based dictionary that includes all names, nicknames, and email addresses extracted in the preprocessing step.

## 4 Experimental Evaluation

We evaluate our mention resolution approach using four test collections, all are based on the CMU version of the Enron collection; each was created by selecting a subset of that collection, selecting a set of query-mentions within emails from that subset, and creating an answer key in which each query-mention is associated with a single email address.

The first two test collections were created by Minkov et al (Minkov et al., 2006). These test collections correspond to two email accounts, “sager-e” (the “Sager” collection) and “shapiro-r” (the “Shapiro” collection). Their mention-queries and answer keys were generated automatically by identifying name mentions that correspond uniquely to individuals referenced in the cc header, and eliminating that cc entry from the header.

The third test collection, which we call the “Enron-subset” is an extended version of the test collection created by Diehl et al (Diehl et al., 2006). Emails from all top-level folders were included in the collection, but only those that were both sent by and received by at least one email address of the form <name1>.<name2>@enron.com were retained. A set of 78 mention-queries were manually selected and manually associated with the email address of the true referent by the third author using an interactive search system developed specifically to support that task. The set of queries was limited to those that resolve to an address of the form <name1>.<name2>@enron.com. Names found in salutation or signature lines or that exactly match <name1> or <name2> of any of the email participants were not selected as query-mentions. Those 78 queries include the 54 used by Diehl et al.

Table 1: Test collections used in the experiments.

Test Coll.	Emails	IDs	Queries	Candidates
Sager	1,628	627	51	4 (1-11)
Shapiro	974	855	49	8 (1-21)
Enron-sub	54,018	27,340	78	152 (1-489)
Enron-all	248,451	123,783	78	518 (3-1785)

For our fourth test collection (“Enron-all”), we used the same 78 mention-queries and the answer key from the Enron-subset collection, but we used the full CMU version of the Enron collection (with duplicates removed). We use this collection to assess the scalability of our techniques.

Some descriptive statistics for each test collection are shown in Table 1. The Sager and Shapiro collections are typical of personal collections, while the other two represent organizational collections. These two types of collections differ markedly in the number of known identities and the candidate list sizes as shown in the table (the candidate list size is presented as an average over that collection’s mention-queries and as the full range of values).

#### 4.1 Evaluation Measures

There are two commonly used single-valued evaluation measures for “known item”-retrieval tasks. The “*Success @ 1*” measure characterizes the accuracy of one-best selection, computed as the mean across queries of the precision at the top rank for each query. For a single-valued figure of merit that considers every list position, we use “*Mean Reciprocal Rank*” (MRR), computed as the mean across queries of the inverse of the rank at which the correct referent is found.

#### 4.2 Results

There are four basic questions which we address in our experimental evaluation: (1) How does our approach perform compared to other approaches?, (2) How is it affected by the size of the collection and by increasing the time period?, (3) Which context makes the most important contribution to the resolution task? and (4) Does the mixture help?

In our experiments, we set the mixing coefficients  $\lambda_k$  and the context priors  $p(x_k)$  to a uniform distribution over all reconstructed contexts.

To compare our system performance with results

Table 2: Accuracy results with different time periods.

	Period (days)	MRR		Success @ 1	
		Prob.	Minkov	Prob.	Minkov
Sager	10	0.899	0.889	0.843	0.804
	100	<b>0.911</b>	0.889	<b>0.863</b>	0.804
	200	<b>0.911</b>	0.889	<b>0.863</b>	0.804
Shapiro	10	<b>0.913</b>	0.879	0.857	0.779
	100	0.910	0.879	0.837	0.779
	200	0.911	0.837	<b>0.878</b>	0.779
Enron-sub	10	0.878	-	0.821	-
	100	<b>0.911</b>	-	<b>0.846</b>	-
	200	<b>0.911</b>	-	<b>0.846</b>	-
Enron-all	10	<b>0.890</b>	-	<b>0.821</b>	-
	100	0.888	-	<b>0.821</b>	-
	200	0.888	-	<b>0.821</b>	-

previously reported, we experimented with different (symmetric) time periods for selecting threads in the social and topical contexts. Three representative time periods, in days, were arbitrarily chosen: 10 (i.e., +/- 5) days, 100 (i.e., +/- 50) days, and 200 (i.e., +/- 100) days. In each case, the mention-email defines the center of this period.

A summary of our results (denoted by “Prob.”) are shown in Table 2 with the best results for each test collection highlighted in bold. The table also includes the results reported in Minkov et al (Minkov et al., 2006) for the small collections for comparison purposes.<sup>4</sup> Each score for our system was the best over all combinations of contexts for these collections and time periods. Given these scores, our results compare favorably with the previously reported results for both Sager and Shapiro collections.

Another notable thing about our results is that they seem to be good enough for practical applications. Specifically, our one-best selection (over all tried conditions) is correct at least 82% of the time over all collections, including the largest one. Of course, the Enron-focused selection of mention-queries in every case is an important caveat on these results; we do not yet know how well our techniques will hold up with less evidence, as might be the case for mentions of people from outside Enron.

It is encouraging that testing on the largest col-

<sup>4</sup>For the “Enron-subset” collection, we do not know which 54 mention-queries Diehl et al used in (Diehl et al., 2006)

lection (with all unrelated and thus noisy data) did not hurt the effectiveness much. For the three different time periods we tried, there was no systematic effect.

Figure 3: Individual contexts, period set to 100 days.

**Individual Contexts:** Our choice of contexts was motivated by intuition rather than experiments, so we also took this opportunity to characterize the contribution of each context to the results. We did that by setting some of the context mixing-coefficients to zero and leaving the others equally-weighted. Figure 3 shows the MRR achieved with each context. In that figure, the “backoff” curve indicates how well the simple context-free resolution would do. The difference between the two smallest and the two largest collections is immediately apparent—this backoff is remarkably effective for the smaller collections, and almost useless for the larger ones, suggesting that the two smaller collections are essentially much easier. The social context is clearly quite useful, more so than any other single context, for every collection. This tends to support our expectation that social networks can be as informative as content networks in email collections. The topical context also seems to be useful on its own. The conversational context is moderately useful on its own in the larger collections. The local context alone is not very informative for the larger collections.

**Mixture of Contexts:** The principal motivation for combining different types of contexts is that different sources may provide complementary evidence. To characterize that effect, we look at combinations of contexts. Figure 4 shows three such context combinations, anchored by the social context alone, with a 100-day window (the results for 10 and 200 day periods are similar). Reassuringly, adding more contexts (hence more evidence) turns out to be a rea-

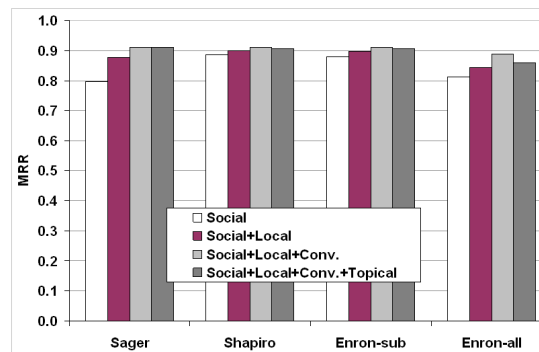

Figure 4: Mixture of contexts, period set to 100 days.

sonable choice in most cases. For the full combination, we notice a drop in the effectiveness from the addition of the topical context.<sup>5</sup> This suggests that the construction of the topical context may need more careful design, and/or that learned  $\lambda_k$ 's could yield better evidence combination (since these results were obtained with equal  $\lambda_k$ 's).

## 5 Conclusion

We have presented an approach to mention resolution in email that flexibly makes use of expanding contexts to accurately resolve the identity of a given mention. Our approach focuses on four naturally occurring contexts in email, including a message, a thread, other emails with senders and/or recipients in common, and other emails with significant topical content in common. Our approach outperforms previously reported techniques and it scales well to larger collections. Moreover, our results serve to highlight the importance of social context when resolving mentions in social media, which is an idea that deserves more attention generally. In future work, we plan to extend our test collection with mention queries that must be resolved in the “long tail” of the identity distribution where less evidence is available. We are also interested in exploring iterative approaches to jointly resolving mentions.

## Acknowledgments

The authors would like to thank Lise Getoor for her helpful advice.

<sup>5</sup>This also occurs even when topical context is combined with only social context.

## Abstract

Previous studies of data-driven dependency parsing have shown that the distribution of parsing errors are correlated with theoretical properties of the models used for learning and inference. In this paper, we show how these results can be exploited to improve parsing accuracy by integrating a graph-based and a transition-based model. By letting one model generate features for the other, we consistently improve accuracy for both models, resulting in a significant improvement of the state of the art when evaluated on data sets from the CoNLL-X shared task.

## 1 Introduction

Syntactic dependency graphs have recently gained a wide interest in the natural language processing community and have been used for many problems ranging from machine translation (Ding and Palmer, 2004) to ontology construction (Snow et al., 2005). A dependency graph for a sentence represents each word and its syntactic dependents through labeled directed arcs, as shown in figure 1. One advantage of this representation is that it extends naturally to discontinuous constructions, which arise due to long distance dependencies or in languages where syntactic structure is encoded in morphology rather than in word order. This is undoubtedly one of the reasons for the emergence of dependency parsers for a wide range of languages. Many of these parsers are based on data-driven parsing models, which learn to produce dependency graphs for sentences solely from an annotated corpus and can be easily ported to any

Figure 1: Dependency graph for an English sentence.

language or domain in which annotated resources exist.

Practically all data-driven models that have been proposed for dependency parsing in recent years can be described as either *graph-based* or *transition-based* (McDonald and Nivre, 2007). In graph-based parsing, we learn a model for scoring possible dependency graphs for a given sentence, typically by factoring the graphs into their component arcs, and perform parsing by searching for the highest-scoring graph. This type of model has been used by, among others, Eisner (1996), McDonald et al. (2005a), and Nakagawa (2007). In transition-based parsing, we instead learn a model for scoring transitions from one parser state to the next, conditioned on the parse history, and perform parsing by greedily taking the highest-scoring transition out of every parser state until we have derived a complete dependency graph. This approach is represented, for example, by the models of Yamada and Matsumoto (2003), Nivre et al. (2004), and Attardi (2006).

Theoretically, these approaches are very different. The graph-based models are globally trained and use exact inference algorithms, but define features over a limited history of parsing decisions. The transition-based models are essentially the opposite. They use local training and greedy inference algorithms, but

define features over a rich history of parsing decisions. This is a fundamental trade-off that is hard to overcome by tractable means. Both models have been used to achieve state-of-the-art accuracy for a wide range of languages, as shown in the CoNLL shared tasks on dependency parsing (Buchholz and Marsi, 2006; Nivre et al., 2007), but McDonald and Nivre (2007) showed that a detailed error analysis reveals important differences in the distribution of errors associated with the two models.

In this paper, we consider a simple way of integrating graph-based and transition-based models in order to exploit their complementary strengths and thereby improve parsing accuracy beyond what is possible by either model in isolation. The method integrates the two models by allowing the output of one model to define features for the other. This method is simple – requiring only the definition of new features – and robust by allowing a model to learn relative to the predictions of the other.

## 2 Two Models for Dependency Parsing

### 2.1 Preliminaries

Given a set  $L = \{l_1, \dots, l_{|L|}\}$  of arc labels (dependency relations), a dependency graph for an input sentence  $x = w_0, w_1, \dots, w_n$  (where  $w_0 = \text{ROOT}$ ) is a labeled directed graph  $G = (V, A)$  consisting of a set of nodes  $V = \{0, 1, \dots, n\}$ <sup>1</sup> and a set of labeled directed arcs  $A \subseteq V \times V \times L$ , i.e., if  $(i, j, l) \in A$  for  $i, j \in V$  and  $l \in L$ , then there is an arc from node  $i$  to node  $j$  with label  $l$  in the graph. A dependency graph  $G$  for a sentence  $x$  must be a directed tree originating out of the root node 0 and spanning all nodes in  $V$ , as exemplified by the graph in figure 1. This is a common constraint in many dependency parsing theories and their implementations.

### 2.2 Graph-Based Models

Graph-based dependency parsers parameterize a model over smaller substructures in order to search the space of valid dependency graphs and produce the most likely one. The simplest parameterization is the arc-factored model that defines a real-valued score function for arcs  $s(i, j, l)$  and further defines the score of a dependency graph as the sum of the

score of all the arcs it contains. As a result, the dependency parsing problem is written:

$$G = \arg \max_{G=(V,A)} \sum_{(i,j,l) \in A} s(i, j, l)$$

This problem is equivalent to finding the highest scoring directed spanning tree in the complete graph over the input sentence, which can be solved in  $O(n^2)$  time (McDonald et al., 2005b). Additional parameterizations are possible that take more than one arc into account, but have varying effects on complexity (McDonald and Satta, 2007). An advantage of graph-based methods is that tractable inference enables the use of standard structured learning techniques that globally set parameters to maximize parsing performance on the training set (McDonald et al., 2005a). The primary disadvantage of these models is that scores – and as a result any feature representations – are restricted to a single arc or a small number of arcs in the graph.

The specific graph-based model studied in this work is that presented by McDonald et al. (2006), which factors scores over pairs of arcs (instead of just single arcs) and uses near exhaustive search for unlabeled parsing coupled with a separate classifier to label each arc. We call this system MSTParser, or simply MST for short, which is also the name of the freely available implementation.<sup>2</sup>

### 2.3 Transition-Based Models

Transition-based dependency parsing systems use a model parameterized over transitions of an abstract machine for deriving dependency graphs, such that every transition sequence from the designated initial configuration to some terminal configuration derives a valid dependency graph. Given a real-valued score function  $s(c, t)$  (for transition  $t$  out of configuration  $c$ ), parsing can be performed by starting from the initial configuration and taking the optimal transition  $t^* = \arg \max_{t \in T} s(c, t)$  out of every configuration  $c$  until a terminal configuration is reached. This can be seen as a greedy search for the optimal dependency graph, based on a sequence of locally optimal decisions in terms of the transition system.

Many transition systems for data-driven dependency parsing are inspired by shift-reduce parsing,

<sup>1</sup>We use the common convention of representing words by their index in the sentence.

<sup>2</sup><http://mstparser.sourceforge.net>

where each configuration  $c$  contains a stack  $\sigma_c$  for storing partially processed nodes and a buffer  $\beta_c$  containing the remaining input. Transitions in such a system add arcs to the dependency graph and manipulate the stack and buffer. One example is the transition system defined by Nivre (2003), which parses a sentence  $x = w_0, w_1, \dots, w_n$  in  $O(n)$  time.

To learn a scoring function on transitions, these systems rely on discriminative learning methods, such as memory-based learning or support vector machines, using a strictly local learning procedure where only single transitions are scored (not complete transition sequences). The main advantage of these models is that features are not restricted to a limited number of graph arcs but can take into account the entire dependency graph built so far. The major disadvantage is that the greedy parsing strategy may lead to error propagation.

The specific transition-based model studied in this work is that presented by Nivre et al. (2006), which uses support vector machines to learn transition scores. We call this system MaltParser, or Malt for short, which is also the name of the freely available implementation.<sup>3</sup>

## 2.4 Comparison and Analysis

These models differ primarily with respect to three properties: *inference*, *learning*, and *feature representation*. MaltParser uses an inference algorithm that greedily chooses the best parsing decision based on the current parser history whereas MSTParser uses exhaustive search algorithms over the space of all valid dependency graphs to find the graph that maximizes the score. MaltParser trains a model to make a single classification decision (choose the next transition) whereas MSTParser trains a model to maximize the global score of correct graphs. MaltParser can introduce a rich feature history based on previous parser decisions, whereas MSTParser is forced to restrict features to a single decision or a pair of nearby decisions in order to retain efficiency.

These differences highlight an inherent trade-off between global inference/learning and expressiveness of feature representations. MSTParser favors the former at the expense of the latter and MaltParser the opposite. This difference was highlighted in the

study of McDonald and Nivre (2007), which showed that the difference is reflected directly in the error distributions of the parsers. Thus, MaltParser is less accurate than MSTParser for long dependencies and those closer to the root of the graph, but more accurate for short dependencies and those farthest away from the root. Furthermore, MaltParser is more accurate for dependents that are nouns and pronouns, whereas MSTParser is more accurate for verbs, adjectives, adverbs, adpositions, and conjunctions.

Given that there is a strong negative correlation between dependency length and tree depth, and given that nouns and pronouns tend to be more deeply embedded than (at least) verbs and conjunctions, these patterns can all be explained by the same underlying factors. Simply put, MaltParser has an advantage in its richer feature representations, but this advantage is gradually diminished by the negative effect of error propagation due to the greedy inference strategy as sentences and dependencies get longer. MSTParser has a more even distribution of errors, which is expected given that the inference algorithm and feature representation should not prefer one type of arc over another. This naturally leads one to ask: Is it possible to integrate the two models in order to exploit their complementary strengths? This is the topic of the remainder of this paper.

## 3 Integrated Models

There are many conceivable ways of combining the two parsers, including more or less complex ensemble systems and voting schemes, which only perform the integration at parsing time. However, given that we are dealing with data-driven models, it should be possible to integrate at learning time, so that the two complementary models can learn from one another. In this paper, we propose to do this by letting one model generate features for the other.

### 3.1 Feature-Based Integration

As explained in section 2, both models essentially learn a scoring function  $s : X \rightarrow \mathbb{R}$ , where the domain  $X$  is different for the two models. For the graph-based model,  $X$  is the set of possible dependency arcs  $(i, j, l)$ ; for the transition-based model,  $X$  is the set of possible configuration-transition pairs  $(c, t)$ . But in both cases, the input is represented

Table 1: Guide features for MST<sub>Malt</sub> and Malt<sub>MST</sub>.

by a  $k$ -dimensional feature vector  $\mathbf{f} : X \rightarrow \mathbb{R}^k$ . In the feature-based integration we simply extend the feature vector for one model, called the *base model*, with a certain number of features generated by the other model, which we call the *guide model* in this context. The additional features will be referred to as *guide features*, and the version of the base model trained with the extended feature vector will be called the *guided model*. The idea is that the guided model should be able to learn in which situations to trust the guide features, in order to exploit the complementary strength of the guide model, so that performance can be improved with respect to the base parser. This method of combining classifiers is sometimes referred to as *classifier stacking*.

The exact form of the guide features depend on properties of the base model and will be discussed in sections 3.2–3.3 below, but the overall scheme for the feature-based integration can be described as follows. To train a guided version  $B_C$  of base model  $B$  with guide model  $C$  and training set  $T$ , the guided model is trained, not on the original training set  $T$ , but on a version of  $T$  that has been parsed with the guide model  $C$  under a cross-validation scheme (to avoid overlap with training data for  $C$ ). This means that, for every sentence  $x \in T$ ,  $B_C$  has access at training time to both the gold standard dependency graph  $G_x$  and the graph  $G_x^C$  predicted by  $C$ , and it is the latter that forms the basis for the additional guide features. When parsing a new sentence  $x'$  with  $B_C$ ,  $x'$  is first parsed with model  $C$  (this time trained on the entire training set  $T$ ) to derive  $G_{x'}^C$ , so that the guide features can be extracted also at parsing time.

### 3.2 The Guided Graph-Based Model

The graph-based model, MSTParser, learns a scoring function  $s(i, j, l) \in \mathbb{R}$  over labeled dependencies. More precisely, dependency arcs (or pairs of arcs) are first represented by a high dimensional feature vector  $\mathbf{f}(i, j, l) \in \mathbb{R}^k$ , where  $\mathbf{f}$  is typically a binary feature vector over properties of the arc as well as the surrounding input (McDonald et al., 2005a; McDonald et al., 2006). The score of an arc is defined as a linear classifier  $s(i, j, l) = \mathbf{w} \cdot \mathbf{f}(i, j, l)$ , where  $\mathbf{w}$  is a vector of feature weights to be learned by the model.

For the guided graph-based model, which we call MST<sub>Malt</sub>, this feature representation is modified to include an additional argument  $G_x^{\text{Malt}}$ , which is the dependency graph predicted by MaltParser on the input sentence  $x$ . Thus, the new feature representation will map an arc *and* the entire predicted MaltParser graph to a high dimensional feature representation,  $\mathbf{f}(i, j, l, G_x^{\text{Malt}}) \in \mathbb{R}^{k+m}$ . These  $m$  additional features account for the guide features over the MaltParser output. The specific features used by MST<sub>Malt</sub> are given in table 1. All features are conjoined with the part-of-speech tags of the words involved in the dependency to allow the guided parser to learn weights relative to different surface syntactic environments. Though MSTParser is capable of defining features over pairs of arcs, we restrict the guide features over single arcs as this resulted in higher accuracies during preliminary experiments.

### 3.3 The Guided Transition-Based Model

The transition-based model, MaltParser, learns a scoring function  $s(c, t) \in \mathbb{R}$  over configurations and transitions. The set of training instances for this learning problem is the set of pairs  $(c, t)$  such that  $t$  is the correct transition out of  $c$  in the transition sequence that derives the correct dependency graph  $G_x$  for some sentence  $x$  in the training set  $T$ . Each training instance  $(c, t)$  is represented by a feature vector  $\mathbf{f}(c, t) \in \mathbb{R}^k$ , where features are defined in terms of arbitrary properties of the configuration  $c$ , including the state of the stack  $\sigma_c$ , the input buffer  $\beta_c$ , and the partially built dependency graph  $G_c$ . In particular, many features involve properties of the two target tokens, the token on top of the stack  $\sigma_c$  ( $\sigma_c^0$ ) and the first token in the input buffer  $\beta_c$  ( $\beta_c^0$ ),

which are the two tokens that may become connected by a dependency arc through the transition out of  $c$ . The full set of features used by the base model MaltParser is described in Nivre et al. (2006).

For the guided transition-based model, which we call Malt<sub>MST</sub>, training instances are extended to triples  $(c, t, G_x^{\text{MST}})$ , where  $G_x^{\text{MST}}$  is the dependency graph predicted by the graph-based MSTParser for the sentence  $x$  to which the configuration  $c$  belongs. We define  $m$  additional guide features, based on properties of  $G_x^{\text{MST}}$ , and extend the feature vector accordingly to  $\mathbf{f}(c, t, G_x^{\text{MST}}) \in \mathbb{R}^{k+m}$ . The specific features used by Malt<sub>MST</sub> are given in table 1. Unlike MSTParser, features are not explicitly defined to conjoin guide features with part-of-speech features. These features are implicitly added through the polynomial kernel used to train the SVM.

## 4 Experiments

In this section, we present an experimental evaluation of the two guided models based on data from the CoNLL-X shared task, followed by a comparative error analysis including both the base models and the guided models. The data for the experiments are training and test sets for all thirteen languages from the CoNLL-X shared task on multilingual dependency parsing with training sets ranging in size from 29,000 tokens (Slovene) to 1,249,000 tokens (Czech). The test sets are all standardized to about 5,000 tokens each. For more information on the data sets, see Buchholz and Marsi (2006).

The guided models were trained according to the scheme explained in section 3, with two-fold cross-validation when parsing the training data with the guide parsers. Preliminary experiments suggested that cross-validation with more folds had a negligible impact on the results. Models are evaluated by their *labeled attachment score* (LAS) on the test set, i.e., the percentage of tokens that are assigned both the correct head and the correct label, using the evaluation software from the CoNLL-X shared task with default settings.<sup>4</sup> Statistical significance was assessed using Dan Bikel’s randomized parsing evaluation comparator with the default setting of 10,000 iterations.<sup>5</sup>

### 4.1 Results

Table 2 shows the results, for each language and on average, for the two base models (MST, Malt) and for the two guided models (MST<sub>Malt</sub>, Malt<sub>MST</sub>). First of all, we see that both guided models show a very consistent increase in accuracy compared to their base model, even though the extent of the improvement varies across languages from about half a percentage point (Malt<sub>MST</sub> on Chinese) up to almost four percentage points (Malt<sub>MST</sub> on Slovene).<sup>6</sup> It is thus quite clear that both models have the capacity to learn from features generated by the other model. However, it is also clear that the graph-based MST model shows a somewhat larger improvement, both on average and for all languages except Czech,

<sup>6</sup>The only exception to this pattern is the result for Malt<sub>MST</sub> on Swedish, where we see an unexpected drop in accuracy compared to the base model.

Figure 3: Dependency arc precision/recall relative to predicted/gold for (a) dependency length and (b) distance to root.

German, Portuguese and Slovene. Finally, given that the two base models had the previously best performance for these data sets, the guided models achieve a substantial improvement of the state of the art. While there is no statistically significant difference between the two base models, they are both outperformed by  $\text{Malt}_{\text{MST}}$  ( $p < 0.0001$ ), which in turn has significantly lower accuracy than  $\text{MST}_{\text{Malt}}$  ( $p < 0.0005$ ).

An extension to the models described so far would be to iteratively integrate the two parsers in the spirit of pipeline iteration (Hollingshead and Roark, 2007). For example, one could start with a Malt model, use it to train a guided  $\text{MST}_{\text{Malt}}$  model, then use that as the guide to train a  $\text{Malt}_{\text{MST}_{\text{Malt}}}$  model, etc. We ran such experiments, but found that accuracy did not increase significantly and in some cases decreased slightly. This was true regardless of which parser began the iterative process. In retrospect, this result is not surprising. Since the initial integration effectively incorporates knowledge from both parsing systems, there is little to be gained by adding additional parsers in the chain.

## 4.2 Analysis

The experimental results presented so far show that feature-based integration is a viable approach for improving the accuracy of both graph-based and transition-based models for dependency parsing, but they say very little about how the integration benefits

the two models and what aspects of the parsing process are improved as a result. In order to get a better understanding of these matters, we replicate parts of the error analysis presented by McDonald and Nivre (2007), where parsing errors are related to different structural properties of sentences and their dependency graphs. For each of the four models evaluated, we compute error statistics for labeled attachment over all twelve languages together.

Figure 2 shows accuracy in relation to sentence length, binned into ten-word intervals (1–10, 11–20, etc.). As expected, Malt and MST have very similar accuracy for short sentences but Malt degrades more rapidly with increasing sentence length because of error propagation (McDonald and Nivre, 2007). The guided models,  $\text{Malt}_{\text{MST}}$  and  $\text{MST}_{\text{Malt}}$ , behave in a very similar fashion with respect to each other but both outperform their base parser over the entire range of sentence lengths. However, except for the two extreme data points (0–10 and 51–60) there is also a slight tendency for  $\text{Malt}_{\text{MST}}$  to improve more for longer sentences and for  $\text{MST}_{\text{Malt}}$  to improve more for short sentences, which indicates that the feature-based integration allows one parser to exploit the strength of the other.

Figure 3(a) plots precision (top) and recall (bottom) for dependency arcs of different lengths (predicted arcs for precision, gold standard arcs for recall). With respect to recall, the guided models appear to have a slight advantage over the base mod-

Part of Speech	MST	MST <sub>Malt</sub>	Malt	Malt <sub>MST</sub>
Verb	82.6	<b>85.1</b> (2.5)	81.9	84.3 (2.4)
Noun	80.0	81.7 (1.7)	80.7	<b>81.9</b> (1.2)
Pronoun	88.4	<b>89.4</b> (1.0)	89.2	89.3 (0.1)
Adjective	89.1	<b>89.6</b> (0.5)	87.9	89.0 (1.1)
Adverb	78.3	<b>79.6</b> (1.3)	77.4	78.1 (0.7)
Adposition	69.9	<b>71.5</b> (1.6)	68.8	70.7 (1.9)
Conjunction	73.1	<b>74.9</b> (1.8)	69.8	72.5 (2.7)

Table 3: Accuracy relative to dependent part of speech (improvement in percentage points).

els for short and medium distance arcs. With respect to precision, however, there are two clear patterns. First, the graph-based models have better precision than the transition-based models when predicting long arcs, which is compatible with the results of McDonald and Nivre (2007). Secondly, both the guided models have better precision than their base model and, for the most part, also their guide model. In particular MST<sub>Malt</sub> outperforms MST and is comparable to Malt for short arcs. More interestingly, Malt<sub>MST</sub> outperforms both Malt and MST for arcs up to length 9, which provides evidence that Malt<sub>MST</sub> has learned specifically to trust the guide features from MST for longer dependencies. The reason that accuracy does not improve for dependencies of length greater than 9 is probably that these dependencies are too rare for Malt<sub>MST</sub> to learn from the guide parser in these situations.

Figure 3(b) shows precision (top) and recall (bottom) for dependency arcs at different distances from the root (predicted arcs for precision, gold standard arcs for recall). Again, we find the clearest patterns in the graphs for precision, where Malt has very low precision near the root but improves with increasing depth, while MST shows the opposite trend (McDonald and Nivre, 2007). Considering the guided models, it is clear that Malt<sub>MST</sub> improves in the direction of its guide model, with a 5-point increase in precision for dependents of the root and smaller improvements for longer distances. Similarly, MST<sub>Malt</sub> improves precision in the range where its base parser is inferior to Malt and for distances up to 4 has an accuracy comparable to or higher than its guide parser Malt. This again provides evidence that the guided parsers are learning from their guide models.

Table 3 gives the accuracy for arcs relative to de-

pendent part-of-speech. As expected, we see that MST does better than Malt for all categories except nouns and pronouns (McDonald and Nivre, 2007). But we also see that the guided models in all cases improve over their base parser and, in most cases, also over their guide parser. The general trend is that MST improves more than Malt, except for adjectives and conjunctions, where Malt has a greater disadvantage from the start and therefore benefits more from the guide features.

Considering the results for parts of speech, as well as those for dependency length and root distance, it is interesting to note that the guided models often improve even in situations where their base parsers are more accurate than their guide models. This suggests that the improvement is not a simple function of the raw accuracy of the guide model but depends on the fact that labeled dependency decisions interact in inference algorithms for both graph-based and transition-based parsing systems. Thus, if a parser can improve its accuracy on one class of dependencies, e.g., longer ones, then we can expect to see improvements on all types of dependencies – as we do.

The interaction between different decisions may also be part of the explanation why MST benefits more from the feature-based integration than Malt, with significantly higher accuracy for MST<sub>Malt</sub> than for Malt<sub>MST</sub> as a result. Since inference is global (or practically global) in the graph-based model, an improvement in one type of dependency has a good chance of influencing the accuracy of other dependencies, whereas in the transition-based model, where inference is greedy, some of these additional benefits will be lost because of error propagation. This is reflected in the error analysis in the following recurrent pattern: Where Malt does well, Malt<sub>MST</sub> does only slightly better. But where MST is good, MST<sub>Malt</sub> is often significantly better.

Another part of the explanation may have to do with the learning algorithms used by the systems. Although both Malt and MST use discriminative algorithms, Malt uses a batch learning algorithm (SVM) and MST uses an online learning algorithm (MIRA). If the original rich feature representation of Malt is sufficient to separate the training data, regularization may force the weights of the guided features to be small (since they are not needed at training time). On the other hand, an online learn-

ing algorithm will recognize the guided features as strong indicators early in training and give them a high weight as a result. Features with high weight early in training tend to have the most impact on the final classifier due to both weight regularization and averaging. This is in fact observed when inspecting the weights of  $MST_{\text{Malt}}$ .

## 5 Related Work

Combinations of graph-based and transition-based models for data-driven dependency parsing have previously been explored by Sagae and Lavie (2006), who report improvements of up to 1.7 percentage points over the best single parser when combining three transition-based models and one graph-based model for unlabeled dependency parsing, evaluated on data from the Penn Treebank. The combined parsing model is essentially an instance of the graph-based model, where arc scores are derived from the output of the different component parsers. Unlike the models presented here, integration takes place only at parsing time, not at learning time, and requires at least three different base parsers. The same technique was used by Hall et al. (2007) to combine six transition-based parsers in the best performing system in the CoNLL 2007 shared task.

Feature-based integration in the sense of letting a subset of the features for one model be derived from the output of a different model has been exploited for dependency parsing by McDonald (2006), who trained an instance of  $MSTParser$  using features generated by the parsers of Collins (1999) and Charniak (2000), which improved unlabeled accuracy by 1.7 percentage points, again on data from the Penn Treebank. In addition, feature-based integration has been used by Taskar et al. (2005), who trained a discriminative word alignment model using features derived from the IBM models, and by Florian et al. (2004), who trained classifiers on auxiliary data to guide named entity classifiers.

Feature-based integration also has points in common with co-training, which have been applied to syntactic parsing by Sarkar (2001) and Steedman et al. (2003), among others. The difference, of course, is that standard co-training is a weakly supervised method, where guide features *replace*, rather than *complement*, the gold standard annotation during

training. Feature-based integration is also similar to parse re-ranking (Collins, 2000), where one parser produces a set of candidate parses and a second-stage classifier chooses the most likely one. However, feature-based integration is not explicitly constrained to any parse decisions that the guide model might make and only the single most likely parse is used from the guide model, making it significantly more efficient than re-ranking.

Finally, there are several recent developments in data-driven dependency parsing, which can be seen as targeting the specific weaknesses of graph-based and transition-based models, respectively, though without integrating the two models. Thus, Nakagawa (2007) and Hall (2007) both try to overcome the limited feature scope of graph-based models by adding global features, in the former case using Gibbs sampling to deal with the intractable inference problem, in the latter case using a re-ranking scheme. For transition-based models, the trend is to alleviate error propagation by abandoning greedy, deterministic inference in favor of beam search with globally normalized models for scoring transition sequences, either generative (Titov and Henderson, 2007a; Titov and Henderson, 2007b) or conditional (Duan et al., 2007; Johansson and Nugues, 2007).

## 6 Conclusion

In this paper, we have demonstrated how the two dominant approaches to data-driven dependency parsing, graph-based models and transition-based models, can be integrated by letting one model learn from features generated by the other. Our experimental results show that both models consistently improve their accuracy when given access to features generated by the other model, which leads to a significant advancement of the state of the art in data-driven dependency parsing. Moreover, a comparative error analysis reveals that the improvements are largely predictable from theoretical properties of the two models, in particular the tradeoff between global learning and inference, on the one hand, and rich feature representations, on the other. Directions for future research include a more detailed analysis of the effect of feature-based integration, as well as the exploration of other strategies for integrating different parsing models.

## Abstract

Discriminative feature-based methods are widely used in natural language processing, but sentence parsing is still dominated by generative methods. While prior feature-based dynamic programming parsers have restricted training and evaluation to artificially short sentences, we present the first general, feature-rich discriminative parser, based on a conditional random field model, which has been successfully scaled to the full WSJ parsing data. Our efficiency is primarily due to the use of stochastic optimization techniques, as well as parallelization and chart prefiltering. On WSJ15, we attain a state-of-the-art F-score of 90.9%, a 14% relative reduction in error over previous models, while being two orders of magnitude faster. On sentences of length 40, our system achieves an F-score of 89.0%, a 36% relative reduction in error over a generative baseline.

## 1 Introduction

Over the past decade, feature-based discriminative models have become the tool of choice for many natural language processing tasks. Although they take much longer to train than generative models, they typically produce higher performing systems, in large part due to the ability to incorporate arbitrary, potentially overlapping features. However, constituency parsing remains an area dominated by generative methods, due to the computational complexity of the problem. Previous work on discriminative parsing falls under one of three approaches. One approach does discriminative reranking of the

$n$ -best list of a generative parser, still usually depending highly on the generative parser score as a feature (Collins, 2000; Charniak and Johnson, 2005). A second group of papers does parsing by a sequence of independent, discriminative decisions, either greedily or with use of a small beam (Ratnaparkhi, 1997; Henderson, 2004). This paper extends the third thread of work, where joint inference via dynamic programming algorithms is used to train models and to attempt to find the globally best parse. Work in this context has mainly been limited to use of artificially short sentences due to exorbitant training and inference times. One exception is the recent work of Petrov et al. (2007), who discriminatively train a grammar with latent variables and do not restrict themselves to short sentences. However their model, like the discriminative parser of Johnson (2001), makes no use of features, and effectively ignores the largest advantage of discriminative training. It has been shown on other NLP tasks that modeling improvements, such as the switch from generative training to discriminative training, usually provide much smaller performance gains than the gains possible from good feature engineering. For example, in (Lafferty et al., 2001), when switching from a generatively trained hidden Markov model (HMM) to a discriminatively trained, linear chain, conditional random field (CRF) for part-of-speech tagging, their error drops from 5.7% to 5.6%. When they add in only a small set of orthographic features, their CRF error rate drops considerably more to 4.3%, and their out-of-vocabulary error rate drops by more than half. This is further supported by Johnson (2001), who saw no parsing gains when switch-

ing from generative to discriminative training, and by Petrov et al. (2007) who saw only small gains of around 0.7% for their final model when switching training methods.

In this work, we provide just such a framework for training a feature-rich discriminative parser. Unlike previous work, we do not restrict ourselves to short sentences, but we do provide results both for training and testing on sentences of length  $\leq 15$  (WSJ15) and for training and testing on sentences of length  $\leq 40$ , allowing previous WSJ15 results to be put in context with respect to most modern parsing literature. Our model is a conditional random field based model. For a rule application, we allow arbitrary features to be defined over the rule categories, span and split point indices, and the words of the sentence. It is well known that constituent length influences parse probability, but PCFGs cannot easily take this information into account. Another benefit of our feature based model is that it effortlessly allows smoothing over previously unseen rules. While the rule may be novel, it will likely contain features which are not. Practicality comes from three sources. We made use of stochastic optimization methods which allow us to find optimal model parameters with very few passes through the data. We found no difference in parser performance between using stochastic gradient descent (SGD), and the more common, but significantly slower, L-BFGS. We also used limited parallelization, and prefiltering of the chart to avoid scoring rules which cannot tile into complete parses of the sentence. This speed-up does not come with a performance cost; we attain an F-score of 90.9%, a 14% relative reduction in errors over previous work on WSJ15.

## 2 The Model

### 2.1 A Conditional Random Field Context Free Grammar (CRF-CFG)

Our parsing model is based on a conditional random field model, however, unlike previous TreeCRF work, e.g., (Cohn and Blunsom, 2005; Jousse et al., 2006), we do not assume a particular tree structure, and instead find the most likely structure *and* labeling. This is similar to conventional probabilistic context-free grammar (PCFG) parsing, with two exceptions: (a) we maximize *conditional* likelihood

of the parse tree, given the sentence, not *joint* likelihood of the tree and sentence; and (b) probabilities are normalized *globally* instead of *locally* – the graphical models depiction of our trees is undirected.

Formally, we have a CFG  $G$ , which consists of (Manning and Schütze, 1999): (i) a set of terminals  $\{w^k, k = 1, \dots, V\}$ ; (ii) a set of nonterminals  $\{N^k, k = 1, \dots, n\}$ ; (iii) a designated start symbol  $ROOT$ ; and (iv) a set of rules,  $\{\rho = N^i \rightarrow \zeta^j\}$ , where  $\zeta^j$  is a sequence of terminals and nonterminals. A PCFG additionally assigns probabilities to each rule  $\rho$  such that  $\forall i \sum_j P(N^i \rightarrow \zeta^j) = 1$ . Our conditional random field CFG (CRF-CFG) instead defines local clique potentials  $\phi(r|s; \theta)$ , where  $s$  is the sentence, and  $r$  contains a one-level subtree of a tree  $t$ , corresponding to a rule  $\rho$ , along with relevant information about the span of words which it encompasses, and, if applicable, the split position (see Figure 1). These potentials are relative to the sentence, unlike a PCFG where rule scores do not have access to words at the leaves of the tree, or even how many words they dominate. We then define a conditional probability distribution over entire trees, using the standard CRF distribution, shown in (1). There is, however, an important subtlety lurking in how we define the partition function. The partition function  $Z_s$ , which makes the probability of all possible parses sum to unity, is defined over all *structures* as well as all labelings of those structures. We define  $\tau(s)$  to be the set of all possible parse trees for the given sentence licensed by the grammar  $G$ .

$$P(t|s; \theta) = \frac{1}{Z_s} \prod_{r \in t} \phi(r|s; \theta) \quad (1)$$

where

$$Z_s = \sum_{t \in \tau(s)} \prod_{r \in t} \phi(r|s; \theta)$$

The above model is not well-defined over all CFGs. Unary rules of the form  $N^i \rightarrow N^j$  can form cycles, leading to infinite unary chains with infinite mass. However, it is standard in the parsing literature to transform grammars into a restricted class of CFGs so as to permit efficient parsing. Binarization of rules (Earley, 1970) is necessary to obtain cubic parsing time, and closure of unary chains is required for finding total probability mass (rather than just best parses) (Stolcke, 1995). To address this issue, we define our model over a restricted class of

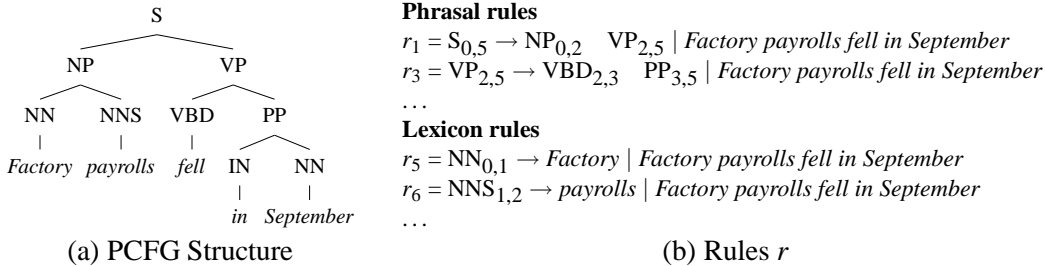

Figure 1: A parse tree and the corresponding rules over which potentials and features are defined.

CFGs which limits unary chains to not have any repeated states. This was done by collapsing all allowed unary chains to single unary rules, and disallowing multiple unary rule applications over the same span.<sup>1</sup> We give the details of our binarization scheme in Section 5. Note that there exists a grammar in this class which is weakly equivalent with any arbitrary CFG.

## 2.2 Computing the Objective Function

Our clique potentials take an exponential form. We have a feature function, represented by  $f(r, s)$ , which returns a vector with the value for each feature. We denote the value of feature  $f_i$  by  $f_i(r, s)$  and our model has a corresponding parameter  $\theta_i$  for each feature. The clique potential function is then:

$$\phi(r|s; \theta) = \exp \sum_i \theta_i f_i(r, s) \quad (2)$$

The log conditional likelihood of the training data  $\mathcal{D}$ , with an additional  $L_2$  regularization term, is then:

$$\mathcal{L}(\mathcal{D}; \theta) = \left( \sum_{(t,s) \in \mathcal{D}} \left( \sum_{r \in \mathcal{R}} \sum_i \theta_i f_i(r, s) \right) - Z_s \right) + \sum_i \frac{\theta_i^2}{2\sigma^2} \quad (3)$$

And the partial derivatives of the log likelihood, with respect to the model weights are, as usual, the difference between the empirical counts and the model expectations:

$$\frac{\partial \mathcal{L}}{\partial \theta_i} = \left( \sum_{(t,s) \in \mathcal{D}} \left( \sum_{r \in \mathcal{R}} f_i(r, s) \right) - E_{\theta} [f_i|s] \right) + \frac{\theta_i}{\sigma^2} \quad (4)$$

<sup>1</sup>In our implementation of the inside-outside algorithm, we then need to keep two inside and outside scores for each span: one from before and one from after the application of unary rules.

The partition function  $Z_s$  and the partial derivatives can be efficiently computed with the help of the inside-outside algorithm.<sup>2</sup>  $Z_s$  is equal to the inside score of *ROOT* over the span of the entire sentence. To compute the partial derivatives, we walk through each rule, and span/split, and add the outside log-score of the parent, the inside log-score(s) of the child(ren), and the log-score for that rule and span/split.  $Z_s$  is subtracted from this value to get the normalized log probability of that rule in that position. Using the probabilities of each rule application, over each span/split, we can compute the expected feature values (the second term in Equation 4), by multiplying this probability by the value of the feature corresponding to the weight for which we are computing the partial derivative. The process is analogous to the computation of partial derivatives in linear chain CRFs. The complexity of the algorithm for a particular sentence is  $O(n^3)$ , where  $n$  is the length of the sentence.

## 2.3 Parallelization

Unlike (Taskar et al., 2004), our algorithm has the advantage of being easily parallelized (see footnote 7 in their paper). Because the computation of both the log likelihood and the partial derivatives involves summing over each tree individually, the computation can be parallelized by having many clients which each do the computation for one tree, and one central server which aggregates the information to compute the relevant information for a set of trees. Because we use a stochastic optimization method, as discussed in Section 3, we compute the objective for only a small portion of the training data at a time, typically between 15 and 30 sentences. In

<sup>2</sup>In our case the values in the chart are the clique potentials which are non-negative numbers, but not probabilities.

this case the gains from adding additional clients decrease rapidly, because the computation time is dominated by the longest sentences in the batch.

## 2.4 Chart Prefiltering

Training is also sped up by prefiltering the chart. On the inside pass of the algorithm one will see many rules which cannot actually be tiled into complete parses. In standard PCFG parsing it is not worth figuring out which rules are viable at a particular chart position and which are not. In our case however this can make a big difference. We are not just looking up a score for the rule, but must compute all the features, and dot product them with the feature weights, which is far more time consuming. We also have to do an outside pass as well as an inside one, which is sped up by not considering impossible rule applications. Lastly, we iterate through the data multiple times, so if we can compute this information just once, we will save time on all subsequent iterations on that sentence. We do this by doing an inside-outside pass that is just boolean valued to determine which rules are possible at which positions in the chart. We simultaneously compute the features for the possible rules and then save the entire data structure to disk. For all but the shortest of sentences, the disk I/O is easily worth the time compared to re-computation. The first time we see a sentence this method is still about one third faster than if we did not do the prefiltering, and on subsequent iterations the improvement is closer to tenfold.

## 3 Stochastic Optimization Methods

Stochastic optimization methods have proven to be extremely efficient for the training of models involving computationally expensive objective functions like those encountered with our task (Vishwanathan et al., 2006) and, in fact, the on-line backpropagation learning used in the neural network parser of Henderson (2004) is a form of stochastic gradient descent. Standard deterministic optimization routines such as L-BFGS (Liu and Nocedal, 1989) make little progress in the initial iterations, often requiring several passes through the data in order to satisfy sufficient descent conditions placed on line searches. In our experiments SGD converged to a lower objective function value than L-BFGS, however it required far

Figure 2: WSJ15 objective value for L-BFGS and SGD versus passes through the data. SGD ultimately converges to a lower objective value, but does equally well on test data.

fewer iterations (see Figure 2) and achieved comparable test set performance to L-BFGS in a fraction of the time. One early experiment on WSJ15 showed a seven time speed up.

### 3.1 Stochastic Function Evaluation

Utilization of stochastic optimization routines requires the implementation of a stochastic objective function. This function,  $\hat{\mathcal{L}}$  is designed to approximate the true function  $\mathcal{L}$  based off a small subset of the training data represented by  $\mathcal{D}_b$ . Here  $b$ , the batch size, means that  $\mathcal{D}_b$  is created by drawing  $b$  training examples, with replacement, from the training set  $\mathcal{D}$ . With this notation we can express the stochastic evaluation of the function as  $\hat{\mathcal{L}}(\mathcal{D}_b; \theta)$ . This stochastic function must be designed to ensure that:

$$\mathbb{E} \left[ \sum_i^n \hat{\mathcal{L}}(\mathcal{D}_b^{(i)}; \theta) \right] = \mathcal{L}(\mathcal{D}; \theta)$$

Note that this property is satisfied, without scaling, for objective functions that sum over the training data, as it is in our case, but any priors must be scaled down by a factor of  $b/|\mathcal{D}|$ . The stochastic gradient,  $\nabla \hat{\mathcal{L}}(\mathcal{D}_b^{(i)}; \theta)$ , is then simply the derivative of the stochastic function value.

### 3.2 Stochastic Gradient Descent

SGD was implemented using the standard update:

$$\theta_{k+1} = \theta_k - \eta_k \nabla \mathcal{L}(\mathcal{D}_b^{(k)}; \theta_k)$$

And employed a gain schedule in the form

$$\eta_k = \eta_0 \frac{\tau}{\tau + k}$$

where parameter  $\tau$  was adjusted such that the gain is halved after five passes through the data. We found that an initial gain of  $\eta_0 = 0.1$  and batch size between 15 and 30 was optimal for this application.

## 4 Features

As discussed in Section 5 we performed experiments on both sentences of length  $\leq 15$  and length  $\leq 40$ . All feature development was done on the length 15 corpus, due to the substantially faster train and test times. This has the unfortunate effect that our features are optimized for shorter sentences and less training data, but we found development on the longer sentences to be infeasible. Our features are divided into two types: *lexicon features*, which are over words and tags, and *grammar features* which are over the local subtrees and corresponding span/split (both have access to the entire sentence). We ran two kinds of experiments: a discriminatively trained model, which used only the rules and no other grammar features, and a feature-based model which did make use of grammar features. Both models had access to the lexicon features. We viewed this as equivalent to the more elaborate, smoothed unknown word models that are common in many PCFG parsers, such as (Klein and Manning, 2003; Petrov et al., 2006).

We preprocessed the words in the sentences to obtain two extra pieces of information. Firstly, each word is annotated with a distributional similarity tag, from a distributional similarity model (Clark, 2000) trained on 100 million words from the British National Corpus and English Gigaword corpus. Secondly, we compute a class for each word based on the unknown word model of Klein and Manning (2003); this model takes into account capitalization, digits, dashes, and other character-level features. The full set of features, along with an explanation of our notation, is listed in Table 1.

## 5 Experiments

For all experiments, we trained and tested on the Penn treebank (PTB) (Marcus et al., 1993). We used

Model	States	Binary Rules	Unary Rules
WSJ15	1,428	5,818	423
WSJ15 relaxed	1,428	22,376	613
WSJ40	7,613	28,240	823

Table 2: Grammar size for each of our models.

the standard splits, training on sections 2 to 21, testing on section 23 and doing development on section 22. Previous work on (non-reranking) discriminative parsing has given results on sentences of length  $\leq 15$ , but most parsing literature gives results on either sentences of length  $\leq 40$ , or all sentences. To properly situate this work with respect to both sets of literature we trained models on both length  $\leq 15$  (WSJ15) and length  $\leq 40$  (WSJ40), and we also tested on all sentences using the WSJ40 models. Our results also provide a context for interpreting previous work which used WSJ15 and not WSJ40.

We used a relatively simple grammar with few additional annotations. Starting with the grammar read off of the training set, we added parent annotations onto each state, including the POS tags, resulting in rules such as  $S-ROOT \rightarrow NP-S VP-S$ . We also added head tag annotations to VPs, in the same manner as (Klein and Manning, 2003). Lastly, for the WSJ40 runs we used a simple, right branching binarization where each active state is annotated with its previous sibling and first child. This is equivalent to children of a state being produced by a second order Markov process. For the WSJ15 runs, each active state was annotated with only its first child, which is equivalent to a first order Markov process. See Table 5 for the number of states and rules produced.

### 5.1 Experiments

For both WSJ15 and WSJ40, we trained a generative model; a discriminative model, which used lexicon features, but no grammar features other than the rules themselves; and a feature-based model which had access to all features. For the length 15 data we also did experiments in which we relaxed the grammar. By this we mean that we added (previously unseen) rules to the grammar, as a means of smoothing. We chose which rules to add by taking existing rules and modifying the parent annotation on the parent of the rule. We used stochastic gradient descent for

Table 1: Lexicon and grammar features.  $w$  is the word and  $t$  the tag.  $r$  represents a particular rule along with span/split information;  $\rho$  is the rule itself,  $r_p$  is the parent of the rule;  $w_b$ ,  $w_s$ , and  $w_e$  are the first, first after the split (for binary rules) and last word that a rule spans in a particular context. All states, including the POS tags, are annotated with parent information;  $b(s)$  represents the base label for a state  $s$  and  $p(s)$  represents the parent annotation on state  $s$ .  $ds(w)$  represents the distributional similarity cluster, and  $lc(w)$  the lower cased version of the word, and  $unk(w)$  the unknown word class.

Lexicon Features	Grammar Features	
$t$		Binary-specific features
$b(t)$	$\rho$	$\langle b(p(r_p)), ds(w_{s-1}, ds w_s) \rangle$
$\langle t, w \rangle$	$\langle b(p(r_p)), ds(w_s) \rangle$	<b>PP feature:</b>
$\langle t, lc(w) \rangle$	$\langle b(p(r_p)), ds(w_e) \rangle$	if right child is a PP then $\langle r, w_s \rangle$
$\langle b(t), w \rangle$	<b>unary?</b>	<b>VP features:</b>
$\langle b(t), lc(w) \rangle$	<b>simplified rule:</b>	if some child is a verb tag, then rule,
$\langle t, ds(w) \rangle$	base labels of states	with that child replaced by the word
$\langle t, ds(w_{-1}) \rangle$	<b>dist sim bigrams:</b>	
$\langle t, ds(w_{+1}) \rangle$	all dist. sim. bigrams below	
$\langle b(t), ds(w) \rangle$	rule, and base parent state	
$\langle b(t), ds(w_{-1}) \rangle$	<b>dist sim bigrams:</b>	Unaries which span one word:
$\langle b(t), ds(w_{+1}) \rangle$	same as above, but trigrams	$\langle r, w \rangle$
$\langle p(t), w \rangle$	<b>heavy feature:</b>	$\langle r, ds(w) \rangle$
$\langle t, unk(w) \rangle$	whether the constituent is “big”	$\langle b(p(r)), w \rangle$
$\langle b(t), unk(w) \rangle$	as described in (Johnson, 2001)	$\langle b(p(r)), ds(w) \rangle$

these experiments; the length 15 models had a batch size of 15 and we allowed twenty passes through the data.<sup>3</sup> The length 40 models had a batch size of 30 and we allowed ten passes through the data. We used development data to decide when the models had converged. Additionally, we provide generative numbers for training on the entire PTB to give a sense of how much performance suffered from the reduced training data (*generative-all* in Table 4).

The full results for WSJ15 are shown in Table 3 and for WSJ40 are shown in Table 4. The WSJ15 models were each trained on a single Dual-Core AMD Opteron™ using three gigabytes of RAM and no parallelization. The discriminatively trained generative model (*discriminative* in Table 3) took approximately 12 minutes per pass through the data, while the feature-based model (*feature-based* in Table 3) took 35 minutes per pass through the data. The feature-based model with the relaxed grammar (*relaxed* in Table 3) took about four times as long as the regular feature-based model. The discrimina-

<sup>3</sup>Technically we did not make passes through the data, because we sampled with replacement to get our batches. By this we mean having seen as many sentences as are in the data, despite having seen some sentences multiple times and some not at all.

tively trained generative WSJ40 model (*discriminative* in Table 4) was trained using two of the same machines, with 16 gigabytes of RAM each for the clients.<sup>4</sup> It took about one day per pass through the data. The feature-based WSJ40 model (*feature-based* in Table 4) was trained using four of these machines, also with 16 gigabytes of RAM each for the clients. It took about three days per pass through the data.

## 5.2 Discussion

The results clearly show that gains came from both the switch from generative to discriminative training, and from the extensive use of features. In Figure 3 we show for an example from section 22 the parse trees produced by our generative model and our feature-based discriminative model, and the correct parse. The parse from the feature-based model better exhibits the right branching tendencies of English. This is likely due to the heavy feature, which encourages long constituents at the end of the sentence. It is difficult for a standard PCFG to learn this aspect of the English language, because the score it assigns to a rule does not take its span into account.

<sup>4</sup>The server does almost no computation.

## 6 Comparison With Related Work

The most similar related work is (Johnson, 2001), which did discriminative training of a generative PCFG. The model was quite similar to ours, except that it did not incorporate any features and it required the parameters (which were just scores for rules) to be locally normalized, as with a generatively trained model. Due to training time, they used the ATIS treebank corpus, which is much smaller than even WSJ15, with only 1,088 training sentences, 294 testing sentences, and an average sentence length of around 11. They found no significant difference in performance between their generatively and discriminatively trained parsers. There are two probable reasons for this result. The training set is very small, and it is a known fact that generative models tend to work better for small datasets and discriminative models tend to work better for larger datasets (Ng and Jordan, 2002). Additionally, they made no use of features, one of the primary benefits of discriminative learning.

Taskar et al. (2004) took a large margin approach to discriminative learning, but achieved only small gains. We suspect that this is in part due to the grammar that they chose – the grammar of (Klein and Manning, 2003), which was hand annotated with the intent of optimizing performance of a PCFG. This

grammar is fairly sparse – for any particular state there are, on average, only a few rules with that state as a parent – so the learning algorithm may have suffered because there were few options to discriminate between. Starting with this grammar we found it difficult to achieve gains as well. Additionally, their long training time (several months for WSJ15, according to (Turian and Melamed, 2006)) made feature engineering difficult; they were unable to really explore the space of possible features.

More recent is the work of (Turian and Melamed, 2006; Turian et al., 2007), which improved both the training time and accuracy of (Taskar et al., 2004). They define a simple linear model, use boosted decision trees to select feature conjunctions, and a line search to optimize the parameters. They use an agenda parser, and define their atomic features, from which the decision trees are constructed, over the entire state being considered. While they make extensive use of features, their setup is much more complex than ours and takes substantially longer to train – up to 5 days on WSJ15 – while achieving only small gains over (Taskar et al., 2004).

The most recent similar research is (Petrov et al., 2007). They also do discriminative parsing of length 40 sentences, but with a substantially different setup. Following up on their previous work (Petrov et al., 2006) on grammar splitting, they do discriminative

Figure 3: Example output from our generative and feature-based discriminative models, along with the correct parse.

parsing with latent variables, which requires them to optimize a non-convex function. Instead of using a stochastic optimization technique, they use L-BFGS, but do coarse-to-fine pruning to approximate their gradients and log likelihood. Because they were focusing on grammar splitting they, like (Johnson, 2001), did not employ any features, and, like (Taskar et al., 2004), they saw only small gains from switching from generative to discriminative training.

## 7 Conclusions

We have presented a new, feature-rich, dynamic programming based discriminative parser which is simpler, more effective, and faster to train and test than previous work, giving us new state-of-the-art performance when training and testing on sentences of length  $\leq 15$  and the first results for such a parser trained and tested on sentences of length  $\leq 40$ . We also show that the use of SGD for training CRFs performs as well as L-BFGS in a fraction of the time. Other recent work on discriminative parsing has neglected the use of features, despite their being one of the main advantages of discriminative training methods. Looking at how other tasks, such as named entity recognition and part-of-speech tagging, have evolved over time, it is clear that greater gains are to be gotten from developing better features than from better models. We have provided just such a framework for improving parsing performance.

## Acknowledgments

Many thanks to Teg Grenager and Paul Heymann for their advice (and their general awesomeness),

and to our anonymous reviewers for helpful comments.

## Abstract

We define a new formalism, based on Sikkel's parsing schemata for constituency parsers, that can be used to describe, analyze and compare dependency parsing algorithms. This abstraction allows us to establish clear relations between several existing projective dependency parsers and prove their correctness.

## 1 Introduction

Dependency parsing consists of finding the structure of a sentence as expressed by a set of directed links (dependencies) between words. This is an alternative to constituency parsing, which tries to find a division of the sentence into segments (constituents) which are then broken up into smaller constituents. Dependency structures directly show head-modifier and head-complement relationships which form the basis of predicate argument structure, but are not represented explicitly in constituency trees, while providing a representation in which no non-lexical nodes have to be postulated by the parser. In addition to this, some dependency parsers are able to represent non-projective structures, which is an important feature when parsing free word order languages in which discontinuous constituents are common.

The formalism of parsing schemata (Sikkel, 1997) is a useful tool for the study of constituency parsers since it provides formal, high-level descriptions of parsing algorithms that can be used to prove their formal properties (such as correctness), establish relations between them, derive new parsers from existing ones and obtain efficient implementations automatically (Gómez-Rodríguez et al., 2007). The formalism was initially defined for context-free grammars and later applied to other constituency-based formalisms, such as tree-adjointing grammars

(Alonso et al., 1999). However, since parsing schemata are defined as deduction systems over sets of constituency trees, they cannot be used to describe dependency parsers.

In this paper, we define an analogous formalism that can be used to define, analyze and compare dependency parsers. We use this framework to provide uniform, high-level descriptions for a wide range of well-known algorithms described in the literature, and we show how they formally relate to each other and how we can use these relations and the formalism itself to prove their correctness.

### 1.1 Parsing schemata

Parsing schemata (Sikkel, 1997) provide a formal, simple and uniform way to describe, analyze and compare different constituency-based parsers.

The notion of a parsing schema comes from considering parsing as a deduction process which generates intermediate results called *items*. An initial set of items is directly obtained from the input sentence, and the parsing process consists of the application of inference rules (*deduction steps*) which produce new items from existing ones. Each item contains a piece of information about the sentence's structure, and a successful parsing process will produce at least one *final item* containing a full parse tree for the sentence or guaranteeing its existence.

Items in parsing schemata are formally defined as sets of partial parse trees from a set denoted  $Trees(G)$ , which is the set of all the possible partial parse trees that do not violate the constraints imposed by a grammar  $G$ . More formally, an item set  $\mathcal{I}$  is defined by Sikkel as a quotient set associated with an equivalence relation on  $Trees(G)$ .<sup>1</sup>

Valid parses for a string are represented by items containing complete *marked parse trees* for that string. Given a context-free grammar  $G =$

\*Partially supported by Ministerio de Educación y Ciencia and FEDER (TIN2004-07246-C03, HUM2007-66607-C04), Xunta de Galicia (PGIDIT07SIN005206PR, PGIDIT05PXIC-10501PN, PGIDIT05PXIC30501PN, Rede Galega de Proc. da Linguaxe e RI) and Programa de Becas FPU.

<sup>1</sup>While Shieber et al. (1995) also view parsers as deduction systems, Sikkel formally defines items and related concepts, providing the mathematical tools to reason about formal properties of parsers.

$(N, \Sigma, P, S)$ , a *marked parse tree* for a string  $w_1 \dots w_n$  is any tree  $\tau \in \text{Trees}(G)/\text{root}(\tau) = S \wedge \text{yield}(\tau) = w_1 \dots w_n$ <sup>2</sup>. An item containing such a tree for some arbitrary string is called a *final item*. An item containing such a tree for a particular string  $w_1 \dots w_n$  is called a *correct final item* for that string.

For each input string, a parsing schema's deduction steps allow us to infer a set of items, called *valid items* for that string. A parsing schema is said to be *sound* if all valid final items it produces for any arbitrary string are correct for that string. A parsing schema is said to be *complete* if all correct final items are valid. A *correct parsing schema* is one which is both sound and complete. A correct parsing schema can be used to obtain a working implementation of a parser by using deductive engines such as the ones described by Shieber et al. (1995) and Gómez-Rodríguez et al. (2007) to obtain all valid final items.

## 2 Dependency parsing schemata

Although parsing schemata were initially defined for context-free parsers, they can be adapted to different constituency-based grammar formalisms, by finding a suitable definition of  $\text{Trees}(G)$  for each particular formalism and a way to define deduction steps from its rules. However, parsing schemata are not directly applicable to dependency parsing, since their formal framework is based on constituency trees.

In spite of this problem, many of the dependency parsers described in the literature are constructive, in the sense that they proceed by combining smaller structures to form larger ones until they find a complete parse for the input sentence. Therefore, it is possible to define a variant of parsing schemata, where these structures can be defined as items and the strategies used for combining them can be expressed as inference rules. However, in order to define such a formalism we have to tackle some issues specific to dependency parsers:

- Traditional parsing schemata are used to define grammar-based parsers, in which the parsing process is guided by some set of rules which are used to license deduction steps: for example, an Earley *Predictor* step is tied to a particular grammar rule, and can only be executed if such a rule exists. Some dependency parsers are also grammar-

<sup>2</sup> $w_i$  is shorthand for the *marked terminal*  $(w_i, i)$ . These are used by Sikkil (1997) to link terminal symbols to string positions so that an input sentence can be represented as a set of trees which are used as initial items (hypotheses) for the deduction system. Thus, a sentence  $w_1 \dots w_n$  produces a set of hypotheses  $\{\{w_1(\underline{w}_1)\}, \dots, \{w_n(\underline{w}_n)\}\}$ .

Figure 1: Representation of a dependency structure with a tree. The arrows below the words correspond to its associated dependency graph.

based: for example, those described by Lombardo and Lesmo (1996), Barbero et al. (1998) and Kahane et al. (1998) are tied to the formalizations of dependency grammar using context-free like rules described by Hays (1964) and Gaifman (1965). However, many of the most widely used algorithms (Eisner, 1996; Yamada and Matsumoto, 2003) do not use a formal grammar at all. In these, decisions about which dependencies to create are taken individually, using probabilistic models (Eisner, 1996) or classifiers (Yamada and Matsumoto, 2003). To represent these algorithms as deduction systems, we use the notion of *D-rules* (Covington, 1990). D-rules take the form  $a \rightarrow b$ , which says that word  $b$  can have  $a$  as a dependent. Deduction steps in non-grammar-based parsers can be tied to the D-rules associated with the links they create. In this way, we obtain a representation of the semantics of these parsing strategies that is independent of the particular model used to take the decisions associated with each D-rule.

- The fundamental structures in dependency parsing are *dependency graphs*. Therefore, as items for constituency parsers are defined as sets of partial constituency trees, it is tempting to define items for dependency parsers as sets of partial dependency graphs. However, predictive grammar-based algorithms such as those of Lombardo and Lesmo (1996) and Kahane et al. (1998) have operations which postulate rules and cannot be defined in terms of dependency graphs, since they do not do any modifications to the graph. In order to make the formalism general enough to include these parsers, we define items in terms of sets of partial dependency *trees* as shown in Figure 1. Note that a dependency graph can always be extracted from such a tree.

- Some of the most popular dependency parsing algorithms, like that of Eisner (1996), work by connecting *spans* which can represent *disconnected* dependency graphs. Such spans cannot be represented by a single dependency tree. Therefore, our formalism allows items to be sets of *forests* of partial dependency trees, instead of sets of trees.

Taking these considerations into account, we define the concepts that we need to describe item sets for dependency parsers:

Let  $\Sigma$  be an alphabet of terminal symbols.

**Partial dependency trees:** We define the set of *partial dependency trees* (*D-trees*) as the set of finite trees where children of each node have a left-to-right ordering, each node is labelled with an element of  $\Sigma \cup (\Sigma \times \mathbb{N})$ , and the following conditions hold:

- All nodes labelled with marked terminals  $\underline{w}_i \in (\Sigma \times \mathbb{N})$  are leaves,
- Nodes labelled with terminals  $w \in \Sigma$  do not have more than one daughter labelled with a marked terminal, and if they have such a daughter node, it is labelled  $\underline{w}_i$  for some  $i \in \mathbb{N}$ ,
- Left siblings of nodes labelled with a marked terminal  $\underline{w}_k$  do not have any daughter labelled  $\underline{w}_j$  with  $j \geq k$ . Right siblings of nodes labelled with a marked terminal  $\underline{w}_k$  do not have any daughter labelled  $\underline{w}_j$  with  $j \leq k$ .

We denote the root node of a partial dependency tree  $t$  as  $root(t)$ . If  $root(t)$  has a daughter node labelled with a marked terminal  $\underline{w}_h$ , we will say that  $\underline{w}_h$  is the *head* of the tree  $t$ , denoted by  $head(t)$ . If all nodes labelled with terminals in  $t$  have a daughter labelled with a marked terminal,  $t$  is *grounded*.

**Relationship between trees and graphs:** Let  $t \in D\text{-trees}$  be a partial dependency tree;  $g(t)$ , its associated dependency graph, is a graph  $(V, E)$

- $V = \{\underline{w}_i \in (\Sigma \times \mathbb{N}) \mid \underline{w}_i \text{ is the label of a node in } t\}$ ,
- $E = \{(\underline{w}_i, \underline{w}_j) \in (\Sigma \times \mathbb{N})^2 \mid C, D \text{ are nodes in } t \text{ such that } D \text{ is a daughter of } C, \underline{w}_j \text{ the label of a daughter of } C, \underline{w}_i \text{ the label of a daughter of } D\}$ .

**Projectivity:** A partial dependency tree  $t \in D\text{-trees}$  is *projective* iff  $yield(t)$  cannot be written as  $\dots \underline{w}_i \dots \underline{w}_j \dots$  where  $i \geq j$ .

It is easy to verify that the dependency graph  $g(t)$  is projective with respect to the linear order of marked terminals  $\underline{w}_i$ , according to the usual definition of projectivity found in the literature (Nivre, 2006), if and only if the tree  $t$  is projective.

**Parse tree:** A partial dependency tree  $t \in D\text{-trees}$  is a *parse tree* for a given string  $w_1 \dots w_n$  if its yield is a permutation of  $\underline{w}_1 \dots \underline{w}_n$ . If its yield is exactly  $\underline{w}_1 \dots \underline{w}_n$ , we will say it is a *projective parse tree* for the string.

**Item set:** Let  $\delta \subseteq D\text{-trees}$  be the set of dependency trees which are acceptable according to a given grammar  $G$  (which may be a grammar of D-rules or of CFG-like rules, as explained above). We

define an *item set* for dependency parsing as a set  $\mathcal{I} \subseteq \Pi$ , where  $\Pi$  is a partition of  $2^\delta$ .

Once we have this definition of an item set for dependency parsing, the remaining definitions are analogous to those in Sikkel’s theory of constituency parsing (Sikkel, 1997), so we will not include them here in full detail. A *dependency parsing system* is a deduction system  $(\mathcal{I}, H, D)$  where  $\mathcal{I}$  is a dependency item set as defined above,  $H$  is a set containing *initial items* or *hypotheses*, and  $D \subseteq (2^{H \cup \mathcal{I}} \times \mathcal{I})$  is a set of *deduction steps* defining an inference relation  $\vdash$ .

*Final items* in this formalism will be those containing some forest  $F$  containing a parse tree for some arbitrary string. An item containing such a tree for a particular string  $w_1 \dots w_n$  will be called a *correct final item* for that string in the case of nonprojective parsers. When defining projective parsers, correct final items will be those containing *projective* parse trees for  $w_1 \dots w_n$ . This distinction is relevant because the concepts of soundness and correctness of parsing schemata are based on correct final items (cf. section 1.1), and we expect correct projective parsers to produce only projective structures, while nonprojective parsers should find all possible structures including nonprojective ones.

### 3 Some practical examples

#### 3.1 Col96 (Collins, 96)

One of the most straightforward projective dependency parsing strategies is the one described by Collins (1996), directly based on the CYK parsing algorithm. This parser works with dependency trees which are linked to each other by creating links between their heads. Its item set is defined as  $\mathcal{I}_{Col96} = \{[i, j, h] \mid 1 \leq i \leq h \leq j \leq n\}$ , where an item  $[i, j, h]$  is defined as the set of forests containing a single projective dependency tree  $t$  such that  $t$  is grounded,  $yield(t) = \underline{w}_i \dots \underline{w}_j$  and  $head(t) = \underline{w}_h$ .

For an input string  $w_1 \dots w_n$ , the set of hypotheses is  $H = \{[i, i, i] \mid 0 \leq i \leq n + 1\}$ , i.e., the set of forests containing a single dependency tree of the form  $w_i(\underline{w}_i)$ . This same set of hypotheses can be used for all the parsers, so we will not make it explicit for subsequent schemata.<sup>3</sup>

The set of final items is  $\{[1, n, h] \mid 1 \leq h \leq n\}$ : these items trivially represent parse trees for the input sentence, where  $w_h$  is the sentence’s head. The deduction steps are shown in Figure 2.

<sup>3</sup>Note that the words  $w_0$  and  $w_{n+1}$  used in the definition do not appear in the input: these are dummy terminals that we will call beginning of sentence (BOS) and end of sentence (EOS) marker, respectively; and will be needed by some parsers.

Figure 2: Deduction steps of the parsing schemata for some well-known dependency parsers.

As we can see, we use D-rules as side conditions for deduction steps, since this parsing strategy is not grammar-based. Conceptually, the schema we have just defined describes a recogniser: given a set of D-rules and an input string  $w_1 \dots w_n$ , the sentence can be parsed (projectively) under those D-rules if and only if this deduction system can infer a correct final item. However, when executing this schema with a deductive engine, we can recover the parse forest by following back pointers in the same way as is done with constituency parsers (Billot and Lang, 1989).

Of course, boolean D-rules are of limited interest in practice. However, this schema provides a formalization of a parsing strategy which is independent of the way linking decisions are taken in a particular implementation. In practice, statistical models can be used to decide whether a step linking words  $a$  and  $b$  (i.e., having  $a \rightarrow b$  as a side condition) is executed or not, and probabilities can be attached to items in order to assign different weights to different analyses of the sentence. The same principle applies to the rest of D-rule-based parsers described in this paper.

### 3.2 Eis96 (Eisner, 96)

By counting the number of free variables used in each deduction step of Collins’ parser, we can conclude that it has a time complexity of  $O(n^5)$ . This complexity arises from the fact that a parentless word (head) may appear in any position in the partial results generated by the parser; the complexity can be reduced to  $O(n^3)$  by ensuring that parentless words can only appear at the first or last position of an item. This is the principle behind the parser defined by Eisner (1996), which is still in wide use today (Corston-Oliver et al., 2006; McDonald et al.,

2005a).

The item set for Eisner’s parsing schema is  $\mathcal{I}_{Eis96} = \{[i, j, T, F] \mid 0 \leq i \leq j \leq n\} \cup \{[i, j, F, T] \mid 0 \leq i \leq j \leq n\} \cup \{[i, j, F, F] \mid 0 \leq i \leq j \leq n\}$ , where each item  $[i, j, T, F]$  is defined as the item  $[i, j, j] \in \mathcal{I}_{Col96}$ , each item  $[i, j, F, T]$  is defined as the item  $[i, j, i] \in \mathcal{I}_{Col96}$ , and each item  $[i, j, F, F]$  is defined as the set of forests of the form  $\{t_1, t_2\}$  such that  $t_1$  and  $t_2$  are grounded,  $head(t_1) = \underline{w}_i$ ,  $head(t_2) = \underline{w}_j$ , and  $\exists k \in \mathbb{N}(i \leq k < j) / yield(t_1) = \underline{w}_i \dots \underline{w}_k \wedge yield(t_2) = \underline{w}_{k+1} \dots \underline{w}_j$ .

Note that the flags  $b, c$  in an item  $[i, j, b, c]$  indicate whether the words in positions  $i$  and  $j$ , respectively, have a parent in the item or not. Items with one of the flags set to  $T$  represent dependency trees where the word in position  $i$  or  $j$  is the head, while items with both flags set to  $F$  represent pairs of trees headed at positions  $i$  and  $j$ , and therefore correspond to disconnected dependency graphs.

Deduction steps<sup>4</sup> are shown in Figure 2. The set of final items is  $\{[0, n, F, T]\}$ . Note that these items represent dependency trees rooted at the BOS marker  $w_0$ , which acts as a “dummy head” for the sentence. In order for the algorithm to parse sentences correctly, we will need to define D-rules to allow  $w_0$  to be linked to the real sentence head.

### 3.3 ES99 (Eisner and Satta, 99)

Eisner and Satta (1999) define an  $O(n^3)$  parser for split head automaton grammars that can be used

<sup>4</sup>Alternatively, we could consider items of the form  $[i, i+1, F, F]$  to be hypotheses for this parsing schema, so we would not need an *Initter* step. However, we have chosen to use a standard set of hypotheses valid for all parsers because this allows for more straightforward proofs of relations between schemata.

for dependency parsing. This algorithm is conceptually simpler than Eis96, since it only uses items representing single dependency trees, avoiding items of the form  $[i, j, F, F]$ . Its item set is  $\mathcal{I}_{ES99} = \{[i, j, i] \mid 0 \leq i \leq j \leq n\} \cup \{[i, j, j] \mid 0 \leq i \leq j \leq n\}$ , where items are defined as in Collins’ parsing schema.

Deduction steps are shown in Figure 2, and the set of final items is  $\{[0, n, 0]\}$ . (Parse trees have  $w_0$  as their head, as in the previous algorithm).

Note that, when described for head automaton grammars as in Eisner and Satta (1999), this algorithm seems more complex to understand and implement than the previous one, as it requires four different kinds of items in order to keep track of the state of the automata used by the grammars. However, this abstract representation of its underlying semantics as a dependency parsing schema shows that this parsing strategy is in fact conceptually simpler for dependency parsing.

### 3.4 YM03 (Yamada and Matsumoto, 2003)

Yamada and Matsumoto (2003) define a deterministic, shift-reduce dependency parser guided by support vector machines, which achieves over 90% dependency accuracy on section 23 of the Penn treebank. Parsing schemata are not suitable for directly describing deterministic parsers, since they work at a high abstraction level where a set of operations are defined without imposing order constraints on them. However, many deterministic parsers can be viewed as particular optimisations of more general, nondeterministic algorithms. In this case, if we represent the actions of the parser as deduction steps while abstracting from the deterministic implementation details, we obtain an interesting nondeterministic parser.

Actions in Yamada and Matsumoto’s parser create links between two target nodes, which act as heads of neighbouring dependency trees. One of the actions creates a link where the left target node becomes a child of the right one, and the head of a tree located directly to the left of the target nodes becomes the new left target node. The other action is symmetric, performing the same operation with a right-to-left link. An  $O(n^3)$  nondeterministic parser generalising this behaviour can be defined by using an item set  $\mathcal{I}_{YM03} = \{[i, j] \mid 0 \leq i \leq j \leq n + 1\}$ , where each item  $[i, j]$  is defined as the item  $[i, j, F, F]$  in  $\mathcal{I}_{Eis96}$ ; and the deduction steps are shown in Figure 2.

The set of final items is  $\{[0, n + 1]\}$ . In order for this set to be well-defined, the grammar must have

no D-rules of the form  $w_i \rightarrow w_{n+1}$ , i.e., it must not allow the EOS marker to govern any words. If this is the case, it is trivial to see that every forest in an item of the form  $[0, n + 1]$  must contain a parse tree rooted at the BOS marker and with yield  $w_0 \dots w_n$ .

As can be seen from the schema, this algorithm requires less bookkeeping than any other of the parsers described here.

### 3.5 LL96 (Lombardo and Lesmo, 96) and other Earley-based parsers

The algorithms in the above examples are based on taking individual decisions about dependency links, represented by D-rules. Other parsers, such as that of Lombardo and Lesmo (1996), use grammars with context-free like rules which encode the preferred order of dependents for each given governor, as defined by Gaifman (1965). For example, a rule of the form  $N(Det * PP)$  is used to allow  $N$  to have  $Det$  as left dependent and  $PP$  as right dependent.

The algorithm by Lombardo and Lesmo (1996) is a version of Earley’s context-free grammar parser (Earley, 1970) using Gaifman’s dependency grammar, and can be written by using an item set  $\mathcal{I}_{LomLes} = \{[A(\alpha.\beta), i, j] \mid A(\alpha\beta) \in P \wedge 1 \leq i \leq j \leq n\}$ , where each item  $[A(\alpha.\beta), i, j]$  represents the set of partial dependency trees rooted at  $A$ , where the direct children of  $A$  are  $\alpha\beta$ , and the subtrees rooted at  $\alpha$  have yield  $w_i \dots w_j$ . The deduction steps for the schema are shown in Figure 2, and the final item set is  $\{[(S.), 1, n]\}$ .

As we can see, the schema for Lombardo and Lesmo’s parser resembles the Earley-style parser in Sikkil (1997), with some changes to adapt it to dependency grammar (for example, the *Scanner* always moves the dot over the head symbol \*).

Analogously, other dependency parsing schemata based on CFG-like rules can be obtained by modifying context-free grammar parsing schemata of Sikkil (1997) in a similar way. The algorithm by Barbero et al. (1998) can be obtained from the left-corner parser, and the one by Courtin and Genthial (1998) is a variant of the head-corner parser.

### 3.6 Pseudo-projectivity

Pseudo-projective parsers can generate non-projective analyses in polynomial time by using a projective parsing strategy and postprocessing the results to establish nonprojective links. For example, the algorithm by Kahane et al. (1998) uses a projective parsing strategy like that of LL96, but using the following initializer step instead of the

*Initter* and *Predictor*:<sup>5</sup>  

$$\text{Initter} \frac{}{[A(\alpha), i, i-1]} A(\alpha) \in P \wedge 1 \leq i \leq n$$

#### 4 Relations between dependency parsers

The framework of parsing schemata can be used to establish relationships between different parsing algorithms and to obtain new algorithms from existing ones, or derive formal properties of a parser (such as soundness or correctness) from the properties of related algorithms.

Sikkel (1994) defines several kinds of relations between schemata, which fall into two categories: *generalisation* relations, which are used to obtain more fine-grained versions of parsers, and *filtering* relations, which can be seen as the reverse of generalisation and are used to reduce the number of items and/or steps needed for parsing. He gives a formal definition of each kind of relation. Informally, a parsing schema can be generalised from another via the following transformations:

- Item refinement: We say that  $P_1 \xrightarrow{ir} P_2$  ( $P_2$  is an item refinement of  $P_1$ ) if there is a mapping between items in both parsers such that single items in  $P_1$  are broken into multiple items in  $P_2$  and individual deductions are preserved.
- Step refinement: We say that  $P_1 \xrightarrow{sr} P_2$  if the item set of  $P_1$  is a subset of that of  $P_2$  and every single deduction step in  $P_1$  can be emulated by a sequence of inferences in  $P_2$ .

On the other hand, a schema can be obtained from another by filtering in the following ways:

- Static/dynamic filtering:  $P_1 \xrightarrow{sf/df} P_2$  if the item set of  $P_2$  is a subset of that of  $P_1$  and  $P_2$  allows a subset of the direct inferences in  $P_1$ <sup>6</sup>.
- Item contraction: The inverse of item refinement.  $P_1 \xrightarrow{ic} P_2$  if  $P_2 \xrightarrow{ir} P_1$ .
- Step contraction: The inverse of step refinement.  $P_1 \xrightarrow{sc} P_2$  if  $P_2 \xrightarrow{sr} P_1$ .

All the parsers described in section 3 can be related via generalisation and filtering, as shown in Figure 3. For space reasons we cannot show formal proofs of all the relations, but we sketch the proofs for some of the more interesting cases:

<sup>5</sup>The initialization step as reported in Kahane’s paper is different from this one, as it directly consumes a nonterminal from the input. However, using this step results in an incomplete algorithm. The problem can be fixed either by using the step shown here instead (bottom-up Earley strategy) or by adding an additional step turning it into a bottom-up Left-Corner parser.

<sup>6</sup>Refer to Sikkel (1994) for the distinction between static and dynamic filtering, which we will not use here.

#### 4.1 YM03 $\xrightarrow{sr}$ Eis96

It is easy to see from the schema definitions that  $\mathcal{I}_{YM03} \subseteq \mathcal{I}_{Eis96}$ . In order to prove the relation between these parsers, we need to verify that every deduction step in YM03 can be emulated by a sequence of inferences in Eis96. In the case of the *Initter* step this is trivial, since the *Initters* of both parsers are equivalent. If we write the *R-Link* step in the notation we have used for Eisner items, we have *R-Link*  $\frac{[i, j, F, F] \quad [j, k, F, F]}{[i, k, F, F]} w_j \rightarrow w_k$

This can be emulated in Eisner’s parser by an *R-Link* step followed by a *CombineSpans* step:

$[j, k, F, F] \vdash [j, k, T, F]$  (by *R-Link*),

$[j, k, T, F], [i, j, F, F] \vdash [i, k, F, F]$  (by *CombineSpans*).

Symmetrically, the *L-Link* step in YM03 can be emulated by an *L-Link* followed by a *CombineSpans* in Eis96.

#### 4.2 ES99 $\xrightarrow{sr}$ Eis96

If we write the *R-Link* step in Eisner and Satta’s parser in the notation for Eisner items, we have *R-Link*  $\frac{[i, j, F, T] \quad [j+1, k, T, F]}{[i, k, T, F]} w_i \rightarrow w_k$

This inference can be emulated in Eisner’s parser as follows:

$\vdash [j, j+1, F, F]$  (by *Initter*),

$[i, j, F, T], [j, j+1, F, F] \vdash [i, j+1, F, F]$  (*CombineSpans*),

$[i, j+1, F, F], [j+1, k, T, F] \vdash [i, k, F, F]$  (*CombineSpans*),

$[i, k, F, F] \vdash [i, k, T, F]$  (by *R-Link*).

The proof corresponding to the *L-Link* step is symmetric. As for the *R-Combiner* and *L-Combiner* steps in ES99, it is easy to see that they are particular cases of the *CombineSpans* step in Eis96, and therefore can be emulated by a single application of *CombineSpans*.

Note that, in practice, the relations in sections 4.1 and 4.2 mean that the ES99 and YM03 parsers are superior to Eis96, since they generate fewer items and need fewer steps to perform the same deductions. These two parsers also have the interesting property that they use disjoint item sets (one uses items representing trees while the other uses items representing pairs of trees); and the union of these disjoint sets is the item set used by Eis96. Also note that the optimisation in YM03 comes from contracting deductions in Eis96 so that linking operations are immediately followed by combining operations; while ES99 does the opposite, forcing combining operations to be followed by linking operations.

#### 4.3 Other relations

If we generalise the linking steps in ES99 so that the head of each item can be in any position, we obtain a

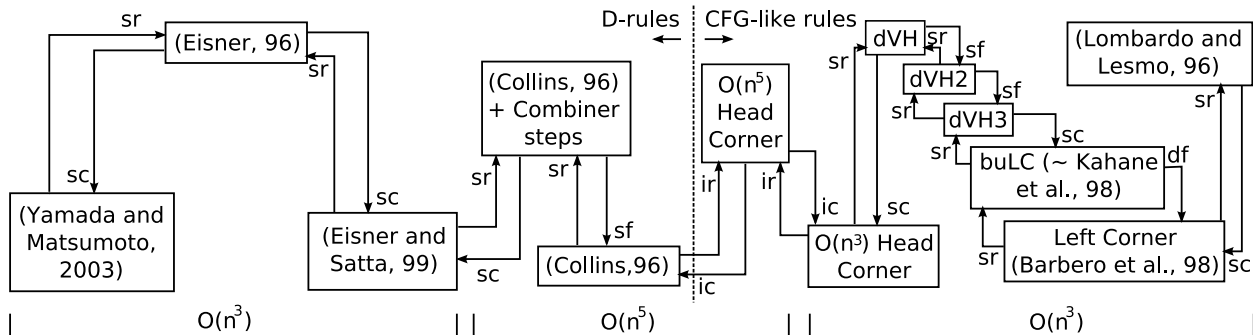

Figure 3: Formal relations between several well-known dependency parsers. Arrows going upwards correspond to generalisation relations, while those going downwards correspond to filtering. The specific subtype of relation is shown in each arrow’s label, following the notation in Section 4.

correct  $O(n^5)$  parser which can be filtered to Col96 just by eliminating the *Combiner* steps.

From Col96, we can obtain an  $O(n^5)$  head-corner parser based on CFG-like rules by an item refinement in which each Collins item  $[i, j, h]$  is split into a set of items  $[A(\alpha.\beta.\gamma), i, j, h]$ . Of course, the formal refinement relation between these parsers only holds if the D-rules used for Collins’ parser correspond to the CFG rules used for the head-corner parser: for every D-rule  $B \rightarrow A$  there must be a corresponding CFG-like rule  $A \rightarrow \dots B \dots$  in the grammar used by the head-corner parser.

Although this parser uses three indices  $i, j, h$ , using CFG-like rules to guide linking decisions makes the  $h$  indices unnecessary, so they can be removed. This simplification is an item contraction which results in an  $O(n^3)$  head-corner parser. From here, we can follow the procedure in Sikkel (1994) to relate this head-corner algorithm to parsers analogous to other algorithms for context-free grammars. In this way, we can refine the head-corner parser to a variant of de Vreught and Honig’s algorithm (Sikkel, 1997), and by successive filters we reach a left-corner parser which is equivalent to the one described by Barbero et al. (1998), and a step contraction of the Earley-based dependency parser LL96. The proofs for these relations are the same as those described in Sikkel (1994), except that the dependency variants of each algorithm are simpler (due to the absence of epsilon rules and the fact that the rules are lexicalised).

## 5 Proving correctness

Another useful feature of the parsing schemata framework is that it provides a formal way to define the correctness of a parser (see last paragraph of Section 1.1) which we can use to prove that our parsers are correct. Furthermore, relations between schemata can be used to derive the correctness of

a schema from that of related ones. In this section, we will show how we can prove that the YM03 and ES99 algorithms are correct, and use that fact to prove the correctness of Eis96.

### 5.1 ES99 is correct

In order to prove the correctness of a parser, we must prove its soundness and completeness (see section 1.1). Soundness is generally trivial to verify, since we only need to check that every individual deduction step in the parser infers a correct consequent item when applied to correct antecedents (i.e., in this case, that steps always generate non-empty items that conform to the definition in 3.3). The difficulty is proving completeness, for which we need to prove that all correct final items are valid (i.e., can be inferred by the schema). To show this, we will prove the stronger result that all correct items are valid.

We will show this by strong induction on the *length* of items, where the length of an item  $\iota = [i, k, h]$  is defined as  $length(\iota) = k - i + 1$ . Correct items of length 1 are the hypotheses of the schema (of the form  $[i, i, i]$ ) which are trivially valid. We will prove that, if all correct items of length  $m$  are valid for all  $1 \leq m < l$ , then items of length  $l$  are also valid.

Let  $[i, k, i]$  be an item of length  $l$  in  $\mathcal{I}_{ES99}$  (thus,  $l = k - i + 1$ ). If this item is correct, then it contains a grounded dependency tree  $t$  such that  $yield(t) = w_i \dots w_k$  and  $head(t) = w_i$ .

By construction, the root of  $t$  is labelled  $w_i$ . Let  $w_j$  be the rightmost daughter of  $w_i$  in  $t$ . Since  $t$  is projective, we know that the yield of  $w_j$  must be of the form  $w_l \dots w_k$ , where  $i < l \leq j \leq k$ . If  $l < j$ , then  $w_l$  is the leftmost transitive dependent of  $w_j$  in  $t$ , and if  $k > j$ , then we know that  $w_k$  is the rightmost transitive dependent of  $w_j$  in  $t$ .

Let  $t_j$  be the subtree of  $t$  rooted at  $w_j$ . Let  $t_1$  be the tree obtained from removing  $t_j$  from  $t$ . Let  $t_2$  be

the tree obtained by removing all the children to the right of  $w_j$  from  $t_j$ , and  $t_3$  be the tree obtained by removing all the children to the left of  $w_j$  from  $t_j$ . By construction,  $t_1$  belongs to a correct item  $[i, l - 1, i]$ ,  $t_2$  belongs to a correct item  $[l, j, j]$  and  $t_3$  belongs to a correct item  $[j, k, j]$ . Since these three items have a length strictly less than  $l$ , by the inductive hypothesis, they are valid. This allows us to prove that the item  $[i, k, i]$  is also valid, since it can be obtained from these valid items by the following inferences:

$[i, l - 1, i], [l, j, j] \vdash [i, j, i]$  (by the *L-Link* step),

$[i, j, i], [j, k, j] \vdash [i, k, i]$  (by the *L-Combiner* step).

This proves that all correct items of length  $l$  which are of the form  $[i, k, i]$  are correct under the inductive hypothesis. The same can be proved for items of the form  $[i, k, k]$  by symmetric reasoning, thus proving that the ES99 parsing schema is correct.

## 5.2 YM03 is correct

In order to prove correctness of this parser, we follow the same procedure as above. Soundness is again trivial to verify. To prove completeness, we use strong induction on the length of items, where the length of an item  $[i, j]$  is defined as  $j - i + 1$ .

The induction step is proven by considering any correct item  $[i, k]$  of length  $l > 2$  ( $l = 2$  is the base case here since items of length 2 are generated by the *Initter* step) and proving that it can be inferred from valid antecedents of length less than  $l$ , so it is valid. To show this, we note that, if  $l > 2$ , either  $w_i$  has at least a right dependent or  $w_k$  has at least a left dependent in the item. Supposing that  $w_i$  has a right dependent, if  $t_1$  and  $t_2$  are the trees rooted at  $w_i$  and  $w_k$  in a forest in  $[i, k]$ , we call  $w_j$  the rightmost daughter of  $w_i$  and consider the following trees:

$v$  = the subtree of  $t_1$  rooted at  $w_j$ ,  $u_1$  = the tree obtained by removing  $v$  from  $t_1$ ,  $u_2$  = the tree obtained by removing all children to the right of  $w_j$  from  $v$ ,  $u_3$  = the tree obtained by removing all children to the left of  $w_j$  from  $v$ .

We observe that the forest  $\{u_1, u_2\}$  belongs to the correct item  $[i, j]$ , while  $\{u_3, t_2\}$  belongs to the correct item  $[j, k]$ . From these two items, we can obtain  $[i, k]$  by using the *L-Link* step. Symmetric reasoning can be applied if  $w_i$  has no right dependents but  $w_k$  has at least a left dependent, and analogously to the case of the previous parser, we conclude that the YM03 parsing schema is correct.

## 5.3 Eis96 is correct

By using the previous proofs and the relationships between schemata that we explained earlier, it is easy to prove that Eis96 is correct: soundness is,

as always, straightforward, and completeness can be proven by using the properties of other algorithms. Since the set of final items in Eis96 and ES99 are the same, and the former is a step refinement of the latter, the completeness of ES99 directly implies the completeness of Eis96.

Alternatively, we can use YM03 to prove the correctness of Eis96 if we redefine the set of final items in the latter to be of the form  $[0, n + 1, F, F]$ , which are equally valid as final items since they always contain parse trees. This idea can be applied to transfer proofs of completeness across any refinement relation.

## 6 Conclusions

We have defined a variant of Sikkel's parsing schemata formalism which allows us to represent dependency parsing algorithms in a simple, declarative way<sup>7</sup>. We have clarified relations between parsers which were originally described very differently. For example, while Eisner presented his algorithm as a dynamic programming algorithm which combines spans into larger spans, Yamada and Matsumoto's works by sequentially executing parsing actions that move a focus point in the input one position to the left or right, (possibly) creating a dependency link. However, in the parsing schemata for these algorithms we can see (and formally prove) that they are related: one is a refinement of the other.

Parsing schemata are also a formal tool that can be used to prove the correctness of parsing algorithms. The relationships between dependency parsers can be exploited to derive properties of a parser from those of others, as we have seen in several examples.

Although the examples in this paper are centered in projective dependency parsing, the formalism does not require projectivity and can be used to represent nonprojective algorithms as well<sup>8</sup>. An interesting line for future work is to use relationships between schemata to find nonprojective parsers that can be derived from existing projective counterparts.

<sup>7</sup>An alternative framework that formally describes some dependency parsers is that of transition systems (McDonald and Nivre, 2007). This model is based on parser configurations and transitions, and has no clear relationship with the approach described here.

<sup>8</sup>Note that spanning tree parsing algorithms based on edge-factored models, such as the one by McDonald et al. (2005b) are not constructive in the sense outlined in Section 2, so the approach described here does not directly apply to them. However, other nonprojective parsers such as (Attardi, 2006) follow a constructive approach and can be analysed deductively.

# Evaluating a Crosslinguistic Grammar Resource: A Case Study of Wambaya

**Emily M. Bender**

University of Washington

Department of Linguistics

Box 354340

Seattle WA 98195-4340

ebender@u.washington.edu

## Abstract

This paper evaluates the LinGO Grammar Matrix, a cross-linguistic resource for the development of precision broad coverage grammars, by applying it to the Australian language Wambaya. Despite large typological differences between Wambaya and the languages on which the development of the resource was based, the Grammar Matrix is found to provide a significant jump-start in the creation of the grammar for Wambaya: With less than 5.5 person-weeks of development, the Wambaya grammar was able to assign correct semantic representations to 76% of the sentences in a naturally occurring text. While the work on Wambaya identified some areas of refinement for the Grammar Matrix, 59% of the Matrix-provided types were invoked in the final Wambaya grammar, and only 4% of the Matrix-provided types required modification.

## 1 Introduction

Hand-built grammars are often dismissed as too expensive to build on the one hand, and too brittle on the other. Nevertheless, they are key to various NLP applications, including those benefiting from deep natural language understanding (e.g., textual inference (Bobrow et al., 2007)), generation of well-formed output (e.g., natural language weather alert systems (Lareau and Wanner, 2007)) or both (as in machine translation (Oepen et al., 2007)). Of particular interest here are applications concerning endangered languages: Endangered languages represent a case of minimal linguistic resources, typically lacking even moderately-sized corpora, let alone

treebanks. In the best case, one finds well-crafted descriptive grammars, bilingual dictionaries, and a handful of translated texts. The methods of precision grammar engineering are well-suited to taking advantage of such resources. At the same time, the applications of interest in the context of endangered languages emphasize linguistic precision: implemented grammars can be used to enrich existing linguistic documentation, to build grammar checkers in the context of language standardization, and to create software language tutors in the context of language preservation efforts.

The LinGO Grammar Matrix (Bender et al., 2002; Bender and Flickinger, 2005; Drellishak and Bender, 2005) is a toolkit for reducing the cost of creating broad-coverage precision grammars by prepackaging both a cross-linguistic core grammar and a series of libraries of analyses of cross-linguistically variable phenomena, such as major-constituent word order or question formation. The Grammar Matrix was developed initially on the basis of broad-coverage grammars for English (Flickinger, 2000) and Japanese (Siegel and Bender, 2002), and has since been extended and refined as it has been used in the development of broad-coverage grammars for Norwegian (Hellan and Haugereid, 2003), Modern Greek (Kordoni and Neu, 2005), and Spanish (Marimon et al., 2007), as well as being applied to 42 other languages from a variety of language families in a classroom context (Bender, 2007).

This paper aims to evaluate both the utility of the Grammar Matrix in jump-starting precision grammar development and the current state of its cross-linguistic hypotheses through a case study of a

language typologically very different from any of the languages above: the non-Pama-Nyungan Australian language Wambaya (Nordlinger, 1998).

The remainder of this paper is structured as follows: §2 provides background on the Grammar Matrix and Wambaya, and situates the project with respect to related work. §3 presents the implemented grammar of Wambaya, describes its development, and evaluates it against unseen, naturally occurring text. §4 uses the Wambaya grammar and its development as one point of reference to measure the usefulness and cross-linguistic validity of the Grammar Matrix. §5 provides further discussion.

## 2 Background

### 2.1 The LinGO Grammar Matrix

The LinGO Grammar Matrix is situated theoretically within Head-Driven Phrase Structure Grammar (HPSG; Pollard and Sag, 1994), a lexicalist, constraint-based framework. Grammars in HPSG are expressed as a collection of typed feature structures which are arranged into a hierarchy such that information shared across multiple lexical entries or construction types is represented only on a single supertype. The Matrix is written in the TDL (type description language) formalism, which is interpreted by the LKB parser, generator, and grammar development environment (Copestake, 2002). It is compatible with the broader range of DELPH-IN tools, e.g., for machine translation (Lønning and Oepen, 2006), treebanking (Oepen et al., 2004) and parse selection (Toutanova et al., 2005).

The Grammar Matrix consists of a cross-linguistic core type hierarchy and a collection of phenomenon-specific libraries. The core type hierarchy defines the basic feature geometry, the ways that heads combine with arguments and adjuncts, linking types for relating syntactic to semantic arguments, and the constraints required to compositionally build up semantic representations in the format of Minimal Recursion Semantics (Copestake et al., 2005; Flickinger and Bender, 2003). The libraries provide collections of analyses for cross-linguistically variable phenomena. The current libraries include analyses of major constituent word order (SOV, SVO, etc), sentential negation, coordination, and yes-no question formation. The Matrix is accessed through

a web-based configuration system<sup>1</sup> which elicits typological information from the user-linguist through a questionnaire and then outputs a grammar consisting of the Matrix core plus selected types and constraints from the libraries according to the specifications in the questionnaire.

### 2.2 Wambaya

Wambaya is a recently extinct language of the West Barkly family from the Northern Territory in Australia (Nordlinger, 1998). Wambaya was selected for this project because of its typological properties and because it is extraordinarily well-documented by Nordlinger in her 1998 descriptive grammar.

Perhaps the most striking feature of Wambaya is its word order: it is a radically non-configurational language with a second position auxiliary/clitic cluster. That is, aside from the constraint that verbal clauses require a clitic cluster (marking subject and object agreement and tense, aspect and mood) in second position, the word order is otherwise free, to the point that noun phrases can be non-contiguous, with head nouns and their modifiers separated by unrelated words. Furthermore, head nouns are generally not required: argument positions can be instantiated by modifiers only, or, if the referent is clear from the context, by no nominal constituent of any kind. It has a rich system of case marking, and adnominal modifiers agree with the heads they modify in case, number, and four genders. An example is given in (1) (Nordlinger, 1998, 223).<sup>2</sup>

- (1) Ngaragana-nguja ngiy-a  
grog-PROP.IV.ACC 3.SG.NM.A-PST  
gujunganjanga-ni jiyawu ngabulu.  
mother.II.ERG give milk.IV.ACC  
'(His) mother gave (him) milk with grog in it.' [wmb]

In (1), *ngaragana-nguja* ('grog-proprietary', or 'having grog') is a modifier of *ngabulu* milk. They agree in case (accusative) and gender (class IV), but they are not contiguous within the sentence.

To relate such discontinuous noun phrases to appropriate semantic representations where 'having-

<sup>1</sup><http://www.delph-in.net/matrix/customize/matrix.cgi>

<sup>2</sup>In this example, the glosses II, IV, and NM indicate gender and ACC and ERG indicate case. A stands for 'agent', PST for 'past', and PROP for 'proprietary'.

grog' and 'milk' are predicated of the same entity requires a departure from the ordinary way that heads are combined with arguments and modifiers combined with heads in HPSG in general and in the Matrix in particular.<sup>3</sup> In the Grammar Matrix, as in most work in HPSG, lexical heads record the dependents they require in valence lists (SUBJ, COMPS, SPR). When a head combines with one of its arguments, the result is a phrase with the same valence requirements as the head daughter, minus the one corresponding to the argument that was just satisfied. In contrast, the project described here has explored a non-cancellation analysis for Wambaya: even after a head combines with one of its arguments, that argument remains on the appropriate valence list of the mother, so that it is visible for further combination with modifiers. In addition, heads can combine directly with modifiers of their arguments (as opposed to just modifiers of themselves).

Argument realization and the combination of heads and modifiers are fairly fundamental aspects of the system implemented in the Matrix. In light of the departure described above, it is interesting to see to what extent the Matrix can still support rapid development of a precision grammar for Wambaya.

### 2.3 Related Work

There are currently many multilingual grammar engineering projects under active development, including ParGram, (Butt et al., 2002; King et al., 2005), the MetaGrammar project (Kinyon et al., 2006), KPML (Bateman et al., 2005), Grammix (Müller, 2007) and OpenCCG (Baldrige et al., 2007). Among approaches to multilingual grammar engineering, the Grammar Matrix's distinguishing characteristics include the deployment of a shared core grammar for crosslinguistically consistent constraints and a series of libraries modeling varying linguistic properties. Thus while other work has successfully exploited grammar porting between typologically related languages (e.g., Kim et al., 2003), to my knowledge, no other grammar porting project has covered the same typological dis-

<sup>3</sup>A linearization-based analysis as suggested by Donohue and Sag (1999) for discontinuous constituents in Warlpiri (another Australian language), is not available, because it relies on disassociating the constituent structure from the surface order of words in a way that is not compatible with the TDL formalism.

tance attempted here. The current project is also situated within a broader trend of using computational linguistics in the service of endangered language documentation (e.g., Robinson et al., 2007, see also [www.emeld.org](http://www.emeld.org)).

## 3 Wambaya grammar

### 3.1 Development

The Wambaya grammar was developed on the basis of the grammatical description in Nordlinger 1998, including the Wambaya-English translation lexicon and glosses of individual example sentences. The development test suite consisted of all 794 distinct positive examples from Ch. 3–8 of the descriptive grammar. This includes elicited examples as well as (sometimes simplified) naturally occurring examples. They range in length from one to thirteen words (mean: 3.65). The test suite was extracted from the descriptive grammar at the beginning of the project and used throughout with only minor refinements as errors in formatting were discovered. The regression testing facilities of [incr tsdb()] allowed for rapid experimentation with alternative analyses as new phenomena were brought into the grammar (cf. Oepen et al., 2002).

With no prior knowledge of this language beyond its most general typological properties, we were able to develop in under 5.5 person-weeks of development time (210 hours) a grammar able to assign appropriate analyses to 91% of the examples in the development set.<sup>4</sup> The 210 hours include 25 hours of an RA's time entering lexical entries, 7 hours spent preparing the development test suite, and 15 hours treebanking (using the LinGO Redwoods software (Oepen et al., 2004) to annotate the intended parse for each item). The remainder of the time was ordinary grammar development work.<sup>5</sup>

In addition, this grammar has relatively low ambiguity, assigning on average 11.89 parses per item in the development set. This reflects the fact that the grammar is modeling grammaticality: the rules are

<sup>4</sup>An additional 6% received some analysis, but not one that matched the translation given in the reference grammar.

<sup>5</sup>These numbers do not include the time put into the original field work and descriptive grammar work. Nordlinger (p.c.) estimates that as roughly 28 linguist-months, plus the native speaker consultants' time.

meant to exclude ungrammatical strings as well as are unwarranted analyses of grammatical strings.

### 3.2 Scope

The grammar encodes mutually interoperable analyses of a wide variety of linguistic phenomena, including:

- Word order: second position clitic cluster, otherwise free word order, discontinuous noun phrases
- Argument optionality: argument positions with no overt head
- Linking of syntactic to semantic arguments
- Case: case assignment by verbs to dependents
- Agreement: subject and object agreement in person and number (and to some extent gender) marked in the clitic cluster, agreement between nouns and adnominal modifiers in case, number and gender
- Lexical adverbs, including manner, time, and location, and adverbs of negation, which vary by clause type (declarative, imperative, or interrogative)
- Derived event modifiers: nominals (nouns, adjectives, noun phrases) used as event modifiers with meaning dependent on their case marking
- Lexical adjectives, including demonstratives adverbs, numerals, and possessive adjectives, as well as ordinary intersective adjectives
- Derived nominal modifiers: modifiers of nouns derived from nouns, adjectives and verbs, including the proprietary, privative, and ‘origin’ constructions
- Subordinate clauses: clausal complements of verbs like “tell” and “remember”, non-finite subordinate clauses such as purposives (“in order to”) and clauses expressing prior or simultaneous events
- Verbless clauses: nouns, adjectives, and adverbs, lexical or derived, functioning as predicates
- Illocutionary force: imperatives, declaratives, and interrogatives (including *wh* questions)
- Coordination: of clauses and noun phrases
- Other: inalienable possession, secondary predicates, causatives of verbs and adjectives

### 3.3 Sample Analysis

This section provides a brief description of the analysis of radical non-configurationality in order to give a sense of the linguistic detail encoded in the Wambaya grammar and give context for the evaluation of the Wambaya grammar and the Grammar Matrix in later sections.

The linguistic analyses encoded in the grammar serve to map the surface strings to semantic representations (in Minimal Recursion Semantics (MRS) format (Copestake et al., 2005)). The MRS in Figure 1 is assigned to the example in (1).<sup>6</sup> It includes the basic propositional structure: a situation of ‘giving’ in which the first argument, or agent, is ‘mother’, the second (recipient) is some third-person entity, and the third (patient), is ‘milk’ which is also related to ‘grog’ through the proprietary relation. It is marked as past tense, and as potentially a statement or a question, depending on the intonation.<sup>7,8</sup>

A simple tree display of the parse giving rise to this MRS is given in Figure 2. The non-branching nodes at the bottom of the tree represent the lexical rules which associate morphosyntactic information with a word according to its suffixes. The general left-branching structure of the tree is a result of the analysis of the second-position clitic cluster: The clitic clusters are treated as argument-composition auxiliaries, which combine with a lexical verb and ‘inherit’ all of the verb’s arguments. The auxiliaries first pick up all dependents to the right, and then combine with exactly one constituent to the left.

The grammar is able to connect *x7* (the index of ‘milk’) to both the ARG3 position of the ‘give’ relation and the ARG1 position of the proprietary relation, despite the separation between *ngaraganaguja* (‘grog-PROP.IV.ACC’) and *ngabulu* (‘milk.IV.ACC’) in the surface structure, as follows: The auxiliary *ngiya* is subject to the constraints in (2), meaning that it combines with a verb as its first complement and then the verb’s complements as its remaining complements.<sup>9</sup> The auxiliary can combine with its complements in any order, thanks to a series of head-complement rules which realize the *n*th element of

<sup>6</sup>The grammar in fact finds 42 parses for this example. The one associated with the MRS in Figure 1 best matches the intended interpretation as indicated by the gloss of the example.

<sup>7</sup>The relations are given English predicate names for the convenience of the grammar developer, and these are not intended as any kind of interlingua.

<sup>8</sup>This MRS is ‘fragmented’ in the sense that the labels of several of the elementary predications (eps) are not related to any argument position of any other ep. This is related to the fact that the grammar doesn’t yet introduce quantifiers for any of the nominal arguments.

<sup>9</sup>In this and other attribute value matrices displayed, feature paths are abbreviated and detail not relevant to the current point is suppressed.

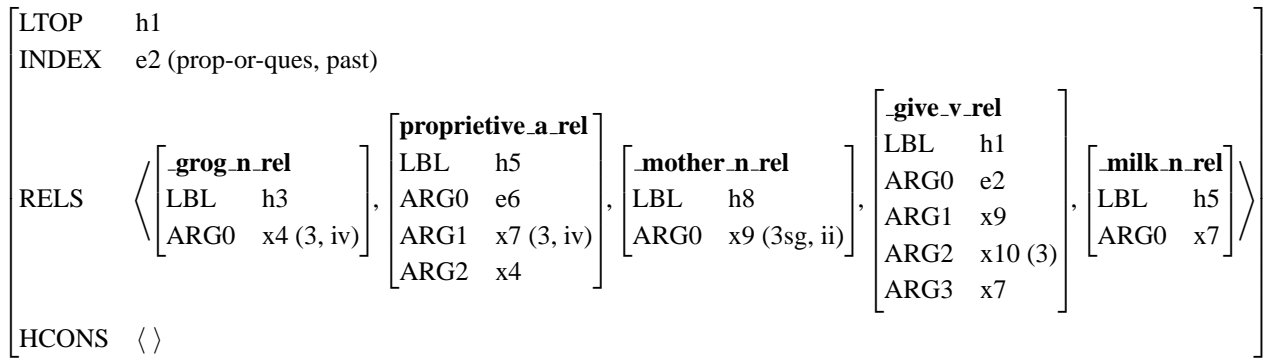

Figure 1: MRS for (1)

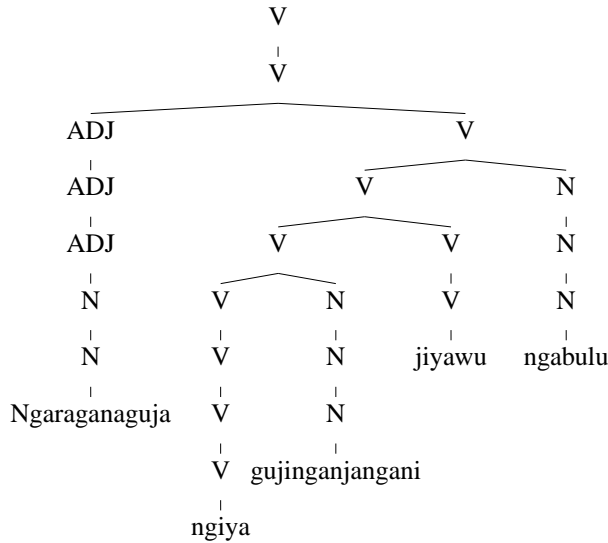

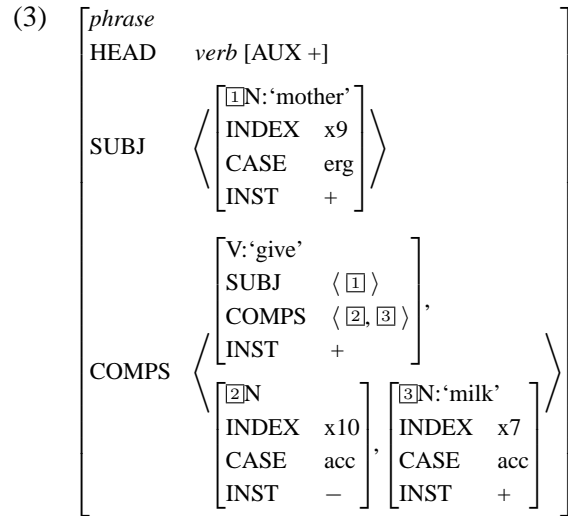

Figure 2: Phrase structure tree for (1)

the COMPS list. In this example, it first picks up the subject *gujunganjangani* (‘mother-ERG’), then the main verb *jiyawu* (‘give’), and then the object *ngabulu* (‘milk-ACC’).

The resulting V node over *ngiya gujunganjangani jiyawu ngabulu* is associated with the constraints sketched in (3).

Unlike in typical HPSG approaches, the information about the realized arguments is still exposed in the COMPS and SUBJ lists of this constituent.<sup>10</sup> This makes the necessary information available to separately-attaching modifiers (such as *ngaraganaguja* (‘grog-PROP.IV.ACC’)) so that they can check for case and number/gender compatibility and connect the semantic index of the argument they modify to a role in their own semantic contribution (in this case, the ARG1 of the ‘propriative’ relation).

### 3.4 Evaluation

The grammar was evaluated against a sample of naturally occurring data taken from one of the texts transcribed and translated by Nordlinger (1998) (‘The two Eaglehawks’, told by Molly Nurlanyma Grueman). Of the 92 sentences in this text, 20 overlapped with items in the development set, so the

<sup>10</sup>The feature INST, newly proposed for this analysis, records the fact that they have been instantiated by lexical heads.

	correct	parsed	unparsed	average
		incorrect		ambiguity
Existing vocab	50%	8%	42%	10.62
w/added vocab	<b>76%</b>	8%	14%	12.56

Table 1: Grammar performance on held-out data

evaluation was carried out only on the remaining 72 sentences. The evaluation was run twice: once with the grammar exactly as is, including the existing lexicon, and a second time after new lexical entries were added, using only existing lexical types. In some cases, the orthographic components of the lexical rules were also adjusted to accommodate the new lexical entries. In both test runs, the analyses of each test item were hand-checked against the translation provided by Nordlinger (1998). An item is counted as correctly analyzed if the set of analyses returned by the parser includes at least one with an MRS that matches the dependency structure, illocutionary force, tense, aspect, mood, person, number, and gender information indicated.

The results are shown in Table 1: With only lexical additions, the grammar was able to assign a correct parse to 55 (76%) of the test sentences, with an average ambiguity over these sentences of 12.56 parses/item.

### 3.5 Parse selection

The parsed portion of the development set (732 items) constitutes a sufficiently large corpus to train a parse selection model using the Redwoods disambiguation technology (Toutanova et al., 2005). As part of the grammar development process, the parses were annotated using the Redwoods parse selection tool (Oepen et al., 2004). The resulting treebank was used to select appropriate parameters by 10-fold cross-validation, applying the experimentation environment and feature templates of (Vellidal, 2007). The optimal feature set included 2-level grandparenting, 3-grams of lexical entry types, and both constituent weight features. In the cross-validation trials on the development set, this model achieved a parse selection accuracy of 80.2% (random choice baseline: 23.9%). A model with the same features was then trained on all 544 ambiguous examples

from the development set and used to rank the parses of the test set. It ranked the correct parse (exact match) highest in 75.0% of the test sentences. This is well above the random-choice baseline of 18.4%, and affirms the cross-linguistic validity of the parse-selection techniques.

### 3.6 Summary

This section has presented the Matrix-derived grammar of Wambaya, illustrating its semantic representations and analyses and measuring its performance against held-out data. I hope to have shown the grammar to be reasonably substantial, and thus an interesting case study with which to evaluate the Grammar Matrix itself.

## 4 Evaluation of Grammar Matrix

It is not possible to directly compare the development of a grammar for the same language, by the same grammar engineer, with and without the assistance of the Grammar Matrix. Therefore, in this section, I evaluate the usefulness of the Grammar Matrix by measuring the extent to which the Wambaya grammar as developed makes use of types defined in Matrix as well as the extent to which Matrix-defined types had to be modified. The former is in some sense a measure of the usefulness of the Matrix, and the latter is a measure of its correctness.

While the libraries and customization system were used in the initial grammar development, this evaluation primarily concerns itself with the Matrix core type hierarchy. The customization-provided Wambaya-specific type definitions for word order, lexical types, and coordination constructions were used for inspiration, but most needed fairly extensive modification. This is particularly unsurprising for basic word order, where the closest available option (“free word order”) was taken, in the absence of a pre-packaged analysis of non-configurationality and second-position phenomena. The other changes to the library output were largely side-effects of this fundamental difference.

Table 2 presents some measurements of the overall size of the Wambaya grammar. Since HPSG grammars consist of types organized into a hierarchy and instances of those types, the unit of measure for these evaluations will be types and/or instances. The

		N
Matrix types		891
ordinary	390	
pos disjunctions	591	
Wambaya-specific types		911
Phrase structure rules		83
Lexical rules		161
Lexical entries		1528

Table 2: Size of Wambaya grammar

	Matrix core types		w/ POS types	
Directly used	132	34%	136	15%
Indirectly used	98	25%	584	66%
Total types used	230	59%	720	81%
Types unused	160	41%	171	19%
Types modified	16	4%	16	2%
Total	390	100%	891	100%

Table 3: Matrix core types used in Wambaya grammar

Wambaya grammar includes 891 types defined in the Matrix core type hierarchy. These in turn include 390 ordinary types, and 591 ‘disjunctive’ types, the powerset of 9 part of speech types. These are provided in the Matrix so that Matrix users can easily refer to classes of, say, “nouns and verbs” or “nouns and verbs and adjectives”. The Wambaya-specific portion of the grammar includes 911 types. These types are invoked in the definitions of the phrase structure rules, lexical rules, and lexical entries.

Including the disjunctive part-of-speech types, just under half (49%) of the types in the grammar are provided by the Matrix. However, it is necessary to look more closely; just because a type is provided in the Matrix core hierarchy doesn’t mean that it is invoked by any rules or lexical entries of the Wambaya grammar. The breakdown of types used is given in Table 3. Types that are used directly are either called as supertypes for types defined in the Wambaya-specific portion of the grammar, or used as the value of some feature in a type constraint in the Wambaya-specific portion of the grammar. Types that are used indirectly are either ancestor types to types that are used directly, or types that are used as the value of a feature in a constraint in the Matrix core types on a type that is used (directly or indirectly) by the Wambaya-specific portion of the grammar.

Relatively few (16) of the Matrix-provided types needed to be modified. These were types that

were useful, but somehow unsuitable, and typically deeply interwoven into the type system, such that not using and then and defining parallel types in their place would be inconvenient.

Setting aside the types for part of speech disjunctions, 59% of the Matrix-provided types are invoked by the Wambaya-specific portion of the grammar. While further development of the Wambaya grammar might make use of some of the remaining 41% of the types, this work suggests that there is a substantial amount of information in the Matrix core type hierarchy which would better be stored as part of the typological libraries. In particular, the analyses of argument realization implemented in the Matrix were not used for this grammar. The types associated with argument realization in configurational languages should be moved into the word-order library, which should also be extended to include an analysis of Wambaya-style radical non-configurationality. At the same time, the lexical amalgamation analysis of the features used in long-distance dependencies (Sag, 1997) was found to be incompatible with the approach to argument realization in Wambaya, and a phrasal amalgamation analysis was implemented instead. This again suggests that lexical v. phrasal amalgamation should be encoded in the libraries, and selected according to the word order pattern of the language.

As for parts of speech, of the nine types provided by the Matrix, five were used in the Wambaya grammar (verb, noun, adj, adv, and det) and four were not (num, conj, comp, and adp(osition)). Four disjunctive types were directly invoked, to describe phenomena applying to nouns and adjectives, verbs and adverbs, anything but nouns, and anything but determiners. While it was convenient to have the disjunctive types predefined, it also seems that a much smaller set of types would suffice in this case. Since the nine proposed part of speech types have varying crosslinguistic validity (e.g., not all languages have conjunctions), it might be better to provide software support for creating the disjunctive types as the need arises, rather than predefining them.

Even though the number of Matrix-provided types is small compared to the grammar as a whole, the relatively short development time indicates that the types that were incorporated were quite useful. In providing the fundamental organization of the gram-

mar, to the extent that that organization is consistent with the language modeled, these types significantly ease the path to creating a working grammar.

The short development time required to create the Wambaya grammar presents a qualitative evaluation of the Grammar Matrix as a crosslinguistic resource, as one goal of the Grammar Matrix is to reduce the cost of developing precision grammars. The fact that a grammar capable of assigning valid analyses to an interesting portion of sentences from naturally occurring text could be developed in less than 5.5 person-weeks of effort suggests that this goal is indeed met. This is particularly encouraging in the case of endangered and other resource-poor languages. A grammar such as the one described here could be a significant aide in analyzing additional texts as they are collected, and in identifying constructions that have not yet been analyzed (cf. Baldwin et al, 2005).

## 5 Conclusion

This paper has presented a precision, hand-built grammar for the Australian language Wambaya, and through that grammar a case study evaluation of the LinGO Grammar Matrix. True validation of the Matrix *qua* hypothesized linguistic universals requires many more such case studies, but this first test is promising. Even though Wambaya is in some respects very different from the well-studied languages on which the Matrix is based, the existing machinery otherwise worked quite well, providing a significant jump-start to the grammar development process. While the Wambaya grammar has a long way to go to reach the complexity and range of linguistic phenomena handled by, for example, the LinGO English Resource Grammar, it was shown to provide analyses of an interesting portion of a naturally occurring text. This suggests that the methodology of building such grammars could be profitably incorporated into language documentation efforts.

The Grammar Matrix allows new grammars to directly leverage the expertise in grammar engineering gained in extensive work on previous grammars of better-studied languages. Furthermore, the design of the Matrix is such that it is not a static object, but intended to evolve and be refined as more languages are brought into its purview. Generalizing

the core hierarchy and libraries of the Matrix to support languages like Wambaya can extend its typological reach and further its development as an investigation in computational linguistic typology.

## Acknowledgments

I would like to thank Rachel Nordlinger for providing access to the data used in this work in electronic form, as well as for answering questions about Wambaya; Russ Hugo for data entry of the lexicon; Stephan Oepen for assistance with the parse ranking experiments; and Scott Drellishak, Stephan Oepen, and Laurie Poulson for general discussion. ## Abstract

Automatic word alignment is a key step in training statistical machine translation systems. Despite much recent work on word alignment methods, alignment accuracy increases often produce little or no improvements in machine translation quality. In this work we analyze a recently proposed agreement-constrained EM algorithm for unsupervised alignment models. We attempt to tease apart the effects that this simple but effective modification has on alignment precision and recall trade-offs, and how rare and common words are affected across several language pairs. We propose and extensively evaluate a simple method for using alignment models to produce alignments better-suited for phrase-based MT systems, and show significant gains (as measured by BLEU score) in end-to-end translation systems for six languages pairs used in recent MT competitions.

## 1 Introduction

The typical pipeline for a machine translation (MT) system starts with a parallel sentence-aligned corpus and proceeds to align the words in every sentence pair. The word alignment problem has received much recent attention, but improvements in standard measures of word alignment performance often do not result in better translations. Fraser and Marcu (2007) note that *none of the tens of papers published over the last five years has shown that significant decreases in alignment error rate (AER) result in significant increases in translation performance*. In this work, we show that by changing the way the word alignment models are trained and

used, we can get not only improvements in alignment performance, but also in the performance of the MT system that uses those alignments.

We present extensive experimental results evaluating a new training scheme for unsupervised word alignment models: an extension of the Expectation Maximization algorithm that allows effective injection of additional information about the desired alignments into the unsupervised training process. Examples of such information include “one word should not translate to many words” or that directional translation models should agree. The general framework for the extended EM algorithm with posterior constraints of this type was proposed by (Graça et al., 2008). Our contribution is a large scale evaluation of this methodology for word alignments, an investigation of how the produced alignments differ and how they can be used to consistently improve machine translation performance (as measured by BLEU score) across many languages on training corpora with up to hundred thousand sentences. In 10 out of 12 cases we improve BLEU score by at least  $\frac{1}{4}$  point and by more than 1 point in 4 out of 12 cases.

After presenting the models and the algorithm in Sections 2 and 3, in Section 4 we examine how the new alignments differ from standard models, and find that the new method consistently improves word alignment performance, measured either as alignment error rate or weighted F-score. Section 5 explores how the new alignments lead to consistent and significant improvement in a state of the art phrase base machine translation by using posterior decoding rather than Viterbi decoding. We propose a heuristic for tuning posterior decoding in the absence of annotated alignment data and show improvements over baseline systems for six different

language pairs used in recent MT competitions.

## 2 Statistical word alignment

Statistical word alignment (Brown et al., 1994) is the task identifying which words are translations of each other in a bilingual sentence corpus. Figure 2 shows two examples of word alignment of a sentence pair. Due to the ambiguity of the word alignment task, it is common to distinguish two kinds of alignments (Och and Ney, 2003). Sure alignments (S), represented in the figure as squares with borders, for single-word translations and possible alignments (P), represented in the figure as alignments without boxes, for translations that are either not exact or where several words in one language are translated to several words in the other language. Possible alignments can be used either to indicate optional alignments, such as the translation of an idiom, or disagreement between annotators. In the figure red/black dots indicates correct/incorrect predicted alignment points.

### 2.1 Baseline word alignment models

We focus on the hidden Markov model (HMM) for alignment proposed by (Vogel et al., 1996). This is a generalization of IBM models 1 and 2 (Brown et al., 1994), where the transition probabilities have a first-order Markov dependence rather than a zeroth-order dependence. The model is an HMM, where the hidden states take values from the source language words and generate target language words according to a translation table. The state transitions depend on the distance between the source language words. For source sentence  $s$  the probability of an alignment  $a$  and target sentence  $t$  can be expressed as:

$$p(\mathbf{t}, \mathbf{a} | \mathbf{s}) = \prod_j p_d(a_j | a_{j-1}) p_t(t_j | s_{a_j}), \quad (1)$$

where  $a_j$  is the index of the hidden state (source language index) generating the target language word at index  $j$ . As usual, a “null” word is added to the source sentence. Figure 1 illustrates the mapping between the usual HMM notation and the HMM alignment model.

### 2.2 Baseline training

All word alignment models we consider are normally trained using the Expectation Maximization

Figure 1: Illustration of an HMM for word alignment.

(EM) algorithm (Dempster et al., 1977). The EM algorithm attempts to maximize the marginal likelihood of the observed data ( $s, t$  pairs) by repeatedly finding a maximal lower bound on the likelihood and finding the maximal point of the lower bound. The lower bound is constructed by using posterior probabilities of the hidden alignments ( $a$ ) and can be optimized in closed form from expected sufficient statistics computed from the posteriors. For the HMM alignment model, these posteriors can be efficiently calculated by the Forward-Backward algorithm.

## 3 Adding agreement constraints

Graça et al. (2008) introduce an augmentation of the EM algorithm that uses constraints on posteriors to guide learning. Such constraints are useful for several reasons. As with any unsupervised induction method, there is no guarantee that the maximum likelihood parameters correspond to the intended meaning for the hidden variables, that is, more accurate alignments using the resulting model. Introducing additional constraints into the model often results in intractable decoding and search errors (e.g., IBM models 4+). The advantage of only constraining the posteriors during training is that the model remains simple while respecting more complex requirements. For example, constraints might include “one word should not translate to many words” or that translation is approximately symmetric.

The modification is to add a KL-projection step after the E-step of the EM algorithm. For each sentence pair instance  $\mathbf{x} = (s, t)$ , we find the posterior

distribution  $p_\theta(\mathbf{z}|\mathbf{x})$  (where  $\mathbf{z}$  are the alignments). In regular EM,  $p_\theta(\mathbf{z}|\mathbf{x})$  is used to complete the data and compute expected counts. Instead, we find the distribution  $q$  that is as close as possible to  $p_\theta(\mathbf{z}|\mathbf{x})$  in KL subject to constraints specified in terms of expected values of features  $\mathbf{f}(\mathbf{x}, \mathbf{z})$

$$\arg \min_q \text{KL}(q(\mathbf{z}) || p_\theta(\mathbf{z}|\mathbf{x})) \text{ s.t. } \mathbf{E}_q[\mathbf{f}(\mathbf{x}, \mathbf{z})] \leq \mathbf{b}. \quad (2)$$

The resulting distribution  $q$  is then used in place of  $p_\theta(\mathbf{z}|\mathbf{x})$  to compute sufficient statistics for the M-step. The algorithm converges to a local maximum of the log of the marginal likelihood,  $p_\theta(\mathbf{x}) = \sum_{\mathbf{z}} p_\theta(\mathbf{z}, \mathbf{x})$ , penalized by the KL distance of the posteriors  $p_\theta(\mathbf{z}|\mathbf{x})$  from the feasible set defined by the constraints (Graça et al., 2008):

$$\mathbf{E}_x[\log p_\theta(\mathbf{x}) - \min_{q: \mathbf{E}_q[\mathbf{f}(\mathbf{x}, \mathbf{z})] \leq \mathbf{b}} \text{KL}(q(\mathbf{z}) || p_\theta(\mathbf{z}|\mathbf{x}))],$$

where  $\mathbf{E}_x$  is expectation over the training data. They suggest how this framework can be used to encourage two word alignment models to agree during training. We elaborate on their description and provide details of implementation of the projection in Equation 2.

### 3.1 Agreement

Most MT systems train an alignment model in each direction and then heuristically combine their predictions. In contrast, Graça et al. encourage the models to agree by training them concurrently. The intuition is that the errors that the two models make are different and forcing them to agree rules out errors only made by one model. This is best exhibited in the rare word alignments, where one-sided “garbage-collection” phenomenon often occurs (Moore, 2004). This idea was previously proposed by (Matusov et al., 2004; Liang et al., 2006) although the the objectives differ.

In particular, consider a feature that takes on value 1 whenever source word  $i$  aligns to target word  $j$  in the forward model and -1 in the backward model. If this feature has expected value 0 under the mixture of the two models, then the forward model and backward model agree on how likely source word  $i$  is to align to target word  $j$ . More formally denote the forward model  $\vec{p}(\mathbf{z})$  and backward model  $\overleftarrow{p}(\mathbf{z})$  where  $\vec{p}(\mathbf{z}) = 0$  for  $\mathbf{z} \notin \vec{\mathbf{Z}}$  and  $\overleftarrow{p}(\mathbf{z}) = 0$  for  $\mathbf{z} \notin \overleftarrow{\mathbf{Z}}$  ( $\vec{\mathbf{Z}}$  and  $\overleftarrow{\mathbf{Z}}$  are possible forward and backward alignments). Define a mixture  $p(\mathbf{z}) = \frac{1}{2}\vec{p}(\mathbf{z}) + \frac{1}{2}\overleftarrow{p}(\mathbf{z})$

for  $\mathbf{z} \in \overleftarrow{\mathbf{Z}} \cup \vec{\mathbf{Z}}$ . Restating the constraints that enforce agreement in this setup:  $\mathbf{E}_q[\mathbf{f}(\mathbf{x}, \mathbf{z})] = \mathbf{0}$  with

$$f_{ij}(\mathbf{x}, \mathbf{z}) = \begin{cases} 1 & \mathbf{z} \in \vec{\mathbf{Z}} \text{ and } z_{ij} = 1 \\ -1 & \mathbf{z} \in \overleftarrow{\mathbf{Z}} \text{ and } z_{ij} = 1 \\ 0 & \text{otherwise} \end{cases}.$$

### 3.2 Implementation

EM training of hidden Markov models for word alignment is described elsewhere (Vogel et al., 1996), so we focus on the projection step:

$$\arg \min_q \text{KL}(q(\mathbf{z}) || p_\theta(\mathbf{z}|\mathbf{x})) \text{ s.t. } \mathbf{E}_q[\mathbf{f}(\mathbf{x}, \mathbf{z})] = \mathbf{0}. \quad (3)$$

The optimization problem in Equation 3 can be efficiently solved in its dual formulation:

$$\arg \min_\lambda \log \sum_{\mathbf{z}} p_\theta(\mathbf{z} | \mathbf{x}) \exp \{ \lambda^\top \mathbf{f}(\mathbf{x}, \mathbf{z}) \} \quad (4)$$

where we have solved for the primal variables  $q$  as:

$$q_\lambda(\mathbf{z}) = p_\theta(\mathbf{z} | \mathbf{x}) \exp \{ \lambda^\top \mathbf{f}(\mathbf{x}, \mathbf{z}) \} / Z, \quad (5)$$

with  $Z$  a normalization constant that ensures  $q$  sums to one. We have only one dual variable per constraint, and we optimize them by taking a few gradient steps. The partial derivative of the objective in Equation 4 with respect to feature  $i$  is simply  $\mathbf{E}_{q_\lambda}[\mathbf{f}_i(\mathbf{x}, \mathbf{z})]$ . So we have reduced the problem to computing expectations of our features under the model  $q$ . It turns out that for the agreement features, this reduces to computing expectations under the normal HMM model. To see this, we have by the definition of  $q_\lambda$  and  $p_\theta$ ,

$$\begin{aligned} q_\lambda(\mathbf{z}) &= \frac{\vec{p}(\mathbf{z} | \mathbf{x}) + \overleftarrow{p}(\mathbf{z} | \mathbf{x})}{2} \exp \{ \lambda^\top \mathbf{f}(\mathbf{x}, \mathbf{z}) \} / Z \\ &= \frac{\vec{q}(\mathbf{z}) + \overleftarrow{q}(\mathbf{z})}{2}. \end{aligned}$$

(To make the algorithm simpler, we have assumed that the expectation of the feature  $f_0(\mathbf{x}, \mathbf{z}) = \{1 \text{ if } \mathbf{z} \in \vec{\mathbf{Z}}; -1 \text{ if } \mathbf{z} \in \overleftarrow{\mathbf{Z}}\}$  is set to zero to ensure that the two models  $\vec{q}, \overleftarrow{q}$  are each properly normalized.) For  $\vec{q}$ , we have: ( $\overleftarrow{q}$  is analogous)

$$\begin{aligned} &\vec{p}(\mathbf{z} | \mathbf{x}) e^{\lambda^\top \mathbf{f}(\mathbf{x}, \mathbf{z})} \\ &= \prod_j \vec{p}_d(a_j | a_j - a_{j-1}) \vec{p}_t(\mathbf{t}_j | \mathbf{s}_{a_j}) \prod_{ij} e^{\lambda_{ij} f_{ij}(\mathbf{x}, z_{ij})} \\ &= \prod_{j, i=a_j} \vec{p}_d(i | i - a_{j-1}) \vec{p}_t(\mathbf{t}_j | \mathbf{s}_i) e^{\lambda_{ij} f_{ij}(\mathbf{x}, z_{ij})} \\ &= \prod_{j, i=a_j} \vec{p}_d(i | i - a_{j-1}) \vec{p}'_t(\mathbf{t}_j | \mathbf{s}_i). \end{aligned}$$

Where we have let  $\vec{p}'_t(\mathbf{t}_j|\mathbf{s}_i) = \vec{p}_t(\mathbf{t}_j|\mathbf{s}_i)e^{\lambda_{ij}}$ , and retained the same form for the model. The final projection step is detailed in Algorithm 1.

### 3.3 Decoding

After training, we want to extract a single alignment from the distribution over alignments allowable for the model. The standard way to do this is to find the most probable alignment, using the Viterbi algorithm. Another alternative is to use posterior decoding. In posterior decoding, we compute for each source word  $i$  and target word  $j$  the posterior probability under our model that  $i$  aligns to  $j$ . If that probability is greater than some threshold, then we include the point  $i - j$  in our final alignment. There are two main differences between posterior decoding and Viterbi decoding. First, posterior decoding can take better advantage of model uncertainty: when several likely alignment have high probability, posteriors accumulate confidence for the edges common to many good alignments. Viterbi, by contrast, must commit to one high-scoring alignment. Second, in posterior decoding, the probability that a

target word aligns to none or more than one word is much more flexible: it depends on the tuned threshold.

## 4 Word alignment results

We evaluated the agreement HMM model on two corpora for which hand-aligned data are widely available: the Hansards corpus (Och and Ney, 2000) of English/French parliamentary proceedings and the Europarl corpus (Koehn, 2002) with EPPS annotation (Lambert et al., 2005) of English/Spanish. Figure 2 shows two machine-generated alignments of a sentence pair. The black dots represent the machine alignments and the shading represents the human annotation (as described in the previous section), on the left using the regular HMM model and on the right using our agreement constraints. The figure illustrates a problem known as garbage collection (Brown et al., 1993), where rare source words tend to align to many target words, since the probability mass of the rare word translations can be hijacked to fit the sentence pair. Agreement constraints solve this problem, because forward and backward models cannot agree on the garbage collection solution.

Graça et al. (2008) show that alignment error rate (Och and Ney, 2003) can be improved with agreement constraints. Since AER is the standard metric for alignment quality, we reproduce their results using all the sentences of length at most 40. For the Hansards corpus we improve from 15.35 to 7.01 for the English  $\rightarrow$  French direction and from 14.45 to 6.80 for the reverse. For English  $\rightarrow$  Spanish we improve from 28.20 to 19.86 and from 27.54 to 19.18 for the reverse. These values are competitive with other state of the art systems (Liang et al., 2006).

Unfortunately, as was shown by Fraser and Marcu (2007) AER can have weak correlation with translation performance as measured by BLEU score (Papineni et al., 2002), when the alignments are used to train a phrase-based translation system. Consequently, in addition to AER, we focus on precision and recall.

Figure 3 shows the change in precision and recall with the amount of provided training data for the Hansards corpus. We see that agreement constraints improve both precision and recall when we

Figure 2: An example of the output of HMM trained on 100k the EPPS data. Left: Baseline training. Right: Using agreement constraints.

Figure 3: Effect of posterior constraints on precision (left) and recall (right) learning curves for Hansards En→Fr.

Figure 4: Left: Precision. Right: Recall. Learning curves for Hansards En→Fr split by rare (at most 5 occurrences) and common words.

use Viterbi decoding, with larger improvements for small amounts of training data. We see a similar improvement on the EPPS corpus.

Motivated by the garbage collection problem, we also analyze common and rare words separately. Figure 4 shows precision and recall learning curves for rare and common words. We see that agreement constraints improve precision but not recall of rare words and improve recall but not precision of common words.

As described above an alternative to Viterbi decoding is to accept all alignments that have probability above some threshold. By changing the threshold, we can trade off precision and recall. Figure 5 compares this tradeoff for the baseline and agreement model. We see that the precision/recall curve for agreement is entirely above the baseline curve, so for any recall value we can achieve higher precision than the baseline for either corpus. In Figure 6 we break down the same analysis into rare and non rare words.

Figure 7 shows an example of the same sentence, using the same model where in one case Viterbi decoding was used and in the other case Posterior decoding tuned to minimize AER on a development set

Figure 5: Precision and recall trade-off for posterior decoding with varying threshold. Left: Hansards En→Fr. Right: EPPS En→Es.

Figure 6: Precision and recall trade-off for posterior on Hansards En→Fr. Left: rare words only. Right: common words only.

was used. An interesting difference is that by using posterior decoding one can have n-n alignments as shown in the picture.

A natural question is how to tune the threshold in order to improve machine translation quality. In the next section we evaluate and compare the effects of the different alignments in a phrase based machine translation system.

## 5 Phrase-based machine translation

In this section we attempt to investigate whether our improved alignments produce improved machine

Figure 7: An example of the output of HMM trained on 100k the EPPS data using agreement HMM. Left: Viterbi decoding. Right: Posterior decoding tuned to minimize AER. The addition is *en-firstly* and *tenemos-have*.

translation. In particular we fix a state of the art machine translation system<sup>1</sup> and measure its performance when we vary the supplied word alignments. The baseline system uses GIZA model 4 alignments and the open source Moses phrase-based machine translation toolkit<sup>2</sup>, and performed close to the best at the competition last year.

For all experiments the experimental setup is as follows: we lowercase the corpora, and train language models from all available data. The reasoning behind this is that even if bilingual texts might be scarce in some domain, monolingual text should be relatively abundant. We then train the competing alignment models and compute competing alignments using different decoding schemes. For each alignment model and decoding type we train Moses and use MERT optimization to tune its parameters on a development set. Moses is trained using the grow-diag-final-and alignment symmetrization heuristic and using the default distance base distortion model. We report BLEU scores using a script available with the baseline system. The competing alignment models are GIZA Model 4, our implementation of the baseline HMM alignment and our agreement HMM. We would like to stress that the fair comparison is between the performance of the baseline HMM and the agreement HMM, since Model 4 is more complicated and can capture more structure. However, we will see that for moderate sized data the agreement HMM performs better than both its baseline and GIZA Model 4.

## 5.1 Corpora

In addition to the Hansards corpus and the Europarl English-Spanish corpus, we used four other corpora for the machine translation experiments. Table 1 summarizes some statistics of all corpora. The German and Finnish corpora are also from Europarl, while the Czech corpus contains news commentary. All three were used in recent ACL workshop shared tasks and are available online<sup>3</sup>. The Italian corpus consists of transcribed speech in the travel domain and was used in the 2007 workshop on spoken language translation<sup>4</sup>. We used the development and

tests sets from the workshops when available. For Italian corpus we used dev-set 1 as development and dev-set 2 as test. For Hansards we randomly chose 1000 and 500 sentences from test 1 and test 2 to be testing and development sets respectively.

Table 1 summarizes the size of the training corpus in thousands of sentences, the average length of the English sentences as well as the size of the testing corpus. We also report the percentage of tokens in the test corpus that are rare or not encountered in the training corpus.

## 5.2 Decoding

Our initial experiments with Viterbi decoding and posterior decoding showed that for our agreement model posterior decoding could provide better alignment quality. When labeled data is available, we can tune the threshold to minimize AER. When labeled data is not available we use a different heuristic to

tune the threshold: we choose a threshold that gives the same number of aligned points as Viterbi decoding produces. In principle, we would like to tune the threshold by optimizing BLEU score on a development set, but that is impractical for experiments with many pairs of languages. We call this heuristic posterior-points decoding. As we shall see, it performs well in practice.

### 5.3 Training data size

The HMM alignment models have a smaller parameter space than GIZA Model 4, and consequently we would expect that they would perform better when the amount of training data is limited. We found that this is generally the case, with the margin by which we beat model 4 slowly decreasing until a crossing point somewhere in the range of  $10^5$  -  $10^6$  sentences. We will see in section 5.3.1 that the Viterbi decoding performs best for the baseline HMM model, while posterior decoding performs best for our agreement HMM model. Figure 8 shows the BLEU score for the baseline HMM, our agreement model and GIZA Model 4 as we vary the amount of training data from  $10^4$  -  $10^6$  sentences. For all but the largest data sizes we outperform Model 4, with a greater margin at lower training data sizes. This trend continues as we lower the amount of training data further. We see a similar trend with other corpora.

#### 5.3.1 Small to Medium Training Sets

Our next set of experiments look at our performance in both directions across our 6 corpora, when we have small to moderate amounts of training data: for the language pairs with more than 100,000 sentences, we use only the first 100,000 sentences. Table 2 shows the performance of all systems on these datasets. In the table, post-pts and post-aer stand for posterior-points decoding and posterior decoding tuned for AER. With the notable exception of Czech and Italian, our system performs better than or comparable to both baselines, even though it uses a much more limited model than GIZA’s Model 4. The small corpora for which our models do not perform as well as GIZA are the ones with a lot of rare words. We suspect that the reason for this is that we do not implement smoothing, which has been shown to be important, especially in situations with a lot of rare words.

		X → En		En → X	
		Base	Agree	Base	Agree
De	GIZA M4	23.92		17.89	
	Viterbi	24.08	23.59	18.15	18.13
	post-pts	24.24	<b>24.65</b> <sup>(+)</sup>	18.18	<b>18.45</b> <sup>(+)</sup>
Fi	GIZA M4	18.29		11.05	
	Viterbi	18.79	18.38	11.17	11.54
	post-pts	18.88	<b>19.45</b> <sup>(++)</sup>	11.47	<b>12.48</b> <sup>(++)</sup>
Fr	GIZA M4	33.12		<b>26.90</b>	
	Viterbi	32.42	32.15	25.85	25.48
	post-pts	33.06	33.09 <sup>(≈)</sup>	25.94	26.54 <sup>(+)</sup>
	post-aer	31.81	<b>33.53</b> <sup>(+)</sup>	26.14	26.68 <sup>(+)</sup>
Es	GIZA M4	30.24		30.09	
	Viterbi	29.65	30.03	29.76	29.85
	post-pts	29.91	30.22 <sup>(++)</sup>	29.71	30.16 <sup>(+)</sup>
	post-aer	29.65	<b>30.34</b> <sup>(++)</sup>	29.78	<b>30.20</b> <sup>(+)</sup>
It	GIZA M4	51.66		<b>41.99</b>	
	Viterbi	<b>52.20</b>	52.09	41.40	41.28
	post-pts	51.06	51.14 <sup>(--)</sup>	41.63	41.79 <sup>(≈)</sup>
Cz	GIZA M4	<b>22.78</b>		<b>12.75</b>	
	Viterbi	21.25	21.89	12.23	12.33
	post-pts	21.37	22.51 <sup>(++)</sup>	12.16	12.47 <sup>(+)</sup>

Table 2: BLEU scores for all language pairs using up to 100k sentences. Results are after MERT optimization. The marks <sup>(++)</sup> and <sup>(+)</sup> denote that agreement with posterior decoding is better by 1 BLEU point and 0.25 BLEU points respectively than the best baseline HMM model; analogously for <sup>(--)</sup>, <sup>(-)</sup>; while <sup>(≈)</sup> denotes smaller differences.

#### 5.3.2 Larger Training Sets

For four of the corpora we have more than 100 thousand sentences. The performance of the systems on all the data is shown in Table 3. German is not included because MERT optimization did not complete in time. We see that even on over a million instances, our model sometimes performs better than GIZA model 4, and always performs better than the baseline HMM.

## 6 Conclusions

In this work we have evaluated agreement-constrained EM training for statistical word alignment models. We carefully studied its effects on word alignment recall and precision. Agreement training has a different effect on rare and common words, probably because it fixes different types of errors. It corrects the garbage collection problem for rare words, resulting in a higher precision. The recall improvement in common words

		X → En		En → X	
		Base	Agree	Base	Agree
Fi	GIZA M4	22.78		14.72	
	Viterbi	22.92	22.89	14.21	14.09

Table 3: BLEU scores for all language pairs using all available data. Markings as in Table 2.

can be explained by the idea that ambiguous common words are different in the two languages, so the un-ambiguous choices in one direction can force the choice for the ambiguous ones in the other through agreement constraints.

To our knowledge this is the first extensive evaluation where improvements in alignment accuracy lead to improvements in machine translation performance. We tested this hypothesis on six different language pairs from three different domains, and found that the new alignment scheme not only performs better than the baseline, but also improves over a more complicated, intractable model. In order to get the best results, it appears that posterior decoding is required for the simplistic HMM alignment model. The success of posterior decoding using our simple threshold tuning heuristic is fortunate since no labeled alignment data are needed: Viterbi alignments provide a reasonable estimate of aligned words needed for phrase extraction. The nature of the complicated relationship between word alignments, the corresponding extracted phrases and the effects on the final MT system still begs for better explanations and metrics. We have investigated the distribution of phrase-sizes used in translation across systems and languages, following recent investigations (Ayan and Dorr, 2006), but unfortunately found no consistent correlation with BLEU improvement. Since the alignments we extracted were better according to all metrics we used, it should not be too surprising that they yield better translation performance, but perhaps a better trade-off can be achieved with a deeper understanding of

the link between alignments and translations.

## Abstract

Documents in languages such as Chinese, Japanese and Korean sometimes annotate terms with their translations in English inside a pair of parentheses. We present a method to extract such translations from a large collection of web documents by building a partially parallel corpus and use a word alignment algorithm to identify the terms being translated. The method is able to generalize across the translations for different terms and can reliably extract translations that occurred only once in the entire web. Our experiment on Chinese web pages produced more than 26 million pairs of translations, which is over two orders of magnitude more than previous results. We show that the addition of the extracted translation pairs as training data provides significant increase in the BLEU score for a statistical machine translation system.

## 1 Introduction

In natural language documents, a term (word or phrase) is sometimes followed by its translation in another language in a pair of parentheses. We call these **parenthetical translations**. The following examples are from Chinese web pages (we added underlines to indicate what is being translated):

- (1) 美国智库布鲁金斯学会 (Brookings Institution) 专研跨大西洋恐怖主义的美欧中心研究部主任杰若米·夏皮罗 (Jeremy Shapiro) 却认为, ...
- (2) 消化性溃疡的症状往往与消化不良 (indigestion), 胃炎 (gastritis) 等其他胃部疾病症状相似.
- (3) 殊不知美国是不会接受 (not going to fly) 这一想法的
- (4) ...当是一次式时, 叫线性规划 (linear programming).

<sup>†</sup>Contributions made during an internship at Google

The parenthetically translated terms are typically new words, technical terminologies, idioms, products, titles of movies, books, songs, and names of persons, organizations locations, *etc.* Commonly, an author might use such a parenthetical when a given term has no standard translation (or transliteration), and does not appear in conventional dictionaries. That is, an author might expect a term to be an *out-of-vocabulary* item for the target reader, and thus helpfully provides a reference translation *in situ*.

For example, in (1), the name *Shapiro* was transliterated as 夏皮罗. The name has many other transliterations in web documents, such as 夏皮洛, 夏比洛, 夏布洛, 夏皮羅, 沙皮罗, 夏皮若, 夏庇罗, 夏皮諾, 夏畢洛, 夏比羅, 夏比罗, 夏普羅, 夏批羅, 夏批罗, 夏彼羅, 夏彼罗, 夏培洛, 夏卜尔, 夏匹若 ..., where the three Chinese characters corresponds to the three syllables in Sha-pi-ro respectively. Each syllable may be mapped into different characters: 'Sha' into 夏 or 沙, 'pi' into 皮, 比, 批, and 'ro' into 罗, 洛, 若, ...

Variation is not limited to the effects of phonetic similarity. Story titles, for instance, are commonly translated semantically, often leading to a number of translations that have similar meaning, yet differ greatly in lexicographic form. For example, while the movie title *Syriana* is sometimes phonetically transliterated as 辛瑞那, 辛瑞纳, it may also be translated semantically according to the plot of the movie, e.g., 迷中迷 (mystery in mystery), 实录 (real log), 谍对谍 (spy against spy), 油激暗战 (oil-triggered secret war), 叙利亚 (Syria), 迷经 (mystery journey), ...

The parenthetical translations are extremely valuable both as a stand-alone on-line dictionary and as training data for statistical machine translation systems. They provide fresh data (new words) and cover a much wider range of topics than typical parallel training data for statistical machine translation systems.

The main contribution of this paper is a method for mining parenthetical translations by treating text snippets containing candidate pairs as a partially parallel corpus and using a word alignment algorithm to establish the correspondences between in-parenthesis and pre-parenthesis words.

This technique allows us to identify translation pairs even if they only appeared once on the entire web. As a result, we were able to obtain 26.7 million Chinese-English translation pairs from web documents in Chinese. This is over two orders of magnitude more than the number of extracted translation pairs in the previously reported results (Cao, *et al.* 2007).

The next section presents an overview of our algorithm, which is then detailed in Sections 3 and 4. We evaluate our results in Section 5 by comparison with bilingually linked Wikipedia titles and by using the extracted pairs as additional training data in a statistical machine translation system.

## 2 Mining Parenthetical Translations

A parenthetical translation matches the pattern:

$$(4) \quad f_1 f_2 \dots f_m (e_1 e_2 \dots e_n)$$

which is a sequence of  $m$  non-English words followed by a sequence of  $n$  English words in parentheses. In the remainder of the paper, we assume the non-English text is Chinese, but our technique works for other languages as well.

There have been two approaches to finding such parenthetical translations. One is to assume that the English term  $e_1 e_2 \dots e_n$  is given and use a search engine to retrieve text snippets containing  $e_1 e_2 \dots e_n$  from predominately non-English web pages (Nagata *et al.*, 2001, Kwok *et al.*, 2005). Another method (Cao *et al.*, 2007) is to go through a non-English corpus and collect all instances that match the parenthetical pattern in (4). We followed the second approach since it does not require a predefined list of English terms and is amendable for extraction at large scale.

In both cases, one can obtain a list of candidate pairs, where the translation of the in-parenthesis terms is a suffix of the pre-parenthesis text. The lengths and frequency counts of the suffixes have been used to determine what is the translation of the in-parenthesis term (Kwok *et al.*, 2005). For example, Table 1 lists a set of Chinese segments (with word-to-word translation underneath) that

precede the English term *Lower Egypt*. Owing to the frequency with which 下埃及 appears as a candidate, and in varying contexts, one has a good reason to believe 下埃及 is the correct translation of *Lower Egypt*.

... 下游 地区 为 下 埃及	downstream region is down Egypt
... 中心 位于 下 埃及	center located-at down Egypt
... 以及 所谓 的 下 埃及	and so-called of down Egypt
... 叫做 下 埃及	called down Egypt

Table 1: Chinese text preceding *Lower Egypt*

Unfortunately, this heuristic does not hold as often as one might imagine. Consider the candidates for *Channel Spacing* in Table 2. The suffix 间隔 (gap) has the highest frequency count. It is nonetheless an incomplete translation of *Channel Spacing*. The correct translations in rows  $c$  to  $h$  occurred with *Channel Spacing* only once.

$a$	... □ 为 频道 间隔	$\lambda$ is channel distance
$b$	... 其 频道 间隔	its channel distance
$c$	... 除了 降低 波道 间隔	in-addition-to reducing wave-passage distance
$d$	... 亦 展示 具 波道 间隔	also showed have wave-passage gap
$e$	... 也 就是 频道 间隔	also therefore is channel gap
$f$	... 且 频道 的 间隔	and channel 's gap
$g$	... 一个 重要 特性 是 信道 间隔	an important property is signal-passage gap
$h$	... 已经 能够 达到 通道 间隔	already able reach passage gap

Table 2: Text preceding *Channel Spacing*

The crucial observation we make here is that although the words like 信道 (in row  $g$ ) co-occurred with *Channel Spacing* only once, there are many co-occurrences of 信道 and *Channel* in other candidate pairs, such as:

- ... 而 不是 语音 信道 (Speech Channel)
- ... 块 平坦 衰落 信道 (Block Flat Fading Channel)
- ... 信道 B (Channel B)
- ... 光纤 信道 探针 (Fiber Channel Probes)

- ... 反向 信道 (Reverse Channel)
- ... 基带 滤波 反向 信道 (Reverse Channel)

Unlike previous approaches that rely solely on the preceding text of a single English term to determine its translation, we treat the entire collection of candidate pairs as a partially parallel corpus and establish the correspondences between the words using a word alignment algorithm.

At first glance, word alignment appears to be a more difficult problem than the extraction of parenthetical translations. Extraction of parenthetical translations need only determine the *first* pre-parenthesis word aligned with an in-parenthesis word, whereas word alignment requires the respective linking of *all* such (pre,in)-parenthesis word pairs. However, by casting the problem as word alignment, we are able to generalize across instances involving different in-parenthesis terms, giving us a larger number of, and more varied, example contexts per word.

For the examples in Table 2, the words 频道 (channel), 波道 (wave passage), 信道 (signal passage), and 通道 (passage) are aligned with *Channel*, and the words 间距 (distance) and 间隔 (gap) are aligned with *Spacing*. Given these alignments, the left boundary of the translated Chinese term is simply the leftmost word that is linked to one of the English words.

Our algorithm consists of two steps:

**Step 1** constructs a partially parallel corpus. This step takes as input a large collection of Chinese web pages and converts the sentences with parentheses containing English text into pairs of candidates.

**Step 2** uses an unsupervised algorithm to align English and Chinese and identify the term being translated according to the left-most aligned Chinese word. If no word alignments can be established, the pair is not considered a translation.

The next two sections present the details of each of the two steps.

### 3 Constructing a Partially Parallel Corpus

#### 3.1 Filtering out non-translations

The first step of our algorithm is to extract parentheticals and then filter out those that are not translations. This filtering is required as parenthetical translations represent only a small fraction of the

usages for parentheses (see Sec. 5.1). Table 3 shows some example of parentheses that are not translations.

The input to Step 1 is a collection of arbitrary web documents. We used the following criteria to identify candidate pairs:

- The pre-parenthesis text ( $T_p$ ) is predominantly in Chinese and the in-parenthesis text ( $T_i$ ) is predominantly in English.
- The concatenation of the digits in  $T_p$  must be identical to the concatenation of the digits in  $T_i$ . For example, rows *a*, *b* and *c* in Table 3 can be ruled out this way.
- If  $T_p$  contains some text in English, the same text must also appear in  $T_i$ . This filters out row *d*.
- Remove the pairs where  $T_i$  is part of anchor text. This rule is often applied to instances like row *e* where the file type tends to be inside a clickable link to a media file.
- The punctuation characters in  $T_p$  must also appear in  $T_i$ , unless they are quotation marks. The example in row *f* is ruled out because ‘/’ is not found in the pre-parenthesis text.

	Examples with translations in <i>italic</i>	Function of the in-parenthesis text
<i>a</i>	其数值通常在1.4~3.0之间 (MacArthur, 1967) <i>The range of its values is within 1.4~3.0 (MacArthur, 1967)</i>	to provide citation
<i>b</i>	越航北京/胡志明 (VN901 15:20-22:30) <i>Vietnam Airlines Beijing/Ho Chi Minh (VN901 15:20-22:30)</i>	flight information
<i>c</i>	销售台球桌 (255-8FT) <i>sale of pool table (255-8FT)</i>	product Id.
<i>d</i>	// 主程序 // void main ( void ) <i>// main program // void main (void )</i>	function declaration
<i>e</i>	电影名称: 千年湖 (DVD) <i>movie title: Thousand Year Lake (DVD)</i>	DVD is the file type
<i>f</i>	水样 所 消耗 的 质量 ( g/L) <i>mass consumed by water sample (g/L)</i>	measurement unit
<i>g</i>	柔和保养面油 (Sensitive) <i>gentle protective facial cream (Sensitive)</i>	to indicate the type of the cream
<i>h</i>	美国九大搜索引擎评测第四章 (Ask Jeeves) <i>Evaluation of Nine Main Search Engines in the US: Chapter 4 (Ask Jeeves)</i>	Chapter 4 is about Ask Jeeves

Table 3: Other uses of parentheses

The instances in rows  $g$  and  $h$  cannot be eliminated by these simple rules, and are filtered only later, as we fail to discover a convincing word alignment.

### 3.2 Constraining term boundaries

Similar to (Cao *et al.* 2007), we segmented the pre-parenthesis Chinese text and restrict the term boundary to be one of the segmentation boundaries. Since parenthetical translations are mostly translation of terms, it makes sense to further constrain the left boundary of the Chinese side to be a term boundary. Determining what should be counted as a term is a difficult task and there are not yet well-accepted solutions (Sag *et al.* 2003).

We compiled an approximate term vocabulary by taking the top 5 million most frequent Chinese queries as according to a fully anonymized collection of search engine query logs.

Given a Chinese sentence, we first identify all (possibly overlapping) sequences of words in the sentence that match one of the top-5M queries. A matching sequence is called a maximal match if it is not properly contained in another matching sequence. We then define the **potential boundary positions** to be the boundaries of maximal matches or words that are not covered by any of the top-5M queries.

### 3.3 Length-based trimming

If there are numerous Chinese words preceding a pair of parentheses containing two English words, it is very unlikely for all but the right-most few Chinese words to be part of the translation of the English words. Including extremely long sequences as potential candidates introduces significantly more noise and makes word alignment harder than necessary. We therefore trimmed the pre-parenthesis text with a length-based constraint. The cut-off point is the first (counting from right to left) potential boundary position (see Sec. 3.2) such that  $C \geq 2E + K$ , where  $C$  is the length of the Chinese text,  $E$  is the length of the English text in the parentheses and  $K$  is a constant (we used  $K=6$  in our experiments). The lengths  $C$  and  $E$  are measured in bytes, except when the English text is an abbreviation (in that case,  $E$  is multiplied by 5).

## 4 Word Alignment

Word alignment is a well-studied topic in Machine Translation with many algorithms having been

proposed (Brown *et al.* 1993; Och and Ney 2003). We used a modified version of one of the simplest word alignment algorithms called Competitive Linking (Melamed, 2000). The algorithm assumes that there is a score associated with each pair of words in a bi-text. It sorts the word pairs in descending order of their scores, selecting pairs based on the resultant order. A pair of words is linked if none of the two words were previously linked to any other words. The algorithm terminates when there are no more links to make.

Tiedemann (2004) compared a variety of alignment algorithms and found Competitive Linking to have one of the highest precision scores. A disadvantage of Competitive Linking, however, is that the alignments are restricted word-to-word alignments, which implies that multi-word expressions can only be partially linked at best.

### 4.1 Dealing with multi-word alignment

We made a small change to Competitive Linking to allow consecutive sequence of words on one side to be linked to the same word on the other side. Specifically, instead of requiring both  $e_i$  and  $f_j$  to have no previous linkages, we only require that at least one of them be unlinked and that (suppose  $e_i$  is unlinked and  $f_j$  is linked to  $e_k$ ) none of the words between  $e_i$  and  $e_k$  be linked to any word other than  $f_j$ .

### 4.2 Link scoring

We used  $\varphi^2$  (Gale and Church, 1991) as the link score in the modified competitive linking algorithm, although there are many other possible choices for the link scores, such as  $\chi^2$  (Zhang, S. Vogel. 2005), log-likelihood ratio (Dunning, 1993) and discriminatively trained weights (Taskar *et al.*, 2005). The  $\varphi^2$  statistics for a pair of words  $e_i$  and  $f_j$  is computed as

$$\varphi^2 = \frac{(ad - bc)^2}{(a+b)(a+c)(b+d)(c+d)}$$

where

$a$  is the number of sentence pairs containing both  $e_i$  and  $f_j$ ;

$a+b$  is the number of sentence pairs containing  $e_i$ ;

$a+c$  is the number of sentence pairs containing  $f_j$ ;

$d$  is the number of sentence pairs containing neither  $e_i$  nor  $f_j$ .

The  $\phi^2$  score ranges from 0 to 1. We set a threshold at 0.001, below which the  $\phi^2$  scores are treated as 0.

### 4.3 Bias in the partially parallel corpus

Since only the last few Chinese words in a candidate pair are expected to be translated, there should be a preference for linking the words towards the end of the Chinese text. One advantage of Competitive Linking is that it is quite easy to introduce such preferences into the algorithm, by using the word positions to break ties of the  $\phi^2$  scores when sorting the word pairs.

### 4.4 Capturing syllable-level regularities

Many of the parenthetical translations involve proper names, which are often transliterated according to the sound. Word alignment algorithms have generally ignored syllable-level regularities in transliterated terms. Consider again the *Shapiro* example in the introduction section. There are numerous correct transliterations for the same English word, some of which are not very frequent. For example, the word 夏布洛 happens to have a similar  $\phi^2$  score with *Shapiro* as the word 流利 (fluency), which is totally unrelated to *Shapiro* but happened to have the same co-occurrence statistics in the (partially) parallel corpus.

Previous approaches to parenthetical translations relied on specialized algorithms to deal with transliterations (Cao *et al*, 2007; Jiang *et al*, 2007; Wu and Chang, 2007). They convert Chinese words into their phonetic representations (Pinyin) and use the known transliterations in a bilingual dictionary to train a transliteration model.

We adopted a simpler approach that does not require any additional resources such as pronunciation dictionaries and bilingual dictionaries. In addition to computing the  $\phi^2$  scores between words, we also compute the  $\phi^2$  scores of prefixes and suffixes of Chinese and English words. For both languages, the prefix of a word is defined as the first three bytes of the word and the suffix is defined as the last three bytes. Since we used UTF-8 encoding, the first and last three bytes of a Chinese word, except in very rare cases, correspond to the first and last Chinese character of the word. Table 4 lists the English prefixes and suffixes that have the highest  $\phi^2$  scores with the Chinese prefix 夏 and suffix 洛.

Type	Chinese	English
prefix	夏	sha, amo, cha, sum, haw, lav, lun, xia, xal, hnl, shy, eve, she, cfh, ...
suffix	洛	rlo, llo, ouh, low, ilo, owe, lol, lor, zlo, klo, gue, ude, vir, row, oro, olo, aro, ulo, ero, iro, rro, loh, lok, ...

Table 4: Example prefixes and suffixes with top  $\phi^2$

In our modified version of the competitive linking algorithm, the link score of a pair of words is the sum of the  $\phi^2$  scores of the words themselves, their prefixes and their suffixes.

In addition to syllable-level correspondences in transliterations, the  $\phi^2$  scores of prefixes and suffixes can also capture correlations in morphologically composed words. For example, the Chinese prefix 三 (three) has a relatively high  $\phi^2$  score with the English prefix *tri*. Such scores enable word alignments to be made that may otherwise be missed. Consider the following text snippet:

..... 三 嗒 氟草胺 (triaziflam)

The correct translation for *triaziflam* is 三嗒氟草胺. However, the Chinese term is segmented as 三 + 嗒 + 氟草胺. The association between 三 (three) and *triaziflam* is very weak because 三 is a very frequent word, whereas *triaziflam* is an extremely rare word. With the addition of the  $\phi^2$  score between 三 and *tri*, we were able to correctly establish the connection between *triaziflam* and 三.

It turns out to be quite effective to assume prefixes and suffixes of words consist of three bytes, despite its apparent simplicity. The benefit of  $\phi^2$  scores for prefixes and suffixes is not limited to morphemes that happen to be three bytes long. For example, the English morpheme “du-” corresponds to the Chinese character 二 (two). Although the  $\phi^2$  between *du* and 二 won’t be computed, we do find high  $\phi^2$  scores between 二 and *due* and between 二 and *dua*. The three letter prefixes account for many of the words with the *du-* prefix.

## 5 Experimental Results

We extracted from Chinese web pages about 1.58 billion unique sentences with parentheses that contain ASCII text. We removed duplicate sentences so that duplications of web documents will not skew the statistics. By applying the filtering algorithm in Sec. 3.1, we constructed a partially paral-

lel corpus with 126,612,447 candidate pairs (46,791,841 unique), which is about 8% of the number of sentences. Using the word alignment algorithm in Sec. 4, we extracted 26,753,972 translation pairs between 13,471,221 unique English terms and 11,577,206 unique Chinese terms.

Parenthetical translations mined from the Web have mostly been evaluated by manual examination of a small sample of results (usually a few hundred entries) or in a Cross Lingual Information Retrieval setup. There does not yet exist a common evaluation data set.

### 5.1 Evaluation with Wikipedia

Our first evaluation is based on translations in Wikipedia, which contains far more terminology and proper names than bilingual dictionaries. We extracted the titles of Chinese and English Wikipedia articles that are linked to each other and treated them as gold standard translations. There are 79,714 such pairs. We removed the following types of pairs because they are not translations or are not terms:

- Pairs with identical strings. For example, both English and Chinese versions have an entry titled “.ch”;
- Pairs where the English term begins with a digit, e.g., “245”, “300 BC”, “1991 in film”;
- Pairs where the English term matches the regular expression ‘List of .\*’, e.g., “List of birds”, “List of cinemas in Hong Kong”;
- Pairs where the Chinese title does not have any non-ASCII code. For example, the English entry “SynCFusion” is linked to “.NET Framework” in the Chinese Wikipedia.

The resulting data set contains 68,131 translation pairs between 62,581 Chinese terms and 67,613 English terms. Only a small percentage of terms have more than one translation. Whenever there is more than one translation, we randomly pick one as the answer key.

For each Chinese and English word in the Wikipedia data, we first find whether there is a translation for the word in the extracted translation pairs. The **Coverage** of the Wikipedia data is measured by the percentage of words for which one or more translations are found. We then see whether our most frequent translation is an **Exact Match** of the answer key in the Wikipedia data.

	Coverage	Exact Match
<b>Full</b>	<b>70.8%</b>	<b>36.4%</b>
<b>-term</b>	67.1%	34.8%
<b>-pre-suffix</b>	67.6%	34.4%
<b>IBM</b>	67.6%	31.2%
<b>LDC</b>	10.8%	4.8%

Table 5: Chinese to English Results

	Coverage	Exact Match
<b>Full</b>	<b>59.6%</b>	<b>27.9%</b>
<b>-term</b>	<b>59.6%</b>	27.5%
<b>-pre-suffix</b>	58.9%	27.4%
<b>IBM</b>	52.4%	13.4%
<b>LDC</b>	3.0%	1.4%

Table 6: English to Chinese Results

Table 5 and 6 show the Chinese-to-English and English-to-Chinese results for the following systems:

**Full** refers to our system described in Sec. 3 and 4;

**-term** is the system without the use of query logs to restrict potential term boundary positions (Sec. 3.2);

**-pre-suffix** is the system without using the  $\phi^2$  score of the prefixes and suffixes;

**IBM** refers to a system where we substitute our word alignment algorithm with IBM Model 1 and Model 2 followed by the HMM alignment (Och and Ney 2003), which is a common configuration for the word alignment components in machine translations systems;

**LDC** refers to the LDC2.0 English to Chinese bilingual dictionary with 161,117 translation pairs.

It can be seen that the use of queries to constrain boundary positions and the addition of  $\phi^2$  scores of prefixes/suffixes improve the percentage of Exact Match. The IBM Model tends to make many more alignments than Complete Linking. While this is often beneficial for machine translation systems, it is not very suitable for creating bilingual dictionaries, where precision is of paramount importance. The LDC dictionary was manually compiled from diverse resources within LDC and (mostly) from the Internet. Its coverage of Wikipedia data is extremely low, compared to our method.

Table 7: A random sample of non-exact-matches

<sup>1</sup>the extracted translation is too short

<sup>2</sup>the extracted translation is too long

<sup>3</sup>the extracted translation contains only the last name

\*the extracted term is completely wrong.

Note that Exact Match is a rather stringent criterion. Table 7 shows a random sample of extracted parenthetical translations that failed the Exact Match test. Only a small percentage of them are genuine errors. We nonetheless adopted this measure because it has the advantage of automated evaluation and our goal is mainly to compare the relative performances.

To determine the upper bound of the coverage of our web data, for each Wikipedia English term we searched within the total set of available parenthesized text fragments (our English candidate set before filtering as by Step 1). We discovered 81% of the Wikipedia titles, which is approximately 10% above the coverage of our final output. This indicates a minor loss of recall because of mistakes made in filtering (Sec. 3.1) and/or word alignment.

## 5.2 Evaluation with term translation requests

To evaluate the coverage of output produced by their method, Cao *et al* (2007) extracted English queries from the query log of a Chinese search engine. They assume that the reason why users typed the English queries in a Chinese search box is mostly to find out their Chinese translations. Examining our own Chinese query logs, however, the most-frequent English queries appear to be navigational queries instead of translation requests. We therefore used the following regular expression to identify queries that are unambiguously translation requests:

`/^[a-zA-Z]*的中文$/`

where的中文means “’s Chinese”. This regular expression matched 1579 unique queries in the logs. We manually judged the translation for 200 of them. A small random sample of the 200 is shown in Table 8. The empty cells indicate that the English term is missing from our translation pairs. We use \* to mark incorrect translations. When compared with the sample queries in (Cao *et al.*, 2007), the queries in our sample seem to contain more phrasal words and technical terminology. It is interesting to see that even though parenthetical translations tend to be out-of-vocabulary words, as we have remarked in the introduction, the sheer size of the web means that occasionally translations of common words such as ‘use’ are sometimes included as well.

Table 8: A small sample of manually judged query translations

We compared our results with translations obtained from Google and Yahoo’s translation services. The numbers of correct translations for the random sample of 200 queries are as follows:

Systems	Google	Yahoo!	Mined	Mined+G
Correct	115	84	116	135

Our system’s outputs (**Mined**) have the same accuracy as the Google Translate. Our outputs have results for 154 out of the 200 queries. The 46 missing results are considered incorrect. If we combine our results with Google Translate by looking up Google results for missing entries, the accuracy increases from 56% to 68% (**Mined+G**). If we treat the LDC Chinese-English Dictionary 2.0 as a translator, it only covers 20.5% of the 200 queries.

### 5.3 Evaluation with SMT

The extracted translations may serve as training data for statistical machine translation systems. To evaluate their effectiveness for this purpose, we trained a baseline phrase-based SMT system (Koehn *et al.*, 2003; Brants *et al.*, 2007) with the FBIS Chinese-English parallel text (NIST, 2003). We then added the extracted translation pairs as

additional parallel training corpus. This resulted in a 0.57 increase of BLEU score based on the test data in the 2006 NIST MT Evaluation Workshop.

## 6 Related Work

Nagata *et al.* (2001) made the first proposal to mine translations from the web. Their work was concentrated on terminologies, and assumed the English terms were given as input. Wu and Chang (2007), Kwok *et al.* (2005) also employed search engines and assumed the English term given as input, but their focus was on name transliteration. It is difficult to build a truly large-scale translation lexicon this way because the English terms themselves may be hard to come by.

Cao *et al.* (2007), like us, used a 300GB collection of web documents as input. They used supervised learning to build models that deal with phonetic transliterations and semantic translations separately. Our work relies on unsupervised learning and does not make a distinction between translations and transliterations. Furthermore, we are able to extract two orders of magnitude more translations from than (Cao *et al.*, 2007).

## 7 Conclusion

We presented a method to apply a word alignment algorithm on a partially parallel corpus to extract translation pairs from the web. Treating the translation extraction problem as a word alignment problem allowed us to generalize across instances involving different in-parenthesis terms. Our algorithm extends Competitive Linking to deal with multi-word alignments and takes advantage of word-internal correspondences between transliterated words or morphologically composed words. Finally, through our discussion of parallel Wikipedia topic titles as a gold standard, we presented the first evaluation of such an extraction system that went beyond manual judgments on small sized samples.

## Abstract

In adding syntax to statistical MT, there is a tradeoff between taking advantage of linguistic analysis, versus allowing the model to exploit linguistically unmotivated mappings learned from parallel training data. A number of previous efforts have tackled this tradeoff by starting with a commitment to linguistically motivated analyses and then finding appropriate ways to soften that commitment. We present an approach that explores the tradeoff from the other direction, starting with a context-free translation model learned directly from aligned parallel text, and then adding soft constituent-level constraints based on parses of the source language. We obtain substantial improvements in performance for translation from Chinese and Arabic to English.

## 1 Introduction

The statistical revolution in machine translation, beginning with (Brown et al., 1993) in the early 1990s, replaced an earlier era of detailed language analysis with automatic learning of shallow source-target mappings from large parallel corpora. Over the last several years, however, the pendulum has begun to swing back in the other direction, with researchers exploring a variety of statistical models that take advantage of source- and particularly target-language syntactic analysis (e.g. (Cowan et al., 2006; Zollmann and Venugopal, 2006; Marcu et al., 2006; Galley et al., 2006) and numerous others).

Chiang (2005) distinguishes statistical MT approaches that are “syntactic” in a *formal* sense, go-

ing beyond the finite-state underpinnings of phrase-based models, from approaches that are syntactic in a *linguistic* sense, i.e. taking advantage of *a priori* language knowledge in the form of annotations derived from human linguistic analysis or treebanking.<sup>1</sup> The two forms of syntactic modeling are doubly dissociable: current research frameworks include systems that are finite state but informed by linguistic annotation prior to training (e.g., (Koehn and Hoang, 2007; Birch et al., 2007; Hassan et al., 2007)), and also include systems employing context-free models trained on parallel text without benefit of any prior linguistic analysis (e.g. (Chiang, 2005; Chiang, 2007; Wu, 1997)). Over time, however, there has been increasing movement in the direction of systems that are syntactic in both the formal and linguistic senses.

In any such system, there is a natural tension between taking advantage of the linguistic analysis, versus allowing the model to use linguistically unmotivated mappings learned from parallel training data. The tradeoff often involves starting with a system that exploits rich linguistic representations and relaxing some part of it. For example, DeNeefe et al. (2007) begin with a tree-to-string model, using treebank-based target language analysis, and find it useful to modify it in order to accommodate useful “phrasal” chunks that are present in parallel training data but not licensed by linguistically motivated parses of the target language. Similarly, Cowan et al. (2006) focus on using syntactically rich representations of source and target parse trees, but they resort to phrase-based translation for modifiers within

<sup>1</sup>See (Lopez, to appear) for a comprehensive survey.

clauses. Finding the right way to balance linguistic analysis with unconstrained data-driven modeling is clearly a key challenge.

In this paper we address this challenge from a less explored direction. Rather than starting with a system based on linguistically motivated parse trees, we begin with a model that is syntactic only in the formal sense. We then introduce soft constraints that take source-language parses into account to a limited extent. Introducing syntactic constraints in this restricted way allows us to take maximal advantage of what can be learned from parallel training data, while effectively factoring in key aspects of linguistically motivated analysis. As a result, we obtain substantial improvements in performance for both Chinese-English and Arabic-English translation.

In Section 2, we briefly review the Hiero statistical MT framework (Chiang, 2005, 2007), upon which this work builds, and we discuss Chiang’s initial effort to incorporate soft source-language constituency constraints for Chinese-English translation. In Section 3, we suggest that an insufficiently fine-grained view of constituency constraints was responsible for Chiang’s lack of strong results, and introduce finer grained constraints into the model. Section 4 demonstrates the value of these constraints via substantial improvements in Chinese-English translation performance, and extends the approach to Arabic-English. Section 5 discusses the results, and Section 6 considers related work. Finally we conclude in Section 7 with a summary and potential directions for future work.

## 2 Hierarchical Phrase-based Translation

### 2.1 Hiero

Hiero (Chiang, 2005; Chiang, 2007) is a hierarchical phrase-based statistical MT framework that generalizes phrase-based models by permitting phrases with gaps. Formally, Hiero’s translation model is a weighted synchronous context-free grammar. Hiero employs a generalization of the standard non-hierarchical phrase extraction approach in order to acquire the synchronous rules of the grammar directly from word-aligned parallel text. Rules have the form  $X \rightarrow \langle \bar{e}, \bar{f} \rangle$ , where  $\bar{e}$  and  $\bar{f}$  are phrases containing terminal symbols (words) and possibly co-indexed instances of the

nonterminal symbol  $X$ .<sup>2</sup> Associated with each rule is a set of translation model features,  $\phi_i(\bar{f}, \bar{e})$ ; for example, one intuitively natural feature of a rule is the phrase translation (log-)probability  $\phi(\bar{f}, \bar{e}) = \log p(\bar{e}|\bar{f})$ , directly analogous to the corresponding feature in non-hierarchical phrase-based models like Pharaoh (Koehn et al., 2003). In addition to this phrase translation probability feature, Hiero’s feature set includes the inverse phrase translation probability  $\log p(\bar{f}|\bar{e})$ , lexical weights  $\text{lexwt}(\bar{f}|\bar{e})$  and  $\text{lexwt}(\bar{e}|\bar{f})$ , which are estimates of translation quality based on word-level correspondences (Koehn et al., 2003), and a rule penalty allowing the model to learn a preference for longer or shorter derivations; see (Chiang, 2007) for details.

These features are combined using a log-linear model, with each synchronous rule contributing

$$\sum_i \lambda_i \phi_i(\bar{f}, \bar{e}) \quad (1)$$

to the total log-probability of a derived hypothesis. Each  $\lambda_i$  is a weight associated with feature  $\phi_i$ , and these weights are typically optimized using minimum error rate training (Och, 2003).

### 2.2 Soft Syntactic Constraints

When looking at Hiero rules, which are acquired automatically by the model from parallel text, it is easy to find many cases that seem to respect linguistically motivated boundaries. For example,

$$X \rightarrow \langle \text{jingtian } X_1, X_1 \text{ this year} \rangle,$$

seems to capture the use of *jingtian/this year* as a temporal modifier when building linguistic constituents such as noun phrases (*the election this year*) or verb phrases (*voted in the primary this year*). However, it is important to observe that nothing in the Hiero framework actually *requires* nonterminal symbols to cover linguistically sensible constituents, and in practice they frequently do not.<sup>3</sup>

<sup>2</sup>This is slightly simplified: Chiang’s original formulation of Hiero, which we use, has two nonterminal symbols,  $X$  and  $S$ . The latter is used only in two special “glue” rules that permit complete trees to be constructed via concatenation of subtrees when there is no better way to combine them.

<sup>3</sup>For example, this rule could just as well be applied with  $X_1$  covering the “phrase” *submitted and* to produce non-constituent substring *submitted and this year* in a hypothesis like *The budget was submitted and this year cuts are likely*.

Chiang (2005) conjectured that there might be value in allowing the Hiero model to favor hypotheses for which the synchronous derivation respects linguistically motivated source-language constituency boundaries, as identified using a parser. He tested this conjecture by adding a soft constraint in the form of a “constituency feature”: if a synchronous rule  $X \rightarrow \langle \bar{e}, \bar{f} \rangle$  is used in a derivation, and the span of  $\bar{f}$  is a constituent in the source-language parse, then a term  $\lambda_c$  is added to the model score in expression (1).<sup>4</sup> Unlike a hard constraint, which would simply prevent the application of rules violating syntactic boundaries, using the feature to introduce a *soft* constraint allows the model to boost the “goodness” for a rule if it is consistent with the source language constituency analysis, and to leave its score unchanged otherwise. The weight  $\lambda_c$ , like all other  $\lambda_i$ , is set via minimum error rate training, and that optimization process determines empirically the extent to which the constituency feature should be trusted.

Figure 1 illustrates the way the constituency feature worked, treating English as the source language for the sake of readability. In this example,  $\lambda_c$  would be added to the hypothesis score for any rule used in the hypothesis whose source side spanned *the minister, a speech, yesterday, gave a speech yesterday, or the minister gave a speech yesterday*. A rule translating, say, *minister gave a* as a unit would receive no such boost.

Chiang tested the constituency feature for Chinese-English translation, and obtained no significant improvement on the test set. The idea then seems essentially to have been abandoned; it does not appear in later discussions (Chiang, 2007).

### 3 Soft Syntactic Constraints, Revisited

On the face of it, there are any number of possible reasons Chiang’s (2005) soft constraint did not work – including, for example, practical issues like the quality of the Chinese parses.<sup>5</sup> However, we focus here on two conceptual issues underlying his use of source language syntactic constituents.

<sup>4</sup>Formally,  $\phi_c(\bar{f}, \bar{e})$  is defined as a binary feature, with value 1 if  $\bar{f}$  spans a source constituent and 0 otherwise. In the latter case  $\lambda_c \phi_c(\bar{f}, \bar{e}) = 0$  and the score in expression (1) is unaffected.

<sup>5</sup>In fact, this turns out not to be the issue; see Section 4.

Figure 1: Illustration of Chiang’s (2005) syntactic constituency feature, which does not distinguish among constituent types.

First, the constituency feature treats all syntactic constituent types equally, making no distinction among them. For any given language pair, however, there might be some source constituents that tend to map naturally to the target language as units, and others that do not (Fox, 2002; Eisner, 2003). Moreover, a parser may tend to be more accurate for some constituents than for others.

Second, the Chiang (2005) constituency feature gives a rule additional credit when the rule’s source side overlaps exactly with a source-side syntactic constituent. Logically, however, it might make sense not just to give a rule  $X \rightarrow \langle \bar{e}, \bar{f} \rangle$  extra credit when  $\bar{f}$  matches a constituent, but to incur a *cost* when  $\bar{f}$  violates a constituent boundary. Using the example in Figure 1, we might want to penalize hypotheses containing rules where  $\bar{f}$  is *the minister gave a* (and other cases, such as *minister gave, minister gave a, and so forth*).<sup>6</sup>

These observations suggest a finer-grained approach to the constituency feature idea, retaining the idea of soft constraints, but applying them using *various* soft-constraint constituency features. Our first observation argues for distinguishing among constituent types (NP, VP, etc.). Our second observation argues for distinguishing the benefit of match-

<sup>6</sup>This accomplishes coverage of the logically complete set of possibilities, which include not only  $\bar{f}$  matching a constituent exactly or crossing its boundaries, but also  $\bar{f}$  being properly contained within the constituent span, properly containing it, or being outside it entirely. Whenever these latter possibilities occur,  $\bar{f}$  will exactly match or cross the boundaries of some other constituent.

ing constituents from the cost of crossing constituent boundaries. We therefore define a space of new features as the cross product

$$\{\text{CP, IP, NP, VP, } \dots\} \times \{=, +\}.$$

where = and + signify matching and crossing boundaries, respectively. For example,  $\phi_{\text{NP}=\}$  would denote a binary feature that matches whenever the span of  $\bar{f}$  exactly covers an NP in the source-side parse tree, resulting in  $\lambda_{\text{NP}=\}$  being added to the hypothesis score (expression (1)). Similarly,  $\phi_{\text{VP}+}$  would denote a binary feature that matches whenever the span of  $\bar{f}$  crosses a VP boundary in the parse tree, resulting in  $\lambda_{\text{VP}+}$  being *subtracted from* the hypothesis score.<sup>7</sup> For readability from this point forward, we will omit  $\phi$  from the notation and refer to features such as NP= (which one could read as “NP match”), VP+ (which one could read as “VP crossing”), etc.

In addition to these individual features, we define three more variants:

- For each constituent type, e.g. NP, we define a feature NP\_ that ties the weights of NP= and NP+. If NP= matches a rule, the model score is incremented by  $\lambda_{\text{NP}_=}$ , and if NP+ matches, the model score is decremented by the same quantity.
- For each constituent type, e.g. NP, we define a version of the model, NP2, in which NP= and NP+ are *both* included as features, with separate weights  $\lambda_{\text{NP}=\}$  and  $\lambda_{\text{NP}+}$ .
- We define a set of “standard” linguistic labels containing {CP, IP, NP, VP, PP, ADJP, ADVP, QP, LCP, DNP} and excluding other labels such as PRN (parentheses), FRAG (fragment), etc.<sup>8</sup> We define feature XP= as the disjunction of {CP=, IP=, ..., DNP=}; i.e. its value equals 1 for a rule if the span of  $\bar{f}$  exactly covers a constituent having any of the standard labels. The

<sup>7</sup>Formally,  $\lambda_{\text{VP}+}$  simply contributes to the sum in expression (1), as with all features in the model, but weight optimization using minimum error rate training should, and does, automatically assign this feature a negative weight.

<sup>8</sup>We map SBAR and S labels in Arabic parses to CP and IP, respectively, consistent with the Chinese parses. We map Chinese DP labels to NP. DNP and LCP appear only in Chinese. We ran no ADJP experiment in Chinese, because this label virtually always spans only one token in the Chinese parses.

definitions of XP+, XP\_, and XP2 are analogous.

- Similarly, since Chiang’s original constituency feature can be viewed as a disjunctive “all-labels=” feature, we also defined “all-labels+”, “all-labels2”, and “all-labels\_” analogously.

## 4 Experiments

We carried out MT experiments for translation from Chinese to English and from Arabic to English, using a descendant of Chiang’s Hiero system. Language models were built using the SRI Language Modeling Toolkit (Stolcke, 2002) with modified Kneser-Ney smoothing (Chen and Goodman, 1998). Word-level alignments were obtained using GIZA++ (Och and Ney, 2000). The baseline model in both languages used the feature set described in Section 2; for the Chinese baseline we also included a rule-based number translation feature (Chiang, 2007).

In order to compute syntactic features, we analyzed source sentences using state of the art, tree-bank trained constituency parsers ((Huang et al., 2008) for Chinese, and the Stanford parser v.2007-08-19 for Arabic (Klein and Manning, 2003a; Klein and Manning, 2003b)). In addition to the baseline condition, and baseline plus Chiang’s (2005) original constituency feature, experimental conditions augmented the baseline with additional features as described in Section 3.

All models were optimized and tested using the BLEU metric (Papineni et al., 2002) with the NIST-implemented (“shortest”) effective reference length, on lowercased, tokenized outputs/references. Statistical significance of difference from the baseline BLEU score was measured by using paired bootstrap re-sampling (Koehn, 2004).<sup>9</sup>

### 4.1 Chinese-English

For the Chinese-English translation experiments, we trained the translation model on the corpora in Table 1, totalling approximately 2.1 million sentence pairs after GIZA++ filtering for length ratio. Chinese text was segmented using the Stanford segmenter (Tseng et al., 2005).

<sup>9</sup>Whenever we use the word “significant”, we mean “statistically significant” (at  $p < .05$  unless specified otherwise).

Table 1: Training corpora for Chinese-English translation

We trained a 5-gram language model using the English (target) side of the training set, pruning 4-gram and 5-gram singletons. For minimum error rate training and development we used the NIST MTeval MT03 set.

Table 2 presents our results. We first evaluated translation performance using the NIST MT06 (nist-text) set. Like Chiang (2005), we find that the original, undifferentiated constituency feature (Chiang-05) introduces a negligible, statistically insignificant improvement over the baseline. However, we find that several of the finer-grained constraints (IP=, VP=, VP+, QP+, and NP=) achieve statistically significant improvements over baseline (up to .74 BLEU), and the latter three also improve significantly on the undifferentiated constituency feature. By combining multiple finer-grained syntactic features, we obtain significant improvements of up to 1.65 BLEU points (NP\_, VP2, IP2, all-labels\_, and XP+).

We also obtained further gains using combinations of features that had performed well; e.g., condition IP2.VP2.NP\_ augments the baseline features with IP2 and VP2 (i.e. IP=, IP+, VP= and VP+), and NP\_ (tying weights of NP= and NP+; see Section 3). Since component features in those combinations were informed by individual-feature performance on the test set, we tested the best performing conditions from MT06 on a new test set, NIST MT08. NP= and VP+ yielded significant improvements of up to 1.53 BLEU. Combination conditions replicated the pattern of results from MT06, including the same increasing order of gains, with improvements up to 1.11 BLEU.

## 4.2 Arabic-English

For Arabic-English translation, we used the training corpora in Table 3, approximately 100,000 sen-

tence pairs after GIZA++ length-ratio filtering. We trained a trigram language model using the English side of this training set, plus the English Gigaword v2 AFP and Gigaword v1 Xinhua corpora. Development and minimum error rate training were done using the NIST MT02 set.

Table 4 presents our results. We first tested on the NIST MT03 and MT06 (nist-text) sets. On MT03, the original, undifferentiated constituency feature did not improve over baseline. Two individual finer-grained features (PP+ and AdvP=) yielded statistically significant gains up to .42 BLEU points, and feature combinations AP2, XP2 and all-labels2 yielded significant gains up to 1.03 BLEU points. XP2 and all-labels2 also improved significantly on the undifferentiated constituency feature, by .72 and 1.11 BLEU points, respectively.

For MT06, Chiang’s original feature improved the baseline significantly — this is a new result using his feature, since he did not experiment with Arabic — as did our our IP=, PP=, and VP= conditions. Adding individual features PP+ and AdvP= yielded significant improvements up to 1.4 BLEU points over baseline, and in fact the improvement for individual feature AdvP= over Chiang’s undifferentiated constituency feature approaches significance ( $p < .075$ ).

More important, several conditions combining features achieved statistically significant improvements over baseline of up 1.94 BLEU points: XP2, IP2, IP, VP=.PP+.AdvP=, AP2, PP+.AdvP=, and AdvP2. Of these, AdvP2 is also a significant improvement over the undifferentiated constituency feature (Chiang-05), with  $p < .01$ . As we did for Chinese, we tested the best-performing models on a new test set, NIST MT08. Consistent patterns reappeared: improvements over the baseline up to 1.69 BLEU ( $p < .01$ ), with AdvP2 again in the lead (also outperforming the undifferentiated constituency feature,  $p < .05$ ).

## 5 Discussion

The results in Section 4 demonstrate, to our knowledge for the first time, that significant and sometimes substantial gains over baseline can be obtained by incorporating soft syntactic constraints into Hiero’s translation model. Within language, we also see considerable consistency across multiple test sets, in terms of which constraints tend to help most.

Furthermore, our results provide some insight into why the original approach may have failed to yield a positive outcome. For Chinese, we found that when we defined finer-grained versions of the exact-match features, there was value for some constituency types in biasing the model to favor matching the source language parse. Moreover, we found that there was significant value in allowing the model to be sensitive to violations (crossing boundaries) of source parses. These results confirm that parser quality was not the limitation in the original work (or at least not the only limitation), since in our experiments the parser was held constant.

Looking at combinations of new features, some “double-feature” combinations (VP2, IP2) achieved large gains, although note that more is not necessarily better: combinations of more features did not yield better scores, and some did not yield any gain at all. No conflated feature reached significance, but it is not the case that all conflated features are worse than their same-constituent “double-feature” counterparts. We found no simple correlation between finer-grained feature scores (and/or boundary condition type) and combination or conflation scores. Since some combinations seem to cancel individual contributions, we can conclude that the higher the number of participant features (of the kinds described here), the more likely a cancellation effect is; therefore, a “double-feature” combination is more likely to yield higher gains than a combination containing more features.

We also investigated whether non-canonical linguistic constituency labels such as PRN, FRAG, UCP and VSB introduce “noise”, by means of the XP features — the XP= feature is, in fact, simply the undifferentiated constituency feature, but sensitive only to “standard” XPs. Although performance of XP=, XP2 and all-labels+ were similar to that of the undifferentiated constituency feature, XP+ achieved

the highest gain. Intuitively, this seems plausible: the feature says, at least for Chinese, that a translation hypothesis should incur a penalty if it is translating a substring as a unit when that substring is not a canonical source constituent.

Having obtained positive results with Chinese, we explored the extent to which the approach might improve translation using a very different source language. The approach on Arabic-English translation yielded large BLEU gains over baseline, as well as significant improvements over the undifferentiated constituency feature. Comparing the two sets of experiments, we see that there are definitely language-specific variations in the value of syntactic constraints; for example, AdvP, the top performer in Arabic, cannot possibly perform well for Chinese, since in our parses the AdvP constituents rarely include more than a single word. At the same time, some IP and VP variants seem to do generally well in both languages. This makes sense, since — at least for these language pairs and perhaps more generally — clauses and verb phrases seem to correspond often on the source and target side. We found it more surprising that no NP variant yielded much gain in Arabic; this question will be taken up in future work.

## 6 Related Work

Space limitations preclude a thorough review of work attempting to navigate the tradeoff between using language analyzers and exploiting unconstrained data-driven modeling, although the recent literature is full of variety and promising approaches. We limit ourselves here to several approaches that seem most closely related.

Among approaches using parser-based syntactic models, several researchers have attempted to reduce the strictness of syntactic constraints in order to better exploit shallow correspondences in parallel training data. Our introduction has already briefly noted Cowan et al. (2006), who relax parse-tree-based alignment to permit alignment of non-constituent subphrases on the source side, and translate modifiers using a separate phrase-based model, and DeNeefe et al. (2007), who modify syntax-based extraction and binarize trees (following (Wang et al., 2007b)) to improve phrasal cov-

erage. Similarly, Marcu et al. (2006) relax their syntax-based system by rewriting target-side parse trees on the fly in order to avoid the loss of “non-syntactifiable” phrase pairs. Setiawan *et al.* (2007) employ a “function-word centered syntax-based approach”, with synchronous CFG and extended ITG models for reordering phrases, and relax syntactic constraints by only using a small number function words (approximated by high-frequency words) to guide the phrase-order inversion. Zollman and Venugopal (2006) start with a target language parser and use it to provide constraints on the extraction of hierarchical phrase pairs. Unlike Hiero, their translation model uses a full range of named nonterminal symbols in the synchronous grammar. As an alternative way to relax strict parser-based constituency requirements, they explore the use of phrases spanning generalized, categorial-style constituents in the parse tree, e.g. type NP/NN denotes a phrase like *the great* that lacks only a head noun (say, *wall*) in order to comprise an NP.

In addition, various researchers have explored the use of hard linguistic constraints on the source side, e.g. via “chunking” noun phrases and translating them separately (Owczarzak et al., 2006), or by performing hard reorderings of source parse trees in order to more closely approximate target-language word order (Wang et al., 2007a; Collins et al., 2005).

Finally, another soft-constraint approach that can also be viewed as coming from the data-driven side, adding syntax, is taken by Riezler and Maxwell (2006). They use LFG dependency trees on both source and target sides, and relax syntactic constraints by adding a “fragment grammar” for unparseable chunks. They decode using Pharaoh, augmented with their own log-linear features (such as  $p(e_{snippet}|f_{snippet})$  and its converse), side by side to “traditional” lexical weights. Riezler and Maxwell (2006) do not achieve higher BLEU scores, but do score better according to human grammaticality judgments for in-coverage cases.

## 7 Conclusion

When hierarchical phrase-based translation was introduced by Chiang (2005), it represented a new and successful way to incorporate syntax into statistical MT, allowing the model to exploit non-local depen-

dencies and lexically sensitive reordering without requiring linguistically motivated parsing of either the source or target language. An approach to incorporating parser-based constituents in the model was explored briefly, treating syntactic constituency as a soft constraint, with negative results.

In this paper, we returned to the idea of linguistically motivated soft constraints, and we demonstrated that they can, in fact, lead to substantial improvements in translation performance when integrated into the Hiero framework. We accomplished this using constraints that not only distinguish among constituent types, but which also distinguish between the benefit of matching the source parse bracketing, versus the cost of using phrases that cross relevant bracketing boundaries. We demonstrated improvements for Chinese-English translation, and succeed in obtaining substantial gains for Arabic-English translation, as well.

Our results contribute to a growing body of work on combining monolingually based, linguistically motivated syntactic analysis with translation models that are closely tied to observable parallel training data. Consistent with other researchers, we find that “syntactic constituency” may be too coarse a notion by itself; rather, there is value in taking a finer-grained approach, and in allowing the model to decide how far to trust each element of the syntactic analysis as part of the system’s optimization process.

## Abstract

Word lattice decoding has proven useful in spoken language translation; we argue that it provides a compelling model for translation of text genres, as well. We show that prior work in translating lattices using finite state techniques can be naturally extended to more expressive synchronous context-free grammar-based models. Additionally, we resolve a significant complication that non-linear word lattice inputs introduce in reordering models. Our experiments evaluating the approach demonstrate substantial gains for Chinese-English and Arabic-English translation.

## 1 Introduction

When Brown and colleagues introduced statistical machine translation in the early 1990s, their key insight – harkening back to Weaver in the late 1940s – was that translation could be viewed as an instance of noisy channel modeling (Brown et al., 1990). They introduced a now standard decomposition that distinguishes modeling sentences in the target language (language models) from modeling the relationship between source and target language (translation models). Today, virtually all statistical translation systems seek the best hypothesis  $e$  for a given input  $f$  in the source language, according to

$$\hat{e} = \arg \max_e Pr(e|f) \quad (1)$$

An exception is the translation of speech recognition output, where the acoustic signal generally underdetermines the choice of source word sequence  $f$ . There, Bertoldi and others have recently found that, rather than translating a single-best transcription  $f$ , it is advantageous to allow the MT decoder to

consider all possibilities for  $f$  by encoding the alternatives compactly as a confusion network or lattice (Bertoldi et al., 2007; Bertoldi and Federico, 2005; Koehn et al., 2007).

Why, however, should this advantage be limited to translation from spoken input? Even for text, there are often multiple ways to derive a sequence of words from the input string. Segmentation of Chinese, decomposing in German, morphological analysis for Arabic — across a wide range of source languages, ambiguity in the input gives rise to multiple possibilities for the source word sequence. Nonetheless, state-of-the-art systems commonly identify a single analysis  $f$  during a preprocessing step, and decode according to the decision rule in (1).

In this paper, we go beyond speech translation by showing that lattice decoding can also yield improvements for text by preserving alternative analyses of the input. In addition, we generalize lattice decoding algorithmically, extending it for the first time to hierarchical phrase-based translation (Chiang, 2005; Chiang, 2007).

Formally, the approach we take can be thought of as a “noisier channel”, where an observed signal  $o$  gives rise to a set of source-language strings  $f' \in \mathcal{F}(o)$  and we seek

$$\hat{e} = \arg \max_e \max_{f' \in \mathcal{F}(o)} Pr(e, f'|o) \quad (2)$$

$$= \arg \max_e \max_{f' \in \mathcal{F}(o)} Pr(e)Pr(f'|e, o) \quad (3)$$

$$= \arg \max_e \max_{f' \in \mathcal{F}(o)} Pr(e)Pr(f'|e)Pr(o|f') \quad (4)$$

Following Och and Ney (2002), we use the maximum entropy framework (Berger et al., 1996) to directly model the posterior  $Pr(e, f'|o)$  with parameters tuned to minimize a loss function representing

the quality only of the resulting translations. Thus, we make use of the following general decision rule:

$$\hat{e} = \arg \max_e \max_{f' \in \mathcal{F}(o)} \sum_{m=1}^M \lambda_m \phi_m(e, f', o) \quad (5)$$

In principle, one could decode according to (2) simply by enumerating and decoding each  $f' \in \mathcal{F}(o)$ ; however, for any interestingly large  $\mathcal{F}(o)$  this will be impractical. We assume that for many interesting cases of  $\mathcal{F}(o)$ , there will be identical substrings that express the same content, and therefore a lattice representation is appropriate.

In Section 2, we discuss decoding with this model in general, and then show how two classes of translation models can easily be adapted for lattice translation; we achieve a unified treatment of finite-state and hierarchical phrase-based models by treating lattices as a subcase of weighted finite state automata (FSAs). In Section 3, we identify and solve issues that arise with reordering in non-linear FSAs, i.e. FSAs where every path does not pass through every node. Section 4 presents two applications of the noisier channel paradigm, demonstrating substantial performance gains in Arabic-English and Chinese-English translation. In Section 5 we discuss relevant prior work, and we conclude in Section 6.

## 2 Decoding

Most statistical machine translation systems model translational equivalence using either finite state transducers or synchronous context free grammars (Lopez, to appear 2008). In this section we discuss the issues associated with adapting decoders from both classes of formalism to process word lattices. The first decoder we present is a SCFG-based decoder similar to the one described in Chiang (2007). The second is a phrase-based decoder implementing the model of Koehn et al. (2003).

### 2.1 Word lattices

A word lattice  $\mathcal{G} = \langle V, E \rangle$  is a directed acyclic graph that formally is a weighted finite state automaton (FSA). We further stipulate that exactly one node has no outgoing edges and is designated the ‘end node’. Figure 1 illustrates three classes of word lattices.

Figure 1: Three examples of word lattices: (a) sentence, (b) confusion network, and (c) non-linear word lattice.

A word lattice is useful for our purposes because it permits any finite set of strings to be represented and allows for substrings common to multiple members of the set to be represented with a single piece of structure. Additionally, all paths from one node to another form an equivalence class representing, in our model, alternative expressions of the same underlying communicative intent.

For translation, we will find it useful to encode  $\mathcal{G}$  in a chart based on a topological ordering of the nodes, as described by Cheppalier et al. (1999). The nodes in the lattices shown in Figure 1 are labeled according to an appropriate numbering.

The chart-representation of the graph is a triple of 2-dimensional matrices  $\langle \mathbf{F}, \mathbf{p}, \mathbf{R} \rangle$ , which can be constructed from the numbered graph.  $\mathbf{F}_{i,j}$  is the word label of the  $j^{\text{th}}$  transition leaving node  $i$ . The corresponding transition cost is  $\mathbf{p}_{i,j}$ .  $\mathbf{R}_{i,j}$  is the node number of the node on the *right* side of the  $j^{\text{th}}$  transition leaving node  $i$ . Note that  $\mathbf{R}_{i,j} > i$  for all  $i, j$ . Table 1 shows the word lattice from Figure 1 represented in matrix form as  $\langle \mathbf{F}, \mathbf{p}, \mathbf{R} \rangle$ .

	0	1	2
a	1 1	b 1 2	c 1 3
a	$\frac{1}{3}$ 1	b 1 2	c $\frac{1}{2}$ 3
x	$\frac{1}{3}$ 1		d $\frac{1}{2}$ 3
ε	$\frac{1}{3}$ 1		
x	$\frac{1}{2}$ 1	y 1 2	b $\frac{1}{2}$ 3
a	$\frac{1}{2}$ 2		c $\frac{1}{2}$ 3

Table 1: Topologically ordered chart encoding of the three lattices in Figure 1. Each cell  $ij$  in this table is a triple  $\langle \mathbf{F}_{ij}, \mathbf{p}_{ij}, \mathbf{R}_{ij} \rangle$

## 2.2 Parsing word lattices

Chiang (2005) introduced hierarchical phrase-based translation models, which are formally based on synchronous context-free grammars (SCFGs). Translation proceeds by parsing the input using the source language side of the grammar, simultaneously building a tree on the target language side via the target side of the synchronized rules. Since decoding is equivalent to parsing, we begin by presenting a parser for word lattices, which is a generalization of a CKY parser for lattices given in Cheppalier et al. (1999).

Following Goodman (1999), we present our lattice parser as a deductive proof system in Figure 2. The parser consists of two kinds of items, the first with the form  $[X \rightarrow \alpha \bullet \beta, i, j]$  representing rules that have yet to be completed and span node  $i$  to node  $j$ . The other items have the form  $[X, i, j]$  and indicate that non-terminal  $X$  spans  $[i, j]$ . As with sentence parsing, the goal is a deduction that covers the spans of the entire input lattice  $[S, 0, |V| - 1]$ .

The three inference rules are: 1) match a terminal symbol and move across one edge in the lattice 2) move across an  $\epsilon$ -edge without advancing the dot in an incomplete rule 3) advance the dot across a non-terminal symbol given appropriate antecedents.

## 2.3 From parsing to MT decoding

A target language model is necessary to generate fluent output. To do so, the grammar is intersected with an  $n$ -gram LM. To mitigate the effects of the combinatorial explosion of non-terminals the LM intersection entails, we use *cube-pruning* to only consider the most promising expansions (Chiang, 2007).

## 2.4 Lattice translation with FSTs

A second important class of translation models includes those based formally on FSTs. We present a description of the decoding process for a word lattice using a representative FST model, the phrase-based translation model described in Koehn et al. (2003).

Phrase-based models translate a foreign sentence  $f$  into the target language  $e$  by breaking up  $f$  into a sequence of phrases  $\bar{f}_1^f$ , where each phrase  $\bar{f}_i$  can contain one or more contiguous words and is translated into a target phrase  $e_i$  of one or more contiguous words. Each word in  $f$  must be translated ex-

actly once. To generalize this model to word lattices, it is necessary to choose both a path through the lattice and a partitioning of the sentence this induces into a sequence of phrases  $\bar{f}_1^f$ . Although the number of source phrases in a word lattice can be exponential in the number of nodes, enumerating the *possible translations* of every span in a lattice is in practice tractable, as described by Bertoldi et al. (2007).

## 2.5 Decoding with phrase-based models

We adapted the Moses phrase-based decoder to translate word lattices (Koehn et al., 2007). The unmodified decoder builds a translation hypothesis from left to right by selecting a range of untranslated words and adding translations of this phrase to the end of the hypothesis being extended. When no untranslated words remain, the translation process is complete.

The word lattice decoder works similarly, only now the decoder keeps track not of the words that have been covered, but of the *nodes*, given a topological ordering of the nodes. For example, assuming the third lattice in Figure 1 is our input, if the edge with word  $a$  is translated, this will cover *two* untranslated nodes  $[0,1]$  in the coverage vector, even though it is only a single word. As with sentence-based decoding, a translation hypothesis is complete when all nodes in the input lattice are covered.

## 2.6 Non-monotonicity and unreachable nodes

The changes described thus far are straightforward adaptations of the underlying phrase-based sentence decoder; however, dealing properly with non-monotonic decoding of word lattices introduces some minor complexity that is worth mentioning. In the sentence decoder, any translation of any span of untranslated words is an allowable extension of a partial translation hypothesis, provided that the coverage vectors of the extension and the partial hypothesis do not intersect. In a non-linear word lattice, a further constraint must be enforced ensuring that there is always a path from the starting node of the translation extension's source to the node representing the nearest right edge of the already-translated material, as well as a path from the ending node of the translation extension's source to future translated spans. Figure 3 illustrates the problem. If  $[0,1]$  is translated, the decoder must not consider translating

Axioms:

$$\overline{[X \rightarrow \bullet \gamma, i, i] : w} \quad (X \xrightarrow{w} \langle \gamma, \alpha \rangle) \in G, i \in [0, |V| - 2]$$

Inference rules:

$$\frac{[X \rightarrow \alpha \bullet \mathbf{F}_{j,k} \beta, i, j] : w}{[X \rightarrow \alpha \mathbf{F}_{j,k} \bullet \beta, i, \mathbf{R}_{j,k}] : w \times \mathbf{p}_{j,k}}$$

$$\frac{[X \rightarrow \alpha \bullet \beta, i, j] : w}{[X \rightarrow \alpha \bullet \beta, i, \mathbf{R}_{j,k}] : w \times \mathbf{p}_{j,k}} \quad \mathbf{F}_{j,k} = \epsilon$$

$$\frac{[Z \rightarrow \alpha \bullet X \beta, i, k] : w_1 \quad [X \rightarrow \gamma \bullet, k, j] : w_2}{[Z \rightarrow \alpha X \bullet \beta, i, j] : w_1 \times w_2}$$

Goal state:

$$[S \rightarrow \gamma \bullet, 0, |V| - 1]$$

Figure 2: Word lattice parser for an unrestricted context free grammar  $G$ .

Figure 3: The span  $[0, 3]$  has one inconsistent covering,  $[0, 1] + [2, 3]$ .

$[2,3]$  as a possible extension of this hypothesis since there is no path from node 1 to node 2 and therefore the span  $[1,2]$  would never be covered. In the parser that forms the basis of the hierarchical decoder described in Section 2.3, no such restriction is necessary since grammar rules are processed in a strictly left-to-right fashion without any skips.

### 3 Distortion in a non-linear word lattice

In both hierarchical and phrase-based models, the distance between words in the source sentence is used to limit where in the target sequence their translations will be generated. In phrase based translation, distortion is modeled explicitly. Models that support non-monotonic decoding generally include a distortion cost, such as  $|a_i - b_{i-1} - 1|$  where  $a_i$  is the starting position of the foreign phrase  $\bar{f}_i$  and  $b_{i-1}$  is the ending position of phrase  $\bar{f}_{i-1}$  (Koehn et al., 2003). The intuition behind this model is that since most translation is monotonic, the cost of skipping ahead or back in the source should be proportional to the number of words that are skipped. Additionally, a maximum distortion limit is used to restrict

Figure 4: Distance-based distortion problem. What is the distance between node 4 to node 0?

the size of the search space.

In linear word lattices, such as confusion networks, the distance metric used for the distortion penalty and for distortion limits is well defined; however, in a non-linear word lattice, it poses the problem illustrated in Figure 4. Assuming the left-to-right decoding strategy described in the previous section, if  $c$  is generated by the first target word, the distortion penalty associated with “skipping ahead” should be either 3 or 2, depending on what path is chosen to translate the span  $[0,3]$ . In large lattices, where a single arc may span many nodes, the possible distances may vary quite substantially depending on what path is ultimately taken, and handling this properly therefore crucial.

Although hierarchical phrase-based models do not model distortion explicitly, Chiang (2007) suggests using a span length limit to restrict the window in which reordering can take place.<sup>1</sup> The decoder enforces the constraint that a synchronous rule learned from the training data (the only mechanism by which reordering can be introduced) can span

<sup>1</sup>This is done to reduce the size of the search space and because hierarchical phrase-based translation models are inaccurate models of long-distance distortion.

Distance metric	MT05	MT06
Difference	0.2943	0.2786
Difference+LexRO	0.2974	0.2890
ShortestP	0.2993	0.2865
ShortestP+LexRO	0.3072	0.2992

Table 2: Effect of distance metric on phrase-based model performance.

maximally  $\Lambda$  words in  $f$ . Like the distortion cost used in phrase-based systems,  $\Lambda$  is also poorly defined for non-linear lattices.

Since we want a distance metric that will restrict as few local reorderings as possible on *any* path, we use a function  $\xi(a, b)$  returning the length of the shortest path between nodes  $a$  and  $b$ . Since this function is not dependent on the exact path chosen, it can be computed in advance of decoding using an all-pairs shortest path algorithm (Cormen et al., 1989).

### 3.1 Experimental results

We tested the effect of the distance metric on translation quality using Chinese word segmentation lattices (Section 4.1, below) using both a hierarchical and phrase-based system modified to translate word lattices. We compared the shortest-path distance metric with a baseline which uses the difference in node number as the distortion distance. For an additional datapoint, we added a lexicalized reordering model that models the probability of each phrase pair appearing in three different orientations (swap, monotone, other) in the training corpus (Koehn et al., 2005).

Table 2 summarizes the results of the phrase-based systems. On both test sets, the shortest path metric improved the BLEU scores. As expected, the lexicalized reordering model improved translation quality over the baseline; however, the improvement was more substantial in the model that used the shortest-path distance metric (which was already a higher baseline). Table 3 summarizes the results of our experiment comparing the performance of two distance metrics to determine whether a rule has exceeded the decoder’s span limit. The pattern is the same, showing a clear increase in BLEU for the shortest path metric over the baseline.

Distance metric	MT05	MT06
Difference	0.3063	0.2957
ShortestP	0.3176	0.3043

Table 3: Effect of distance metric on hierarchical model performance.

## 4 Exploiting Source Language Alternatives

**Chinese word segmentation.** A necessary first step in translating Chinese using standard models is segmenting the character stream into a sequence of words. Word-lattice translation offers two possible improvements over the conventional approach. First, a lattice may represent multiple alternative segmentations of a sentence; input represented in this way will be more robust to errors made by the segmenter.<sup>2</sup> Second, different segmentation granularities may be more or less optimal for translating different spans. By encoding alternatives in the input in a word lattice, the decision as to which granularity to use for a given span can be resolved during decoding rather than when constructing the system. Figure 5 illustrates a lattice based on three different segmentations.

**Arabic morphological variation.** Arabic orthography is problematic for lexical and phrase-based MT approaches since a large class of functional elements (prepositions, pronouns, tense markers, conjunctions, definiteness markers) are attached to their host stems. Thus, while the training data may provide good evidence for the translation of a particular stem by itself, the same stem may not be attested when attached to a particular conjunction. The general solution taken is to take the best possible morphological analysis of the text (it is often ambiguous whether a piece of a word is part of the stem or merely a neighboring functional element), and then make a subset of the bound functional elements in the language into freestanding tokens. Figure 6 illustrates the unsegmented Arabic surface form as well as the morphological segmentation variant we made use of. The limitation of this approach is that as the amount and variety of training data increases, the optimal segmentation strategy changes: more aggressive segmentation results

<sup>2</sup>The segmentation process is ambiguous, even for native speakers of Chinese.

Figure 5: Sample Chinese segmentation lattice using three segmentations.

in fewer OOV tokens, but automatic evaluation metrics indicate lower translation quality, presumably because the smaller units are being translated less idiomatically (Habash and Sadat, 2006). Lattices allow the decoder to make decisions about what granularity of segmentation to use *subsentially*.

#### 4.1 Chinese Word Segmentation Experiments

In our experiments we used two state-of-the-art Chinese word segmenters: one developed at Harbin Institute of Technology (Zhao et al., 2001), and one developed at Stanford University (Tseng et al., 2005). In addition, we used a character-based segmentation. In the remaining of this paper, we use **CS** for character segmentation, **HS** for Harbin segmentation and **SS** for Stanford segmentation. We built two types of lattices: one that combines the Harbin and Stanford segmenters (**HS+SS**), and one which uses all three segmentations (**HS+SS+CS**).

**Data and Settings.** The systems used in these experiments were trained on the NIST MT06 Eval corpus without the UN data (approximately 950K sentences). The corpus was analyzed with the three segmentation schemes. For the systems using word lattices, the training data contained the versions of the corpus appropriate for the segmentation schemes used in the input. That is, for the **HS+SS** condition, the training data consisted of two copies of the corpus: one segmented with the Harbin segmenter and the other with the Stanford segmenter.<sup>3</sup> A trigram English language model with modified Kneser-Ney smoothing (Kneser and Ney, 1995) was trained on the English side of our training data as well as portions of the Gigaword v2 English Corpus, and was used for all experiments. The NIST MT03 test set was used as a development set for optimizing the interpolation weights using minimum error rate train-

<sup>3</sup>The corpora were word-aligned independently and then concatenated for rule extraction.

ing (Och, 2003). The testing was done on the NIST 2005 and 2006 evaluation sets (MT05, MT06).

**Experimental results: Word-lattices improve translation quality.** We used both a phrase-based translation model, decoded using our modified version of Moses (Koehn et al., 2007), and a hierarchical phrase-based translation model, using our modified version of Hiero (Chiang, 2005; Chiang, 2007). These two translation model types illustrate the applicability of the theoretical contributions presented in Section 2 and Section 3.

We observed that the coverage of named entities (NEs) in our baseline systems was rather poor. Since names in Chinese can be composed of relatively long strings of characters that cannot be translated individually, when generating the segmentation lattices that included **CS** arcs, we avoided segmenting NEs of type **PERSON**, as identified using a Chinese NE tagger (Florian et al., 2004).

The results are summarized in Table 4. We see that using word lattices improves BLEU scores both in the phrase-based model and hierarchical model as compared to the single-best segmentation approach. All results using our word-lattice decoding for the hierarchical models (**HS+SS** and **HS+SS+CS**) are significantly better than the best segmentation (**SS**).<sup>4</sup> For the phrase-based model, we obtain significant gains using our word-lattice decoder using all three segmentations on MT05. The other results, while better than the best segmentation (**HS**) by at least 0.3 BLEU points, are not statistically significant. Even if the results are not statistically significant for MT06, there is a high decrease in OOV items when using word-lattices. For example, for MT06 the number of OOVs in the **HS** translation is 484.

<sup>4</sup>Significance testing was carried out using the bootstrap resampling technique advocated by Koehn (2004). Unless otherwise noted, all reported improvements are significant at least  $p < 0.05$ .

Figure 6: Example of Arabic morphological segmentation.

The number of OOVs decreased by 19% for **hs+ss** and by 75% for **hs+ss+cs**. As mentioned in Section 3, using lexical reordering for word-lattices further improves the translation quality.

## 4.2 Arabic Morphology Experiments

We created lattices from an unsegmented version of the Arabic test data and generated alternative arcs where clitics as well as the definiteness marker and the future tense marker were segmented into tokens. We used the Buckwalter morphological analyzer and disambiguated the analysis using a simple unigram model trained on the Penn Arabic Treebank.

**Data and Settings.** For these experiments we made use of the entire NIST MT08 training data, although for training of the system, we used a sub-sampling method proposed by Kishore Papineni that aims to include training sentences containing  $n$ -grams in the test data (personal communication). For all systems, we used a 5-gram English LM trained on 250M words of English training data. The NIST MT03 test set was used as development set for optimizing the interpolation weights using MER training (Och, 2003). Evaluation was carried out on the NIST 2005 and 2006 evaluation sets (MT05, MT06).

**Experimental results: Word-lattices improve translation quality.** Results are presented in Table 5. Using word-lattices to combine the surface forms with morphologically segmented forms significantly improves BLEU scores both in the phrase-based and hierarchical models.

## 5 Prior work

**Lattice Translation.** The ‘noisier channel’ model of machine translation has been widely used in spoken language translation as an alternative to selecting the single-best hypothesis from an ASR system and translating it (Ney, 1999; Casacuberta et al., 2004; Zhang et al., 2005; Saleem et al., 2005; Matusov et al., 2005; Bertoldi et al., 2007; Mathias, 2007). Several authors (e.g. Saleem et al. (2005)

and Bertoldi et al. (2007)) comment directly on the impracticality of using  $n$ -best lists to translate speech.

Although translation is fundamentally a non-monotonic relationship between most language pairs, reordering has tended to be a secondary concern to the researchers who have worked on lattice translation. Matusov et al. (2005) decodes monotonically and then uses a finite state reordering model on the single-best translation, along the lines of Bangalore and Riccardi (2000). Mathias (2007) and Saleem et al. (2004) only report results of monotonic decoding for the systems they describe. Bertoldi et al. (2007) solve the problem by requiring that their input be in the format of a confusion network, which enables the standard distortion penalty to be used. Finally, the system described by Zhang et al. (2005) uses IBM Model 4 features to translate lattices. For the distortion model, they use the maximum probability value over all possible paths in the lattice for each jump considered, which is similar to the approach we have taken. Mathias and Byrne (2006) build a phrase-based translation system as a cascaded series of FSTs which can accept any input FSA; however, the only reordering that is permitted is the swapping of two adjacent phrases.

Applications of source lattices outside of the domain of spoken language translation have been far more limited. Costa-jussà and Fonollosa (2007) take steps in this direction by using lattices to encode multiple reorderings of the source language. Dyer (2007) uses confusion networks to encode morphological alternatives in Czech-English translation, and Xu et al. (2005) takes an approach very similar to ours for Chinese-English translation and encodes multiple word segmentations in a lattice, but which is decoded with a conventionally trained translation model and without a sophisticated reordering model.

The Arabic-English morphological segmentation lattices are similar in spirit to backoff translation models (Yang and Kirchhoff, 2006), which consider alternative morphological segmentations and simpli-

fications of a surface token when the surface token can not be translated.

**Parsing and formal language theory.** There has been considerable work on parsing word lattices, much of it for language modeling applications in speech recognition (Ney, 1991; Cheppalier and Rajman, 1998). Additionally, Grune and Jacobs (2008) refines an algorithm originally due to Bar-Hillel for intersecting an arbitrary FSA (of which word lattices are a subset) with a CFG. Klein and Manning (2001) formalize parsing as a hypergraph search problem and derive an  $O(n^3)$  parser for lattices.

## 6 Conclusions

We have achieved substantial gains in translation performance by decoding compact representations of alternative source language analyses, rather than single-best representations. Our results generalize previous gains for lattice translation of spoken language input, and we have further generalized the approach by introducing an algorithm for lattice decoding using a hierarchical phrase-based model. Additionally, we have shown that although word lattices complicate modeling of word reordering, a simple heuristic offers good performance and enables many standard distortion models to be used directly with lattice input.

## Acknowledgments

This research was supported by the GALE program of the Defense Advanced Research Projects Agency, Contract No. HR0011-06-2-0001. The authors wish to thank Niyu Ge for the Chinese named-entity analysis, Pi-Chuan Chang for her assistance with the Stanford Chinese segmenter, and Tie-Jun Zhao and Congui Zhu for making the Harbin Chinese segmenter available to us.

## Abstract

This paper proposes a novel method that exploits multiple resources to improve statistical machine translation (SMT) based paraphrasing. In detail, a phrasal paraphrase table and a feature function are derived from each resource, which are then combined in a log-linear SMT model for sentence-level paraphrase generation. Experimental results show that the SMT-based paraphrasing model can be enhanced using multiple resources. The phrase-level and sentence-level precision of the generated paraphrases are above 60% and 55%, respectively. In addition, the contribution of each resource is evaluated, which indicates that all the exploited resources are useful for generating paraphrases of high quality.

## 1 Introduction

Paraphrases are alternative ways of conveying the same meaning. Paraphrases are important in many natural language processing (NLP) applications, such as machine translation (MT), question answering (QA), information extraction (IE), multi-document summarization (MDS), and natural language generation (NLG).

This paper addresses the problem of sentence-level paraphrase generation, which aims at generating paraphrases for input sentences. An example of sentence-level paraphrases can be seen below:

*S1: The table was set up in the carriage shed.*

*S2: The table was laid under the cart-shed.*

---

\*This research was finished while the first author worked as an intern in Microsoft Research Asia.

Paraphrase generation can be viewed as monolingual machine translation (Quirk et al., 2004), which typically includes a translation model and a language model. The translation model can be trained using monolingual parallel corpora. However, acquiring such corpora is not easy. Hence, data sparseness is a key problem for the SMT-based paraphrasing. On the other hand, various methods have been presented to extract phrasal paraphrases from different resources, which include thesauri, monolingual corpora, bilingual corpora, and the web. However, little work has been focused on using the extracted phrasal paraphrases in sentence-level paraphrase generation.

In this paper, we exploit multiple resources to improve the SMT-based paraphrase generation. In detail, six kinds of resources are utilized, including: (1) an automatically constructed thesaurus, (2) a monolingual parallel corpus from novels, (3) a monolingual comparable corpus from news articles, (4) a bilingual phrase table, (5) word definitions from Encarta dictionary, and (6) a corpus of similar user queries. Among the resources, (1), (2), (3), and (4) have been investigated by other researchers, while (5) and (6) are first used in this paper. From those resources, six phrasal paraphrase tables are extracted, which are then used in a log-linear SMT-based paraphrasing model.

Both phrase-level and sentence-level evaluations were carried out in the experiments. In the former one, phrase substitutes occurring in the paraphrase sentences were evaluated. While in the latter one, the acceptability of the paraphrase sentences was evaluated. Experimental results show that: (1) The

SMT-based paraphrasing is enhanced using multiple resources. The phrase-level and sentence-level precision of the generated paraphrases exceed 60% and 55%, respectively. (2) Although the contributions of the resources differ a lot, all the resources are useful. (3) The performance of the method varies greatly on different test sets and it performs best on the test set of news sentences, which are from the same source as most of the training data.

The rest of the paper is organized as follows: Section 2 reviews related work. Section 3 introduces the log-linear model for paraphrase generation. Section 4 describes the phrasal paraphrase extraction from different resources. Section 5 presents the parameter estimation method. Section 6 shows the experiments and results. Section 7 draws the conclusion.

## 2 Related Work

Paraphrases have been used in many NLP applications. In MT, Callison-Burch et al. (2006) utilized paraphrases of unseen source phrases to alleviate data sparseness. Kauchak and Barzilay (2006) used paraphrases of the reference translations to improve automatic MT evaluation. In QA, Lin and Pantel (2001) and Ravichandran and Hovy (2002) paraphrased the answer patterns to enhance the recall of answer extraction. In IE, Shinyama et al. (2002) automatically learned paraphrases of IE patterns to reduce the cost of creating IE patterns by hand. In MDS, McKeown et al. (2002) identified paraphrase sentences across documents before generating summarizations. In NLG, Iordanskaja et al. (1991) used paraphrases to generate more varied and fluent texts.

Previous work has examined various resources for acquiring paraphrases, including thesauri, monolingual corpora, bilingual corpora, and the web. Thesauri, such as WordNet, have been widely used for extracting paraphrases. Some researchers extract synonyms as paraphrases (Kauchak and Barzilay, 2006), while some others use looser definitions, such as hypernyms and holonyms (Barzilay and Elhadad, 1997). Besides, the automatically constructed thesauri can also be used. Lin (1998) constructed a thesaurus by automatically clustering words based on context similarity.

Barzilay and McKeown (2001) used monolingual parallel corpora for identifying paraphrases. They

exploited a corpus of multiple English translations of the same source text written in a foreign language, from which phrases in aligned sentences that appear in similar contexts were extracted as paraphrases. In addition, Finch et al. (2005) applied MT evaluation methods (BLEU, NIST, WER and PER) to build classifiers for paraphrase identification.

Monolingual parallel corpora are difficult to find, especially in non-literature domains. Alternatively, some researchers utilized monolingual comparable corpora for paraphrase extraction. Different news articles reporting on the same event are commonly used as monolingual comparable corpora, from which both paraphrase patterns and phrasal paraphrases can be derived (Shinyama et al., 2002; Barzilay and Lee, 2003; Quirk et al., 2004).

Lin and Pantel (2001) learned paraphrases from a parsed monolingual corpus based on an extended distributional hypothesis, where if two paths in dependency trees tend to occur in similar contexts it is hypothesized that the meanings of the paths are similar. The monolingual corpus used in their work is not necessarily parallel or comparable. Thus it is easy to obtain. However, since this resource is used to extract paraphrase patterns other than phrasal paraphrases, we do not use it in this paper.

Bannard and Callison-Burch (2005) learned phrasal paraphrases using bilingual parallel corpora. The basic idea is that if two phrases are aligned to the same translation in a foreign language, they may be paraphrases. This method has been demonstrated effective in extracting large volume of phrasal paraphrases. Besides, Wu and Zhou (2003) exploited bilingual corpora and translation information in learning synonymous collocations.

In addition, some researchers extracted paraphrases from the web. For example, Ravichandran and Hovy (2002) retrieved paraphrase patterns from the web using hand-crafted queries. Pasca and Dienes (2005) extracted sentence fragments occurring in identical contexts as paraphrases from one billion web documents. Since web mining is rather time consuming, we do not exploit the web to extract paraphrases in this paper.

So far, two kinds of methods have been proposed for sentence-level paraphrase generation, i.e., the pattern-based and SMT-based methods. Automatically learned patterns have been used in para-

phrase generation. For example, Barzilay and Lee (2003) applied multiple-sequence alignment (MSA) to parallel news sentences and induced paraphrasing patterns for generating new sentences. Pang et al. (2003) built finite state automata (FSA) from semantically equivalent translation sets based on syntactic alignment and used the FSAs in paraphrase generation. The pattern-based methods can generate complex paraphrases that usually involve syntactic variation. However, the methods were demonstrated to be of limited generality (Quirk et al., 2004).

Quirk et al. (2004) first recast paraphrase generation as monolingual SMT. They generated paraphrases using a SMT system trained on parallel sentences extracted from clustered news articles. In addition, Madnani et al. (2007) also generated sentence-level paraphrases based on a SMT model. The advantage of the SMT-based method is that it achieves better coverage than the pattern-based method. The main difference between their methods and ours is that they only used bilingual parallel corpora as paraphrase resource, while we exploit and combine multiple resources.

### 3 SMT-based Paraphrasing Model

The SMT-based paraphrasing model used by Quirk et al. (2004) was the noisy channel model of Brown et al. (1993), which identified the optimal paraphrase  $T^*$  of a sentence  $S$  by finding:

$$\begin{aligned} T^* &= \arg \max_T \{P(T|S)\} \\ &= \arg \max_T \{P(S|T)P(T)\} \end{aligned} \quad (1)$$

In contrast, we adopt a log-linear model (Och and Ney, 2002) in this work, since multiple paraphrase tables can be easily combined in the log-linear model. Specifically, feature functions are derived from each paraphrase resource and then combined with the language model feature<sup>1</sup>:

$$T^* = \arg \max_T \left\{ \sum_{i=1}^N \lambda_{TM.i} h_{TM.i}(T, S) + \lambda_{LM} h_{LM}(T, S) \right\} \quad (2)$$

where  $N$  is the number of paraphrase tables.  $h_{TM.i}(T, S)$  is the feature function based on the  $i$ -th paraphrase table  $PT_i$ .  $h_{LM}(T, S)$  is the language

<sup>1</sup>The reordering model is not considered in our model.

model feature.  $\lambda_{TM.i}$  and  $\lambda_{LM}$  are the weights of the feature functions.  $h_{TM.i}(T, S)$  is defined as:

$$h_{TM.i}(T, S) = \log \prod_{k=1}^{K_i} \text{Score}_i(T_k, S_k) \quad (3)$$

where  $K_i$  is the number of phrase substitutes from  $S$  to  $T$  based on  $PT_i$ .  $T_k$  in  $T$  and  $S_k$  in  $S$  are phrasal paraphrases in  $PT_i$ .  $\text{Score}_i(T_k, S_k)$  is the paraphrase likelihood according to  $PT_i$ <sup>2</sup>. A 5-gram language model is used, therefore:

$$h_{LM}(T, S) = \log \prod_{j=1}^J p(t_j | t_{j-4}, \dots, t_{j-1}) \quad (4)$$

where  $J$  is the length of  $T$ ,  $t_j$  is the  $j$ -th word of  $T$ .

## 4 Exploiting Multiple Resources

This section describes the extraction of phrasal paraphrases using various resources. Similar to Pharaoh (Koehn, 2004), our decoder<sup>3</sup> uses top 20 paraphrase options for each input phrase in the default setting. Therefore, we keep at most 20 paraphrases for a phrase when extracting phrasal paraphrases using each resource.

**1 - Thesaurus:** The thesaurus<sup>4</sup> used in this work was automatically constructed by Lin (1998). The similarity of two words  $e_1$  and  $e_2$  was calculated through the surrounding context words that have dependency relations with the investigated words:

$$\begin{aligned} \text{Sim}(e_1, e_2) &= \frac{\sum_{(r,e) \in T_r(e_1) \cap T_r(e_2)} (I(e_1, r, e) + I(e_2, r, e))}{\sum_{(r,e) \in T_r(e_1)} I(e_1, r, e) + \sum_{(r,e) \in T_r(e_2)} I(e_2, r, e)} \end{aligned} \quad (5)$$

where  $T_r(e_i)$  denotes the set of words that have dependency relation  $r$  with word  $e_i$ .  $I(e_i, r, e)$  is the mutual information between  $e_i$ ,  $r$  and  $e$ .

For each word, we keep 20 most similar words as paraphrases. In this way, we extract 502,305 pairs of paraphrases. The paraphrasing score  $\text{Score}_1(p_1, p_2)$  used in Equation (3) is defined as the similarity based on Equation (5).

<sup>2</sup>If none of the phrase substitutes from  $S$  to  $T$  is from  $PT_i$  (i.e.,  $K_i = 0$ ), we cannot compute  $h_{TM.i}(T, S)$  as in Equation (3). In this case, we assign  $h_{TM.i}(T, S)$  a minimum value.

<sup>3</sup>The decoder used here is a re-implementation of Pharaoh.

<sup>4</sup><http://www.cs.ualberta.ca/~lindek/downloads.htm>.

**2 - Monolingual parallel corpus:** Following Barzilay and McKeown (2001), we exploit a corpus of multiple English translations of foreign novels, which contains 25,804 parallel sentence pairs. We find that most paraphrases extracted using the method of Barzilay and McKeown (2001) are quite short. Thus we employ a new approach for paraphrase extraction. Specifically, we parse the sentences with CollinsParser<sup>5</sup> and extract the chunks from the parsing results. Let  $S_1$  and  $S_2$  be a pair of parallel sentences,  $p_1$  and  $p_2$  two chunks from  $S_1$  and  $S_2$ , we compute the similarity of  $p_1$  and  $p_2$  as:

$$Sim(p_1, p_2) = \alpha Sim_{content}(p_1, p_2) + (1 - \alpha) Sim_{context}(p_1, p_2) \quad (6)$$

where,  $Sim_{content}(p_1, p_2)$  is the content similarity, which is the word overlapping rate of  $p_1$  and  $p_2$ .  $Sim_{context}(p_1, p_2)$  is the context similarity, which is the word overlapping rate of the contexts of  $p_1$  and  $p_2$ <sup>6</sup>. If the similarity of  $p_1$  and  $p_2$  exceeds a threshold  $Th_1$ , they are identified as paraphrases. We extract 18,698 pairs of phrasal paraphrases from this resource. The paraphrasing score  $Score_2(p_1, p_2)$  is defined as the similarity in Equation (6). For the paraphrases occurring more than once, we use their maximum similarity as the paraphrasing score.

**3 - Monolingual comparable corpus:** Similar to the methods in (Shinyama et al., 2002; Barzilay and Lee, 2003), we construct a corpus of comparable documents from a large corpus  $D$  of news articles. The corpus  $D$  contains 612,549 news articles. Given articles  $d_1$  and  $d_2$  from  $D$ , if their publication date interval is less than 2 days and their similarity<sup>7</sup> exceeds a threshold  $Th_2$ , they are recognized as comparable documents. In this way, a corpus containing 5,672,864 pairs of comparable documents is constructed. From the comparable corpus, parallel sentences are extracted. Let  $s_1$  and  $s_2$  be two sentences from comparable documents  $d_1$  and  $d_2$ , if their similarity based on word overlapping rate is above a threshold  $Th_3$ ,  $s_1$  and  $s_2$  are identified as parallel sentences. In this way, 872,330 parallel sentence pairs are extracted.

<sup>5</sup><http://people.csail.mit.edu/mcollins/code.html>

<sup>6</sup>The context of a chunk is made up of 6 words around the chunk, 3 to the left and 3 to the right.

<sup>7</sup>The similarity of two documents is computed using the vector space model and the word weights are based on tf-idf.

We run Giza++ (Och and Ney, 2000) on the parallel sentences and then extract aligned phrases as described in (Koehn, 2004). The generated paraphrase table is pruned by keeping the top 20 paraphrases for each phrase. After pruning, 100,621 pairs of paraphrases are extracted. Given phrase  $p_1$  and its paraphrase  $p_2$ , we compute  $Score_3(p_1, p_2)$  by relative frequency (Koehn et al., 2003):

$$Score_3(p_1, p_2) = p(p_2|p_1) = \frac{count(p_2, p_1)}{\sum_{p'} count(p', p_1)} \quad (7)$$

People may wonder why we do not use the same method on the monolingual parallel and comparable corpora. This is mainly because the volumes of the two corpora differ a lot. In detail, the monolingual parallel corpus is fairly small, thus automatic word alignment tool like Giza++ may not work well on it. In contrast, the monolingual comparable corpus is quite large, hence we cannot conduct the time-consuming syntactic parsing on it as we do on the monolingual parallel corpus.

**4 - Bilingual phrase table:** We first construct a bilingual phrase table that contains 15,352,469 phrase pairs from an English-Chinese parallel corpus. We extract paraphrases from the bilingual phrase table and compute the paraphrasing score of phrases  $p_1$  and  $p_2$  as in (Bannard and Callison-Burch, 2005):

$$Score_4(p_1, p_2) = \sum_f p(f|p_1)p(p_2|f) \quad (8)$$

where  $f$  denotes a Chinese translation of both  $p_1$  and  $p_2$ .  $p(f|p_1)$  and  $p(p_2|f)$  are the translation probabilities provided by the bilingual phrase table. For each phrase, the top 20 paraphrases are kept according to the score in Equation (8). As a result, 3,177,600 pairs of phrasal paraphrases are extracted.

**5 - Encarta dictionary definitions:** Words and their definitions can be regarded as paraphrases. Here are some examples from Encarta dictionary: “*hurricane: severe storm*”, “*clever: intelligent*”, “*travel: go on journey*”. In this work, we extract words’ definitions from Encarta dictionary web pages<sup>8</sup>. If a word has more than one definition, all of them are extracted. Note that the words and definitions in the

<sup>8</sup><http://encarta.msn.com/encnet/features/dictionary/dictionaryhome.aspx>

dictionary are lemmatized, but words in sentences are usually inflected. Hence, we expand the word - definition pairs by providing the inflected forms. Here we use an inflection list and some rules for inflection. After expanding, 159,456 pairs of phrasal paraphrases are extracted. Let  $\langle p_1, p_2 \rangle$  be a word - definition pair, the paraphrasing score is defined according to the rank of  $p_2$  in all of  $p_1$ 's definitions:

$$Score_5(p_1, p_2) = \gamma^{i-1} \quad (9)$$

where  $\gamma$  is a constant (we empirically set  $\gamma = 0.9$ ) and  $i$  is the rank of  $p_2$  in  $p_1$ 's definitions.

**6 - Similar user queries:** Clusters of similar user queries have been used for query expansion and suggestion (Gao et al., 2007). Since most queries are at the phrase level, we exploit similar user queries as phrasal paraphrases. In our experiment, we use the corpus of clustered similar MSN queries constructed by Gao et al. (2007). The similarity of two queries  $p_1$  and  $p_2$  is computed as:

$$Sim(p_1, p_2) = \beta Sim_{content}(p_1, p_2) + (1 - \beta) Sim_{click-through}(p_1, p_2) \quad (10)$$

where  $Sim_{content}(p_1, p_2)$  is the content similarity, which is computed as the word overlapping rate of  $p_1$  and  $p_2$ .  $Sim_{click-through}(p_1, p_2)$  is the click through similarity, which is the overlapping rate of the user clicked documents for  $p_1$  and  $p_2$ . For each query  $q$ , we keep the top 20 similar queries, whose similarity with  $q$  exceeds a threshold  $Th_4$ . As a result, 395,284 pairs of paraphrases are extracted. The score  $Score_6(p_1, p_2)$  is defined as the similarity in Equation (10).

**7 - Self-paraphrase:** In addition to the six resources introduced above, a special paraphrase table is used, which is made up of pairs of identical words. The reason why this paraphrase table is necessary is that a word should be allowed to keep unchanged in paraphrasing. This is a difference between paraphrasing and MT, since all words should be translated in MT. In our experiments, all the words that occur in the six paraphrase table extracted above are gathered to form the self-paraphrase table, which contains 110,403 word pairs. The score  $Score_7(p_1, p_2)$  is set 1 for each identical word pair.

## 5 Parameter Estimation

The weights of the feature functions, namely  $\lambda_{TM.i}$  ( $i = 1, 2, \dots, 7$ ) and  $\lambda_{LM}$ , need estimation<sup>9</sup>. In MT, the max-BLEU algorithm is widely used to estimate parameters. However, it may not work in our case, since it is more difficult to create a reference set of paraphrases.

We propose a new technique to estimate parameters in paraphrasing. The assumption is that, since a SMT-based paraphrase is generated through phrase substitution, we can measure the quality of a generated paraphrase by measuring its phrase substitutes. Generally, the paraphrases containing more correct phrase substitutes are judged as better paraphrases<sup>10</sup>. We therefore present the phrase substitution error rate (PSER) to score a generated paraphrase  $T$ :

$$PSER(T) = \|PS_0(T)\|/\|PS(T)\| \quad (11)$$

where  $PS(T)$  is the set of phrase substitutes in  $T$  and  $PS_0(T)$  is the set of incorrect substitutes.

In practice, we keep top  $n$  paraphrases for each sentence  $S$ . Thus we calculate the PSER for each source sentence  $S$  as:

$$PSER(S) = \|\bigcup_{i=1}^n PS_0(T_i)\|/\|\bigcup_{i=1}^n PS(T_i)\| \quad (12)$$

where  $T_i$  is the  $i$ -th generated paraphrase of  $S$ .

Suppose there are  $N$  sentences in the development set, the overall PSER is computed as:

$$PSER = \sum_{j=1}^N PSER(S_j) \quad (13)$$

where  $S_j$  is the  $j$ -th sentence in the development set.

Our development set contains 75 sentences (described in detail in Section 6). For each sentence, all possible phrase substitutes are extracted from the six paraphrase tables above. The extracted phrase substitutes are then manually labeled as ‘‘correct’’ or ‘‘incorrect’’. A phrase substitute is considered as correct only if the two phrases have the same meaning in the given sentence and the sentence generated by

<sup>9</sup>Note that, we also use some other parameters when extracting phrasal paraphrases from different resources, such as the thresholds  $Th_1, Th_2, Th_3, Th_4$ , as well as  $\alpha$  and  $\beta$  in Equation (6) and (10). These parameters are estimated using different development sets from the investigated resources. We do not describe the estimation of them due to space limitation.

<sup>10</sup>Paraphrasing a word to itself (based on the 7-th paraphrase table above) is not regarded as a substitute.

substituting the source phrase with the target phrase remains grammatical. In decoding, the phrase substitutes are printed out and then the PSER is computed based on the labeled data.

Using each set of parameters, we generate paraphrases for the sentences in the development set based on Equation (2). PSER is then computed as in Equation (13). We use the gradient descent algorithm (Press et al., 1992) to minimize PSER on the development set and get the optimal parameters.

## 6 Experiments

To evaluate the performance of the method on different types of test data, we used three kinds of sentences for testing, which were randomly extracted from Google news, free online novels, and forums, respectively. For each type, 50 sentences were extracted as test data and another 25 were extracted as development data. For each test sentence, top 10 of the generated paraphrases were kept for evaluation.

### 6.1 Phrase-level Evaluation

The phrase-level evaluation was carried out to investigate the contributions of the paraphrase tables. For each test sentence, all possible phrase substitutes were first extracted from the paraphrase tables and manually labeled as “correct” or “incorrect”. Here, the criterion for identifying paraphrases is the same as that described in Section 5. Then, in the stage of decoding, the phrase substitutes were printed out and evaluated using the labeled data.

Two metrics were used here. The first is the number of distinct correct substitutes (#DCS). Obviously, the more distinct correct phrase substitutes a paraphrase table can provide, the more valuable it is. The second is the accuracy of the phrase substitutes, which is computed as:

$$Accuracy = \frac{\#correct\ phrase\ substitutes}{\#all\ phrase\ substitutes} \quad (14)$$

To evaluate the PTs learned from different resources, we first used each PT (from 1 to 6) along with PT-7 in decoding. The results are shown in Table 1. It can be seen that PT-4 is the most useful, as it provides the most correct substitutes and the accuracy is the highest. We believe that it is because PT-4 is much larger than the other PTs. Compared with PT-4, the accuracies of the other PTs are fairly

PT combination	#DCS	Accuracy
1+7	178	14.61%
2+7	94	25.06%
3+7	202	18.35%
4+7	553	56.93%
5+7	231	20.48%
6+7	21	14.42%

Table 1: Contributions of the paraphrase tables.

PT-1: from the thesaurus; PT-2: from the monolingual parallel corpus; PT-3: from the monolingual comparable corpus; PT-4: from the bilingual parallel corpus; PT-5: from the Encarta dictionary definitions; PT-6: from the similar MSN user queries; PT-7: self-paraphrases.

low. This is because those PTs are smaller, thus they can provide fewer correct phrase substitutes. As a result, plenty of incorrect substitutes were included in the top 10 generated paraphrases.

PT-6 provides the least correct phrase substitutes and the accuracy is the lowest. There are several reasons. First, many phrases in PT-6 are not real phrases but only sets of keywords (e.g., “*lottery results ny*”), which may not appear in sentences. Second, many words in this table have spelling mistakes (e.g., “*widows vista*”). Third, some phrase pairs in PT-6 are not paraphrases but only “related queries” (e.g., “*back tattoo*” vs. “*butterfly tattoo*”). Fourth, many phrases of PT-6 contain proper names or out-of-vocabulary words, which are difficult to be matched. The accuracy based on PT-1 is also quite low. We found that it is mainly because the phrase pairs in PT-1 are automatically clustered, many of which are merely “similar” words rather than synonyms (e.g., “*borrow*” vs. “*buy*”).

Next, we try to find out whether it is necessary to combine all PTs. Thus we conducted several runs, each of which added the most useful PT from the left ones. The results are shown in Table 2. We can see that all the PTs are useful, as each PT provides some new correct phrase substitutes and the accuracy increases when adding each PT except PT-1.

Since the PTs are extracted from different resources, they have different contributions. Here we only discuss the contributions of PT-5 and PT-6, which are first used in paraphrasing in this paper. PT-5 is useful for paraphrasing uncommon concepts since it can “explain” concepts with their definitions.

PT combination	#DCS	Accuracy
4+7	553	56.93%
4+5+7	581	58.97%
4+5+3+7	638	59.42%
4+5+3+2+7	649	60.15%
4+5+3+2+1+7	699	60.14%
4+5+3+2+1+6+7	711	60.16%

Table 2: Performances of different combinations of paraphrase tables.

For instance, in the following test sentence  $S_1$ , the word “*amnesia*” is a relatively uncommon word, especially for the people using English as the second language. Based on PT-5,  $S_1$  can be paraphrased into  $T_1$ , which is much easier to understand.

$S_1$ : I was suffering from **amnesia**.  
 $T_1$ : I was suffering from **memory loss**.

The disadvantage of PT-5 is that substituting words with the definitions sometimes leads to grammatical errors. For instance, substituting “*heat shield*” in the sentence  $S_2$  with “*protective barrier against heat*” keeps the meaning unchanged. However, the paraphrased sentence  $T_2$  is ungrammatical.

$S_2$ : The U.S. space agency has been cautious about **heat shield** damage.  
 $T_2$ : The U.S. space administration has been cautious about **protective barrier against heat** damage.

As previously mentioned, PT-6 is less effective compared with the other PTs. However, it is useful for paraphrasing some special phrases, such as digital products, computer software, etc, since these phrases often appear in user queries. For example,  $S_3$  below can be paraphrased into  $T_3$  using PT-6.

$S_3$ : I have a **canon powershot** S230 that uses CF memory cards.  
 $T_3$ : I have a **canon digital camera** S230 that uses CF memory cards.

The phrase “*canon powershot*” can hardly be paraphrased using the other PTs. It suggests that PT-6 is useful for paraphrasing new emerging concepts and expressions.

Test sentences	Top-1	Top-5	Top-10
All 150	55.33%	45.20%	39.28%
50 from news	70.00%	62.00%	57.03%
50 from novel	56.00%	46.00%	37.42%
50 from forum	40.00%	27.60%	23.34%

Table 3: Top-n accuracy on different test sentences.

## 6.2 Sentence-level Evaluation

In this section, we evaluated the sentence-level quality of the generated paraphrases<sup>11</sup>. In detail, each generated paraphrase was manually labeled as “acceptable” or “unacceptable”. Here, the criterion for counting a sentence  $T$  as an acceptable paraphrase of sentence  $S$  is that  $T$  is understandable and its meaning is not evidently changed compared with  $S$ . For example, for the sentence  $S_4$ ,  $T_4$  is an acceptable paraphrase generated using our method.

$S_4$ : The **strain on US forces** of fighting in Iraq and Afghanistan **was exposed** yesterday when the Pentagon **published a report** showing that the **number** of suicides among US **troops** is at its **highest level** since the 1991 Gulf war.  
 $T_4$ : The **pressure on US troops** of fighting in Iraq and Afghanistan **was revealed** yesterday when the Pentagon **released a report** showing that the **amount** of suicides among US **forces** is at its **top** since the 1991 Gulf conflict.

We carried out sentence-level evaluation using the top-1, top-5, and top-10 results of each test sentence. The accuracy of the top-n results was computed as:

$$Accuracy_{top-n} = \frac{\sum_{i=1}^N n_i}{N \times n} \quad (15)$$

where  $N$  is the number of test sentences.  $n_i$  is the number of acceptable paraphrases in the top-n paraphrases of the  $i$ -th test sentence.

We computed the accuracy on the whole test set (150 sentences) as well as on the three subsets, i.e., the 50 news sentences, 50 novel sentences, and 50 forum sentences. The results are shown in table 3.

It can be seen that the accuracy varies greatly on different test sets. The accuracy on the news sentences is the highest, while that on the forum sentences is the lowest. There are several reasons. First,

<sup>11</sup>The evaluation was based on the paraphrasing results using the combination of all seven PTs.

the largest PT used in the experiments is extracted using the bilingual parallel data, which are mostly from news documents. Thus, the test set of news sentences is more similar to the training data.

Second, the news sentences are formal while the novel and forum sentences are less formal. Especially, some of the forum sentences contain spelling mistakes and grammar mistakes.

Third, we find in the results that, most phrases paraphrased in the novel and forum sentences are commonly used phrases or words, such as “*food*”, “*good*”, “*find*”, etc. These phrases are more difficult to paraphrase than the less common phrases, since they usually have much more paraphrases in the PTs. Therefore, it is more difficult to choose the right paraphrase from all the candidates when conducting sentence-level paraphrase generation.

Fourth, the forum sentences contain plenty of words such as “*board* (means *computer board*)”, “*site* (means *web site*)”, “*mouse* (means *computer mouse*)”, etc. These words are polysemous and have particular meanings in the domains of computer science and internet. Our method performs poor when paraphrasing these words since the domain of a context sentence is hard to identify.

After observing the results, we find that there are three types of errors: (1) syntactic errors: the generated sentences are ungrammatical. About 32% of the unacceptable results are due to syntactic errors. (2) semantic errors: the generated sentences are incomprehensible. Nearly 60% of the unacceptable paraphrases have semantic errors. (3) non-paraphrase: the generated sentences are well formed and comprehensible but are not paraphrases of the input sentences. 8% of the unacceptable results are of this type. We believe that many of the errors above can be avoided by applying syntactic constraints and by making better use of context information in decoding, which is left as our future work.

## 7 Conclusion

This paper proposes a method that improves the SMT-based sentence-level paraphrase generation using phrasal paraphrases automatically extracted from different resources. Our contribution is that we combine multiple resources in the framework of SMT for paraphrase generation, in which the dic-

tionary definitions and similar user queries are first used as phrasal paraphrases. In addition, we analyze and compare the contributions of different resources.

Experimental results indicate that although the contributions of the exploited resources differ a lot, they are all useful to sentence-level paraphrase generation. Especially, the dictionary definitions and similar user queries are effective for paraphrasing some certain types of phrases.

In the future work, we will try to use syntactic and context constraints in paraphrase generation to enhance the acceptability of the paraphrases. In addition, we will extract paraphrase patterns that contain more structural variation and try to combine the SMT-based and pattern-based systems for sentence-level paraphrase generation.

## Acknowledgments

We would like to thank Mu Li for providing us with the SMT decoder. We are also grateful to Dongdong Zhang for his help in the experiments.

## Abstract

This paper studies textual inference by investigating comma structures, which are highly frequent elements whose major role in the extraction of semantic relations has not been hitherto recognized. We introduce the problem of comma resolution, defined as understanding the role of commas and extracting the relations they imply. We show the importance of the problem using examples from Textual Entailment tasks, and present *A Sentence Transformation Rule Learner (ASTRL)*, a machine learning algorithm that uses a syntactic analysis of the sentence to learn sentence transformation rules that can then be used to extract relations. We have manually annotated a corpus identifying comma structures and relations they entail and experimented with both gold standard parses and parses created by a leading statistical parser, obtaining F-scores of 80.2% and 70.4% respectively.

## 1 Introduction

Recognizing relations expressed in text sentences is a major topic in NLP, fundamental in applications such as Textual Entailment (or Inference), Question Answering and Text Mining. In this paper we address this issue from a novel perspective, that of understanding the role of the commas in a sentence, which we argue is a key component in sentence comprehension. Consider for example the following three sentences:

1. *Authorities have arrested John Smith, a retired police officer.*
2. *Authorities have arrested John Smith, his friend and his brother.*

3. *Authorities have arrested John Smith, a retired police officer announced this morning.*

Sentence (1) states that John Smith is a retired police officer. The comma and surrounding sentence structure represent the relation ‘IsA’. In (2), the comma and surrounding structure signifies a list, so the sentence states that three people were arrested: (i) John Smith, (ii) his friend, and (iii) his brother. In (3), a retired police officer announced that John Smith has been arrested. Here, the comma and surrounding sentence structure indicate clause boundaries.

In all three sentences, the comma and the surrounding sentence structure signify relations essential to comprehending the meaning of the sentence, in a way that is not easily captured using lexical or even shallow parse-level information. As a human reader, we understand them easily, but automated systems for Information Retrieval, Question Answering, and Textual Entailment are likely to encounter problems when comparing structures like these, which are lexically similar, but whose meanings are so different.

In this paper we present an algorithm for *comma resolution*, a task that we define to consist of (1) disambiguating comma type and (2) determining the relations entailed from the sentence given the commas’ interpretation. Specifically, in (1) we assign each comma to one of five possible types, and in (2) we generate a set of natural language sentences that express the relations, if any, signified by each comma structure. The algorithm uses information extracted from parse trees. This work, in addition to having immediate significance for natural language processing systems that use semantic content, has potential applications in improving a range of auto-

mated analysis by decomposing complex sentences into a set of simpler sentences that capture the same meaning. Although there are many other widely-used structures that express relations in a similar way, commas are one of the most commonly used symbols<sup>1</sup>. By addressing comma resolution, we offer a promising first step toward resolving relations in sentences.

To evaluate the algorithm, we have developed annotation guidelines, and manually annotated sentences from the WSJ PennTreebank corpus. We present a range of experiments showing the good performance of the system, using gold-standard and parser-generated parse trees.

In Section 2 we motivate comma resolution through Textual Entailment examples. Section 3 describes related work. Sections 4 and 5 present our corpus annotation and learning algorithm. Results are given in Section 6.

## 2 Motivating Comma Resolution Through Textual Entailment

Comma resolution involves not only comma disambiguation but also inference of the arguments (and argument boundaries) of the relationship represented by the comma structure, and the relationships holding between these arguments and the sentence as a whole. To our knowledge, this is the first paper that deals with this problem, so in this section we motivate it in depth by showing its importance to the semantic inference task of Textual Entailment (TE) (Dagan et al., 2006), which is increasingly recognized as a crucial direction for improving a range of NLP tasks such as information extraction, question answering and summarization.

TE is the task of deciding whether the meaning of a text  $T$  (usually a short snippet) can be inferred from the meaning of another text  $S$ . If this is the case, we say that  $S$  entails  $T$ . For example<sup>2</sup>, we say that sentence (1) entails sentence (2):

1.  $S$ : *Parviz Davudi was representing Iran at a meeting of the Shanghai Co-operation Organization (SCO), the fledgling association that*

<sup>1</sup>For example, the WSJ corpus has 49K sentences, among which 32K with one comma or more, 17K with two or more, and 7K with three or more.

<sup>2</sup>The examples of this section are variations of pairs taken from the Pascal RTE3 (Dagan et al., 2006) dataset.

*binds two former Soviet republics of central Asia, Russia and China to fight terrorism.*

2.  $T$ : *SCO is the fledgling association that binds several countries.*

To see that (1) entails (2), one must understand that the first comma structure in sentence (1) is an apposition structure, and does not indicate the beginning of a list. The second comma marks a boundary between entities in a list. To make the correct inference one must determine that the second comma is a list separator, not an apposition marker. Misclassifying the second comma in (1) as an apposition leads to the conclusion that (1) entails (3):

3.  $T$ : *Russia and China are two former Soviet republics of central Asia .*

Note that even to an educated native speaker of English, sentence 1 may be initially confusing; during the first reading, one might interpret the first comma as indicating a list, and that ‘the Shanghai Co-operation Organization’ and ‘the fledgling association that binds...’ are two separate entities that are meeting, rather than two representations of the same entity.

From these examples we draw the following conclusions: 1. Comma resolution is essential in comprehending natural language text. 2. Explicitly representing relations derived from comma structures can assist a wide range of NLP tasks; this can be done by directly augmenting the lexical-level representation, e.g., by bringing surface forms of two text fragments with the same meaning closer together. 3. Comma structures might be highly ambiguous, nested and overlapping, and consequently their interpretation is a difficult task. The argument boundaries of the corresponding extracted relations are also not easy to detect.

The output of our system could be used to augment sentences with an explicit representation of entailed relations that hold in them. In Textual Entailment systems this can increase the likelihood of correct identification of entailed sentences, and in other NLP systems it can help understanding the shallow lexical/syntactic content of a sentence. A similar approach has been taken in (Bar-Haim et al., 2007; de Salvo Braz et al., 2005), which augment the source sentence with entailed relations.

### 3 Related Work

Since we focus on extracting the relations represented by commas, there are two main strands of research with similar goals: 1) systems that directly analyze commas, whether labeling them with syntactic information or correcting inappropriate use in text; and 2) systems that extract relations from text, typically by trying to identify paraphrases.

The significance of interpreting the role of commas in sentences has already been identified by (van Delden and Gomez, 2002; Bayraktar et al., 1998) and others. A review of the first line of research is given in (Say and Akman, 1997).

In (Bayraktar et al., 1998) the WSJ PennTreebank corpus (Marcus et al., 1993) is analyzed and a very detailed list of syntactic patterns that correspond to different roles of commas is created. However, they do not study the extraction of entailed relations as a function of the comma's interpretation. Furthermore, the syntactic patterns they identify are unlexicalized and would not support the level of semantic relations that we show in this paper. Finally, theirs is a manual process completely dependent on syntactic patterns. While our comma resolution system uses syntactic parse information as its main source of features, the approach we have developed focuses on the *entailed relations*, and does not limit implementations to using only syntactic information.

The most directly comparable prior work is that of (van Delden and Gomez, 2002), who use finite state automata and a greedy algorithm to learn comma syntactic roles. However, their approach differs from ours in a number of critical ways. First, their comma annotation scheme does not identify arguments of predicates, and therefore cannot be used to extract complete relations. Second, for each comma type they identify, a new Finite State Automaton must be hand-encoded; the learning component of their work simply constrains which FSAs that accept a given, comma containing, text span may co-occur. Third, their corpus is preprocessed by hand to identify specialized phrase types needed by their FSAs; once our system has been trained, it can be applied directly to raw text. Fourth, they exclude from their analysis and evaluation any comma they deem to have been incorrectly used in the source text. We include all commas that are present in the

text in our annotation and evaluation.

There is a large body of NLP literature on punctuation. Most of it, however, is concerned with aiding syntactic analysis of sentences and with developing comma checkers, much based on (Nunberg, 1990).

Pattern-based relation extraction methods (e.g., (Davidov and Rappoport, 2008; Davidov et al., 2007; Banko et al., 2007; Pasca et al., 2006; Sekine, 2006)) could in theory be used to extract relations represented by commas. However, the types of patterns used in web-scale lexical approaches currently constrain discovered patterns to relatively short spans of text, so will most likely fail on structures whose arguments cover large spans (for example, appositional clauses containing relative clauses). Relation extraction approaches such as (Roth and Yih, 2004; Roth and Yih, 2007; Hirano et al., 2007; Culotta and Sorenson, 2004; Zelenko et al., 2003) focus on relations between Named Entities; such approaches miss the more general apposition and list relations we recognize in this work, as the arguments in these relations are not confined to Named Entities.

Paraphrase Acquisition work such as that by (Lin and Pantel, 2001; Pantel and Pennacchiotti, 2006; Szpektor et al., 2004) is not constrained to named entities, and by using dependency trees, avoids the locality problems of lexical methods. However, these approaches have so far achieved limited accuracy, and are therefore hard to use to augment existing NLP systems.

### 4 Corpus Annotation

For our corpus, we selected 1,000 sentences containing at least one comma from the Penn Treebank (Marcus et al., 1993) WSJ section 00, and manually annotated them with comma information<sup>3</sup>. This annotated corpus served as both training and test datasets (using cross-validation).

By studying a number of sentences from WSJ (not among the 1,000 selected), we identified four significant types of relations expressed through commas: SUBSTITUTE, ATTRIBUTE, LOCATION, and LIST. Each of these types can in principle be expressed using more than a single comma. We define the notion

<sup>3</sup>The guidelines and annotations are available at <http://L2R.cs.uiuc.edu/~cogcomp/data.php>.

of a *comma structure* as a set of one or more commas that all relate to the same relation in the sentence.

SUBSTITUTE indicates an IS-A relation. An example is ‘John Smith, a Renaissance artist, was famous’. By removing the relation expressed by the commas, we can derive three sentences: ‘John Smith is a Renaissance artist’, ‘John Smith was famous’, and ‘a Renaissance artist was famous’. Note that in theory, the third relation will not be valid: one example is ‘The brothers, all honest men, testified at the trial’, which does not entail ‘all honest men testified at the trial’. However, we encountered no examples of this kind in the corpus, and leave this refinement to future work.

ATTRIBUTE indicates a relation where one argument describes an attribute of the other. For example, from ‘John, who loved chocolate, ate with gusto’, we can derive ‘John loved chocolate’ and ‘John ate with gusto’.

LOCATION indicates a LOCATED-IN relation. For example, from ‘Chicago, Illinois saw some heavy snow today’ we can derive ‘Chicago is located in Illinois’ and ‘Chicago saw some heavy snow today’.

LIST indicates that some predicate or property is applied to multiple entities. In our annotation, the list does not generate explicit relations; instead, the boundaries of the units comprising the list are marked so that they can be treated as a single unit, and are considered to be related by the single relation ‘GROUP’. For example, the derivation of ‘John, James and Kelly all left last week’ is written as ‘[John, James, and Kelly] [all left last week]’.

Any commas not fitting one of the descriptions above are designated as OTHER. This does not indicate that the comma signifies no relations, only that it does not signify a relation of interest in this work (future work will address relations currently subsumed by this category). Analysis of 120 OTHER commas show that approximately half signify clause boundaries, which may occur when sentence constituents are reordered for emphasis, but may also encode implicit temporal, conditional, and other relation types (for example, ‘Opening the drawer, he found the gun.’). The remainder comprises mainly coordination structures (for example, ‘Although he won, he was sad’) and discourse markers indicating inter-sentence relations (such as ‘However, he soon cheered up.’). While we plan to develop an anno-

Rel. Type	Avg. Agreement	# of Commas	# of Rel.s
SUBSTITUTE	0.808	243	729
ATTRIBUTE	0.687	193	386
LOCATION	0.929	71	140
LIST	0.803	230	230
OTHER	0.949	909	0
<i>Combined</i>	0.869	1646	1485

Table 1: Average inter-annotator agreement for identifying relations.

tation scheme for such relations, this is beyond the scope of the present work.

Four annotators annotated the same 10% of the WSJ sentences in order to evaluate inter-annotator agreement. The remaining sentences were divided among the four annotators. The resulting corpus was checked by two judges and the annotation corrected where appropriate; if the two judges disagreed, a third judge was consulted and consensus reached. Our annotators were asked to identify comma structures, and for each structure to write its relation type, its arguments, and all possible simplified version(s) of the original sentence in which the relation implied by the comma has been removed. Arguments must be contiguous units of the sentence and will be referred to as *chunks* hereafter. Agreement statistics and the number of commas and relations of each type are shown in Table 4. The Accuracy closely approximates Kappa score in this case, since the baseline probability of chance agreement is close to zero.

## 5 A Sentence Transformation Rule Learner (ASTRL)

In this section, we describe a new machine learning system that learns Sentence Transformation Rules (STRs) for comma resolution. We first define the hypothesis space (i.e., STRs) and two operations – substitution and introduction. We then define the feature space, motivating the use of Syntactic Parse annotation to learn STRs. Finally, we describe the ASTRL algorithm.

### 5.1 Sentence Transformation Rules

A **Sentence Transformation Rule (STR)** takes a parse tree as input and generates new sentences. We formalize an STR as the pair  $l \rightarrow r$ , where  $l$  is a tree fragment that can consist of non-terminals, POS tags and lexical items.  $r$  is a set  $\{r_i\}$ , each element of which is a template that consists of the non-

terminals of  $l$  and, possibly, some new tokens. This template is used to generate a new sentence, called a *relation*.

The process of applying an STR  $l \rightarrow r$  to a parse tree  $T$  of a sentence  $s$  begins with finding a match for  $l$  in  $T$ . A match is said to be found if  $l$  is a subtree of  $T$ . If matched, the non-terminals of each  $r_i$  are instantiated with the terminals that they cover in  $T$ . Instantiation is followed by generation of the output relations in one of two ways: *introduction* or *substitution*, which is specified by the corresponding  $r_i$ . If an  $r_i$  is marked as an introductory one, then the relation is the terminal sequence obtained by replacing the non-terminals in  $r_i$  with their instantiations. For substitution, firstly, the non-terminals of the  $r_i$  are replaced by their instantiations. The instantiated  $r_i$  replaces all the terminals in  $s$  that are covered by the  $l$ -match. The notions of introduction and substitution were motivated by ideas introduced in (Bar-Haim et al., 2007).

Figure 1 shows an example of an STR and Figure 2 shows the application of this STR to a sentence. In the first relation,  $NP_1$  and  $NP_2$  are instantiated with the corresponding terminals in the parse tree. In the second and third relations, the terminals of  $NP_1$  and  $NP_2$  replace the terminals covered by  $NP_p$ .

Figure 1: Example of a Sentence Transformation Rule. If the *LHS* matches a part of a given parse tree, then the *RHS* will generate three relations.

## 5.2 The Feature Space

In Section 2, we discussed the example where there could be an ambiguity between a list and an apposition structure in the fragment *two former Soviet republics, Russia and China*. In addition, simple surface examination of the sentence could also identify the noun phrases ‘*Shanghai Co-operation Organization (SCO)*’, ‘*the fledgling association that binds*

- 1 [John Smith]/ $NP_1$  be [a renaissance artist]/ $NP_2$
- 2 [John Smith] / $NP_1$  [was famous]
- 3 [a renaissance artist]/ $NP_2$  [was famous]

Figure 2: Example of application of the STR in Figure 1. In the first relation, an introduction, we use the verb ‘be’, without dealing with its inflections.  $NP_1$  and  $NP_2$  are both substitutions, each replacing  $NP_p$  to generate the last two relations.

*two former Soviet Republics*’, ‘*Russia*’ and ‘*China*’ as the four members of a list. To resolve such ambiguities, we need a nested representation of the sentence. This motivates the use of syntactic parse trees as a logical choice of feature space. (Note, however, that semantic and pragmatic ambiguities might still remain.)

## 5.3 Algorithm Overview

In our corpus annotation, the relations and their argument boundaries (chunks) are explicitly marked. For each training example, our learning algorithm first finds the smallest valid STR – the STR with the smallest *LHS* in terms of depth. Then it refines the *LHS* by specializing it using statistics taken from the entire data set.

## 5.4 Generating the Smallest Valid STR

To transform an example into the smallest valid STR, we utilize the augmented parse tree of the sentence. For each chunk in the sentence, we find the lowest node in the parse tree that covers the chunk and does not cover other chunks (even partially). It may, however, cover words that do not belong to any chunk. We refer to such a node as a *chunk root*. We then find the lowest node that covers all the chunk roots, referring to it as the *pattern root*. The initial *LHS* consists of the subtree of the parse tree rooted at the pattern root and whose leaf nodes are all either chunk roots or nodes that do not belong to any chunk. All the nodes are labeled with the corresponding labels in the aug-

mented parse tree. For example, if we consider the parse tree and relations shown in Figure 2, then doing the above procedure gives us the initial *LHS* as  $S(NP_p(NP_1, NP_2), VP)$ . The three relations gives us the *RHS* with three elements ‘ $NP_1$  be  $NP_2$ ’, ‘ $NP_1 VP$ ’ and ‘ $NP_1 VP$ ’, all three being introduction.

This initial *LHS* need not be the smallest one that explains the example. So, we proceed by finding the lowest node in the initial *LHS* such that the subtree of the *LHS* at that node can form a new STR that covers the example using both introduction *and* substitution. In our example, the initial *LHS* has a subtree,  $NP_p(NP_1, NP_2, )$  that can cover all the relations with the *RHS* consisting of ‘ $NP_1$  be  $NP_2$ ’,  $NP_1$  and  $NP_2$ . The first *RHS* is an introduction, while the second and the third are both substitutions. Since no subtree of this *LHS* can generate all three relations even with substitution, this is the required STR. The final step ensures that we have the smallest valid STR at this stage.

## 5.5 Statistical Refinement

The STR generated using the procedure outlined above explains the relations generated by a single example. In addition to covering the relations generated by the example, we wish to ensure that it does not cover erroneous relations by matching any of the other comma types in the annotated data.

---

### Algorithm 1 ASTRL: A Sentence Transformation Rule Learning.

---

```

1: for all  $t$ : Comma type do
2:   Initialize  $STRList[t] = \emptyset$ 
3:    $\mathbf{p} =$  Set of annotated examples of type  $t$ 
4:    $\mathbf{n} =$  Annotated examples of all other types
5:   for all  $x \in \mathbf{p}$  do
6:      $r =$  Smallest Valid STR that covers  $x$ 
7:     Get fringe of  $r.LHS$  using the parse tree
8:      $S = Score(r, \mathbf{p}, \mathbf{n})$ 
9:      $S_{prev} = -\infty$ 
10:    while  $S \neq S_{prev}$  do
11:      if adding some fringe node to  $r.LHS$  causes a significant change in score then
12:        Set  $r =$  New rule that includes that fringe node
13:         $S_{prev} = S$ 
14:         $S = Score(r, \mathbf{p}, \mathbf{n})$ 
15:        Recompute new fringe nodes
16:      end if
17:    end while
18:    Add  $r$  to  $STRList[t]$ 
19:    Remove all examples from  $\mathbf{p}$  that are covered by  $r$ 
20:  end for
21: end for

```

---

For this purpose, we specialize the *LHS* so that it covers as few examples from the other comma types as possible, while covering as many examples from the current comma type as possible. Given the most general STR, we generate a set of additional, more detailed, candidate rules. Each of these is obtained from the original rule by adding a single node to the tree pattern in the rule’s *LHS*, and updating the rule’s *RHS* accordingly. We then score each of the candidates (including the original rule). If there is a clear winner, we continue with it using the same procedure (i.e., specialize it). If there isn’t a clear winner, we stop and use the current winner. After finishing with a rule (line 18), we remove from the set of positive examples of its comma type all examples that are covered by it (line 19).

To generate the additional candidate rules that we add, we define the *fringe* of a rule as the siblings and children of the nodes in its *LHS* in the original parse tree. Each fringe node defines an additional candidate rule, whose *LHS* is obtained by adding the fringe node to the rule’s *LHS* tree. We refer to the set of these candidate rules, plus the original one, as the rule’s *fringe rules*. We define the score of an STR as

$$Score(Rule, \mathbf{p}, \mathbf{n}) = \frac{R_p}{|\mathbf{p}|} - \frac{R_n}{|\mathbf{n}|}$$

where  $\mathbf{p}$  and  $\mathbf{n}$  are the set of positive and negative examples for this comma type, and  $R_p$  and  $R_n$  are the number of positive and negative examples that are covered by the STR. For each example, all examples annotated with the same comma type are positive while all examples of all other comma types are negative. The score is used to select the winner among the fringe rules. The complete algorithm we have used is listed in Algorithm 1. For convenience, the algorithm’s main loop is given in terms of comma types, although this is not strictly necessary. The stopping criterion in line 11 checks whether any fringe rule has a significantly better score than the rule it was derived from, and exits the specialization loop if there is none.

Since we start with the smallest STR, we only need to add nodes to it to refine it and never have to delete any nodes from the tree. Also note that the algorithm is essentially a greedy algorithm that performs a single pass over the examples; other, more

complex, search strategies could also be used.

## 6 Evaluation

### 6.1 Experimental Setup

To evaluate ASTRL, we used the WSJ derived corpus. We experimented with three scenarios; in two of them we trained using the gold standard trees and then tested on gold standard parse trees (*Gold-Gold*), and text annotated using a state-of-the-art statistical parser (Charniak and Johnson, 2005) (*Gold-Charniak*), respectively. In the third, we trained and tested on the Charniak Parser (*Charniak-Charniak*).

In gold standard parse trees the syntactic categories are annotated with functional tags. Since current statistical parsers do not annotate sentences with such tags, we augment the syntactic trees with the output of a Named Entity tagger. For the Named Entity information, we used a publicly available NE Recognizer capable of recognizing a range of categories including Person, Location and Organization. On the CoNLL-03 shared task, its f-score is about 90%<sup>4</sup>. We evaluate our system from different points of view, as described below. For all the evaluation methods, we performed five-fold cross validation and report the average precision, recall and f-scores.

### 6.2 Relation Extraction Performance

Firstly, we present the evaluation of the performance of ASTRL from the point of view of relation extraction. After learning the STRs for the different comma types using the gold standard parses, we generated relations by applying the STRs on the test set once. Table 2 shows the precision, recall and f-score of the relations, without accounting for the comma type of the STR that was used to generate them. This metric, called the *Relation metric* in further discussion, is the most relevant one from the point of view of the TE task. Since a list does not generate any relations in our annotation scheme, we use the commas to identify the list elements. Treating each list in a sentence as a single relation, we score the list with the fraction of its correctly identified elements.

In addition to the Gold-Gold and Gold-Charniak

<sup>4</sup>A web demo of the NER is at <http://L2R.cs.uiuc.edu/~cogcomp/demos.php>.

settings described above, for this metric, we also present the results of the Charniak-Charniak setting, where both the train and test sets were annotated with the output of the Charniak parser. The improvement in recall in this setting over the Gold-Charniak case indicates that the parser makes systematic errors with respect to the phenomena considered.

Setting	P	R	F
Gold-Gold	86.1	75.4	80.2
Gold-Charniak	77.3	60.1	68.1
Charniak-Charniak	77.2	64.8	70.4

Table 2: ASTRL performance (precision, recall and f-score) for relation extraction. The comma types were used only to learn the rules. During evaluation, only the relations were scored.

### 6.3 Comma Resolution Performance

We present a detailed analysis of the performance of the algorithm for comma resolution. Since this paper is the first one that deals with the task, we could not compare our results to previous work. Also, there is no clear baseline to use. We tried a variant of the most frequent baseline common in other disambiguation tasks, in which we labeled all commas as OTHER (the most frequent type) except when there are list indicators like *and*, *or* and *but* in adjacent chunks (which are obtained using a shallow parser), in which case the commas are labeled LIST. This gives an average precision 0.85 and an average recall of 0.36 for identifying the comma type. However, this baseline does not help in identifying relations.

We use the following approach to evaluate the comma type resolution *and* relation extraction performance – a relation extracted by the system is considered correct only if both the relation and the type of the comma structure that generated it are correctly identified. We call this metric the *Relation-Type metric*. Another way of measuring the performance of comma resolution is to measure the correctness of the relations per comma type. In both cases, lists are scored as in the Relation metric. The performance of our system with respect to these two metrics are presented in Table 3. In this table, we also compare the performance of the STRs learned by ASTRL with the smallest valid STRs without further specialization (i.e., using just the procedure outlined in Section 5.4).

Type	Gold-Gold Setting						Gold-Charniak Setting					
	Relation-Type metric											
	Smallest Valid STRs			ASTRL			Smallest Valid STRs			ASTRL		
	P	R	F	P	R	F	P	R	F	P	R	F
Total	66.2	76.1	70.7	81.8	73.9	<b>77.6</b>	61.0	58.4	59.5	72.2	59.5	<b>65.1</b>
Relations Metric, Per Comma Type												
ATTRIBUTE	40.4	68.2	50.4	70.6	59.4	<b>64.1</b>	35.5	39.7	36.2	56.6	37.7	<b>44.9</b>
SUBSTITUTE	80.0	84.3	81.9	87.9	84.8	<b>86.1</b>	75.8	72.9	74.3	78.0	76.1	<b>76.9</b>
LIST	70.9	58.1	63.5	76.2	57.8	<b>65.5</b>	58.7	53.4	55.6	65.2	53.3	<b>58.5</b>
LOCATION	93.8	86.4	<b>89.1</b>	93.8	86.4	<b>89.1</b>	70.3	37.2	<b>47.2</b>	70.3	37.2	<b>47.2</b>

Table 3: Performance of STRs learned by ASTRL and the smallest valid STRs in identifying comma types and generating relations.

There is an important difference between the Relation metric (Table 2) and the Relation-type metric (top part of Table 3) that depends on the semantic interpretation of the comma types. For example, consider the sentence ‘John Smith, 59, went home.’ If the system labels the commas in this as both ATTRIBUTE and SUBSTITUTE, then, both will generate the relation ‘John Smith is 59.’ According to the Relation metric, there is no difference between them. However, there is a semantic difference between the two sentences – the ATTRIBUTE relation says that being 59 is an attribute of John Smith while the SUBSTITUTE relation says that John Smith is the number 59. This difference is accounted for by the Relation-Type metric.

From this standpoint, we can see that the specialization step performed in the full ASTRL algorithm greatly helps in disambiguating between the ATTRIBUTE and SUBSTITUTE types and consequently, the Relation-Type metric shows an error reduction of 23.5% and 13.8% in the Gold-Gold and Gold-Charniak settings respectively. In the Gold-Gold scenario the performance of ASTRL is much better than in the Gold-Charniak scenario. This reflects the non-perfect performance of the parser in annotating these sentences (parser F-score of 90%).

Another key evaluation question is the performance of the method in identification of the OTHER category. A comma is judged to be as OTHER if no STR in the system applies to it. The performance of ASTRL in this aspect is presented in Table 4. The categorization of this category is important if we wish to further classify the OTHER commas into finer categories.

Setting	P	R	F
Gold-Gold	78.9	92.8	85.2
Gold-Charniak	72.5	92.2	81.2

Table 4: ASTRL performance (precision, recall and f-score) for OTHER identification.

## 7 Conclusions

We defined the task of comma resolution, and developed a novel machine learning algorithm that learns Sentence Transformation Rules to perform this task. We experimented with both gold standard and parser annotated sentences, and established a performance level that seems good for a task of this complexity, and which will provide a useful measure of future systems developed for this task. When given automatically parsed sentences, performance degrades but is still much higher than random, in both scenarios. We designed a comma annotation scheme, where each comma unit is assigned one of four types and an inference rule mapping the patterns of the unit with the entailed relations. We created annotated datasets which will be made available over the web to facilitate further research.

Future work will investigate four main directions: (i) studying the effects of inclusion of our approach on the performance of Textual Entailment systems; (ii) using features other than those derivable from syntactic parse and named entity annotation of the input sentence; (iii) recognizing a wider range of implicit relations, represented by commas and in other ways; (iv) adaptation to other domains.

## Abstract

Detecting conflicting statements is a foundational text understanding task with applications in information analysis. We propose an appropriate definition of contradiction for NLP tasks and develop available corpora, from which we construct a typology of contradictions. We demonstrate that a system for contradiction needs to make more fine-grained distinctions than the common systems for entailment. In particular, we argue for the centrality of event coreference and therefore incorporate such a component based on topicality. We present the first detailed breakdown of performance on this task. Detecting some types of contradiction requires deeper inferential paths than our system is capable of, but we achieve good performance on types arising from negation and antonymy.

## 1 Introduction

In this paper, we seek to understand the ways contradictions occur across texts and describe a system for automatically detecting such constructions. As a foundational task in text understanding (Condoravdi et al., 2003), contradiction detection has many possible applications. Consider applying a contradiction detection system to political candidate debates: by drawing attention to topics in which candidates have conflicting positions, the system could enable voters to make more informed choices between candidates and sift through the amount of available information. Contradiction detection could also be applied to intelligence reports, demonstrating which information may need further verification. In bioinfor-

matics where protein-protein interaction is widely studied, automatically finding conflicting facts about such interactions would be beneficial.

Here, we shed light on the complex picture of contradiction in text. We provide a definition of contradiction suitable for NLP tasks, as well as a collection of contradiction corpora. Analyzing these data, we find contradiction is a rare phenomenon that may be created in different ways; we propose a typology of contradiction classes and tabulate their frequencies. Contradictions arise from relatively obvious features such as antonymy, negation, or numeric mismatches. They also arise from complex differences in the structure of assertions, discrepancies based on world-knowledge, and lexical contrasts.

- (1) Police specializing in explosives defused the rockets. Some 100 people were working inside the plant.
- (2) 100 people were injured.

This pair is contradictory: defused rockets cannot go off, and thus cannot injure anyone. Detecting contradictions appears to be a harder task than detecting entailments. Here, it is relatively easy to identify the lack of entailment: the first sentence involves no injuries, so the second is unlikely to be entailed. Most entailment systems function as weak proof theory (Hickl et al., 2006; MacCartney et al., 2006; Zanzotto et al., 2007), but contradictions require deeper inferences and model building. While mismatching information between sentences is often a good cue of non-entailment (Vanderwende et al., 2006), it is not sufficient for contradiction detection which requires more precise comprehension of the consequences of sentences. Assessing event coreference is also essential: for texts to contradict, they must

refer to the same event. The importance of event coreference was recognized in the MUC information extraction tasks in which it was key to identify scenarios related to the same event (Humphreys et al., 1997). Recent work in text understanding has not focused on this issue, but it must be tackled in a successful contradiction system. Our system includes event coreference, and we present the first detailed examination of contradiction detection performance, on the basis of our typology.

## 2 Related work

Little work has been done on contradiction detection. The PASCAL Recognizing Textual Entailment (RTE) Challenges (Dagan et al., 2006; Bar-Haim et al., 2006; Giampiccolo et al., 2007) focused on textual inference in any domain. Condoravdi et al. (2003) first recognized the importance of handling entailment and contradiction for text understanding, but they rely on a strict logical definition of these phenomena and do not report empirical results. To our knowledge, Harabagiu et al. (2006) provide the first empirical results for contradiction detection, but they focus on specific kinds of contradiction: those featuring negation and those formed by paraphrases. They constructed two corpora for evaluating their system. One was created by overtly negating each entailment in the RTE2 data, producing a balanced dataset (LCC\_negation). To avoid overtraining, negative markers were also added to each non-entailment, ensuring that they did not create contradictions. The other was produced by paraphrasing the hypothesis sentences from LCC\_negation, removing the negation (LCC\_paraphrase): *A hunger strike was not attempted* → *A hunger strike was called off*. They achieved very good performance: accuracies of 75.63% on LCC\_negation and 62.55% on LCC\_paraphrase. Yet, contradictions are not limited to these constructions; to be practically useful, any system must provide broader coverage.

## 3 Contradictions

### 3.1 What is a contradiction?

One standard is to adopt a strict logical definition of contradiction: sentences A and B are contradictory if there is no possible world in which A and B are both true. However, for contradiction detection to be

useful, a looser definition that more closely matches human intuitions is necessary; contradiction occurs when two sentences are extremely unlikely to be true simultaneously. Pairs such as *Sally sold a boat to John* and *John sold a boat to Sally* are tagged as contradictory even though it could be that each sold a boat to the other. This definition captures intuitions of incompatibility, and perfectly fits applications that seek to highlight discrepancies in descriptions of the same event. Examples of contradiction are given in table 1. For texts to be contradictory, they must involve the same event. Two phenomena must be considered in this determination: implied coreference and embedded texts. Given limited context, whether two entities are coreferent may be probable rather than certain. To match human intuitions, compatible noun phrases between sentences are assumed to be coreferent in the absence of clear countervailing evidence. In the following example, it is not necessary that the *woman* in the first and second sentences is the same, but one would likely assume it is if the two sentences appeared together:

- (1) Passions surrounding Germany’s final match turned violent when a woman stabbed her partner because she didn’t want to watch the game.
- (2) A woman passionately wanted to watch the game.

We also mark as contradictions pairs reporting contradictory statements. The following sentences refer to the same event (*de Menezes in a subway station*), and display incompatible views of this event:

- (1) Eyewitnesses said de Menezes had jumped over the turnstile at Stockwell subway station.
- (2) The documents leaked to ITV News suggest that Menezes walked casually into the subway station.

This example contains an “embedded contradiction.” Contrary to Zaenen et al. (2005), we argue that recognizing embedded contradictions is important for the application of a contradiction detection system: if *John thinks that he is incompetent*, and *his boss believes that John is not being given a chance*, one would like to detect that the targeted information in the two sentences is contradictory, even though the two sentences can be true simultaneously.

### 3.2 Typology of contradictions

Contradictions may arise from a number of different constructions, some overt and others that are com-

ID	Type	Text	Hypothesis
1	Antonym	Capital punishment is a catalyst for more crime.	Capital punishment is a deterrent to crime.
2	Negation	A closely divided Supreme Court said that juries and not judges must impose a death sentence.	The Supreme Court decided that only judges can impose the death sentence.
3	Numeric	The tragedy of the explosion in Qana that killed more than 50 civilians has presented Israel with a dilemma.	An investigation into the strike in Qana found 28 confirmed dead thus far.
4	Factive	Prime Minister John Howard says he will not be swayed by a warning that Australia faces more terrorism attacks unless it withdraws its troops from Iraq.	Australia withdraws from Iraq.
5	Factive	The bombers had not managed to enter the embassy.	The bombers entered the embassy.
6	Structure	Jacques Santer succeeded Jacques Delors as president of the European Commission in 1995.	Delors succeeded Santer in the presidency of the European Commission.
7	Structure	The Channel Tunnel stretches from England to France. It is the second-longest rail tunnel in the world, the longest being a tunnel in Japan.	The Channel Tunnel connects France and Japan.
8	Lexical	The Canadian parliament's Ethics Commission said former immigration minister, Judy Sgro, did nothing wrong and her staff had put her into a conflict of interest.	The Canadian parliament's Ethics Commission accuses Judy Sgro.
9	Lexical	In the election, Bush called for U.S. troops to be withdrawn from the peacekeeping mission in the Balkans.	He cites such missions as an example of how America must "stay the course."
10	WK	Microsoft Israel, one of the first Microsoft branches outside the USA, was founded in 1989.	Microsoft was established in 1989.

Table 1: Examples of contradiction types.

plex even for humans to detect. Analyzing contradiction corpora (see section 3.3), we find two primary categories of contradiction: (1) those occurring via antonymy, negation, and date/number mismatch, which are relatively simple to detect, and (2) contradictions arising from the use of factive or modal words, structural and subtle lexical contrasts, as well as world knowledge (WK).

We consider contradictions in category (1) ‘easy’ because they can often be automatically detected without full sentence comprehension. For example, if words in the two passages are antonyms and the sentences are reasonably similar, especially in polarity, a contradiction occurs. Additionally, little external information is needed to gain broad coverage of antonymy, negation, and numeric mismatch contradictions; each involves only a closed set of words or data that can be obtained using existing resources and techniques (e.g., WordNet (Fellbaum, 1998), VerbOcean (Chklovski and Pantel, 2004)).

However, contradictions in category (2) are more difficult to detect automatically because they require precise models of sentence meaning. For instance,

to find the contradiction in example 8 (table 1), it is necessary to learn that *X said Y did nothing wrong* and *X accuses Y* are incompatible. Presently, there exist methods for learning oppositional terms (Marcu and Echihabi, 2002) and paraphrase learning has been thoroughly studied, but successfully extending these techniques to learn incompatible phrases poses difficulties because of the data distribution. Example 9 provides an even more difficult instance of contradiction created by a lexical discrepancy. Structural issues also create contradictions (examples 6 and 7). Lexical complexities and variations in the function of arguments across verbs can make recognizing these contradictions complicated. Even when similar verbs are used and argument differences exist, structural differences may indicate non-entailment or contradiction, and distinguishing the two automatically is problematic. Consider contradiction 7 in table 1 and the following non-contradiction:

- (1) The CFAP purchases food stamps from the government and distributes them to eligible recipients.
- (2) A government purchases food.

Data	# contradictions	# total pairs
RTE1_dev1	48	287
RTE1_dev2	55	280
RTE1_test	149	800
RTE2_dev	111	800
RTE3_dev	80	800
RTE3_test	72	800

Table 2: Number of contradictions in the RTE datasets.

In both cases, the first sentence discusses one entity (*CFAP*, *The Channel Tunnel*) with a relationship (*purchase*, *stretch*) to other entities. The second sentence posits a similar relationship that includes one of the entities involved in the original relationship as well as an entity that was not involved. However, different outcomes result because a tunnel connects only two unique locations whereas more than one entity may purchase food. These frequent interactions between world-knowledge and structure make it hard to ensure that any particular instance of structural mismatch is a contradiction.

### 3.3 Contradiction corpora

Following the guidelines above, we annotated the RTE datasets for contradiction. These datasets contain pairs consisting of a short text and a one-sentence hypothesis. Table 2 gives the number of contradictions in each dataset. The RTE datasets are balanced between entailments and non-entailments, and even in these datasets targeting inference, there are few contradictions. Using our guidelines, RTE3\_test was annotated by NIST as part of the RTE3 Pilot task in which systems made a 3-way decision as to whether pairs of sentences were entailed, contradictory, or neither (Voorhees, 2008).<sup>1</sup>

Our annotations and those of NIST were performed on the original RTE datasets, contrary to Harabagiu et al. (2006). Because their corpora are constructed using negation and paraphrase, they are unlikely to cover all types of contradictions in section 3.2. We might hypothesize that rewriting explicit negations commonly occurs via the substitution of antonyms. Imagine, e.g.:

H: Bill has finished his math.

<sup>1</sup>Information about this task as well as data can be found at <http://nlp.stanford.edu/RTE3-pilot/>.

Type	RTE sets	'Real' corpus
1	Antonym	15.0
	Negation	8.8
	Numeric	8.8
2	Factive/Modal	5.0
	Structure	16.3
	Lexical	18.8
	WK	27.5

Table 3: Percentages of contradiction types in the RTE3\_dev dataset and the real contradiction corpus.

Neg-H: Bill hasn't finished his math.

Para-Neg-H: Bill is still working on his math.

The rewriting in both the negated and the paraphrased corpora is likely to leave one in the space of 'easy' contradictions and addresses fewer than 30% of contradictions (table 3). We contacted the LCC authors to obtain their datasets, but they were unable to make them available to us. Thus, we simulated the LCC\_negation corpus, adding negative markers to the RTE2 test data (Neg\_test), and to a development set (Neg\_dev) constructed by randomly sampling 50 pairs of entailments and 50 pairs of non-entailments from the RTE2 development set.

Since the RTE datasets were constructed for textual inference, these corpora do not reflect 'real-life' contradictions. We therefore collected contradictions 'in the wild.' The resulting corpus contains 131 contradictory pairs: 19 from newswire, mainly looking at related articles in Google News, 51 from Wikipedia, 10 from the Lexis Nexis database, and 51 from the data prepared by LDC for the distillation task of the DARPA GALE program. Despite the randomness of the collection, we argue that this corpus best reflects naturally occurring contradictions.<sup>2</sup>

Table 3 gives the distribution of contradiction types for RTE3\_dev and the real contradiction corpus. Globally, we see that contradictions in category (2) occur frequently and dominate the RTE development set. In the real contradiction corpus, there is a much higher rate of the negation, numeric and lexical contradictions. This supports the intuition that in the real world, contradictions primarily occur for two reasons: information is updated as knowledge

<sup>2</sup>Our corpora—the simulation of the LLC\_negation corpus, the RTE datasets and the real contradictions—are available at <http://nlp.stanford.edu/projects/contradiction>.

of an event is acquired over time (e.g., a rising death toll) or various parties have divergent views of an event (e.g., example 9 in table 1).

## 4 System overview

Our system is based on the stage architecture of the Stanford RTE system (MacCartney et al., 2006), but adds a stage for event coreference decision.

### 4.1 Linguistic analysis

The first stage computes linguistic representations containing information about the semantic content of the passages. The text and hypothesis are converted to typed dependency graphs produced by the Stanford parser (Klein and Manning, 2003; de Marneffe et al., 2006). To improve the dependency graph as a pseudo-semantic representation, collocations in WordNet and named entities are collapsed, causing entities and multiword relations to become single nodes.

### 4.2 Alignment between graphs

The second stage provides an alignment between text and hypothesis graphs, consisting of a mapping from each node in the hypothesis to a unique node in the text or to null. The scoring measure uses node similarity (irrespective of polarity) and structural information based on the dependency graphs. Similarity measures and structural information are combined via weights learned using the passive-aggressive online learning algorithm MIRA (Crammer and Singer, 2001). Alignment weights were learned using manually annotated RTE development sets (see Chambers et al., 2007).

### 4.3 Filtering non-coreferent events

Contradiction features are extracted based on mismatches between the text and hypothesis. Therefore, we must first remove pairs of sentences which do not describe the same event, and thus cannot be contradictory to one another. In the following example, it is necessary to recognize that *Pluto's moon* is not the same as *the moon Titan*; otherwise conflicting diameters result in labeling the pair a contradiction.

T: Pluto's moon, which is only about 25 miles in diameter, was photographed 13 years ago.

H: The moon Titan has a diameter of 5100 kms.

This issue does not arise for textual entailment: elements in the hypothesis not supported by the text lead to non-entailment, regardless of whether the same event is described. For contradiction, however, it is critical to filter unrelated sentences to avoid finding false evidence of contradiction when there is contrasting information about different events.

Given the structure of RTE data, in which the hypotheses are shorter and simpler than the texts, one straightforward strategy for detecting coreferent events is to check whether the root of the hypothesis graph is aligned in the text graph. However, some RTE hypotheses are testing systems' abilities to detect relations between entities (e.g., *John of IBM* . . .  $\rightarrow$  *John works for IBM*). Thus, we do not filter verb roots that are indicative of such relations. As shown in table 4, this strategy improves results on RTE data. For real world data, however, the assumption of directionality made in this strategy is unfounded, and we cannot assume that one sentence will be short and the other more complex. Assuming two sentences of comparable complexity, we hypothesize that modeling topicality could be used to assess whether the sentences describe the same event.

There is a continuum of topicality from the start to the end of a sentence (Firbas, 1971). We thus originally defined the topicality of an NP by  $n^w$  where  $n$  is the  $n$ th NP in the sentence. Additionally, we accounted for multiple clauses by weighting each clause equally; in example 4 in table 1, *Australia* receives the same weight as *Prime Minister* because each begins a clause. However, this weighting was not supported empirically, and we thus use a simpler, unweighted model. The topicality score of a sentence is calculated as a normalized score across all aligned NPs.<sup>3</sup> The text and hypothesis are topically related if either sentence score is above a tuned threshold. Modeling topicality provides an additional improvement in precision (table 4).

While filtering provides improvements in performance, some examples of non-coreferent events are still not filtered, such as:

T: Also Friday, five Iraqi soldiers were killed and nine

<sup>3</sup>Since dates can often be viewed as scene setting rather than what the sentence is about, we ignore these in the model. However, ignoring or including dates in the model creates no significant differences in performance on RTE data.

Strategy	Precision	Recall
No filter	55.10	32.93
Root	61.36	32.93
Root + topic	61.90	31.71

Table 4: Precision and recall for contradiction detection on RTE3\_dev using different filtering strategies.

wounded in a bombing, targeting their convoy near Beiji, 150 miles north of Baghdad.

H: Three Iraqi soldiers also died Saturday when their convoy was attacked by gunmen near Adhaim.

It seems that the real world frequency of events needs to be taken into account. In this case, attacks in Iraq are unfortunately frequent enough to assert that it is unlikely that the two sentences present mismatching information (i.e., different location) about the same event. But compare the following example:

T: President Kennedy was assassinated in Texas.

H: Kennedy’s murder occurred in Washington.

The two sentences refer to one unique event, and the location mismatch renders them contradictory.

#### 4.4 Extraction of contradiction features

In the final stage, we extract contradiction features on which we apply logistic regression to classify the pair as contradictory or not. The feature weights are hand-set, guided by linguistic intuition.

### 5 Features for contradiction detection

In this section, we define each of the feature sets used to capture salient patterns of contradiction.

**Polarity features.** Polarity difference between the text and hypothesis is often a good indicator of contradiction, provided there is a good alignment (see example 2 in table 1). The polarity features capture the presence (or absence) of linguistic markers of negative polarity contexts. These markers are scoped such that words are considered negated if they have a negation dependency in the graph or are an explicit linguistic marker of negation (e.g., simple negation (*not*), downward-monotone quantifiers (*no*, *few*), or restricting prepositions). If one word is negated and the other is not, we may have a polarity difference. This difference is confirmed by checking

that the words are not antonyms and that they lack unaligned prepositions or other context that suggests they do not refer to the same thing. In some cases, negations are propagated onto the governor, which allows one to see that *no bullet penetrated* and a *bullet did not penetrate* have the same polarity.

**Number, date and time features.** Numeric mismatches can indicate contradiction (example 3 in table 1). The numeric features recognize (mis-)matches between numbers, dates, and times. We normalize date and time expressions, and represent numbers as ranges. This includes expression matching (e.g., *over 100* and *200* is not a mismatch). Aligned numbers are marked as mismatches when they are incompatible and surrounding words match well, indicating the numbers refer to the same entity.

**Antonymy features.** Aligned antonyms are a very good cue for contradiction. Our list of antonyms and contrasting words comes from WordNet, from which we extract words with direct antonymy links and expand the list by adding words from the same synset as the antonyms. We also use oppositional verbs from VerbOcean. We check whether an aligned pair of words appears in the list, as well as checking for common antonym prefixes (e.g., *anti*, *un*). The polarity of the context is used to determine if the antonyms create a contradiction.

**Structural features.** These features aim to determine whether the syntactic structures of the text and hypothesis create contradictory statements. For example, we compare the subjects and objects for each aligned verb. If the subject in the text overlaps with the object in the hypothesis, we find evidence for a contradiction. Consider example 6 in table 1. In the text, the subject of *succeed* is *Jacques Santer* while in the hypothesis, *Santer* is the object of *succeed*, suggesting that the two sentences are incompatible.

**Factivity features.** The context in which a verb phrase is embedded may give rise to contradiction, as in example 5 (table 1). Negation influences some factivity patterns: *Bill forgot to take his wallet* contradicts *Bill took his wallet* while *Bill did not forget to take his wallet* does not contradict *Bill took his wallet*. For each text/hypothesis pair, we check the (grand)parent of the text word aligned to the hypothesis verb, and generate a feature based on its factiv-

ity class. Factivity classes are formed by clustering our expansion of the PARC lists of factive, implicative and non-factive verbs (Nairn et al., 2006) according to how they create contradiction.

**Modality features.** Simple patterns of modal reasoning are captured by mapping the text and hypothesis to one of six modalities (*(not\_)possible*, *(not\_)actual*, *(not\_)necessary*), according to the presence of predefined modality markers such as *can* or *maybe*. A feature is produced if the text/hypothesis modality pair gives rise to a contradiction. For instance, the following pair will be mapped to the contradiction judgment (*possible*, *not\_possible*):

T: The trial court may allow the prevailing party reasonable attorney fees as part of costs.

H: The prevailing party may not recover attorney fees.

**Relational features.** A large proportion of the RTE data is derived from information extraction tasks where the hypothesis captures a relation between elements in the text. Using Semgrep, a pattern matching language for dependency graphs, we find such relations and ensure that the arguments between the text and the hypothesis match. In the following example, we detect that *Fernandez* works for *FEMA*, and that because of the negation, a contradiction arises.

T: Fernandez, of FEMA, was on scene when Martin arrived at a FEMA base camp.

H: Fernandez doesn't work for FEMA.

Relational features provide accurate information but are difficult to extend for broad coverage.

## 6 Results

Our contradiction detection system was developed on all datasets listed in the first part of table 5. As test sets, we used RTE1\_test, the independently annotated RTE3\_test, and Neg\_test. We focused on attaining high precision. In a real world setting, it is likely that the contradiction rate is extremely low; rather than overwhelming true positives with false positives, rendering the system impractical, we mark contradictions conservatively. We found reasonable inter-annotator agreement between NIST and our post-hoc annotation of RTE3\_test ( $\kappa = 0.81$ ), showing that, even with limited context, humans tend to

	Precision	Recall	Accuracy
RTE1_dev1	70.37	40.43	–
RTE1_dev2	72.41	38.18	–
RTE2_dev	64.00	28.83	–
RTE3_dev	61.90	31.71	–
Neg_dev	74.07	78.43	75.49
Neg_test	62.97	62.50	62.74
LCC_negation	–	–	75.63
RTE1_test	42.22	26.21	–
RTE3_test	22.95	19.44	–
Avg. RTE3_test	10.72	11.69	–

Table 5: Precision and recall figures for contradiction detection. Accuracy is given for balanced datasets only. ‘LCC\_negation’ refers to performance of Harabagiu et al. (2006); ‘Avg. RTE3\_test’ refers to mean performance of the 12 submissions to the RTE3 Pilot.

agree on contradictions.<sup>4</sup> The results on the test sets show that performance drops on new data, highlighting the difficulty in generalizing from a small corpus of positive contradiction examples, as well as underlining the complexity of building a broad coverage system. This drop in accuracy on the test sets is greater than that of many RTE systems, suggesting that generalizing for contradiction is more difficult than for entailment. Particularly when addressing contradictions that require lexical and world knowledge, we are only able to add coverage in a piecemeal fashion, resulting in improved performance on the development sets but only small gains for the test sets. Thus, as shown in table 6, we achieve 13.3% recall on lexical contradictions in RTE3\_dev but are unable to identify any such contradictions in RTE3\_test. Additionally, we found that the precision of category (2) features was less than that of category (1) features. Structural features, for example, caused us to tag 36 non-contradictions as contradictions in RTE3\_test, over 75% of the precision errors. Despite these issues, we achieve much higher precision and recall than the average submission to the RTE3 Pilot task on detecting contradictions, as shown in the last two lines of table 5.

<sup>4</sup>This stands in contrast with the low inter-annotator agreement reported by Sanchez-Graillet and Poesio (2007) for contradictions in protein-protein interactions. The only hypothesis we have to explain this contrast is the difficulty of scientific material.

	Type	RTE3_dev	RTE3_test
1	Antonym	25.0 (3/12)	42.9 (3/7)
	Negation	71.4 (5/7)	60.0 (3/5)
	Numeric	71.4 (5/7)	28.6 (2/7)
2	Factive/Modal	25.0 (1/4)	10.0 (1/10)
	Structure	46.2 (6/13)	21.1 (4/19)
	Lexical	13.3 (2/15)	0.0 (0/12)
	WK	18.2 (4/22)	8.3 (1/12)

Table 6: Recall by contradiction type.

## 7 Error analysis and discussion

One significant issue in contradiction detection is lack of feature generalization. This problem is especially apparent for items in category (2) requiring lexical and world knowledge, which proved to be the most difficult contradictions to detect on a broad scale. While we are able to find certain specific relationships in the development sets, these features attained only limited coverage. Many contradictions in this category require multiple inferences and remain beyond our capabilities:

T: The Auburn High School Athletic Hall of Fame recently introduced its Class of 2005 which includes 10 members.

H: The Auburn High School Athletic Hall of Fame has ten members.

Of the types of contradictions in category (2), we are best at addressing those formed via structural differences and factive/modal constructions as shown in table 6. For instance, we detect examples 5 and 6 in table 1. However, creating features with sufficient precision is an issue for these types of contradictions. Intuitively, two sentences that have aligned verbs with the same subject and different objects (or vice versa) are contradictory. This indeed indicates a contradiction 55% of the time on our development sets, but this is not high enough precision given the rarity of contradictions.

Another type of contradiction where precision falters is numeric mismatch. We obtain high recall for this type (table 6), as it is relatively simple to determine if two numbers are compatible, but high precision is difficult to achieve due to differences in what numbers may mean. Consider:

T: Nike Inc. said that its profit grew 32 percent, as the company posted broad gains in sales and orders.

H: Nike said orders for footwear totaled \$4.9 billion, including a 12 percent increase in U.S. orders.

Our system detects a mismatch between *32 percent* and *12 percent*, ignoring the fact that one refers to *profit* and the other to *orders*. Accounting for context requires extensive text comprehension; it is not enough to simply look at whether the two numbers are headed by similar words (*grew* and *increase*). This emphasizes the fact that mismatching information is not sufficient to indicate contradiction.

As demonstrated by our 63% accuracy on Neg\_test, we are reasonably good at detecting negation and correctly ascertaining whether it is a symptom of contradiction. Similarly, we handle single word antonymy with high precision (78.9%). Nevertheless, Harabagiu et al.’s performance demonstrates that further improvement on these types is possible; indeed, they use more sophisticated techniques to extract oppositional terms and detect polarity differences. Thus, detecting category (1) contradictions is feasible with current systems.

While these contradictions are only a third of those in the RTE datasets, detecting such contradictions accurately would solve half of the problems found in the real corpus. This suggests that we may be able to gain sufficient traction on contradiction detection for real world applications. Even so, category (2) contradictions must be targeted to detect many of the most interesting examples and to solve the entire problem of contradiction detection. Some types of these contradictions, such as lexical and world knowledge, are currently beyond our grasp, but we have demonstrated that progress may be made on the structure and factive/modal types.

Despite being rare, contradiction is foundational in text comprehension. Our detailed investigation demonstrates which aspects of it can be resolved and where further research must be directed.

## Abstract

We present a novel approach to weakly supervised semantic class learning from the web, using a single powerful hyponym pattern combined with graph structures, which capture two properties associated with pattern-based extractions: *popularity* and *productivity*. Intuitively, a candidate is *popular* if it was discovered many times by other instances in the hyponym pattern. A candidate is *productive* if it frequently leads to the discovery of other instances. Together, these two measures capture not only frequency of occurrence, but also cross-checking that the candidate occurs both near the class name and near other class members. We developed two algorithms that begin with just a class name and one seed instance and then automatically generate a ranked list of new class instances. We conducted experiments on four semantic classes and consistently achieved high accuracies.

## 1 Introduction

Knowing the semantic classes of words (e.g., “trout” is a kind of FISH) can be extremely valuable for many natural language processing tasks. Although some semantic dictionaries do exist (e.g., WordNet (Miller, 1990)), they are rarely complete, especially for large open classes (e.g., classes of people and objects) and rapidly changing categories (e.g., computer technology). (Roark and Charniak, 1998) reported that 3 of every 5 terms generated by their semantic lexicon learner were not present in WordNet. Automatic semantic lexicon acquisition could

be used to enhance existing resources such as WordNet, or to produce semantic lexicons for specialized categories or domains.

A variety of methods have been developed for automatic semantic class identification, under the rubrics of lexical acquisition, hyponym acquisition, semantic lexicon induction, semantic class learning, and web-based information extraction. Many of these approaches employ surface-level patterns to identify words and their associated semantic classes. However, such patterns tend to overgenerate (i.e., deliver incorrect results) and hence require additional filtering mechanisms.

To overcome this problem, we employed one single powerful *doubly-anchored* hyponym pattern to query the web and extract semantic class instances: CLASS\_NAME *such as* CLASS\_MEMBER *and* \*.

We hypothesized that a doubly-anchored pattern, which includes both the class name and a class member, would achieve high accuracy because of its specificity. To address concerns about coverage, we embedded the search in a bootstrapping process. This method produced many correct instances, but despite the highly restrictive nature of the pattern, still produced many incorrect instances. This result led us to explore new ways to improve the accuracy of hyponym patterns without requiring additional training resources.

The main contribution of this work is a novel method for combining hyponym patterns with graph structures that capture two properties associated with pattern extraction: *popularity* and *productivity*. Intuitively, a candidate word (or phrase) is *popular* if it was discovered many times by other words (or

phrases) in a hyponym pattern. A candidate word is *productive* if it frequently leads to the discovery of other words. Together, these two measures capture not only frequency of occurrence, but also cross-checking that the word occurs both near the class name and near other class members.

We present two algorithms that use *hyponym pattern linkage graphs (HPLGs)* to represent popularity and productivity information. The first method uses a dynamically constructed HPLG to assess the popularity of each candidate and steer the bootstrapping process. This approach produces an efficient bootstrapping process that performs reasonably well, but it cannot take advantage of productivity information because of the dynamic nature of the process.

The second method is a two-step procedure that begins with an exhaustive pattern search that acquires popularity and productivity information about candidate instances. The candidates are then ranked based on properties of the HPLG. We conducted experiments with four semantic classes, achieving high accuracies and outperforming the results reported by others who have worked on the same classes.

## 2 Related Work

A substantial amount of research has been done in the area of semantic class learning, under a variety of different names and with a variety of different goals. Given the great deal of similar work in information extraction and ontology learning, we focus here only on techniques for weakly supervised or unsupervised semantic class (i.e., supertype-based) learning, since that is most related to the work in this paper.

Fully unsupervised semantic clustering (e.g., (Lin, 1998; Lin and Pantel, 2002; Davidov and Rappoport, 2006)) has the disadvantage that it may or may not produce the types and granularities of semantic classes desired by a user. Another related line of work is automated ontology construction, which aims to create lexical hierarchies based on semantic classes (e.g., (Caraballo, 1999; Cimiano and Volker, 2005; Mann, 2002)), and learning semantic relations such as meronymy (Berland and Charniak, 1999; Girju et al., 2003).

Our research focuses on semantic lexicon induction, which aims to generate lists of words that be-

long to a given semantic class (e.g., lists of FISH or VEHICLE words). Weakly supervised learning methods for semantic lexicon generation have utilized co-occurrence statistics (Riloff and Shepherd, 1997; Roark and Charniak, 1998), syntactic information (Tanev and Magnini, 2006; Pantel and Ravichandran, 2004; Phillips and Riloff, 2002), lexico-syntactic contextual patterns (e.g., “*resides in <location>*” or “*moved to <location>*”) (Riloff and Jones, 1999; Thelen and Riloff, 2002), and local and global contexts (Fleischman and Hovy, 2002). These methods have been evaluated only on fixed corpora<sup>1</sup>, although (Pantel et al., 2004) demonstrated how to scale up their algorithms for the web.

Several techniques for semantic class induction have also been developed specifically for learning from the web. (Paşca, 2004) uses Hearst’s patterns (Hearst, 1992) to learn semantic class instances and class groups by acquiring contexts around the pattern. Paşca also developed a second technique (Paşca, 2007b) that creates context vectors for a group of seed instances by searching web query logs, and uses them to learn similar instances.

The work most closely related to ours is Hearst’s early work on hyponym learning (Hearst, 1992) and more recent work that has followed up on her idea. Hearst’s system exploited patterns that explicitly identify a hyponym relation between a semantic class and a word (e.g., “*such authors as Shakespeare*”). We will refer to these as *hyponym patterns*. Paşca’s previously mentioned system (Paşca, 2004) applies hyponym patterns to the web and acquires contexts around them. The KnowItAll system (Etzioni et al., 2005) also uses hyponym patterns to extract class instances from the web and then evaluates them further by computing mutual information scores based on web queries.

The work by (Widdows and Dorow, 2002) on lexical acquisition is similar to ours because they also use graph structures to learn semantic classes. However, their graph is based entirely on syntactic relations between words, while our graph captures the ability of instances to find each other in a hyponym pattern based on web querying, without any part-of-speech tagging or parsing.

<sup>1</sup>Meta-bootstrapping (Riloff and Jones, 1999) was evaluated on web pages, but used a precompiled corpus of downloaded web pages.

### 3 Semantic Class Learning with Hyponym Pattern Linkage Graphs

#### 3.1 A Doubly-Anchored Hyponym Pattern

Our work was motivated by early research on hyponym learning (Hearst, 1992), which applied patterns to a corpus to associate words with semantic classes. Hearst’s system exploited patterns that explicitly link a class name with a class member, such as “*X and other Ys*” and “*Ys such as X*”. Relying on surface-level patterns, however, is risky because incorrect items are frequently extracted due to polysemy, idiomatic expressions, parsing errors, etc.

Our work began with the simple idea of using an *extremely* specific pattern to extract semantic class members with high accuracy. Our expectation was that a very specific pattern would virtually eliminate the most common types of false hits that are caused by phenomena such as polysemy and idiomatic expressions. A concern, however, was that an extremely specific pattern would suffer from sparse data and not extract many new instances. By using the web as a corpus, we hoped that the pattern could extract at least a few instances for virtually any class, and then we could gain additional traction by bootstrapping these instances.

All of the work presented in this paper uses just one *doubly-anchored* pattern to identify candidate instances for a semantic class:

*<class\_name> such as <class\_member> and \**

This pattern has two variables: the name of the semantic class to be learned (*class\_name*) and a member of the semantic class (*class\_member*). The asterisk (\*) indicates the location of the extracted words. We describe this pattern as being *doubly-anchored* because it is instantiated with both the name of the semantic class as well as a class member.

For example, the pattern “*CARS such as FORD and \**” will extract automobiles, and the pattern “*PRESIDENTS such as FORD and \**” will extract presidents. The doubly-anchored nature of the pattern serves two purposes. First, it increases the likelihood of finding a true list construction for the class. Our system does not use part-of-speech tagging or parsing, so the pattern itself is the only guide for finding an appropriate linguistic context.

Second, the doubly-anchored pattern virtually

```
Members = {Seed};
P0 = “Class such as Seed and *”;
P = {P0};
iter = 0;
While ((iter < Max_Iters) and (P ≠ {}))
  iter++;
  For each Pi ∈ P
    Snippets = web_query(Pi);
    Candidates = extract_words(Snippets, Pi);
    Pnew = {};
    For each Candidatek ∈ Candidates
      If (Candidatek ∉ Members);
        Members = Members ∪ {Candidatek};
        Pk = “Class such as Candidatek and *”;
        Pnew = Pnew ∪ { Pk };
    P = Pnew;
```

Figure 1: Reckless Bootstrapping

eliminates ambiguity because the *class\_name* and *class\_member* mutually disambiguate each other. For example, the word FORD could refer to an automobile or a person, but in the pattern “*CARS such as FORD and \**” it will almost certainly refer to an automobile. Similarly, the class “PRESIDENT” could refer to country presidents or corporate presidents, and “BUSH” could refer to a plant or a person. But in the pattern “*PRESIDENTS such as BUSH*”, both words will surely refer to country presidents.

Another advantage of the doubly-anchored pattern is that an ambiguous or underspecified class name will be constrained by the presence of the class member. For example, to generate a list of company presidents, someone might naively define the class name as PRESIDENTS. A singly-anchored pattern (e.g., “*PRESIDENTS such as \**”) might generate lists of other types of presidents (e.g., country presidents, university presidents, etc.). Because the doubly-anchored pattern also requires a class member (e.g., “*PRESIDENTS such as BILL GATES and \**”), it is likely to generate only the desired types of instances.

#### 3.2 Reckless Bootstrapping

To evaluate the performance of the doubly-anchored pattern, we began by using the pattern to search the web and embedded this process in a simple bootstrapping loop, which is presented in Figure 1. As input, the user must provide the name of the desired

semantic class (*Class*) and a seed example (*Seed*), which are used to instantiate the pattern. On the first iteration, the pattern is given to Google as a web query, and new class members are extracted from the retrieved text snippets. We wanted the system to be as language-independent as possible, so we refrained from using any taggers or parsing tools. As a result, instances are extracted using only word boundaries and orthographic information. For proper name classes, we extract all capitalized words that immediately follow the pattern. For common noun classes, we extract just one word, if it is not capitalized. Examples are shown below, with the extracted items underlined:

*countries such as China and Sri Lanka are ...*  
*fishes such as trout and bass can ...*

One limitation is that our system cannot learn multi-word instances of common noun categories, or proper names that include uncapitalized words (e.g., “United States of America”). These limitations could be easily overcome by incorporating a noun phrase (NP) chunker and extracting NPs.

Each new class member is then used as a seed instance in the bootstrapping loop. We implemented this process as breadth-first search, where each “ply” of the search process is the result of bootstrapping the class members learned during the previous iteration as seed instances for the next one. During each iteration, we issue a new web query and add the newly extracted class members to the queue for the next cycle. We run this bootstrapping process for a fixed number of iterations (search ply), or until no new class members are produced. We will refer to this process as *reckless bootstrapping* because there are no checks of any kind. Every term extracted by the pattern is assumed to be a class member.

### 3.2.1 Results

Table 1 shows the results for 4 iterations of reckless bootstrapping for four semantic categories: *U.S. states*, *countries*, *singers*, and *fish*. The first two categories are relatively small, closed sets (our gold standard contains 50 U.S. states and 194 countries). The *singers* and *fish* categories are much larger, open sets (see Section 4 for details).

Table 1 reveals that the doubly-anchored pattern achieves high accuracy during the first iteration, but

Iter.	<i>countries</i>	<i>states</i>	<i>singers</i>	<i>fish</i>
1	.80	.79	.91	.76
2	.57	.21	.87	.64
3	.21	.18	.86	.54
4	.16	–	.83	.54

Table 1: *Reckless Bootstrapping Accuracies*

quality deteriorates rapidly as bootstrapping progresses. Figure 2 shows the recall and precision curves for countries and states. High precision is achieved only with low levels of recall for countries. Our initial hypothesis was that such a specific pattern would be able to maintain high precision because non-class members would be unlikely to co-occur with the pattern. But we were surprised to find that many incorrect entries were generated for reasons such as broken expressions like “Mercede -dez”, misidentified list constructions (e.g., “*In countries such as China U.S. Policy is failing...*”), and incomplete proper names due to insufficient length of the retrieved text snippet.

Incorporating a noun phrase chunker would eliminate some of these cases, but far from all of them. We concluded that even such a restrictive pattern is not sufficient for semantic class learning on its own.

Figure 2: Recall/precision for reckless bootstrapping

In the next section, we present a new approach that creates a Hyponym Pattern Linkage Graph to steer bootstrapping and improve accuracy.

### 3.3 Using Dynamic Graphs to Steer Bootstrapping

Intuitively, we expect true class members to occur frequently in pattern contexts with other class mem-

bers. To operationalize this intuition, we create a *hyponym pattern linkage graph*, which represents the frequencies with which candidate instances generate each other in the pattern contexts.

We define a *hyponym pattern linkage graph (HPLG)* as a  $G = (V, E)$ , where each vertex  $v \in V$  is a candidate instance and each edge  $(u, v) \in E$  means that instance  $v$  was generated by instance  $u$ . The weight  $w$  of an edge is the frequency with which  $u$  generated  $v$ . For example, consider the following sentence, where the pattern is italicized and the extracted instance is underlined:

*Countries such as China and Laos have been...*

In the HPLG, an edge  $e = (China, Laos)$  would be created because the pattern anchored by China extracted Laos as a new candidate instance. If this pattern extracted Laos from 15 different snippets, then the edge’s weight would be 15. The in-degree of a node represents its *popularity*, i.e., the number of instance occurrences that generated it.

The graph is constructed dynamically as bootstrapping progresses. Initially, the seed is the only *trusted class member* and the only vertex in the graph. The bootstrapping process begins by instantiating the doubly-anchored pattern with the seed class member, issuing a web query to generate new candidate instances, and adding these new instances to the graph. A score is then assigned to every node in the graph, using one of several different metrics defined below. The highest-scoring unexplored node is then added to the set of *trusted class members*, and used as the seed for the next bootstrapping iteration.

We experimented with three scoring functions for selecting nodes. The **In-Degree (inD) score** for vertex  $v$  is the sum of the weights of all incoming edges  $(u, v)$ , where  $u$  is a trusted class member. Intuitively, this captures the popularity of  $v$  among instances that have already been identified as good instances. The **Best Edge (BE) score** for vertex  $v$  is the maximum edge weight among the incoming edges  $(u, v)$ , where  $u$  is a trusted class member.

The Key Player Problem (KPP) measure is used in social network analysis (Borgatti and Everett, 2006) to identify nodes whose removal would result in a residual network of minimum cohesion. A node receives a high value if it is highly connected and relatively close to most other nodes in the graph. The

**KPP score** for vertex  $v$  is computed as:

$$KPP(v) = \frac{\sum_{u \in V} \frac{1}{d(u, v)}}{|V|-1}$$

where  $d(u, v)$  is the shortest path between two vertices, where  $u$  is a trusted node. For tie-breaking, the distances are multiplied by the weight of the edge.

Note that all of these measures rely only on incoming edges because a node does not acquire outgoing edges until it has already been selected as a trusted class member and used to acquire new instances. In the next section, we describe a two-step process for creating graphs that can take advantage of both incoming and outgoing edges.

### 3.4 Re-Ranking with Precompiled Graphs

One way to try to confirm (or disconfirm) whether a candidate instance is a true class member is to see whether it can produce new candidate instances. If we instantiate our pattern with the candidate (i.e., “CLASS\_NAME *such as* CANDIDATE *and* \*”) and successfully extract many new instances, then this is evidence that the candidate frequently occurs with the CLASS\_NAME in list constructions. We will refer to the ability of a candidate to generate new instances as its *productivity*.

The previous bootstrapping algorithm uses a dynamically constructed graph that is constantly evolving as new nodes are selected and explored. Each node is scored based only on the set of instances that have been generated and identified as “trusted” at that point in the bootstrapping process. To use productivity information, we must adopt a different procedure because we need to know not only who generated each candidate, but also the complete set of instances that the candidate itself can generate.

We adopted a two-step process that can use both popularity and productivity information in a hyponym pattern linkage graph to assess the quality of candidate instances. First, we perform *reckless bootstrapping* for a *class\_name* and *seed* until no new instances are generated. Second, we assign a score to each node in the graph using a scoring function that takes into account both the in-degree (popularity) and out-degree (productivity) of each node. We experimented with four different scoring functions, some of which were motivated by work on word

sense disambiguation to identify the most “important” node in a graph containing its possible senses (Navigli and Lapata, 2007).

The **Out-degree (outD) score** for vertex  $v$  is the weighted sum of  $v$ ’s outgoing edges, normalized by the number of other nodes in the graph.

$$outD(v) = \frac{\sum_{\forall(v,p) \in E} w(v,p)}{|V|-1}$$

This measure captures only productivity, while the next three measures consider both productivity and popularity. The **Total-degree (totD) score** for vertex  $v$  is the weighted sum of both incoming and outgoing edges, normalized by the number of other nodes in the graph. The **Betweenness (BT) score** (Freeman, 1979) considers a vertex to be important if it occurs on many shortest paths between other vertices.

$$BT(v) = \sum_{s,t \in V: s \neq v \neq t} \frac{\sigma_{st}(v)}{\sigma_{st}}$$

where  $\sigma_{st}$  is the number of shortest paths from  $s$  to  $t$ , and  $\sigma_{st}(v)$  is the number of shortest paths from  $s$  to  $t$  that pass through vertex  $v$ . PageRank (Page et al., 1998) establishes the relative importance of a vertex  $v$  through an iterative Markov chain model. The **PageRank (PR) score** of a vertex  $v$  is determined on the basis of the nodes it is connected to.

$$PR(v) = \frac{(1-\alpha)}{|V|} + \alpha \sum_{u,v \in E} \frac{PR(u)}{outdegree(u)}$$

$\alpha$  is a damping factor that we set to 0.85. We discarded all instances that produced zero productivity links, meaning that they did not generate any other candidates when used in web queries.

## 4 Experimental evaluation

### 4.1 Data

We evaluated our algorithms on four semantic categories: *U.S. states*, *countries*, *singers*, and *fish*. The *states* and *countries* categories are relatively small, closed sets: our gold standards consist of 50 U.S. states and 194 countries (based on a list found on Wikipedia). The *singers* and *fish* categories are much larger, open classes. As our gold standard for *fish*, we used a list of common fish names found on Wikipedia.<sup>2</sup> All the singer names generated by our

<sup>2</sup>We also counted as correct plural versions of items found on the list. The total size of our fish list is 1102.

algorithms were manually reviewed for correctness. We evaluated performance in terms of accuracy (the percentage of instances that were correct).<sup>3</sup>

### 4.2 Performance

Table 2 shows the accuracy results of the two algorithms that use hyponym pattern linkage graphs. We display results for the top-ranked N candidates, for all instances that have a productivity value  $>$  zero.<sup>4</sup> The Popularity columns show results for the

<sup>3</sup>We never generated duplicates so the instances are distinct.

<sup>4</sup>Obviously, this cutoff is not available to the popularity-based bootstrapping algorithm, but here we are just comparing the top N results for both algorithms.

bootstrapping algorithm described in Section 3.3, using three different scoring functions. The results for the ranking algorithm described in Section 3.4 are shown in the Productivity (Prd) and Popularity&Productivity (Pop&Prd) columns. For the *states*, *countries*, and *singers* categories, we randomly selected 5 different initial seeds and then averaged the results. For the *fish* category we ran each algorithm using just the seed “salmon”.

The popularity-based metrics produced good accuracies on the *states*, *countries*, and *singers* categories under all 3 scoring functions. For *fish*, KPP performed better than the others.

The *Out-degree (outD)* scoring function, which uses only Productivity information, obtained the best results across all 4 categories. OutD achieved 100% accuracy for the first 50 states and fish, 100% accuracy for the top 150 countries, and 97% accuracy for the top 50 singers. The three scoring metrics that use both popularity and productivity also performed well, but productivity information by itself seems to perform better in some cases.

It can be difficult to compare the results of different semantic class learners because there is no standard set of benchmark categories, so researchers report results for different classes. For the state and country categories, however, we can compare our results with that of other web-based semantic class learners such as Pasca (Paşca, 2007a) and the KnowItAll system (Etzioni et al., 2005). For the U.S. states category, our system achieved 100% recall and 100% precision for the first 50 items generated, and KnowItAll performed similarly achieving 98% recall with 100% precision. Pasca did not evaluate his system on states.

For the *countries* category, our system achieved 100% precision for the first 150 generated instances (77% recall). (Paşca, 2007a) reports results of 100% precision for the first 25 instances generated, and 82% precision for the first 150 instances generated. The KnowItAll system (Etzioni et al., 2005) achieved 97% precision with 58% recall, and 79% precision with 87% recall.<sup>5</sup> To the best of our knowledge, other researchers have not reported results for the singer and fish categories.

<sup>5</sup>(Etzioni et al., 2005) do not report exactly how many countries were in their gold standard.

Figure 3: Learning curve for Placido Domingo

Figure 3 shows the learning curve for both algorithms using their best scoring functions on the *singer* category with *Placido Domingo* as the initial seed. In total, 400 candidate words were generated. The *Out-degree* scoring function ranked the candidates well. Figure 3 also includes a vertical line indicating where the candidate list was cut (at 180 instances) based on the zero productivity cutoff.

One observation is that the rankings do a good job of identifying borderline cases, which typically are ranked just below most correct instances but just above the obviously bad entries. For example, for *states*, the 50 U.S. states are ranked first, followed by 14 more entries (in order):

Russia, Ukraine, Uzbekistan, Azerbaijan, Moldova, Tajikistan, Armenia, Chicago, Boston, Atlanta, Detroit, Philadelphia, Tampa, Moldavia

The first 7 entries are all former states of the Soviet Union. In retrospect, we realized that we should have searched for “U.S. states” instead of just “states”. This example illustrates the power of the doubly-anchored hyponym pattern to correctly identify our intended semantic class by disambiguating our class name based on the seed class member.

The algorithms also seem to be robust with respect to initial seed choice. For the *states*, *countries*, and *singers* categories, we ran experiments with 5 different initial seeds, which were randomly selected. The 5 country seeds represented a diverse set of nations, some of which are rarely mentioned in the news: *Brazil*, *France*, *Guinea-Bissau*, *Uganda*,

and *Zimbabwe*. All of these seeds obtained  $\geq 92\%$  recall with  $\geq 90\%$  precision.

### 4.3 Error Analysis

We examined the incorrect instances produced by our algorithms and found that most of them fell into five categories.

Type 1 errors were caused by incorrect proper name extraction. For example, in the sentence “*states such as Georgia and English speaking countries like Canada...*”, “*English*” was extracted as a state. These errors resulted from complex noun phrases and conjunctions, as well as unusual syntactic constructions. An NP chunker might prevent some of these cases, but we suspect that many of them would have been misparsed regardless.

Type 2 errors were caused by instances that formerly belonged to the semantic class (e.g., *Serbia-Montenegro* and *Czechoslovakia* are no longer countries). In this error type, we also include borderline cases that could arguably belong to the semantic class (e.g., *Wales* as a country).

Type 3 errors were spelling variants (e.g., *Kyrgystan* vs. *Kyrgyzstan*) and name variants (e.g., *Beyonce* vs. *Beyonce Knowles*). Officially, every entity has one official spelling and one complete name, but in practice there are often variations that may occur nearly as frequently as the official name. For example, it is most common to refer to the singer *Beyonce* by just her first name.

Type 4 errors were caused by sentences that were just flat out wrong in their factual assertions. For example, some sentences referred to “*North America*” as a country.

Type 5 errors were caused by broken expressions found in the retrieved snippets (e.g. *Michi -gan*). These errors may be fixable by cleaning up the web pages or applying heuristics to prevent or recognize partial words.

It is worth noting that incorrect instances of Types 2 and 3 may not be problematic to encounter in a dictionary or ontology. Name variants and former class members may in fact be useful to have.

## 5 Conclusions

Combining hyponym patterns with pattern linkage graphs is an effective way to produce a highly ac-

curate semantic class learner that requires truly minimal supervision: just the class name and one class member as a seed. Our results consistently produced high accuracy and for the *states* and *countries* categories produced very high recall.

The *singers* and *fish* categories, which are much larger open classes, also achieved high accuracy and generated many instances, but the resulting lists are far from complete. Even on the web, the doubly-anchored hyponym pattern eventually ran out of steam and could not produce more instances. However, all of our experiments were conducted using just a single hyponym pattern. Other researchers have successfully used sets of hyponym patterns (e.g., (Hearst, 1992; Etzioni et al., 2005; Paşca, 2004)), and multiple patterns could be used with our algorithms as well. Incorporating additional hyponym patterns will almost certainly improve coverage, and could potentially improve the quality of the graphs as well.

Our popularity-based algorithm was very effective and is practical to use. Our best-performing algorithm, however, was the 2-step process that begins with an exhaustive search (reckless bootstrapping) and then ranks the candidates using the *Out-degree* scoring function, which represents productivity. The first step is expensive, however, because it exhaustively applies the pattern to the web until no more extractions are found. In our evaluation, we ran this process on a single PC and it usually finished overnight, and we were able to learn a substantial number of new class instances. If more hyponym patterns are used, then this could get considerably more expensive, but the process could be easily parallelized to perform queries across a cluster of machines. With access to a cluster of ordinary PCs, this technique could be used to automatically create extremely large, high-quality semantic lexicons, for virtually any categories, without external training resources.
