## Table of Contents

Preface: General Chair .....	xi
Preface: Program Chairs .....	xii
Organizers .....	xv
Program Committee .....	xvii
Conference Program .....	xxi
<i>Mining Wiki Resources for Multilingual Named Entity Recognition</i> Alexander E. Richman and Patrick Schone .....	1
<i>Distributional Identification of Non-Referential Pronouns</i> Shane Bergsma, Dekang Lin and Randy Goebel .....	10
<i>Weakly-Supervised Acquisition of Open-Domain Classes and Class Attributes from Web Documents and Query Logs</i> Marius Paşca and Benjamin Van Durme .....	19
<i>The Tradeoffs Between Open and Traditional Relation Extraction</i> Michele Banko and Oren Etzioni .....	28
<i>PDT 2.0 Requirements on a Query Language</i> Jiří Mírovský .....	37
<i>Task-oriented Evaluation of Syntactic Parsers and Their Representations</i> Yusuke Miyao, Rune Sætne, Kenji Sagae, Takuya Matsuzaki and Jun'ichi Tsujii .....	46
<i>MAXSIM: A Maximum Similarity Metric for Machine Translation Evaluation</i> Yee Seng Chan and Hwee Tou Ng .....	55
<i>Contradictions and Justifications: Extensions to the Textual Entailment Task</i> Ellen M. Voorhees .....	63
<i>Cohesive Phrase-Based Decoding for Statistical Machine Translation</i> Colin Cherry .....	72
<i>Phrase Table Training for Precision and Recall: What Makes a Good Phrase and a Good Phrase Pair?</i> Yonggang Deng, Jia Xu and Yuqing Gao .....	81
<i>Measure Word Generation for English-Chinese SMT Systems</i> Dongdong Zhang, Mu Li, Nan Duan, Chi-Ho Li and Ming Zhou .....	89
<i>Bayesian Learning of Non-Compositional Phrases with Synchronous Parsing</i> Hao Zhang, Chris Quirk, Robert C. Moore and Daniel Gildea .....	97

<i>Applying a Grammar-Based Language Model to a Simplified Broadcast-News Transcription Task</i> Tobias Kaufmann and Beat Pfister .....	106
<i>Automatic Editing in a Back-End Speech-to-Text System</i> Maximilian Bisani, Paul Vozila, Olivier Divay and Jeff Adams .....	114
<i>Grounded Language Modeling for Automatic Speech Recognition of Sports Video</i> Michael Fleischman and Deb Roy .....	121
<i>Lexicalized Phonotactic Word Segmentation</i> Margaret M. Fleck .....	130
<i>A Re-examination of Query Expansion Using Lexical Resources</i> Hui Fang .....	139
<i>Selecting Query Term Alternations for Web Search by Exploiting Query Contexts</i> Guihong Cao, Stephen Robertson and Jian-Yun Nie .....	148
<i>Searching Questions by Identifying Question Topic and Question Focus</i> Huizhong Duan, Yunbo Cao, Chin-Yew Lin and Yong Yu .....	156
<i>Trainable Generation of Big-Five Personality Styles through Data-Driven Parameter Estimation</i> François Mairesse and Marilyn Walker .....	165
<i>Correcting Misuse of Verb Forms</i> John Lee and Stephanie Seneff .....	174
<i>Hypertagging: Supertagging for Surface Realization with CCG</i> Dominic Espinosa, Michael White and Dennis Mehay .....	183
<i>Forest-Based Translation</i> Haitao Mi, Liang Huang and Qun Liu .....	192
<i>A Discriminative Latent Variable Model for Statistical Machine Translation</i> Phil Blunsom, Trevor Cohn and Miles Osborne .....	200
<i>Efficient Multi-Pass Decoding for Synchronous Context Free Grammars</i> Hao Zhang and Daniel Gildea .....	209
<i>Regular Tree Grammars as a Formalism for Scope Underspecification</i> Alexander Koller, Michaela Regneri and Stefan Thater .....	218
<i>Classification of Semantic Relationships between Nominals Using Pattern Clusters</i> Dmitry Davidov and Ari Rappoport .....	227
<i>Vector-based Models of Semantic Composition</i> Jeff Mitchell and Mirella Lapata .....	236
<i>Exploiting Feature Hierarchy for Transfer Learning in Named Entity Recognition</i> Andrew Arnold, Ramesh Nallapati and William W. Cohen .....	245

<i>Refining Event Extraction through Cross-Document Inference</i> Heng Ji and Ralph Grishman .....	254
<i>Learning Document-Level Semantic Properties from Free-Text Annotations</i> S.R.K. Branavan, Harr Chen, Jacob Eisenstein and Regina Barzilay .....	263
<i>Automatic Image Annotation Using Auxiliary Text Information</i> Yansong Feng and Mirella Lapata .....	272
<i>Hedge Classification in Biomedical Texts with a Weakly Supervised Selection of Keywords</i> György Szarvas .....	281
<i>When Specialists and Generalists Work Together: Overcoming Domain Dependence in Sentiment Tagging</i> Alina Andreevskaia and Sabine Bergler .....	290
<i>A Generic Sentence Trimmer with CRFs</i> Tadashi Nomoto .....	299
<i>A Joint Model of Text and Aspect Ratings for Sentiment Summarization</i> Ivan Titov and Ryan McDonald .....	308
<i>Improving Parsing and PP Attachment Performance with Sense Information</i> Eneko Agirre, Timothy Baldwin and David Martinez .....	317
<i>A Logical Basis for the D Combinator and Normal Form in CCG</i> Frederick Hoyt and Jason Baldridge .....	326
<i>Parsing Noun Phrase Structure with CCG</i> David Vadas and James R. Curran .....	335
<i>Sentence Simplification for Semantic Role Labeling</i> David Vickrey and Daphne Koller .....	344
<i>Summarizing Emails with Conversational Cohesion and Subjectivity</i> Giuseppe Carenini, Raymond T. Ng and Xiaodong Zhou .....	353
<i>Ad Hoc Treebank Structures</i> Markus Dickinson .....	362
<i>A Single Generative Model for Joint Morphological Segmentation and Syntactic Parsing</i> Yoav Goldberg and Reut Tsarfaty .....	371
<i>Which Words Are Hard to Recognize? Prosodic, Lexical, and Disfluency Factors that Increase ASR Error Rates</i> Sharon Goldwater, Dan Jurafsky and Christopher D. Manning .....	380
<i>Name Translation in Statistical Machine Translation - Learning When to Transliterate</i> Ulf Hermjakob, Kevin Knight and Hal Daumé III .....	389

<i>Using Adaptor Grammars to Identify Synergies in the Unsupervised Acquisition of Linguistic Structure</i> Mark Johnson .....	398
<i>Inducing Gazetteers for Named Entity Recognition by Large-Scale Clustering of Dependency Relations</i> Jun'ichi Kazama and Kentaro Torisawa .....	407
<i>Evaluating Roget's Thesauri</i> Alistair Kennedy and Stan Szpakowicz .....	416
<i>Unsupervised Translation Induction for Chinese Abbreviations using Monolingual Corpora</i> Zhifei Li and David Yarowsky .....	425
<i>Which Are the Best Features for Automatic Verb Classification</i> Jianguo Li and Chris Brew .....	434
<i>Collecting a Why-Question Corpus for Development and Evaluation of an Automatic QA-System</i> Joanna Mrozinski, Edward Whittaker and Sadaoki Furui .....	443
<i>Solving Relational Similarity Problems Using the Web as a Corpus</i> Preslav Nakov and Marti A. Hearst .....	452
<i>Combining Speech Retrieval Results with Generalized Additive Models</i> J. Scott Olsson and Douglas W. Oard .....	461
<i>A Critical Reassessment of Evaluation Baselines for Speech Summarization</i> Gerald Penn and Xiaodan Zhu .....	470
<i>Intensional Summaries as Cooperative Responses in Dialogue: Automation and Evaluation</i> Joseph Polifroni and Marilyn Walker .....	479
<i>Word Clustering and Word Selection Based Feature Reduction for MaxEnt Based Hindi NER</i> Sujan Kumar Saha, Pabitra Mitra and Sudeshna Sarkar .....	488
<i>Combining EM Training and the MDL Principle for an Automatic Verb Classification Incorporating Selectional Preferences</i> Sabine Schulte im Walde, Christian Hying, Christian Scheible and Helmut Schmid .....	496
<i>Randomized Language Models via Perfect Hash Functions</i> David Talbot and Thorsten Brants .....	505
<i>Applying Morphology Generation Models to Machine Translation</i> Kristina Toutanova, Hisami Suzuki and Achim Ruopp .....	514
<i>Multilingual Harvesting of Cross-Cultural Stereotypes</i> Tony Veale, Yanfen Hao and Guofu Li .....	523
<i>Semi-Supervised Convex Training for Dependency Parsing</i> Qin Iris Wang, Dale Schuurmans and Dekang Lin .....	532

<i>Chinese-English Backward Transliteration Assisted with Mining Monolingual Web Pages</i> Fan Yang, Jun Zhao, Bo Zou, Kang Liu and Feifan Liu .....	541
<i>Robustness and Generalization of Role Sets: PropBank vs. VerbNet</i> Beñat Zepirain, Eneko Agirre and Lluís Màrquez .....	550
<i>A Tree Sequence Alignment-based Tree-to-Tree Translation Model</i> Min Zhang, Hongfei Jiang, Aiti Aw, Haizhou Li, Chew Lim Tan and Sheng Li .....	559
<i>Automatic Syllabification with Structured SVMs for Letter-to-Phoneme Conversion</i> Susan Bartlett, Grzegorz Kondrak and Colin Cherry .....	568
<i>A New String-to-Dependency Machine Translation Algorithm with a Target Dependency Language Model</i> Libin Shen, Jinxi Xu and Ralph Weischedel .....	577
<i>Forest Reranking: Discriminative Parsing with Non-Local Features</i> Liang Huang .....	586
<i>Simple Semi-supervised Dependency Parsing</i> Terry Koo, Xavier Carreras and Michael Collins .....	595
<i>Optimal k-arization of Synchronous Tree-Adjoining Grammar</i> Rebecca Nesson, Giorgio Satta and Stuart M. Shieber .....	604
<i>Enhancing Performance of Lexicalised Grammars</i> Rebecca Dridan, Valia Kordoni and Jeremy Nicholson .....	613
<i>Assessing Dialog System User Simulation Evaluation Measures Using Human Judges</i> Hua Ai and Diane J. Litman .....	622
<i>Robust Dialog Management with N-Best Hypotheses Using Dialog Examples and Agenda</i> Cheongjae Lee, Sangkeun Jung and Gary Geunbae Lee .....	630
<i>Learning Effective Multimodal Dialogue Strategies from Wizard-of-Oz Data: Bootstrapping and Evaluation</i> Verena Rieser and Oliver Lemon .....	638
<i>Phrase Chunking Using Entropy Guided Transformation Learning</i> Ruy Luiz Milidiú, Cícero Nogueira dos Santos and Julio C. Duarte .....	647
<i>Learning Bigrams from Unigrams</i> Xiaojin Zhu, Andrew B. Goldberg, Michael Rabbat and Robert Nowak .....	656
<i>Semi-Supervised Sequential Labeling and Segmentation Using Giga-Word Scale Unlabeled Data</i> Jun Suzuki and Hideki Isozaki .....	665
<i>Large Scale Acquisition of Paraphrases for Learning Surface Patterns</i> Rahul Bhagat and Deepak Ravichandran .....	674

<i>Contextual Preferences</i>	
Idan Szpektor, Ido Dagan, Roy Bar-Haim and Jacob Goldberger .....	683
<i>Unsupervised Discovery of Generic Relationships Using Pattern Clusters and its Evaluation by Automatically Generated SAT Analogy Questions</i>	
Dmitry Davidov and Ari Rappoport .....	692
<i>Improving Search Results Quality by Customizing Summary Lengths</i>	
Michael Kaisser, Marti A. Hearst and John B. Lowe .....	701
<i>Using Conditional Random Fields to Extract Contexts and Answers of Questions from Online Forums</i>	
Shilin Ding, Gao Cong, Chin-Yew Lin and Xiaoyan Zhu .....	710
<i>Learning to Rank Answers on Large Online QA Collections</i>	
Mihai Surdeanu, Massimiliano Ciaramita and Hugo Zaragoza .....	719
<i>Unsupervised Lexicon-Based Resolution of Unknown Words for Full Morphological Analysis</i>	
Meni Adler, Yoav Goldberg, David Gabay and Michael Elhadad .....	728
<i>Unsupervised Multilingual Learning for Morphological Segmentation</i>	
Benjamin Snyder and Regina Barzilay .....	737
<i>EM Can Find Pretty Good HMM POS-Taggers (When Given a Good Start)</i>	
Yoav Goldberg, Meni Adler and Michael Elhadad .....	746
<i>Distributed Word Clustering for Large Scale Class-Based Language Modeling in Machine Translation</i>	
Jakob Uszkoreit and Thorsten Brants .....	755
<i>Enriching Morphologically Poor Languages for Statistical Machine Translation</i>	
Eleftherios Avramidis and Philipp Koehn .....	763
<i>Learning Bilingual Lexicons from Monolingual Corpora</i>	
Aria Haghighi, Percy Liang, Taylor Berg-Kirkpatrick and Dan Klein .....	771
<i>Pivot Approach for Extracting Paraphrase Patterns from Bilingual Corpora</i>	
Shiqi Zhao, Haifeng Wang, Ting Liu and Sheng Li .....	780
<i>Unsupervised Learning of Narrative Event Chains</i>	
Nathanael Chambers and Dan Jurafsky .....	789
<i>Semantic Role Labeling Systems for Arabic using Kernel Methods</i>	
Mona Diab, Alessandro Moschitti and Daniele Pighin .....	798
<i>An Unsupervised Approach to Biography Production Using Wikipedia</i>	
Fadi Biadisy, Julia Hirschberg and Elena Filatova .....	807
<i>Generating Impact-Based Summaries for Scientific Literature</i>	
Qiaozhu Mei and ChengXiang Zhai .....	816

<i>Can You Summarize This? Identifying Correlates of Input Difficulty for Multi-Document Summarization</i> Ani Nenkova and Annie Louis .....	825
<i>You Talking to Me? A Corpus and Algorithm for Conversation Disentanglement</i> Micha Elsner and Eugene Charniak .....	834
<i>An Entity-Mention Model for Coreference Resolution with Inductive Logic Programming</i> Xiaofeng Yang, Jian Su, Jun Lang, Chew Lim Tan, Ting Liu and Sheng Li .....	843
<i>Gestural Cohesion for Topic Segmentation</i> Jacob Eisenstein, Regina Barzilay and Randall Davis .....	852
<i>Multi-Task Active Learning for Linguistic Annotations</i> Roi Reichart, Katrin Tomanek, Udo Hahn and Ari Rappoport .....	861
<i>Generalized Expectation Criteria for Semi-Supervised Learning of Conditional Random Fields</i> Gideon S. Mann and Andrew McCallum .....	870
<i>Analyzing the Errors of Unsupervised Learning</i> Percy Liang and Dan Klein .....	879
<i>Joint Word Segmentation and POS Tagging Using a Single Perceptron</i> Yue Zhang and Stephen Clark .....	888
<i>A Cascaded Linear Model for Joint Chinese Word Segmentation and Part-of-Speech Tagging</i> Wenbin Jiang, Liang Huang, Qun Liu and Yajuan Lü .....	897
<i>Joint Processing and Discriminative Training for Letter-to-Phoneme Conversion</i> Sittichai Jiampojarn, Colin Cherry and Grzegorz Kondrak .....	905
<i>A Probabilistic Model for Fine-Grained Expert Search</i> Shenghua Bao, Huizhong Duan, Qi Zhou, Miao Xiong, Yunbo Cao and Yong Yu .....	914
<i>Credibility Improves Topical Blog Post Retrieval</i> Wouter Weerkamp and Maarten de Rijke .....	923
<i>Linguistically Motivated Features for Enhanced Back-of-the-Book Indexing</i> Andras Csomai and Rada Mihalcea .....	932
<i>Resolving Personal Names in Email Using Context Expansion</i> Tamer Elsayed, Douglas W. Oard and Galileo Namata .....	941
<i>Integrating Graph-Based and Transition-Based Dependency Parsers</i> Joakim Nivre and Ryan McDonald .....	950
<i>Efficient, Feature-based, Conditional Random Field Parsing</i> Jenny Rose Finkel, Alex Kleeman and Christopher D. Manning .....	959
<i>A Deductive Approach to Dependency Parsing</i> Carlos Gómez-Rodríguez, John Carroll and David Weir .....	968

<i>Evaluating a Crosslinguistic Grammar Resource: A Case Study of Wambaya</i> Emily M. Bender .....	977
<i>Better Alignments = Better Translations?</i> Kuzman Ganchev, João V. Graça and Ben Taskar .....	986
<i>Mining Parenthetical Translations from the Web by Word Alignment</i> Dekang Lin, Shaojun Zhao, Benjamin Van Durme and Marius Paşca .....	994
<i>Soft Syntactic Constraints for Hierarchical Phrased-Based Translation</i> Yuval Marton and Philip Resnik .....	1003
<i>Generalizing Word Lattice Translation</i> Christopher Dyer, Smaranda Muresan and Philip Resnik .....	1012
<i>Combining Multiple Resources to Improve SMT-based Paraphrasing Model</i> Shiqi Zhao, Cheng Niu, Ming Zhou, Ting Liu and Sheng Li .....	1021
<i>Extraction of Entailed Semantic Relations Through Syntax-Based Comma Resolution</i> Vivek Srikumar, Roi Reichart, Mark Sammons, Ari Rappoport and Dan Roth .....	1030
<i>Finding Contradictions in Text</i> Marie-Catherine de Marneffe, Anna N. Rafferty and Christopher D. Manning .....	1039
<i>Semantic Class Learning from the Web with Hyponym Pattern Linkage Graphs</i> Zornitsa Kozareva, Ellen Riloff and Eduard Hovy .....	1048

## Preface: General Chair

I am honored to be serving as General Conference Chair for the annual conference in our field. This year's conference, ACL-08: HLT, is jointly sponsored by the Association for Computational Linguistics and the North American Chapter of the Association for Computational Linguistics and it thus brings together the traditions of both organizations. As is evident from the title, one of those traditions is the focus on research from all areas of Human Language Technology, including information retrieval, natural language processing and speech. The conference features invited speakers in speech and information retrieval and there are sessions devoted to all three of these areas. I hope this conference will again encourage interaction among researchers from the different areas.

Since I was last involved in organizing the ACL Conferences back in the 90's, the conferences have grown dramatically. I was surprised to learn the number of people required to make the conference happen. Some 30 odd people are serving in Chair or Co-Chair capacity of various aspects of the conference. While I was pleased to have the opportunity of shaping aspects of the conference, I have to say that the real bulk of the work is done by the many Chairs involved. So I want to express my gratitude to all of them for their commitment and dedication to making sure that all ran smoothly. I am impressed by the energy and time that everyone gave to this volunteer activity.

I would like to thank the Program Chairs, Johanna Moore, Simone Teufel, James Allan and Sadaoki Furui, who have put in many hours to provide us with the main program for the conference and the Local Arrangements Chair, Chris Brew, who has provided us with the venue for the conference and oversaw the many time-demanding details. DJ Hovermale also put in many hours as webmaster, collecting information from everyone. I would like to thank the Chairs of the Student Research Workshop, Ebru Arisoy, Wolfgang Maier and Keisuke Inoue, who worked quite independently, along with the Faculty Advisor, Jan Wiebe. The Workshop Chair, Ming Zhou, managed the workshop program with ease, a program that has grown over the years so that it seems like a conference in and of itself. The Tutorial Chairs, Ani Nenkova, Marilyn Walker and Eugene Agichtein, have put together a fine tutorial program and the Demo Chair, Jimmy Lin, has organized a nice series of demos. The Sponsorship Chairs are responsible for bringing in funding to cover various programs and I would like to thank Inderjeet Mani, Josef van Genabith and Michael White for their efforts in this regard. The Publicity Chairs, Hal Daumé III, Eric Fosler-Lussier and Diane Kelly, reached out to communities outside the central natural language areas to encourage people to submit papers and attend the conference. Finally, I would like to give a big thanks to the Publication Chairs, Joakim Nivre and Noah A. Smith, who were very organized and handily managed the job of pulling all materials together for the main conference and workshop proceedings, no small feat.

In addition to the Chairs, individuals within the ACL organization itself deserve recognition. First and foremost, my thanks goes to Dragomir Radev, who provided guidance about what to do next at every step and who had the answer to every question I had within seconds. Owen Rambow also provided much needed advice from the perspective of the North American Chapter. Priscilla Rasmussen is critical to the running of the conference, with her organizational history of how things work. Finally, I would like to thank the Coordinating Committee for being available for discussion and for providing advice.

Kathleen McKeown  
ACL-08: HLT General Chair

## Preface: Program Chairs

The program for ACL-08: HLT features a wide variety of avenues for authors to present their latest work in computational linguistics, information retrieval, and speech technology. The program includes: full papers, short papers, posters, demonstrations, and a student research workshop, as well as pre- and post-conference tutorials and workshops. In our program design, we attempted to combine the successful approach of ACL07, which had four parallel oral sessions of 25-min full paper presentations, with the HLT model of presenting late-breaking results in parallel sessions of 15-min short paper presentations. We also experimented with an idea adopted from Interspeech, in which authors can choose their desired mode of presentation, oral or poster, based on their assessment of how best to present their work. There is no distinction between posters and oral presentations in terms of quality or in terms of how they appear in the Proceedings. Although it will take more than one year to see this change fully taken up by the membership, we were happy to see some authors choose the poster option from the very outset. Area chairs also used their discretion in indicating which submissions would benefit from which mode of presentation. If the number of submissions continues to grow as it has done in the past few years, poster sessions will be one way to managing this growth without creating a large number of parallel sessions.

This year, the program committee received yet another record-breaking number of submissions, with 470 full and 275 short paper submissions. Full papers were due in mid-January, and the program committee accepted 119 (25%) of these, 95 as oral presentations and 24 as posters. Short papers were due in mid-March, and the committee accepted 64 (23%) of these, 32 for oral presentation and 32 for poster presentation.

First and foremost, we thank all the authors for submitting papers describing their recent work; the sheer number of submissions reflects how active our field is. We are greatly indebted to the 34 area chairs who recruited 720 reviewers, and who managed the reviewing process of both full and short papers in their areas. Reviewers wrote three reviews for each full paper submission, and two reviews for each short paper submission, for a staggering total of just under 2000 reviews! Miraculously, there were only a handful of late reviews. Well done everyone!

As the number of submissions and, consequently the number of area chairs, has risen over the last few years, the ACL program committee has moved away from having a face-to-face meeting of all area chairs. For ACL08: HLT, two of the program co-chairs met for two days at Edinburgh University, using email and teleconferencing to get input from the two program co-chairs not based in Europe, and all of the area chairs. For short paper decision making, three of the four program co-chairs held a teleconference, with input from the fourth co-chair by email as time zone differences permitted.

Another first this year was our decision to award several outstanding paper prizes, rather than trying to identify a single best paper. We did this because we felt that it is typical for conferences as large as this to have several particularly exciting, innovative, and well-crafted papers, and it is extremely difficult to compare quality across areas. We asked area chairs to nominate papers for the various awards and then formed an Outstanding Paper Committee, who wish to remain anonymous, and to whom we owe a great debt of gratitude for their hard work at short notice.

As usual, the main program will run for three days: there will be four parallel sessions of paper presentations. One of these is devoted to the Student Research Workshop, which we would like to thank Ebru Abrisoy, Wolfgang Maier and Keisuke Inoue for organizing. There will also be a poster session on Monday evening, with food and drink to keep everyone going. The demo session, organized by Jimmy Lin, will be held concurrently with the poster session. This year there will be five plenary sessions: two for our very distinguished invited speakers, Susan Dumais and Marc Swerts, one for presentation of the four outstanding papers, one for the presentation by this year's Lifetime Achievement Award winner, and finally one for the ACL business meeting.

Also as usual the conference is flanked by tutorial sessions and workshops. We would like to thank Ani Nenkova, Marilyn Walker and Eugene Agichtein for organizing the tutorials, and Ming Zhou, ChengXiang Zhai and Helen Meng for compiling an excellent program of workshops.

We also thank Kathy McKeown, General Conference Chair, the Local Arrangements Committee headed by Chris Brew, the ACL executive committee, for their help and advice, and last year's co-chairs, Antal van den Bosch and Annie Zaenen, for sharing their experience.

Finally, there were three things that made this all possible. First, we were helped immensely by Jason Eisner, who has compiled an excellent web site on "How to Serve as Program Chair of a Conference" (<http://www.cs.jhu.edu/~jason/advice/how-to-chair-a-conference.html>). This saved us more than once! Second, we employed a recent PhD, James Clarke, to help us get started with START, and to simply deal with the large volume of work that must be processed within the first few days after submissions are received. James kept us sane. Third, there is the invaluable START system for managing paper submission, reviewing, and decision making. We owe Rich Gerber and the START team a million thanks for responding to questions quickly, and even modifying START overnight to provide what we asked for.

Our most sincere thanks go to Joakim Nivre and Noah A. Smith who took all of our labors and put together the wonderful Proceedings you are now reading.

We hope you enjoy the conference,

Johanna D. Moore, Simone Teufel, James Allan, and Sadaoki Furui  
ACL-08: HLT Program Chairs

# Organizers

## General Chair:

Kathleen McKeown, Columbia University, USA

## Local Arrangements Chair:

Chris Brew, The Ohio State University, USA

## Program Chairs:

Johanna Moore (Natural Language Processing), University of Edinburgh, UK

Simone Teufel (Natural Language Processing), University of Cambridge, UK

James Allan (Information Retrieval), University of Massachusetts, USA

Sadaoki Furui (Speech), Tokyo Institute of Technology, Japan

## Student Research Workshop:

Ebru Arisoy (Speech co-chair), Bogazici University, Turkey

Wolfgang Maier (Natural Language Processing co-chair), University of Tuebingen, Germany

Keisuke Inoue (Information Retrieval co-chair), Syracuse University, USA

Janyce Wiebe (Faculty Advisor), University of Pittsburgh, USA

## Workshop Chair:

Ming Zhou, Microsoft Research China, China

## Tutorial Chairs:

Ani Nenkova (Coordinator), University of Pennsylvania, USA

Marilyn Walker, University of Sheffield, UK

Eugene Agichtein, Emory University, USA

## Demo Chair:

Jimmy Lin, University of Maryland, USA

## Sponsorship Chairs:

Inderjeet Mani, Mitre Corporation, USA

Josef van Genabith, Dublin City University, Ireland

Michael White, The Ohio State University, USA

**Publications Chairs:**

Joakim Nivre, Växjö University and Uppsala University, Sweden  
Noah Smith, Carnegie Mellon University, USA

**Publicity Chairs:**

Hal Daumé III, University of Utah, USA  
Eric Fosler-Lussier, The Ohio State University, USA  
Diane Kelly, University of North Carolina, USA

**Student Volunteers:**

Ilana Bromberg (Volunteer co-ordinator)  
Crystal Nakatsu (Accommodation requests)  
Dominic Espinosa (Conference booklet)

**Webmaster:**

DJ Hovermale, The Ohio State University, USA

**Publications Committee:**

Marco Kuhlmann, Uppsala University, Sweden  
Carol Sisson, Carnegie Mellon University, USA  
Filip Salomonsson, Uppsala University, Sweden

**Registration:**

Priscilla Rasmussen, Association for Computational Linguistics (ACL)

**ACL Coordinating Committee:**

Nicoletta Calzolari, Università di Pisa, Italy  
Jennifer Chu-Carroll, IBM, USA  
Graeme Hirst, University of Toronto, Canada  
Chris Manning, Stanford University, USA  
Kathleen McCoy, University of Delaware, US  
Dragomir Radev, University of Michigan, USA  
Owen Rambow, Columbia University, USA  
Priscilla Rasmussen, Association for Computational Linguistics (ACL)  
Mark Steedman, The University of Edinburgh, UK  
Suzanne Stevenson, University of Toronto, Canada

# Program Committee

## Program Chairs:

Johanna D. Moore, University of Edinburgh (UK)  
Simone Teufel, Cambridge University (UK)  
James Allan, University of Massachusetts Amherst (USA)  
Sadaoki Furui, Tokyo Institute of Technology (Japan)

## Area Chairs:

Jason Baldridge, University of Texas at Austin (USA)  
Regina Barzilay, Massachusetts Institute of Technology (USA)  
Pushpak Bhattacharaya, Indian Institute of Technology Bombay (India)  
David Carmel, IBM Research (Israel)  
David Chiang, USC/Information Sciences Institute (USA)  
Steve Clark, Oxford University (UK)  
Hal Daumé III, University of Utah (USA)  
Dina Demner-Fushman, National Library of Medicine (USA)

Phil Edmonds, Markus Egg, Patrick Ehlen, Andreas Eisele, Jacob Eisenstein, Michael Elhadad, Micha Elsner, Katrin Erk, Gunes Erkan, David Evans, Stefan Evert

Yi Fang, Afsaneh Fazly, Ronen Feldman, Christiane Fellbaum, Raul Fernandez, Elena Filatova, Jenny Finkel, Michael Fleischman, Dan Flickinger, Radu Florian, Katherine Forbes, Eric Fosler-Lussier, Frederik Fouvry, Nissim Francez, Robert Frank, Alex Fraser, Bob Frederking, Marjorie Freedman, Dayne Freitag, Junichi Fukumoto

Evgeniy Gabrilovich, Robert Gaizauskas, Michael Gamon, Sudeep Gandhe, Yuqing Gao, Claire Gardent, Ulrich Germann, Roxana Girju, Natalie Glance, Oren Glickman, Amir Globerson, Yoav Goldberg, Ayelet Goldstein, Jade Goldstein, Sharon Goldwater, Gregory Grefenstette, Thomas Griffiths, Ralph Grishman, Iryna Gurevych, Joakim Gustafson

Stephanie Haas, Nizar Habash, Aria Haghighi, Tom Hain, Dilek Hakkani-Tur, Keith Hall, Sanda Harabagiu, Donna Harman, Sasa Hasan, Timothy Hazen, Daqing He, Xiaodong He, Mary Hearne, Marti Hearst, Ulrich Heid, James Henderson, Ulf Hermjakob, Andrew Hickl, Julia Hirschberg, Lynette Hirschman, Graeme Hirst, Julia Hockenmaier, Mark Hopkins, Veronique Hoste, Eduard Hovy, Churen Huang, Liang Huang, Sarmad Hussain, Bouke Huurnink, Mei-Yuh Hwang

Nancy Ide, Diana Inkpen, Kentaro Inui, Mitsuru Ishizuka, Abe Ittycheriah

Jagadeesh Jagarlamudi, Martin Jansche, Mark Johnson, Rie Johnson, Kristiina Jokinen, Gareth Jones, Rosie Jones, Aravind Joshi

Laura Kallmeyer, Nanda Kambhatla, Hiroshi Kanayama, Noriko Kando, Damianos Karakos, Nikiforos Karamanis, Hideki Kashioka, Yasuhiro Katagiri, Rohit Kate, Tsuneaki Kato, Boris Katz, Tatsuya Kawahara, Junichi Kazama, Bill Keler, Frank Keller, Charles Kemp, Andre Kempe, Stanley Yong Wai Keong, Sharam Khadivi, Mahboob Khalid, Rodger Kibble, Bernd Kiefer, Adam Kilgarriff, Chunyu Kit, Dan Klein, Kevin Knight, Alistair Knott, Philipp Koehn, Rob Koeling, Alexander Koller, Terry Koo, Moshe Koppel, Anna Korhonen, Kimmo Koskenniemi, Emiel Kraemer, Geert-Jan Kruijff, Yuval Krymlowski, Sandra Kuebler, Marco Kuhlmann, Jonas Kuhn, Seth Kulick, Shankar Kumar, A Kumaran, June-Jei Kuo, Sadao Kurohashi

Philippe Langlais, Mirella Lapata, Alex Lascarides, Alberto Lavelli, Alon Lavie, Victor Lavrenko, Alan Lee, Gary Lee, Lillian Lee, Yoong Keok Lee, Xin Lei, Gregor Leusch, Lori Levin, Hang Li, Jianguo Li, Qing Li, Xiaolong Li, Xiaoyan Li, Jimmy Lin, Krister Lindén, Lucian Lita, Ken Litkowski, Diane Litman, Bing Liu, Qun Liu, Tie-Yan Liu, Yang Liu, Karen Livescu, Andrei Ljolje, Adam Lopez, Yajuan Lu, Anke Lüdeling, Xiaoqiang Luo

Brian Mak, Rob Malouf, Inderjeet Mani, Gideon Mann, Daniel Marcu, Lluís Màrquez, Brandeis Marshall, Maria Antònia Martí, James Martin, Jean-Claude Martin, David Martínez, Gregory Marton, Mstislav Maslennikov, Tomoko Matsui, Yuji Matsumoto, Evgeny Matusov, Arne Mauser, Jonathan May, Mark Maybury, Diana McCarthy, Mark McConnville, Kathleen McCoy, Ryan McDonald, Tony Mcenry, Chris Mellish, Helen Meng, Paola Merlo, Detmar Meurers, Rada Mihalcea, Brian Milch, Eleni Miltsakaki, David Mimno, Wolfgang Minker, Einat Minkov, Gilad Mishne, Dipti Misra, Teruko Mitamura, Mandar Mitra, Vibhu Mittal, Yusuke Miyao, Noboru Miyazaki, Sien Moens, Saif Mohammad, Rajat Mohanty, Dan Moldovan, Diego Mollá, Christian Monson, Christof Monz, Raymond Mooney, Bob Moore, Glyn Morrill, Alessandro Moschitti, Karin Müller, Dragos Munteanu, Smaranda Muresan, Reinhard Muskens, Sung Hyon Myaeng

Masaaki Nagata, Mikio Nakano, Yukiko Nakano, Vivi Nastase, Roberto Navigli, Mark-Jan Nederhof, Ani Nenkova, John Nerbonne, Günter Neumann, Hermann Ney, Hwee Tou Ng, Vincent Ng, Patrick Nguyen, Jian-Yun Nie, Zaiqing Nie, Takashi Ninomiya, Malvina Nissim, Cheng Niu, Joakim Nivre, Chikashi Nobata, Elena Not, Adrian Novischi

Jon Oberlander, Franz Och, Stephan Oepen, Kemal Oflazer, Manabu Okumura, Miles Osborne, Jahna Otterbacher

Sebastian Pado, Tim Paek, Martha Palmer, Bo Pang, Cecile Paris, Marius Pasca, Rebecca Passonneau, Jon Patrick, Siddharth Patwardhan, Michael Paul, Adam Pease, Ted Pedersen, Catherine Pelachaud, Anselmo Peñas, Gerald Penn, Wim Peters, Paul Piwek, Massimo Poesio, Octavian Popescu, Andrei Popescu-Belis, Maja Popovic, Chris Potts, Richard Power, Sameer Pradhan, John Prager, Rashmi Prasad, Detlef Prescher, Stephen Pulman, Amruta Purandare, James Pustejovsky

Long Qiu, Yan Qu, Chris Quirk

Hema Raghavan, Bhuvana Ramabhadran, Ganesh Ramakrishnan, Owen Rambow, Lance Ramshaw, Deepak Ravichandran, Ehud Reiter, Norbert Reithinger, Philip Resnik, Giuseppe Riccardi, Stefan Riezler, German Rigau, Ellen Riloff, Hae-Chang Rim, Fabio Rinaldi, Brian Roark, James Rogers, Maribel Romero, Barbara Rosario, Dan Roth, Victoria Rubin

Kenji Sagae, Horacio Saggion, Tetsuya Sakai, Joan A. Sánchez, Mark Sanderson, Murat Saraclar, Anoop Sarkar, Shudeshna Sarkar, Yutaka Sasaki, Giorgio Satta, Jan Schehl, Michael Schiehlen, Anne Schiller, David Schlangen, Judith Schlesinger, Helmut Schmid, Marc Schroeder, Hinrich Schütze, Holger Schwenk, Donia Scott, Satoshi Sekine, Mike Seltzer, Vijay Shanker, Libin Shen, Akira Shimazu, Luo Si, Advait Siddharthan, Melanie Siegel, Khalil Simaan, Michel Simard, David Smith, Rion Snow, Benjamin Snyder, Stephen Soderland, Anders Sjøgaard, Swapna Somasundaran, David Sonntag, Jennifer Spenader, Caroline Sporleder, Richard Sproat, Manfred Stede, Mark Steedman, Amanda Stent, Mark Stevenson, Suzanne Stevenson, Nicola Stokes, Matthew Stone, Veselin Stoyanov, Carlo Strapparava, Michael Strube, Tomek Strzalkowski, Jian Su, Keh-Yih Su, Eiichiro Sumita, Jian-Tao Sun, Richard Sutcliffe, Charles Sutton, Idan Szpektor

Maite Taboada, John Tait, Hiroya Takamura, David Talbot, Pasi Tapanainen, Joel Tetreault, Mariet Theune, Vu Thuy, Jörg Tiedemann, Christoph Tillmann, Roberto Togneri, Takenobu Tokunaga, Kristina Toutanova, David Traum, Benjamin Tsou, Hajime Tsukada, Yoshimasa Tsuruoka, Gokhan Tur, Peter Turney

Raghavendra Udupa, Nicola Ueffing, Masao Utiyama

Antal van den Bosch, Josef van Genabith, Hans van Halteren, Lucy Vanderwende, Tony Veale, Sriram Venkatapathy, Ashish Venugopal, Marc Verhagen, Paola Verlardi, Yannick Versley, Renata Vieira, David Vilar, Piek Vossen, Atro Voutilainen

Joachim Wagner, Marilyn Walker, Michael Walsh, Xiaojun Wan, Haifeng Wang, Wei Wang, Bonnie Webber, Wouter Weerkamp, Ben Wellner, Fuiliang Weng, Michael White, Richard Wicentowski, Yorick Wilks, Theresa Wilson, Shuly Wintner, Yuk Wah Wong, Johan Wouters, Dekai Wu

Fei Xia, Jingfang Xu, Peng Xu

Atsushi Yamada, Kazuhide Yamamoto, Xiaofeng Yang, Alexander Yates, Shiren Ye, Scott Wen-tau Yih, Clem Yu, Deniz Yuret

Dmitry Zaykovskiy, Dmitry Zelenko, Luke Zettlemoyer, ChengXiang Zhai, Hao Zhang, Min Zhang, Rong Zhang, Tong Zhang, Yue Zhang, Jerry Zhu, Andreas Zollmann, Chengqing Zong, Ingrid Zukerman, Pierre Zweigenbaum

# Conference Program

## Monday, June 16, 2008

9:00–9:10      Opening Session

9:10–10:10    Invited Talk: Marc Swerts, *Facial Expressions in Human-Human and Human-Machine Interactions*

10:10–10:40    **Break**

### Session 1A: Information Extraction 1

10:40–11:05    *Mining Wiki Resources for Multilingual Named Entity Recognition*  
Alexander E. Richman and Patrick Schone

11:05–11:30    *Distributional Identification of Non-Referential Pronouns*  
Shane Bergsma, Dekang Lin and Randy Goebel

11:30–11:55    *Weakly-Supervised Acquisition of Open-Domain Classes and Class Attributes from Web Documents and Query Logs*  
Marius Paşca and Benjamin Van Durme

11:55–12:20    *The Tradeoffs Between Open and Traditional Relation Extraction*  
Michele Banko and Oren Etzioni

### Session 1B: Language Resources and Evaluation

10:40–11:05    *PDT 2.0 Requirements on a Query Language*  
Jiří Mírovský

11:05–11:30    *Task-oriented Evaluation of Syntactic Parsers and Their Representations*  
Yusuke Miyao, Rune Sætre, Kenji Sagae, Takuya Matsuzaki and Jun'ichi Tsujii

11:30–11:55    *MAXSIM: A Maximum Similarity Metric for Machine Translation Evaluation*  
Yee Seng Chan and Hwee Tou Ng

11:55–12:20    *Contradictions and Justifications: Extensions to the Textual Entailment Task*  
Ellen M. Voorhees

**Monday, June 16, 2008 (continued)**

**Session 1C: Machine Translation 1**

- 10:40–11:05 *Cohesive Phrase-Based Decoding for Statistical Machine Translation*  
Colin Cherry
- 11:05–11:30 *Phrase Table Training for Precision and Recall: What Makes a Good Phrase and a Good Phrase Pair?*  
Yonggang Deng, Jia Xu and Yuqing Gao
- 11:30–11:55 *Measure Word Generation for English-Chinese SMT Systems*  
Dongdong Zhang, Mu Li, Nan Duan, Chi-Ho Li and Ming Zhou
- 11:55–12:20 *Bayesian Learning of Non-Compositional Phrases with Synchronous Parsing*  
Hao Zhang, Chris Quirk, Robert C. Moore and Daniel Gildea

**Session 1D: Speech Processing**

- 10:40–11:05 *Applying a Grammar-Based Language Model to a Simplified Broadcast-News Transcription Task*  
Tobias Kaufmann and Beat Pfister
- 11:05–11:30 *Automatic Editing in a Back-End Speech-to-Text System*  
Maximilian Bisani, Paul Vozila, Olivier Divay and Jeff Adams
- 11:30–11:55 *Grounded Language Modeling for Automatic Speech Recognition of Sports Video*  
Michael Fleischman and Deb Roy
- 11:55–12:20 *Lexicalized Phonotactic Word Segmentation*  
Margaret M. Fleck
- 12:20–2:00 **Lunch**

**Monday, June 16, 2008 (continued)**

**Session 2A: Information Retrieval 1**

- 2:00–2:25 *A Re-examination of Query Expansion Using Lexical Resources*  
Hui Fang
- 2:25–2:50 *Selecting Query Term Alternations for Web Search by Exploiting Query Contexts*  
Guihong Cao, Stephen Robertson and Jian-Yun Nie
- 2:50–3:15 *Searching Questions by Identifying Question Topic and Question Focus*  
Huizhong Duan, Yunbo Cao, Chin-Yew Lin and Yong Yu

**Session 2B: Language Generation**

- 2:00–2:25 *Trainable Generation of Big-Five Personality Styles through Data-Driven Parameter Estimation*  
François Mairesse and Marilyn Walker
- 2:25–2:50 *Correcting Misuse of Verb Forms*  
John Lee and Stephanie Seneff
- 2:50–3:15 *Hypertagging: Supertagging for Surface Realization with CCG*  
Dominic Espinosa, Michael White and Dennis Mehay

**Session 2C: Machine Translation 2**

- 2:00–2:25 *Forest-Based Translation*  
Haitao Mi, Liang Huang and Qun Liu
- 2:25–2:50 *A Discriminative Latent Variable Model for Statistical Machine Translation*  
Phil Blunsom, Trevor Cohn and Miles Osborne
- 2:50–3:15 *Efficient Multi-Pass Decoding for Synchronous Context Free Grammars*  
Hao Zhang and Daniel Gildea

**Monday, June 16, 2008 (continued)**

**Session 2D: Semantics 1**

- 2:00–2:25 *Regular Tree Grammars as a Formalism for Scope Underspecification*  
Alexander Koller, Michaela Regneri and Stefan Thater
- 2:25–2:50 *Classification of Semantic Relationships between Nominals Using Pattern Clusters*  
Dmitry Davidov and Ari Rappoport
- 2:50–3:15 *Vector-based Models of Semantic Composition*  
Jeff Mitchell and Mirella Lapata
- 3:15–3:45 **Break**

**Session 3A: Information Extraction 2**

- 3:45–4:10 *Exploiting Feature Hierarchy for Transfer Learning in Named Entity Recognition*  
Andrew Arnold, Ramesh Nallapati and William W. Cohen
- 4:10–4:35 *Refining Event Extraction through Cross-Document Inference*  
Heng Ji and Ralph Grishman
- 4:35–5:00 *Learning Document-Level Semantic Properties from Free-Text Annotations*  
S.R.K. Branavan, Harr Chen, Jacob Eisenstein and Regina Barzilay
- 5:00–5:25 *Automatic Image Annotation Using Auxiliary Text Information*  
Yansong Feng and Mirella Lapata

**Monday, June 16, 2008 (continued)**

**Session 3B: Sentiment Analysis**

- 3:45–4:10 *Hedge Classification in Biomedical Texts with a Weakly Supervised Selection of Keywords*  
György Szarvas
- 4:10–4:35 *When Specialists and Generalists Work Together: Overcoming Domain Dependence in Sentiment Tagging*  
Alina Andreevskaia and Sabine Bergler
- 4:35–5:00 *A Generic Sentence Trimmer with CRFs*  
Tadashi Nomoto
- 5:00–5:25 *A Joint Model of Text and Aspect Ratings for Sentiment Summarization*  
Ivan Titov and Ryan McDonald

**Session 3C: Syntax and Parsing 1**

- 3:45–4:10 *Improving Parsing and PP Attachment Performance with Sense Information*  
Eneko Agirre, Timothy Baldwin and David Martinez
- 4:10–4:35 *A Logical Basis for the D Combinator and Normal Form in CCG*  
Frederick Hoyt and Jason Baldridge
- 4:35–5:00 *Parsing Noun Phrase Structure with CCG*  
David Vadas and James R. Curran
- 5:00–5:25 *Sentence Simplification for Semantic Role Labeling*  
David Vickrey and Daphne Koller

**Monday, June 16, 2008 (continued)**

**Session 3D: Student Research Workshop**

- 3:45–4:10 *A Supervised Learning Approach to Automatic Synonym Identification Based on Distributional Features*  
Masato Hagiwara
- 4:10–4:35 *An Integrated Architecture for Generating Parenthetical Constructions*  
Eva Banik
- 4:35–5:00 *Inferring Activity Time in News through Event Modeling*  
Vladimir Eidelman
- 5:00–5:25 *Combining Source and Target Language Information for Name Tagging of Machine Translation Output*  
Shasha Liao
- 5:25–5:50 *A Re-examination on Features in Regression Based Approach to Automatic MT Evaluation*  
Shuqi Sun, Yin Chen and Jufeng Li
- 5:25–6:00 **Break**
- 6:00–8:30 **Poster and Demo Session**

**Long Paper Posters**

*Summarizing Emails with Conversational Cohesion and Subjectivity*  
Giuseppe Carenini, Raymond T. Ng and Xiaodong Zhou

*Ad Hoc Treebank Structures*  
Markus Dickinson

*A Single Generative Model for Joint Morphological Segmentation and Syntactic Parsing*  
Yoav Goldberg and Reut Tsarfaty

*Which Words Are Hard to Recognize? Prosodic, Lexical, and Disfluency Factors that Increase ASR Error Rates*  
Sharon Goldwater, Dan Jurafsky and Christopher D. Manning

*Name Translation in Statistical Machine Translation - Learning When to Transliterate*  
Ulf Hermjakob, Kevin Knight and Hal Daumé III

**Monday, June 16, 2008 (continued)**

*Using Adaptor Grammars to Identify Synergies in the Unsupervised Acquisition of Linguistic Structure*

Mark Johnson

*Inducing Gazetteers for Named Entity Recognition by Large-Scale Clustering of Dependency Relations*

Jun'ichi Kazama and Kentaro Torisawa

*Evaluating Roget's Thesauri*

Alistair Kennedy and Stan Szpakowicz

*Unsupervised Translation Induction for Chinese Abbreviations using Monolingual Corpora*

Zhifei Li and David Yarowsky

*Which Are the Best Features for Automatic Verb Classification*

Jianguo Li and Chris Brew

*Collecting a Why-Question Corpus for Development and Evaluation of an Automatic QA-System*

Joanna Mrozinski, Edward Whittaker and Sadaoki Furui

*Solving Relational Similarity Problems Using the Web as a Corpus*

Preslav Nakov and Marti A. Hearst

*Combining Speech Retrieval Results with Generalized Additive Models*

J. Scott Olsson and Douglas W. Oard

*A Critical Reassessment of Evaluation Baselines for Speech Summarization*

Gerald Penn and Xiaodan Zhu

*Intensional Summaries as Cooperative Responses in Dialogue: Automation and Evaluation*

Joseph Polifroni and Marilyn Walker

*Word Clustering and Word Selection Based Feature Reduction for MaxEnt Based Hindi NER*

Sujan Kumar Saha, Pabitra Mitra and Sudeshna Sarkar

*Combining EM Training and the MDL Principle for an Automatic Verb Classification Incorporating Selectional Preferences*

Sabine Schulte im Walde, Christian Hying, Christian Scheible and Helmut Schmid

**Monday, June 16, 2008 (continued)**

*Randomized Language Models via Perfect Hash Functions*

David Talbot and Thorsten Brants

*Applying Morphology Generation Models to Machine Translation*

Kristina Toutanova, Hisami Suzuki and Achim Ruopp

*Multilingual Harvesting of Cross-Cultural Stereotypes*

Tony Veale, Yanfen Hao and Guofu Li

*Semi-Supervised Convex Training for Dependency Parsing*

Qin Iris Wang, Dale Schuurmans and Dekang Lin

*Chinese-English Backward Transliteration Assisted with Mining Monolingual Web Pages*

Fan Yang, Jun Zhao, Bo Zou, Kang Liu and Feifan Liu

*Robustness and Generalization of Role Sets: PropBank vs. VerbNet*

Beñat Zepirain, Eneko Agirre and Lluís Màrquez

*A Tree Sequence Alignment-based Tree-to-Tree Translation Model*

Min Zhang, Hongfei Jiang, Aiti Aw, Haizhou Li, Chew Lim Tan and Sheng Li

#### **Short Paper Posters**

*Language Dynamics and Capitalization using Maximum Entropy*

Fernando Batista, Nuno Mamede and Isabel Trancoso

*Surprising Parser Actions and Reading Difficulty*

Marisa Ferrara Boston, John T. Hale, Reinhold Kliegl and Shravan Vasishth

*Improving the Performance of the Random Walk Model for Answering Complex Questions*

Yllias Chali and Shafiq Joty

*Dimensions of Subjectivity in Natural Language*

Wei Chen

*Extractive Summaries for Educational Science Content*

Sebastian de la Chica, Faisal Ahmad, James H. Martin and Tamara Sumner

**Monday, June 16, 2008 (continued)**

*Dialect Classification for Online Podcasts Fusing Acoustic and Language Based Structural and Semantic Information*

Rahul Chitturi and John Hansen

*The Complexity of Phrase Alignment Problems*

John DeNero and Dan Klein

*Novel Semantic Features for Verb Sense Disambiguation*

Dmitriy Dligach and Martha Palmer

*Icelandic Data Driven Part of Speech Tagging*

Mark Dredze and Joel Wallenberg

*Beyond Log-Linear Models: Boosted Minimum Error Rate Training for N-best Re-ranking*

Kevin Duh and Katrin Kirchhoff

*Coreference-inspired Coherence Modeling*

Micha Elsner and Eugene Charniak

*Enforcing Transitivity in Coreference Resolution*

Jenny Rose Finkel and Christopher D. Manning

*Simulating the Behaviour of Older versus Younger Users when Interacting with Spoken Dialogue Systems*

Kallirroi Georgila, Maria Wolters and Johanna Moore

*Active Sample Selection for Named Entity Transliteration*

Dan Goldwasser and Dan Roth

*Four Techniques for Online Handling of Out-of-Vocabulary Words in Arabic-English Statistical Machine Translation*

Nizar Habash

*Combined One Sense Disambiguation of Abbreviations*

Yaakov HaCohen-Kerner, Ariel Kass and Ariel Peretz

*Assessing the Costs of Sampling Methods in Active Learning for Annotation*

Robbie Haertel, Eric Ringger, Kevin Seppi, Carroll James and McClanahan Peter

*Blog Categorization Exploiting Domain Dictionary and Dynamically Estimated Domains of Unknown Words*

Chikara Hashimoto and Sadao Kurohashi

**Monday, June 16, 2008 (continued)**

*Mixture Model POMDPs for Efficient Handling of Uncertainty in Dialogue Management*  
James Henderson and Oliver Lemon

*Recent Improvements in the CMU Large Scale Chinese-English SMT System*  
Almut Silja Hildebrand, Kay Rottmann, Mohamed Noamany, Quin Gao, Sanjika Hewavitharana, Nguyen Bach and Stephan Vogel

*Machine Translation System Combination using ITG-based Alignments*  
Damianos Karakos, Jason Eisner, Sanjeev Khudanpur and Markus Dreyer

*Dictionary Definitions based Homograph Identification using a Generative Hierarchical Model*  
Anagha Kulkarni and Jamie Callan

*A Novel Feature-based Approach to Chinese Entity Relation Extraction*  
Wenjie Li, Peng Zhang, Furu Wei, Yuexian Hou and Qin Lu

*Using Structural Information for Identifying Similar Chinese Characters*  
Chao-Lin Liu and Jen-Hsiang Lin

*You've Got Answers: Towards Personalized Models for Predicting Success in Community Question Answering*  
Yandong Liu and Eugene Agichtein

*Self-Training for Biomedical Parsing*  
David McClosky and Eugene Charniak

*A Unified Syntactic Model for Parsing Fluent and Disfluent Speech*  
Tim Miller and William Schuler

*The Good, the Bad, and the Unknown: Morphosyllabic Sentiment Tagging of Unseen Words*  
Karo Moilanen and Stephen Pulman

*Kernels on Linguistic Structures for Answer Extraction*  
Alessandro Moschitti and Silvia Quarteroni

*Arabic Morphological Tagging, Diacritization, and Lemmatization Using Lexeme Models and Feature Ranking*  
Ryan Roth, Owen Rambow, Nizar Habash, Mona Diab and Cynthia Rudin

*Using Automatically Transcribed Dialogs to Learn User Models in a Spoken Dialog System*  
Umar Syed and Jason Williams

**Monday, June 16, 2008 (continued)**

*Robust Extraction of Named Entity Including Unfamiliar Word*  
Masatoshi Tsuchiya, Shinya Hida and Seichi Nakagawa

*In-Browser Summarisation: Generating Elaborative Summaries Biased Towards the Reading Context*  
Stephen Wan and Cécile Paris

*Lyric-based Song Sentiment Classification with Sentiment Vector Space Model*  
Yunqing Xia, Linlin Wang, Kam-Fai Wong and Mingxing Xu

*Mining Wikipedia Revision Histories for Improving Sentence Compression*  
Elif Yamangil and Rani Nelken

*Smoothing a Tera-word Language Model*  
Deniz Yuret

**Student Research Workshop Posters**

*The Role of Positive Feedback in Intelligent Tutoring Systems*  
Davide Fossati

*Arabic Language Modeling with Finite State Transducers*  
Ilana Heintz

*Impact of Initiative on Collaborative Problem Solving*  
Cynthia Kersey

*An Unsupervised Vector Approach to Biomedical Term Disambiguation: Integrating UMLS and Medline*  
Bridget McInnes

*A Subcategorization Acquisition System for French Verbs*  
Cédric Messiant

*Adaptive Language Modeling for Word Prediction*  
Keith Trnka

*A Hierarchical Approach to Encoding Medical Concepts for Clinical Notes*  
Yitao Zhang

**Monday, June 16, 2008 (continued)**

**Demonstrations**

*Demonstration of a POMDP Voice Dialer*

Jason Williams

*Generating Research Websites Using Summarisation Techniques*

Advaith Siddharthan and Ann Copestake

*BART: A Modular Toolkit for Coreference Resolution*

Yannick Versley, Simone Paolo Ponzetto, Massimo Poesio, Vladimir Eidelman, Alan Jern, Jason Smith, Xiaofeng Yang and Alessandro Moschitti

*Demonstration of the UAM CorpusTool for Text and Image Annotation*

Mick O'Donnell

*Interactive ASR Error Correction for Touchscreen Devices*

David Huggins-Daines and Alexander I. Rudnicky

*Yawat: Yet Another Word Alignment Tool*

Ulrich Germann

*SIDE: The Summarization Integrated Development Environment*

Moonyoung Kang, Sourish Chaudhuri, Mahesh Joshi and Carolyn P. Rosé

*ModelTalker Voice Recorder—An Interface System for Recording a Corpus of Speech for Synthesis*

Debra Yarrington, John Gray, Chris Pennington, H. Timothy Bunnell, Allegra Cornaglia, Jason Lilley, Kyoko Nagao and James Polikoff

*The QuALiM Question Answering Demo: Supplementing Answers with Paragraphs drawn from Wikipedia*

Michael Kaiser

**Tuesday, June 17, 2008**

**Session: Outstanding Paper Award Presentations**

9:00–9:10 Presentation of Awards

9:10–9:35 *Automatic Syllabification with Structured SVMs for Letter-to-Phoneme Conversion*  
Susan Bartlett, Grzegorz Kondrak and Colin Cherry

9:35–10:00 *A New String-to-Dependency Machine Translation Algorithm with a Target Dependency Language Model*  
Libin Shen, Jinxi Xu and Ralph Weischedel

10:00–10:25 *Forest Reranking: Discriminative Parsing with Non-Local Features*  
Liang Huang

10:25–10:40 *Event Matching Using the Transitive Closure of Dependency Relations*  
Daniel M. Bikel and Vittorio Castelli

10:40–11:10 **Break**

**Session 4A: Syntax and Parsing 2**

11:10–11:35 *Simple Semi-supervised Dependency Parsing*  
Terry Koo, Xavier Carreras and Michael Collins

11:35–12:00 *Optimal  $k$ -arization of Synchronous Tree-Adjoining Grammar*  
Rebecca Nesson, Giorgio Satta and Stuart M. Shieber

12:00–12:25 *Enhancing Performance of Lexicalised Grammars*  
Rebecca Dridan, Valia Kordoni and Jeremy Nicholson

**Tuesday, June 17, 2008 (continued)**

**Session 4B: Dialogue**

- 11:10–11:35 *Assessing Dialog System User Simulation Evaluation Measures Using Human Judges*  
Hua Ai and Diane J. Litman
- 11:35–12:00 *Robust Dialog Management with N-Best Hypotheses Using Dialog Examples and Agenda*  
Cheongjae Lee, Sangkeun Jung and Gary Geunbae Lee
- 12:00–12:25 *Learning Effective Multimodal Dialogue Strategies from Wizard-of-Oz Data: Bootstrapping and Evaluation*  
Verena Rieser and Oliver Lemon

**Session 4C: Machine Learning 2**

- 11:10–11:35 *Phrase Chunking Using Entropy Guided Transformation Learning*  
Ruy Luiz Milidiú, Cícero Nogueira dos Santos and Julio C. Duarte
- 11:35–12:00 *Learning Bigrams from Unigrams*  
Xiaojin Zhu, Andrew B. Goldberg, Michael Rabbat and Robert Nowak
- 12:00–12:25 *Semi-Supervised Sequential Labeling and Segmentation Using Giga-Word Scale Unlabeled Data*  
Jun Suzuki and Hideki Isozaki

**Session 4D: Semantics 2**

- 11:10–11:35 *Large Scale Acquisition of Paraphrases for Learning Surface Patterns*  
Rahul Bhagat and Deepak Ravichandran
- 11:35–12:00 *Contextual Preferences*  
Idan Szpektor, Ido Dagan, Roy Bar-Haim and Jacob Goldberger
- 12:00–12:25 *Unsupervised Discovery of Generic Relationships Using Pattern Clusters and its Evaluation by Automatically Generated SAT Analogy Questions*  
Dmitry Davidov and Ari Rappoport
- 12:25–2:00 **Lunch**

**Tuesday, June 17, 2008 (continued)**

**Session 5A: Short Papers 1 (Machine Translation)**

- 2:00–2:15 *A Linguistically Annotated Reordering Model for BTG-based Statistical Machine Translation*  
Deyi Xiong, Min Zhang, Aiti Aw and Haizhou Li
- 2:15–2:30 *Segmentation for English-to-Arabic Statistical Machine Translation*  
Ibrahim Badr, Rabih Zbib and James Glass
- 2:30–2:45 *Exploiting N-best Hypotheses for SMT Self-Enhancement*  
Boxing Chen, Min Zhang, Aiti Aw and Haizhou Li
- 2:45–3:00 *Partial Matching Strategy for Phrase-based Statistical Machine Translation*  
Zhongjun He, Qun Liu and Shouxun Lin

**Session 5B: Short Papers 2 (Speech)**

- 2:00–2:15 No presentation
- 2:15–2:30 *Unsupervised Learning of Acoustic Sub-word Units*  
Balakrishnan Varadarajan, Sanjeev Khudanpur and Emmanuel Dupoux
- 2:30–2:45 *High Frequency Word Entrainment in Spoken Dialogue*  
Ani Nenkova, Agustín Gravano and Julia Hirschberg
- 2:45–3:00 *Distributed Listening: A Parallel Processing Approach to Automatic Speech Recognition*  
Yolanda McMillian and Juan Gilbert

**Tuesday, June 17, 2008 (continued)**

**Session 5C: Short Papers 3 (Semantics)**

- 2:00–2:15 *Learning Semantic Links from a Corpus of Parallel Temporal and Causal Relations*  
Steven Bethard and James H. Martin
- 2:15–2:30 *Evolving New Lexical Association Measures Using Genetic Programming*  
Jan Šnajder, Bojana Dalbelo Bašič, Saša Petrovič and Ivan Sikirič
- 2:30–2:45 *Semantic Types of Some Generic Relation Arguments: Detection and Evaluation*  
Sophia Katrenko and Pieter Adriaans
- 2:45–3:00 *Mapping between Compositional Semantic Representations and Lexical Semantic Resources: Towards Accurate Deep Semantic Parsing*  
Sergio Roa, Valia Kordoni and Yi Zhang

**Session 5D: Short Papers 4 (Generation/Summarization)**

- 2:00–2:15 *Query-based Sentence Fusion is Better Defined and Leads to More Preferred Results than Generic Sentence Fusion*  
Emiel Kraemer, Erwin Marsi and Paul van Pelt
- 2:15–2:30 *Intrinsic vs. Extrinsic Evaluation Measures for Referring Expression Generation*  
Anja Belz and Albert Gatt
- 2:30–2:45 *Correlation between ROUGE and Human Evaluation of Extractive Meeting Summaries*  
Feifan Liu and Yang Liu
- 2:45–3:00 *FastSum: Fast and Accurate Query-based Multi-document Summarization*  
Frank Schilder and Ravikumar Kondadadi
- 3:00–3:15 **Break**

**Tuesday, June 17, 2008 (continued)**

**Session 5E: Short Papers 1 (Syntax)**

- 3:15–3:30     *Construct State Modification in the Arabic Treebank*  
Ryan Gabbard and Seth Kulick
- 3:30–3:45     *Unlexicalised Hidden Variable Models of Split Dependency Grammars*  
Gabriele Antonio Musillo and Paola Merlo
- 3:45–4:00     *Computing Confidence Scores for All Sub Parse Trees*  
Feng Lin and Fuliang Weng

## Abstract

In this paper, we describe a system by which the multilingual characteristics of Wikipedia can be utilized to annotate a large corpus of text with Named Entity Recognition (NER) tags requiring minimal human intervention and no linguistic expertise. This process, though of value in languages for which resources exist, is particularly useful for less commonly taught languages. We show how the Wikipedia format can be used to identify possible named entities and discuss in detail the process by which we use the Category structure inherent to Wikipedia to determine the named entity type of a proposed entity. We further describe the methods by which English language data can be used to bootstrap the NER process in other languages. We demonstrate the system by using the generated corpus as training sets for a variant of BBN's Identifinder in French, Ukrainian, Spanish, Polish, Russian, and Portuguese, achieving overall F-scores as high as 84.7% on independent, human-annotated corpora, comparable to a system trained on up to 40,000 words of human-annotated newswire.

## 1 Introduction

Named Entity Recognition (NER) has long been a major task of natural language processing. Most of the research in the field has been restricted to a few languages and almost all methods require substantial linguistic expertise, whether creating a rule-based technique specific to a language or manually annotating a body of text to be used as a training set for a statistical engine or machine learning.

In this paper, we focus on using the multilingual Wikipedia (wikipedia.org) to automatically create an annotated corpus of text in any given language, with no linguistic expertise required on the part of the user at run-time (and only English knowledge

required during development). The expectation is that for any language in which Wikipedia is sufficiently well-developed, a usable set of training data can be obtained with minimal human intervention. As Wikipedia is constantly expanding, it follows that the derived models are continually improved and that increasingly many languages can be usefully modeled by this method.

In order to make sure that the process is as language-independent as possible, we declined to make use of any non-English linguistic resources outside of the Wikimedia domain (specifically, Wikipedia and the English language Wiktionary (en.wiktionary.org)). In particular, we did not use any semantic resources such as WordNet or part of speech taggers. We used our automatically annotated corpus along with an internally modified variant of BBN's Identifinder (Bikel et al., 1999), specifically modified to emphasize fast text processing, called "PhoenixIDF," to create several language models that could be tested outside of the Wikipedia framework. We built on top of an existing system, and left existing lists and tables intact. Depending on language, we evaluated our derived models against human or machine annotated data sets to test the system.

## 2 Wikipedia

### 2.1 Structure

Wikipedia is a multilingual, collaborative encyclopedia on the Web which is freely available for research purposes. As of October 2007, there were over 2 million articles in English, with versions available in 250 languages. This includes 30 languages with at least 50,000 articles and another 40 with at least 10,000 articles. Each language is available for download (download.wikimedia.org) in a text format suitable for inclusion in a database. For the remainder of this paper, we refer to this format.

Within Wikipedia, we take advantage of five major features:

- *Article links*, links from one article to another of the same language;
- *Category links*, links from an article to special “Category” pages;
- *Interwiki links*, links from an article to a presumably equivalent, article in another language;
- *Redirect pages*, short pages which often provide equivalent names for an entity; and
- *Disambiguation pages*, a page with little content that links to multiple similarly named articles.

The first three types are collectively referred to as *wikilinks*.

A typical sentence in the database format looks like the following:

“Nescopeck Creek is a [[tributary]] of the [[North Branch Susquehanna River]] in [[Luzerne County, Pennsylvania|Luzerne County]].”

The double bracket is used to signify wikilinks. In this snippet, there are three articles links to English language Wikipedia pages, titled “Tributary,” “North Branch Susquehanna River,” and “Luzerne County, Pennsylvania.” Notice that in the last link, the phrase preceding the vertical bar is the name of the article, while the following phrase is what is actually displayed to a visitor of the webpage.

Near the end of the same article, we find the following representations of Category links: [[Category:Luzerne County, Pennsylvania]], [[Category:Rivers of Pennsylvania]], {{Pennsylvania-geo-stub}}. The first two are direct links to Category pages. The third is a link to a Template, which (among other things) links the article to “Category:Pennsylvania geography stubs”. We will typically say that a given entity *belongs to* those categories to which it is linked in these ways.

The last major type of wikilink is the link between different languages. For example, in the Turkish language article “Kanuni Sultan Süleyman” one finds a set of links including [[en:Suleiman the Magnificent]] and [[ru:Сулейман I]]. These represent links to the English language article “Suleiman the Magnificent” and the Russian language article “Сулейман I.” In almost all cases, the articles linked in this manner represent articles on the same subject.

A redirect page is a short entry whose sole purpose is to direct a query to the proper page. There are a few reasons that redirect pages exist, but the primary purpose is exemplified by the fact that “USA” is an entry which redirects the user to the page entitled “United States.” That is, in the vast majority of cases, redirect pages provide another name for an entity.

A disambiguation page is a special article which contains little content but typically lists a number of entries which might be what the user was seeking. For instance, the page “Franklin” contains 70 links, including the singer “Aretha Franklin,” the town “Franklin, Virginia,” the “Franklin River” in Tasmania, and the cartoon character “Franklin (Peanuts).” Most disambiguation pages are in Category:Disambiguation or one of its subcategories.

## 2.2 Related Studies

Wikipedia has been the subject of a considerable amount of research in recent years including Gabrilovich and Markovitch (2007), Strube and Ponzetto (2006), Milne et al. (2006), Zesch et al. (2007), and Weale (2007). The most relevant to our work are Kazama and Torisawa (2007), Toral and Muñoz (2006), and Cucerzan (2007). More details follow, but it is worth noting that all known prior results are fundamentally monolingual, often developing algorithms that can be adapted to other languages pending availability of the appropriate semantic resource. In this paper, we emphasize the use of links between articles of different languages, specifically between English (the largest and best linked Wikipedia) and other languages.

Toral and Muñoz (2006) used Wikipedia to create lists of named entities. They used the first sentence of Wikipedia articles as likely definitions of the article titles, and used them to attempt to classify the titles as people, locations, organizations, or none. Unlike the method presented in this paper, their algorithm relied on WordNet (or an equivalent resource in another language). The authors noted that their results would need to pass a manual supervision step before being useful for the NER task, and thus did not evaluate their results in the context of a full NER system.

Similarly, Kazama and Torisawa (2007) used Wikipedia, particularly the first sentence of each article, to create lists of entities. Rather than building entity dictionaries associating words and

phrases to the classical NER tags (PERSON, LOCATION, etc.) they used a noun phrase following forms of the verb “to be” to derive a label. For example, they used the sentence “Franz Fischler ... is an Austrian politician” to associate the label “politician” to the surface form “Franz Fischler.” They proceeded to show that the dictionaries generated by their method are useful when integrated into an NER system. We note that their technique relies upon a part of speech tagger, and thus was not appropriate for inclusion as part of our non-English system.

Cucerzan (2007), by contrast to the above, used Wikipedia primarily for Named Entity Disambiguation, following the path of Bunescu and Paşca (2006). As in this paper, and unlike the above mentioned works, Cucerzan made use of the explicit Category information found within Wikipedia. In particular, Category and related list-derived data were key pieces of information used to differentiate between various meanings of an ambiguous surface form. Unlike in this paper, Cucerzan did not make use of the Category information to identify a given entity as a member of any particular class. We also note that the NER component was not the focus of the research, and was specific to the English language.

### 3 Training Data Generation

#### 3.1 Initial Set-up and Overview

Our approach to multilingual NER is to pull back the decision-making process to English whenever possible, so that we could apply some level of linguistic expertise. In particular, by focusing on only one language, we could take maximum advantage of the Category structure, something very difficult to do in the general multilingual case.

For computational feasibility, we downloaded various language Wikipedias and the English language Wiktionary in their text (.xml) format and stored each language as a table within a single MySQL database. We only stored the title, id number, and body (the portion between the <TEXT> and </TEXT> tags) of each article.

We elected to use the ACE Named Entity types PERSON, GPE (Geo-Political Entities), ORGANIZATION, VEHICLE, WEAPON, LOCATION, FACILITY, DATE, TIME, MONEY, and PERCENT. Of course, if some of these types were

not marked in an existing corpus or not needed for a given purpose, the system can easily be adapted.

Our goal was to automatically annotate the text portion of a large number of non-English articles with tags like <ENAMEX TYPE=“GPE”>Place Name</ENAMEX> as used in MUC (Message Understanding Conference). In order to do so, our system first identifies words and phrases within the text that might represent entities, primarily through the use of wikilinks. The system then uses category links and/or interwiki links to associate that phrase with an English language phrase or set of Categories. Finally, it determines the appropriate type of the English language data and assumes that the original phrase is of the same type.

In practice, the English language categorization should be treated as one-time work, since it is identical regardless of the language model being built. It is also the only stage of development at which we apply substantial linguistic knowledge, even of English.

In the sections that follow, we begin by showing how the English language categorization is done. We go on to describe how individual non-English phrases are associated with English language information. Next, we explain how possible entities are initially selected. Finally, we discuss some optional steps as well as how and why they could be used.

#### 3.2 English Language Categorization

For each article title of interest (specifically excluding Template pages, Wikipedia administrative pages, and articles whose title begins with “List of”), we extracted the categories to which that entry was assigned. Certainly, some of these category assignments are much more useful than others

For instance, we would expect that any entry in “Category:Living People” or “Category:British Lawyers” will refer to a person while any entry in “Category:Cities in Norway” will refer to a GPE. On the other hand, some are entirely unhelpful, such as “Category:1912 Establishments” which includes articles on Fenway Park (a facility), the Republic of China (a GPE), and the Better Business Bureau (an organization). Other categories can reliably be used to determine that the article does not refer to a named entity, such as “Category:Endangered species.” We manually derived a relatively small set of key phrases, the most important of which are shown in Table 1.

**Table 1: Some Useful Key Category Phrases**

PERSON	“People by”, “People in”, “People from”, “Living people”, “births”, “deaths”, “by occupation”, “Surname”, “Given names”, “Biography stub”, “human names”
ORG	“Companies”, “Teams”, “Organizations”, “Businesses”, “Media by”, “Political parties”, “Clubs”, “Advocacy groups”, “Unions”, “Corporations”, “Newspapers”, “Agencies”, “Colleges”, “Universities”, “Legislatures”, “Company stub”, “Team stub”, “University stub”, “Club stub”
GPE	“Cities”, “Countries”, “Territories”, “Counties”, “Villages”, “Municipalities”, “States” (not part of “United States”), “Republics”, “Regions”, “Settlements”
DATE	“Days”, “Months”, “Years”, “Centuries”
NONE	“Lists”, “List of”, “Wars”, “Incidents”

For each article, we searched the category hierarchy until a threshold of reliability was passed or we had reached a preset limit on how far we would search.

For example, when the system tries to classify “Jacqueline Bhabha,” it extracts the categories “British Lawyers,” “Jewish American Writers,” and “Indian Jews.” Though easily identifiable to a human, none of these matched any of our key phrases, so the system proceeded to extract the second order categories “Lawyers by nationality,” “British legal professionals,” “American writers by ethnicity,” “Jewish writers,” “Indian people by religion,” and “Indian people by ethnic or national origin” among others. “People by” is on our key phrase list, and the two occurrences passed our threshold, and she was then correctly identified.

If an article is not classified by this method, we check whether it is a disambiguation page (which often are members solely of “Category:Disambiguation”). If it is, the links within are checked to see whether there is a dominant type. For instance, the page “Amanda Foreman” is a disambiguation page, with each link on the page leading to an easily classifiable article.

Finally, we use Wiktionary, an online collaborative dictionary, to eliminate some common nouns. For example, “Tributary” is an entry in Wikipedia which would be classified as a Location if viewed solely by Category structure. However, it is found as a common noun in Wiktionary, overruling the category based result.

### 3.3 Multilingual Categorization

When attempting to categorize a non-English term that has an entry in its language’s Wikipedia, we use two techniques to make a decision based on English language information. First, whenever possible, we find the title of an associated English language article by searching for a wikilink beginning with “en:”. If such a title is found, then we categorize the English article as shown in Section 3.2, and decide that the non-English title is of the same type as its English counterpart. We note that links to/from English are the most common interlingual wikilinks.

Of course, not all articles worldwide have English equivalents (or are linked to such even if they do exist). In this case, we attempt to make a decision based on Category information, associating the categories with their English equivalents, when possible. Fortunately, many of the most useful categories have equivalents in many languages.

For example, the Breton town of Erquy has a substantial article in the French language Wikipedia, but no article in English. The system proceeds by determining that Erquy belongs to four French language categories: “Catégorie:Commune des Côtes-d’Armor,” “Catégorie:Ville portuaire de France,” “Catégorie:Port de plaisance,” and “Catégorie:Station balnéaire.” The system proceeds to associate these, respectively, with “Category:Communes of Côtes-d’Armor,” UNKNOWN, “Category:Marinas,” and “Category:Seaside resorts” by looking in the French language pages of each for wikilinks of the form [[en:...]].

The first is a subcategory of “Category:Cities, towns and villages in France” and is thus easily identified by the system as a category consisting of entities of type GPE. The other two are ambiguous categories (facility and organization elements in addition to GPE). Erquy is then determined to be a GPE by majority vote of useful categories.

We note that the second French category actually has a perfectly good English equivalent (Category:Port cities and towns in France), but no one has linked them as of this writing. We also note that the ambiguous categories are much more GPE-oriented in French. The system still makes the correct decision despite these factors.

We do not go beyond the first level categories or do any disambiguation in the non-English case. Both are avenues for future improvement.

### 3.4 The Full System

To generate a set of training data in a given language, we select a large number of articles from its Wikipedia (50,000 or more is recommended, when possible). We prepare the text by removing external links, links to images, category and interlingual links, as well as some formatting. The main processing of each article takes place in several stages, whose primary purposes are as follows:

- The first pass uses the explicit article links within the text.
- We then search an associated English language article, if available, for additional information.
- A second pass checks for multi-word phrases that exist as titles of Wikipedia articles.
- We look for certain types of person and organization instances.
- We perform additional processing for alphabetic or space-separated languages, including a third pass looking for single word Wikipedia titles.
- We use regular expressions to locate additional entities such as numeric dates.

In the first pass, we attempt to replace all wiki-links with appropriate entity tags. We assume at this stage that any phrase identified as an entity at some point in the article will be an entity of the same type throughout the article, since it is common for contributors to make the explicit link only on the first occasion that it occurs. We also assume that a phrase in a bold font within the first 100 characters is an equivalent form of the title of the article as in this start of the article on Erquy: “**Erquy (Erge-ar-Mor** en breton, **Erqi** en gallo)”. The parenthetical notation gives alternate names in the Breton and Gallo languages. (In Wiki database format, bold font is indicated by three apostrophes in succession.)

If the article has an English equivalent, we search that article for wikilinked phrases as well, on the assumption that both articles will refer to many of the same entities. As the English language Wikipedia is the largest, it frequently contains explicit references to and articles on secondary people and places mentioned, but not linked, within a given non-English article. After this point, the text to be annotated contains no Wikipedia specific information or formatting.

In the second pass, we look for strings of 2 to 4 words which were not wikilinked but which have

Wikipedia entries of their own or are partial matches to known people and organizations (i.e. “Mary Washington” in an article that contains “University of Mary Washington”). We require that each such string contains something other than a lower case letter (when a language does not use capitalization, nothing in that writing system is considered to be lower case for this purpose). When a word is in more than one such phrase, the longest match is used.

We then do some special case processing. When an organization is followed by something in parentheses such as `<ENAMEX TYPE=“ORGANIZATION”>Maktab al-Khadamāt</ENAMEX>` (MAK), we hypothesize that the text in the parentheses is an alternate name of the organization. We also looked for unmarked strings of the form X.X. followed by a capitalized word, where X represents any capital letter, and marked each occurrence as a PERSON.

For space-separated or alphabetic languages, we did some additional processing at this stage to attempt to identify more names of people. Using a list of names derived from Wiktionary (Appendix:Names) and optionally a list derived from Wikipedia (see Section 3.5.1), we mark possible parts of names. When two or more are adjacent, we mark the sequence as a PERSON. Also, we fill in partial lists of names by assuming single non-lower case words between marked names are actually parts of names themselves. That is, we would replace `<ENAMEX TYPE=“PERSON”>Fred Smith</ENAMEX>`, `Somename <ENAMEX TYPE=“PERSON”>Jones </ENAMEX>` with `<ENAMEX TYPE=“PERSON”> Fred Smith</ENAMEX>`, `<ENAMEX TYPE= “PERSON”> Somename Jones</ENAMEX>`. At this point, we performed a third pass through the article. We marked all non-lower case single words which had their own Wikipedia entry, were part of a known person's name, or were part of a known organization's name.

Afterwards, we used a series of simple, language-neutral regular expressions to find additional TIME, PERCENT, and DATE entities such as “05:30” and “12-07-05”. We also executed code that included quantities of money within a NUMEX tag, as in converting `500 <NUMEX TYPE=“MONEY”>USD</NUMEX>` into `<NUMEX TYPE=“MONEY”>500 USD</NUMEX>`.

## 3.5 Optional Processing

### 3.5.1 Recommended Additions

All of the above could be run with almost no understanding of the language being modeled (knowing whether the language was space-separated and whether it was alphabetic or character-based were the only things used). However, for most languages, we spent a small amount of time (less than one hour) browsing Wikipedia pages to improve performance in some areas.

We suggest compiling a small list of stop words. For our purposes, the determiners and the most common prepositions are sufficient, though a longer list could be used for the purpose of computational efficiency.

We also recommend compiling a list of number words as well as compiling a list of currencies, since they are not capitalized in many languages, and may not be explicitly linked either. Many languages have a page on ISO 4217 which contains all of the currency information, but the format varies sufficiently from language to language to make automatic extraction difficult. Together, these allow phrases like this (taken from the French Wikipedia) to be correctly marked in its entirety as an entity of type MONEY: “25 millions de dollars.”

If a language routinely uses honorifics such as Mr. and Mrs., that information can also be found quickly. Their use can lead to significant improvements in PERSON recognition.

During preprocessing, we typically collected a list of people names automatically, using the entity identification methods appropriate to titles of Wikipedia articles. We then used these names along with the Wiktionary derived list of names during the main processing. This does introduce some noise as the person identification is not perfect, but it ordinarily increases recall by more than it reduces precision.

### 3.5.2 Language Dependent Additions

Our usual, language-neutral processing only considers wikilinks within a single article when determining the type of unlinked words and phrases. For example, if an article included the sentence “The [[Delaware River|Delaware]] forms the boundary between [[Pennsylvania]] and [[New Jersey]]”, our system makes the assumption that every occurrence of the unlinked word “Delaware”

appearing in the same article is also referring to the river and thus mark it as a LOCATION.

For some languages, we preferred an alternate approach, best illustrated by an example: The word “Washington” without context could refer to (among others) a person, a GPE, or an organization. We could work through all of the explicit wikilinks in all articles (as a preprocessing step) whose surface form is Washington and count the number pointing to each. We could then decide that every time the word Washington appears without an explicit link, it should be marked as its most common type. This is useful for the Slavic languages, where the nominative form is typically used as the title of Wikipedia articles, while other cases appear frequently (and are rarely wikilinked).

At the same time, we can do a second type of preprocessing which allows more surface forms to be categorized. For instance, imagine that we were in a Wikipedia with no article or redirect associated to “District of Columbia” but that someone had made a wikilink of the form [[Washington|District of Columbia]]. We would then make the assumption that for all articles, District of Columbia is of the same type as Washington.

For less developed wikipeidias, this can be helpful. For languages that have reasonably well developed Wikipeidias and where entities rarely, if ever, change form for grammatical reasons (such as French), this type of preprocessing is virtually irrelevant. Worse, this processing is definitely not recommended for languages that do not use capitalization because it is not unheard of for people to include sections like: “The [[Union Station|train station]] is located at ...” which would cause the phrase “train station” to be marked as a FACILITY each time it occurred. Of course, even in languages with capitalization, “train station” would be marked incorrectly in the article in which the above was located, but the mistake would be isolated, and should have minimal impact overall.

## 4 Evaluation and Results

After each data set was generated, we used the text as a training set for input to PhoenixIDF. We had three human annotated test sets, Spanish, French and Ukrainian, consisting of newswire. When human annotated sets were not available, we held out more than 100,000 words of text generated by our wiki-mining process to use as a test set. For the above languages, we included wiki test sets for

comparison purposes. We will give our results as F-scores in the Overall, DATE, GPE, ORGANIZATION, and PERSON categories using the scoring metric in (Bikel et. al, 1999). The other ACE categories are much less common, and contribute little to the overall score.

#### 4.1 Spanish Language Evaluation

The Spanish Wikipedia is a substantial, well-developed Wikipedia, consisting of more than 290,000 articles as of October 2007. We used two test sets for comparison purposes. The first consists of 25,000 words of human annotated newswire derived from the ACE 2007 test set, manually modified to conform to our extended MUC-style standards. The second consists of 335,000 words of data generated by the Wiki process held-out during training.

**Table 2: Spanish Results**

F (prec. / recall)	Newswire	Wiki test set
<b>ALL</b>	<b>.827</b> (.851 / .805)	.846 (.843 / .848)
<b>DATE</b>	.912 (.861 / .970)	.925 (.918 / .932)
<b>GPE</b>	.877 (.914 / .843)	.877 (.886 / .868)
<b>ORG</b>	.629 (.681 / .585)	.701 (.703 / .698)
<b>PERSON</b>	.906 (.921 / .892)	.821 (.810 / .833)

There are a few particularly interesting results to note. First, because of the optional processing, recall was boosted in the PERSON category at the expense of precision. The fact that this category scores higher against newswire than against the wiki data suggests that the not-uncommon, but isolated, occurrences of non-entities being marked as PERSONs in training have little effect on the overall system. Contrarily, we note that deletions are the dominant source of error in the ORGANIZATION category, as seen by the lower recall. The better performance on the wiki set seems to suggest that either Wikipedia is relatively poor in Organizations or that PhoenixIDF underperforms when identifying Organizations relative to other categories or a combination.

An important question remains: “How do these results compare to other methodologies?” In particular, while we can get these results for free, how much work would traditional methods require to achieve comparable results?

To attempt to answer this question, we trained PhoenixIDF on additional ACE 2007 Spanish language data converted to MUC-style tags, and scored its performance using the same set of newswire. Evidently, comparable performance to our Wikipedia derived system requires between 20,000 and 40,000 words of human-annotated newswire. It is worth noting that Wikipedia itself is not newswire, so we do not have a perfect comparison.

**Table 3: Traditional Training**

~ Words of Training	Overall F-score
3500	.746
10,000	.760
20,000	<b>.807</b>
40,000	<b>.847</b>

#### 4.2 French Language Evaluation

The French Wikipedia is one of the largest Wikipedias, containing more than 570,000 articles as of October 2007. For this evaluation, we have 25,000 words of human annotated newswire (*Agence France Presse*, 30 April and 1 May 1997) covering diverse topics. We used 920,000 words of Wiki-derived data for the second test.

**Table 4: French Results**

F (prec. / recall)	Newswire	Wiki test set
<b>ALL</b>	<b>.847</b> (.877 / .819)	.844 (.847 / .840)
<b>DATE</b>	.921 (.897 / .947)	.910 (.888 / .934)
<b>GPE</b>	.907 (.933 / .882)	.868 (.889 / .849)
<b>ORG</b>	.700 (.794 / .625)	.718 (.747 / .691)
<b>PERSON</b>	.880 (.874 / .885)	.823 (.818 / .827)

The overall results seem comparable to the Spanish, with the slightly better overall performance likely correlated to the somewhat more developed Wikipedia. We did not have sufficient quantities of annotated data to run a test of the traditional methods, but Spanish and French are sufficiently similar languages that we expect this model is comparable to one created with about 40,000 words of human-annotated data.

### 4.3 Ukrainian Language Evaluation

The Ukrainian Wikipedia is a medium-sized Wikipedia with 74,000 articles as of October 2007. Also, the typical article is shorter and less well-linked to other articles than in the French or Spanish versions. Moreover, entities tend to appear in many surface forms depending on case, leading us to expect somewhat worse results. In the Ukrainian case, the newswire consisted of approximately 25,000 words from various online news sites covering primarily political topics. We also held out around 395,000 words for testing. We were also able to run a comparison test as in Spanish.

**Table 5: Ukrainian Results**

F (prec. / recall)	Newswire	Wiki test set
<b>ALL</b>	<b>.747</b> (.863 / .649)	.807 (.809 / .806)
<b>DATE</b>	.780 (.759 / .803)	.848 (.842 / .854)
<b>GPE</b>	.837 (.833 / .841)	.887 (.901 / .874)
<b>ORG</b>	.585 (.800 / .462)	.657 (.678 / .637)
<b>PERSON</b>	.764 (.899 / .664)	.690 (.675 / .706)

**Table 6: Traditional Training**

~ Words of Training	Overall F-score
5000	.662
10,000	.692
15,000	<b>.740</b>
20,000	<b>.761</b>

The Ukrainian newswire contained a much higher proportion of organizations than the French or Spanish versions, contributing to the overall lower score. The Ukrainian language Wikipedia itself contains very few articles on organizations relative to other types, so the distribution of entities of the two test sets are quite different. We also see that the Wiki-derived model performs comparably to a model trained on 15-20,000 words of human-annotated text.

### 4.4 Other Languages

For Portuguese, Russian, and Polish, we did not have human annotated corpora available for test-

ing. In each case, at least 100,000 words were held out from training to be used as a test set. It seems safe to suppose that if suitable human-annotated sets were available for testing, the PERSON score would likely be higher, and the ORGANIZATION score would likely be lower, while the DATE and GPE scores would probably be comparable.

**Table 7: Other Language Results**

F-score	Polish	Portuguese	Russian
<b>ALL</b>	<b>.859</b>	<b>.804</b>	<b>.802</b>
<b>DATE</b>	.891	.861	.822
<b>GPE</b>	.916	.826	.867
<b>ORG</b>	.785	.706	.712
<b>PERSON</b>	.836	.802	.751

## 5 Conclusions

In conclusion, we have demonstrated that Wikipedia can be used to create a Named Entity Recognition system with performance comparable to one developed from 15-40,000 words of human-annotated newswire, while not requiring any linguistic expertise on the part of the user. This level of performance, usable on its own for many purposes, can likely be obtained currently in 20-40 languages, with the expectation that more languages will become available, and that better models can be developed, as Wikipedia grows.

Moreover, it seems clear that a Wikipedia-derived system could be used as a supplement to other systems for many more languages. In particular, we have, for all practical purposes, embedded in our system an automatically generated entity dictionary.

In the future, we would like to find a way to automatically generate the list of key words and phrases for useful English language categories. This could implement the work of Kazama and Torisawa, in particular. We also believe performance could be improved by using higher order non-English categories and better disambiguation. We could also experiment with introducing automatically generated lists of entities into PhoenixIDF directly. Lists of organizations might be particularly useful, and “List of” pages are common in many languages.

## Abstract

We present an automatic approach to determining whether a pronoun in text refers to a preceding noun phrase or is instead *non-referential*. We extract the surrounding textual context of the pronoun and gather, from a large corpus, the distribution of words that occur within that context. We learn to reliably classify these distributions as representing either referential or non-referential pronoun instances. Despite its simplicity, experimental results on classifying the English pronoun *it* show the system achieves the highest performance yet attained on this important task.

## 1 Introduction

The goal of coreference resolution is to determine which noun phrases in a document refer to the same real-world entity. As part of this task, coreference resolution systems must decide which pronouns refer to preceding noun phrases (called antecedents) and which do not. In particular, a long-standing challenge has been to correctly classify instances of the English pronoun *it*. Consider the sentences:

- (1) You can make it in advance.
- (2) You can make it in Hollywood.

In sentence (1), *it* is an anaphoric pronoun referring to some previous noun phrase, like “the sauce” or “an appointment.” In sentence (2), *it* is part of the idiomatic expression “make it” meaning “succeed.” A coreference resolution system should find an antecedent for the first *it* but not the second. Pronouns

that do not refer to preceding noun phrases are called *non-anaphoric* or *non-referential* pronouns.

The word *it* is one of the most frequent words in the English language, accounting for about 1% of tokens in text and over a quarter of all third-person pronouns.<sup>1</sup> Usually between a quarter and a half of *it* instances are non-referential (e.g. Section 4, Table 3). As with other pronouns, the preceding discourse can affect *it*’s interpretation. For example, sentence (2) can be interpreted as referential if the preceding sentence is “You want to make a movie?” We show, however, that we can reliably classify a pronoun as being referential or non-referential based solely on the local context surrounding the pronoun.

We do this by turning the context into patterns and enumerating all the words that can take the place of *it* in these patterns. For sentence (1), we can extract the context pattern “make \* in advance” and for sentence (2) “make \* in Hollywood,” where “\*” is a wildcard that can be filled by any token. Non-referential distributions tend to have the word *it* filling the wildcard position. Referential distributions occur with many other noun phrase fillers. For example, in our n-gram collection (Section 3.4), “make it in advance” and “make them in advance” occur roughly the same number of times (442 vs. 449), indicating a referential pattern. In contrast, “make it in Hollywood” occurs 3421 times while “make them in Hollywood” does not occur at all.

These simple counts strongly indicate whether another noun can replace the pronoun. Thus we can computationally distinguish between a) pronouns that refer to nouns, and b) all other instances: including those that have no antecedent, like sentence (2),

<sup>1</sup>e.g. <http://ucrel.lancs.ac.uk/bncfreq/flists.html>

and those that refer to sentences, clauses, or implied topics of discourse. Beyond the practical value of this distinction, Section 3 provides some theoretical justification for our binary classification.

Section 3 also shows how to automatically extract and collect counts for context patterns, and how to combine the information using a machine learned classifier. Section 4 describes our data for learning and evaluation, *It-Bank*: a set of over three thousand labelled instances of the pronoun *it* from a variety of text sources. Section 4 also explains our comparison approaches and experimental methodology. Section 5 presents our results, including an interesting comparison of our system to human classification given equivalent segments of context.

## 2 Related Work

The difficulty of non-referential pronouns has been acknowledged since the beginning of computational resolution of anaphora. Hobbs (1978) notes his algorithm does not handle pronominal references to sentences nor cases where *it* occurs in time or weather expressions. Hirst (1981, page 17) emphasizes the importance of detecting non-referential pronouns, “lest precious hours be lost in bootless searches for textual referents.” Müller (2006) summarizes the evolution of computational approaches to non-referential *it* detection. In particular, note the pioneering work of Paice and Husk (1987), the inclusion of non-referential *it* detection in a full anaphora resolution system by Lappin and Leass (1994), and the machine learning approach of Evans (2001).

There has recently been renewed interest in non-referential pronouns, driven by three primary sources. First of all, research in coreference resolution has shown the benefits of modules for general noun anaphoricity determination (Ng and Cardie, 2002; Denis and Baldridge, 2007). Unfortunately, these studies handle pronouns inadequately; judging from the decision trees and performance figures, Ng and Cardie (2002)’s system treats all pronouns as anaphoric by default. Secondly, while most pronoun resolution evaluations simply exclude non-referential pronouns, recent unsupervised approaches (Cherry and Bergsma, 2005; Haghighi and Klein, 2007) must deal with all pronouns in unrestricted text, and therefore need robust modules to

automatically handle non-referential instances. Finally, reference resolution has moved beyond written text into spoken dialog. Here, non-referential pronouns are pervasive. Eckert and Strube (2000) report that in the Switchboard corpus, only 45% of demonstratives and third-person pronouns have a noun phrase antecedent. Handling the common non-referential instances is thus especially vital.

One issue with systems for non-referential detection is the amount of language-specific knowledge that must be encoded. Consider a system that jointly performs anaphora resolution and word alignment in parallel corpora for machine translation. For this task, we need to identify non-referential anaphora in multiple languages. It is not always clear to what extent the features and modules developed for English systems apply to other languages. For example, the detector of Lappin and Leass (1994) labels a pronoun as non-referential if it matches one of several syntactic patterns, including: “It is **Cogv-ed** that **Sentence**,” where **Cogv** is a “cognitive verb” such as *recommend*, *think*, *believe*, *know*, *anticipate*, etc. Porting this approach to a new language would require not only access to a syntactic parser and a list of cognitive verbs in that language, but the development of new patterns to catch non-referential pronoun uses that do not exist in English.

Moreover, writing a set of rules to capture this phenomenon is likely to miss many less-common uses. Alternatively, recent machine-learning approaches leverage a more general representation of a pronoun instance. For example, Müller (2006) has a feature for “distance to next complementizer (*that*, *if*, *whether*)” and features for the tokens and part-of-speech tags of the context words. Unfortunately, there is still a lot of implicit and explicit English-specific knowledge needed to develop these features, including, for example, lists of “seem” verbs such as *appear*, *look*, *mean*, *happen*. Similarly, the machine-learned system of Boyd et al. (2005) uses a set of “idiom patterns” like “*on the face of it*” that trigger binary features if detected in the pronoun context. Although machine learned systems can flexibly balance the various indicators and contra-indicators of non-referentiality, a particular feature is only useful if it is relevant to an example in limited labelled training data.

Our approach avoids hand-crafting a set of spe-

cific indicator features; we simply use the distribution of the pronoun’s context. Our method is thus related to previous work based on Harris (1985)’s distributional hypothesis.<sup>2</sup> It has been used to determine both word and syntactic path similarity (Hindle, 1990; Lin, 1998a; Lin and Pantel, 2001). Our work is part of a trend of extracting other important information from statistical distributions. Dagan and Itai (1990) use the distribution of a pronoun’s context to determine which candidate antecedents can fit the context. Bergsma and Lin (2006) determine the likelihood of coreference along the syntactic path connecting a pronoun to a possible antecedent, by looking at the distribution of the path in text. These approaches, like ours, are ways to inject sophisticated “world knowledge” into anaphora resolution.

### 3 Methodology

#### 3.1 Definition

Our approach distinguishes contexts where pronouns cannot be replaced by a preceding noun phrase (non-noun-referential) from those where nouns can occur (noun-referential). Although coreference evaluations, such as the MUC (1997) tasks, also make this distinction, it is not necessarily used by all researchers. Evans (2001), for example, distinguishes between “clause anaphoric” and “pleonastic” as in the following two instances:

- (3) The paper reported that it had snowed. *It* was obvious. (*clause anaphoric*)
- (4) *It* was obvious that it had snowed. (*pleonastic*)

The word *It* in sentence (3) is considered referential, while the word *It* in sentence (4) is considered non-referential.<sup>3</sup> From our perspective, this interpretation is somewhat arbitrary. One could also say that the *It* in both cases refers to the clause “that it had snowed.” Indeed, annotation experiments using very fine-grained categories show low annotation reliability (Müller, 2006). On the other hand, there is no debate over the importance nor the definition of distinguishing pronouns that refer to nouns from those that do not. We adopt this distinction for our

work, and show it has good inter-annotator reliability (Section 4.1). We henceforth refer to non-noun-referential simply as non-referential, and thus consider the word *It* in both sentences (3) and (4) as non-referential.

Non-referential pronouns are widespread in natural language. The *es* in the German “Wie geht es Ihnen” and the *il* in the French “S’il vous plaît” are both non-referential. In pro-drop languages that may omit subject pronouns, there remains the question of whether an omitted pronoun is referential (Zhao and Ng, 2007). Although we focus on the English pronoun *it*, our approach should differentiate any words that have both a structural and a referential role in language, e.g. words like *this*, *there* and *that* (Müller, 2007). We believe a distributional approach could also help in related tasks like identifying the generic use of *you* (Gupta et al., 2007).

#### 3.2 Context Distribution

Our method extracts the context surrounding a pronoun and determines which other words can take the place of the pronoun in the context. The extracted segments of context are called *context patterns*. The words that take the place of the pronoun are called *pattern fillers*. We gather pattern fillers from a large collection of n-gram frequencies. The maximum size of a context pattern depends on the size of n-grams available in the data. In our n-gram collection (Section 3.4), the lengths of the n-grams range from unigrams to 5-grams, so our maximum pattern size is five. For a particular pronoun in text, there are five possible 5-grams that span the pronoun. For example, in the following instance of *it*:

... said here Thursday that it is unnecessary to continue ...  
We can extract the following 5-gram patterns:

```
said here Thursday that *
here Thursday that * is
Thursday that * is unnecessary
that * is unnecessary to
* is unnecessary to continue
```

Similarly, we extract the four 4-gram patterns. Shorter n-grams were not found to improve performance on development data and hence are not extracted. We only use context within the current sentence (including the beginning-of-sentence and end-of-sentence tokens) so if a pronoun occurs near a sentence boundary, some patterns may be missing.

<sup>2</sup>Words occurring in similar contexts have similar meanings

<sup>3</sup>The *it* in “it had snowed” is, of course, non-referential.

Pattern Filler Type	String
#1: 3rd-person pron. sing.	<i>it/its</i>
#2: 3rd-person pron. plur.	<i>they/them/their</i>
#3: any other pronoun	<i>he/him/his/, I/me/my, etc.</i>
#4: infrequent word token	$\langle UNK \rangle$
#5: any other token	*

Table 1: Pattern filler types

We take a few steps to improve generality. We change the patterns to lower-case, convert sequences of digits to the # symbol, and run the Porter stemmer<sup>4</sup> (Porter, 1980). To generalize rare names, we convert capitalized words longer than five characters to a special *NE* tag. We also added a few simple rules to stem the irregular verbs *be*, *have*, *do*, and *said*, and convert the common contractions *'nt*, *'s*, *'m*, *'re*, *'ve*, *'d*, and *'ll* to their most likely stem.

We do the same processing to our n-gram corpus. We then find all n-grams matching our patterns, allowing any token to match the wildcard in place of *it*. Also, other pronouns in the pattern are allowed to match a corresponding pronoun in an n-gram, regardless of differences in inflection and class.

We now discuss how to use the distribution of pattern fillers. For identifying non-referential *it* in English, we are interested in how often *it* occurs as a pattern filler versus other *nouns*. However, determining part-of-speech in a large n-gram corpus is not simple, nor would it easily extend to other languages. Instead, we gather counts for five different classes of words that fill the wildcard position, easily determined by string match (Table 1). The third-person plural *they* (#2) reliably occurs in patterns where referential *it* also resides. The occurrence of *any other pronoun* (#3) guarantees that at the very least the pattern filler is a noun. A match with the infrequent word token  $\langle UNK \rangle$  (#4) (explained in Section 3.4) will likely be a noun because nouns account for a large proportion of rare words in a corpus. Gathering *any other token* (#5) also mostly finds nouns; inserting another part-of-speech usually

<sup>4</sup>Adapted from the Bow-toolkit (McCallum, 1996). Our method also works without the stemmer; we simply truncate the words in the pattern at a given maximum length (see Section 5.1). With simple truncation, all the pattern processing can be easily applied to other languages.

Pattern	Filler Counts			
	#1	#2	#3	#5
sai here <i>NE</i> that *	84	0	291	3985
here <i>NE</i> that * be	0	0	0	93
<i>NE</i> that * be unnecessari	0	0	0	0
that * be unnecessari to	16726	56	0	228
* be unnecessari to continu	258	0	0	0

Table 2: 5-gram context patterns and pattern-filler counts for the Section 3.2 example.

results in an unlikely, ungrammatical pattern.

Table 2 gives the stemmed context patterns for our running example. It also gives the n-gram counts of pattern fillers matching the first four filler types (there were no matches of the  $\langle UNK \rangle$  type, #4).

### 3.3 Feature Vector Representation

There are many possible ways to use the above counts. Intuitively, our method should identify as non-referential those instances that have a high proportion of fillers of type #1 (i.e., the word *it*), while labelling as referential those with high counts for other types of fillers. We would also like to leverage the possibility that some of the patterns may be more predictive than others, depending on where the wildcard lies in the pattern. For example, in Table 2, the cases where the *it*-position is near the beginning of the pattern best reflect the non-referential nature of this instance. We can achieve these aims by ordering the counts in a feature vector, and using a labelled set of training examples to learn a classifier that optimally weights the counts.

For classification, we define non-referential as positive and referential as negative. Our feature representation very much resembles Table 2. For each of the five 5-gram patterns, ordered by the position of the wildcard, we have features for the logarithm of counts for filler types #1, #2, ... #5. Similarly, for each of the four 4-gram patterns, we provide the log-counts corresponding to types #1, #2, ... #5 as well. Before taking the logarithm, we smooth the counts by adding a fixed number to all observed values. We also provide, for each pattern, a feature that indicates if the pattern is not available because the *it*-position would cause the pattern to span beyond the current sentence. There are twenty-five 5-gram, twenty 4-gram, and nine indicator features in total.

Our classifier should learn positive weights on the type #1 counts and negative weights on the other types, with higher absolute weights on the more predictive filler types and pattern positions. Note that leaving the pattern counts unnormalized automatically allows patterns with higher counts to contribute more to the prediction of their associated instances.

### 3.4 N-Gram Data

We now describe the collection of n-grams and their counts used in our implementation. We use, to our knowledge, the largest publicly available collection: the Google Web 1T 5-gram Corpus Version 1.1.<sup>5</sup> This collection was generated from approximately 1 trillion tokens of online text. In this data, tokens appearing less than 200 times have been mapped to the  $\langle \text{UNK} \rangle$  symbol. Also, only n-grams appearing more than 40 times are included. For languages where such an extensive n-gram resource is not available, the n-gram counts could also be taken from the page-counts returned by an Internet search engine.

## 4 Evaluation

### 4.1 Labelled *It* Data

We need labelled data for training and evaluation of our system. This data indicates, for every occurrence of the pronoun *it*, whether it refers to a preceding noun phrase or not. Standard coreference resolution data sets annotate all noun phrases that have an antecedent noun phrase in the text. Therefore, we can extract labelled instances of *it* from these sets. We do this for the dry-run and formal sets from MUC-7 (1997), and merge them into a single data set.

Of course, full coreference-annotated data is a precious resource, with the pronoun *it* making up only a small portion of the marked-up noun phrases. We thus created annotated data specifically for the pronoun *it*. We annotated 1020 instances in a collection of Science News articles (from 1995-2000), downloaded from the Science News website. We also annotated 709 instances in the WSJ portion of the DARPA TIPSTER Project (Harman, 1992), and 279 instances in the English portion of the Europarl Corpus (Koehn, 2005).

A single annotator ( $A_1$ ) labelled all three data sets, while two additional annotators not connected

Data Set	Number of <i>It</i>	% Non-Referential
<i>Europarl</i>	279	50.9
<i>Sci-News</i>	1020	32.6
<i>WSJ</i>	709	25.1
<i>MUC</i>	129	31.8
<i>Train</i>	1069	33.2
<i>Test</i>	1067	31.7
<i>Test-200</i>	200	30.0

Table 3: Data sets used in experiments.

with the project ( $A_2$  and  $A_3$ ) were asked to separately re-annotate a portion of each, so that inter-annotator agreement could be calculated.  $A_1$  and  $A_2$  agreed on 96% of annotation decisions, while  $A_1$ - $A_3$ , and  $A_2$ - $A_3$ , agreed on 91% and 93% of decisions, respectively. The *Kappa* statistic (Jurafsky and Martin, 2000, page 315), with  $P(E)$  computed from the confusion matrices, was a high 0.90 for  $A_1$ - $A_2$ , and 0.79 and 0.81 for the other pairs, around the 0.80 considered to be good reliability. These are, perhaps surprisingly, the only known *it*-annotation-agreement statistics available for written text. They contrast favourably with the low agreement seen on categorizing *it* in spoken dialog (Müller, 2006).

We make all the annotations available in *It-Bank*, an online repository for annotated *it*-instances.<sup>6</sup> *It-Bank* also allows other researchers to distribute their *it* annotations. Often, the full text of articles containing annotations cannot be shared because of copyright. However, sharing just the sentences containing the word *it*, randomly-ordered, is permissible under fair-use guidelines. The original annotators retain their copyright on the annotations.

We use our annotated data in two ways. First of all, we perform cross-validation experiments on each of the data sets individually, to help gauge the difficulty of resolution on particular domains and volumes of training data. Secondly, we randomly distribute all instances into two main sets, a training set and a test set. We also construct a smaller test set, *Test-200*, containing only the first 200 instances in the *Test* set. We use *Test-200* for human experiments and error analysis (Section 5.2). Table 3 summarizes all the sets used in the experiments.

<sup>5</sup>Available from the LDC as LDC2006T13

<sup>6</sup>[www.cs.ualberta.ca/~bergma/ItBank/](http://www.cs.ualberta.ca/~bergma/ItBank/). *It-Bank* also contains an additional 1,077 examples used as development data.

## 4.2 Comparison Approaches

We represent feature vectors exactly as described in Section 3.3. We smooth by adding 40 to all counts, equal to the minimum count in the n-gram data. For classification, we use a maximum entropy model (Berger et al., 1996), from the logistic regression package in Weka (Witten and Frank, 2005), with all default parameter settings. Results with our distributional approach are labelled as DISTRIB. Note that our maximum entropy classifier actually produces a *probability* of non-referentiality, which is thresholded at 50% to make a classification.

As a baseline, we implemented the non-referential *it* detector of Lappin and Leass (1994), labelled as LL in the results. This is a *syntactic* detector, a point missed by Evans (2001) in his criticism: the patterns are robust to intervening words and modifiers (e.g. “it was *never* thought *by the committee* that...”) provided the sentence is parsed correctly.<sup>7</sup> We automatically parse sentences with Minipar, a broad-coverage dependency parser (Lin, 1998b).

We also use a separate, extended version of the LL detector, implemented for large-scale non-referential detection by Cherry and Bergsma (2005). This system, also for Minipar, additionally detects instances of *it* labelled with Minipar’s pleonastic category *Subj*. It uses Minipar’s named-entity recognition to identify time expressions, such as “it was midnight,” and provides a number of other patterns to match common non-referential *it* uses, such as in expressions like “darn it,” “don’t overdo it,” etc. This extended detector is labelled as MINIPL (for Minipar pleonasticity) in our results.

Finally, we tested a system that combines the above three approaches. We simply add the LL and MINIPL decisions as binary features in the DISTRIB system. This system is called COMBO in our results.

## 4.3 Evaluation Criteria

We follow Müller (2006)’s evaluation criteria. Precision (P) is the proportion of instances that we label as non-referential that are indeed non-referential. Recall (R) is the proportion of true non-referentials that we detect, and is thus a measure of the coverage

<sup>7</sup>Our approach, on the other hand, would seem to be susceptible to such intervening material, if it pushes indicative context tokens out of the 5-token window.

System	P	R	F	Acc
LL	<b>93.4</b>	21.0	34.3	74.5
MINIPL	66.4	49.7	56.9	76.1
DISTRIB	81.4	71.0	75.8	85.7
COMBO	81.3	<b>73.4</b>	<b>77.1</b>	<b>86.2</b>

Table 4: *Train/Test*-split performance (%).

of the system. F-Score (F) is the geometric average of precision and recall; it is the most common non-referential detection metric. Accuracy (Acc) is the percentage of instances labelled correctly.

## 5 Results

### 5.1 System Comparison

Table 4 gives precision, recall, F-score, and accuracy on the *Train/Test* split. Note that while the LL system has high detection precision, it has very low recall, sharply reducing F-score. The MINIPL approach sacrifices some precision for much higher recall, but again has fairly low F-score. To our knowledge, our COMBO system, with an F-Score of 77.1%, achieves the highest performance of any non-referential system yet implemented. Even more importantly, DISTRIB, which requires only minimal linguistic processing and no encoding of specific indicator patterns, achieves 75.8% F-Score. The difference between COMBO and DISTRIB is not statistically significant, while both are significantly better than the rule-based approaches.<sup>8</sup> This provides strong motivation for a “light-weight” approach to non-referential *it* detection – one that does not require parsing or hand-crafted rules and – is easily ported to new languages and text domains.

Since applying an English stemmer to the context words (Section 3.2) reduces the portability of the distributional technique, we investigated the use of more portable pattern abstraction. Figure 1 compares the use of the stemmer to simply truncating the words in the patterns at a certain maximum length. Using no truncation (Unaltered) drops the F-Score by 4.3%, while truncating the patterns to a length of four only drops the F-Score by 1.4%, a difference which is not statistically significant. Simple truncation may be a good option for other languages where stemmers are not readily available. The optimum

<sup>8</sup>All significance testing uses McNemar’s test,  $p < 0.05$

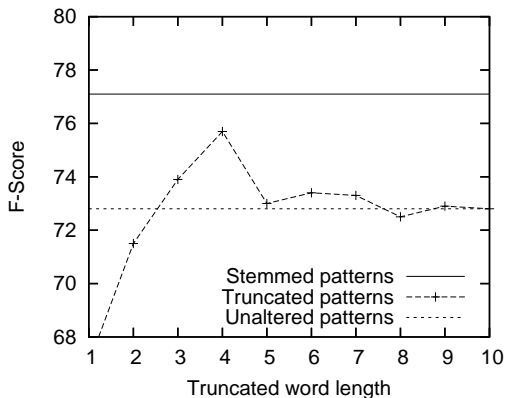

Figure 1: Effect of pattern-word truncation on non-referential *it* detection (COMBO system, *Train/Test* split).

System	<i>Europl.</i>	<i>Sci-News</i>	<i>WSJ</i>	<i>MUC</i>
LL	44.0	39.3	21.5	13.3
MINIPL	70.3	61.8	22.0	50.7
DISTRIB	79.7	77.2	<b>69.5</b>	68.2
COMBO	76.2	<b>78.7</b>	68.1	65.9
COMBO4	<b>83.6</b>	76.5	67.1	<b>74.7</b>

Table 5: 10-fold cross validation F-Score (%).

truncation size will likely depend on the length of the base forms of words in that language. For real-world application of our approach, truncation also reduces the table sizes (and thus storage and lookup costs) of any pre-compiled *it*-pattern database.

Table 5 compares the 10-fold cross-validation F-score of our systems on the four data sets. The performance of COMBO on *Europarl* and *MUC* is affected by the small number of instances in these sets (Section 4, Table 3). We can reduce data fragmentation by removing features. For example, if we only use the length-4 patterns in COMBO (labelled as COMBO4), performance increases dramatically on *Europarl* and *MUC*, while dipping slightly for the larger *Sci-News* and *WSJ* sets. Furthermore, selecting just the three most useful filler type counts as features (#1,#2,#5), boosts F-Score on *Europarl* to 86.5%, 10% above the full COMBO system.

## 5.2 Analysis and Discussion

In light of these strong results, it is worth considering where further gains in performance might yet be found. One key question is to what extent a limited context restricts identification performance. We first tested the importance of the pattern length by

System	P	R	F	Acc
DISTRIB	80.0	73.3	76.5	86.5
COMBO	80.7	76.7	78.6	87.5
Human-1	92.7	63.3	75.2	87.5
Human-2	84.0	70.0	76.4	87.0
Human-3	72.2	86.7	78.8	86.0

Table 6: Evaluation on *Test-200* (%).

using only the length-4 counts in the DISTRIB system (*Train/Test* split). Surprisingly, the drop in F-Score was only one percent, to 74.8%. Using only the length-5 counts drops F-Score to 71.4%. Neither are statistically significant; however there seems to be diminishing returns from longer context patterns.

Another way to view the limited context is to ask, given the amount of context we have, are we making optimum use of it? We answer this by seeing how well humans can do with the same information. As explained in Section 3.2, our system uses 5-gram context patterns that together span from four-to-the-left to four-to-the-right of the pronoun. We thus provide these same nine-token windows to our human subjects, and ask them to decide whether the pronouns refer to previous noun phrases or not, based on these contexts. Subjects first performed a dry-run experiment on separate development data. They were shown their errors and sources of confusion were clarified. They then made the judgments unassisted on the final *Test-200* data. Three humans performed the experiment. Their results show a range of preferences for precision versus recall, with both F-Score and Accuracy on average below the performance of COMBO (Table 6). Foremost, these results show that our distributional approach is already getting good leverage from the limited context information, around that achieved by our best human.

It is instructive to inspect the twenty-five *Test-200* instances that the COMBO system classified incorrectly, given human performance on this same set. Seventeen of the twenty-five COMBO errors were also made by one or more human subjects, suggesting system errors are also mostly due to limited context. For example, one of these errors was for the context: “it takes an astounding amount...” Here, the non-referential nature of the instance is not apparent without the infinitive clause that ends the sentence: “... of time to compare very long DNA sequences

with each other.”

Six of the eight errors unique to the COMBO system were cases where the system falsely said the pronoun was non-referential. Four of these could have referred to entire sentences or clauses rather than nouns. These confusing cases, for both humans and our system, result from our definition of a referential pronoun: pronouns with verbal or clause antecedents are considered non-referential (Section 3.1). If an antecedent verb or clause is replaced by a nominalization (*Smith researched...* to *Smith’s research*), a referring pronoun, in the same context, becomes referential. When we inspect the probabilities produced by the maximum entropy classifier (Section 4.2), we see only a weak bias for the non-referential class on these examples, reflecting our classifier’s uncertainty. It would likely be possible to improve accuracy on these cases by encoding the presence or absence of preceding nominalizations as a feature of our classifier.

Another false non-referential decision is for the phrase “... machine he had installed it on.” The *it* is actually referential, but the extracted patterns (e.g. “he had install \* on”) are nevertheless usually filled with *it*.<sup>9</sup> Again, it might be possible to fix such examples by leveraging the preceding discourse. Notably, the first noun-phrase before the context is the word “software.” There is strong compatibility between the pronoun-parent “install” and the candidate antecedent “software.” In a full coreference resolution system, when the anaphora resolution module has a strong preference to link *it* to an antecedent (which it should when the pronoun is indeed referential), we can override a weak non-referential probability. Non-referential *it* detection should not be a pre-processing step, but rather part of a globally-optimal configuration, as was done for general noun phrase anaphoricity by Denis and Baldridge (2007).

The suitability of this kind of approach to correcting some of our system’s errors is especially obvious when we inspect the probabilities of the maximum entropy model’s output decisions on the *Test-200* set. Where the maximum entropy classifier makes mistakes, it does so with less confidence than when it classifies correct examples. The average predicted

---

<sup>9</sup>This example also suggests using filler counts for the word “the” as a feature when *it* is the last word in the pattern.

probability of the incorrect classifications is 76.0% while the average probability of the correct classifications is 90.3%. Many incorrect decisions are ready to switch sides; our next step will be to use features of the preceding discourse and the candidate antecedents to help give them a push.

## 6 Conclusion

We have presented an approach to detecting non-referential pronouns in text based on the distribution of the pronoun’s context. The approach is simple to implement, attains state-of-the-art results, and should be easily ported to other languages. Our technique demonstrates how large volumes of data can be used to gather world knowledge for natural language processing. A consequence of this research was the creation of *It-Bank*, a collection of thousands of labelled examples of the pronoun *it*, which will benefit other coreference resolution researchers.

Error analysis reveals that our system is getting good leverage out of the pronoun context, achieving results comparable to human performance given equivalent information. To boost performance further, we will need to incorporate information from preceding discourse. Future research will also test the distributional classification of other ambiguous pronouns, like *this*, *you*, *there*, and *that*. Another avenue of study will look at the interaction between coreference resolution and machine translation. For example, if a single form in English (e.g. *that*) is separated into different meanings in another language (e.g., Spanish demonstrative *ese*, nominal reference *ése*, abstract or statement reference *eso*, and complementizer *que*), then aligned examples provide automatically-disambiguated English data. We could extract context patterns and collect statistics from these examples like in our current approach. In general, jointly optimizing translation and coreference is an exciting and largely unexplored research area, now partly enabled by our portable non-referential detection methodology.

## Abstract

A new approach to large-scale information extraction exploits both Web documents and query logs to acquire thousands of open-domain classes of instances, along with relevant sets of open-domain class attributes at precision levels previously obtained only on small-scale, manually-assembled classes.

## 1 Introduction

Current methods for large-scale information extraction take advantage of unstructured text available from either Web documents (Banko et al., 2007; Snow et al., 2006) or, more recently, logs of Web search queries (Paşca, 2007) to acquire useful knowledge with minimal supervision. Given a manually-specified target attribute (e.g., birth years for people) and starting from as few as 10 seed facts such as (e.g., *John Lennon, 1941*), as many as a million facts of the same type can be derived from unstructured text within Web documents (Paşca et al., 2006). Similarly, given a manually-specified target class (e.g., *Drug*) with its instances (e.g., *Vicodin* and *Xanax*) and starting from as few as 5 seed attributes (e.g., *side effects* and *maximum dose* for *Drug*), other relevant attributes can be extracted for the same class from query logs (Paşca, 2007). These and other previous methods require the manual specification of the input classes of instances before any knowledge (e.g., facts or attributes) can be acquired for those classes.

The extraction method introduced in this paper mines a collection of Web search queries and a collection of Web documents to acquire open-domain classes in the form of instance sets (e.g., {*whales, seals, dolphins, sea lions,...*}) associated with class labels (e.g., *marine animals*), as well as large sets of open-domain attributes for each class (e.g., *circulatory system, life cycle, evolution, food chain* and *scientific name* for the class *marine animals*). In this light, the contributions of this paper are four-fold. First, instead of separately addressing the tasks of collecting unlabeled sets of instances (Lin, 1998), assigning appropriate class labels to a given set of instances (Pantel and Ravichandran, 2004), and identifying relevant attributes for a given set of classes (Paşca, 2007), our integrated method from Section 2 enables the *simultaneous extraction* of class instances, associated labels and attributes. Second, by exploiting the contents of query logs during the extraction of labeled classes of instances from Web documents, we acquire thousands (4,583, to be exact) of *open-domain classes* covering a wide range of topics and domains. The accuracy reported in Section 3.2 exceeds 80% for both instance sets and class labels, although the extraction of classes requires a remarkably small amount of supervision, in the form of only a few commonly-used Is-A extraction patterns. Third, we conduct the first study in extracting attributes for thousands of open-domain, *automatically-acquired* classes, at precision levels over 70% at rank 10, and 67% at rank 20 as described in Section 3.3. The amount of supervision is limited to five seed attributes provided for only one reference class. In comparison, the largest previous

---

\*Contributions made during an internship at Google.

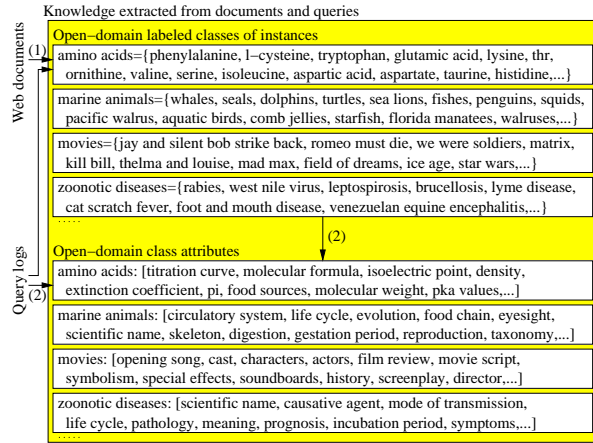

Figure 1: Overview of weakly-supervised extraction of class instances, class labels and class attributes from Web documents and query logs

study in attribute extraction reports results on a set of 40 *manually-assembled* classes, and requires five seed attributes to be provided as input for each class. Fourth, we introduce the first approach to information extraction from a combination of *both* Web documents and search query logs, to extract open-domain knowledge that is expected to be suitable for later use. In contrast, the textual data sources used in previous studies in large-scale information extraction are *either* Web documents (Mooney and Bunescu, 2005; Banko et al., 2007) *or*, recently, query logs (Paşca, 2007), but not both.

## 2 Extraction from Documents and Queries

### 2.1 Open-Domain Labeled Classes of Instances

Figure 1 provides an overview of how Web documents and queries are used together to acquire open-domain, labeled classes of instances (phase (1) in the figure); and to acquire attributes that capture quantifiable properties of those classes, by mining query logs based on the class instances acquired from the documents, while guiding the extraction based on a few attributes provided as seed examples (phase (2)).

As described in Figure 2, the algorithm for deriving labeled sets of class instances starts with the acquisition of candidate pairs  $\{\mathcal{M}_E\}$  of a class label and an instance, by applying a few extraction patterns to unstructured text within Web documents  $\{\mathcal{D}\}$ , while guiding the extraction by the contents of query logs  $\{\mathcal{Q}\}$  (Step 1 in Figure 2). This is fol-

Input: set of Is-A extraction patterns  $\{\mathcal{E}\}$   
 . large repository of search queries  $\{\mathcal{Q}\}$   
 . large repository of Web docs  $\{\mathcal{D}\}$   
 . weighting parameters  $\mathcal{T} \in [0,1]$  and  $\mathcal{K} \in \overline{1..∞}$   
 Output: set of pairs of a class label and an instance  $\{\langle \mathcal{C}, \mathcal{I} \rangle\}$   
 Variables:  $\{\mathcal{S}\}$  = clusters of distributionally similar phrases  
 .  $\{\mathcal{V}\}$  = vectors of contextual matches of queries in text  
 .  $\{\mathcal{M}_E\}$  = set of pairs of a class label and an instance  
 .  $\{\mathcal{C}_S\}$  = set of class labels  
 .  $\{\mathcal{X}\}, \{\mathcal{Y}\}$  = sets of queries

Steps:

01.  $\{\mathcal{M}_E\}$  = Match patterns  $\{\mathcal{E}\}$  in docs  $\{\mathcal{D}\}$  around  $\{\mathcal{Q}\}$
02.  $\{\mathcal{V}\}$  = Match phrases  $\{\mathcal{Q}\}$  in docs  $\{\mathcal{D}\}$
03.  $\{\mathcal{S}\}$  = Generate clusters of queries based on vectors  $\{\mathcal{V}\}$
04. For each cluster of phrases  $\mathcal{S}$  in  $\{\mathcal{S}\}$
05.  $\{\mathcal{C}_S\} = \emptyset$
06. For each query  $\mathcal{Q}$  of  $\mathcal{S}$
07. Insert labels of  $\mathcal{Q}$  from  $\{\mathcal{M}_E\}$  into  $\{\mathcal{C}_S\}$
08. For each label  $\mathcal{C}_S$  of  $\{\mathcal{C}_S\}$
09.  $\{\mathcal{X}\}$  = Find queries of  $\mathcal{S}$  with the label  $\mathcal{C}_S$  in  $\{\mathcal{M}_E\}$
10.  $\{\mathcal{Y}\}$  = Find clusters of  $\{\mathcal{S}\}$  containing some query with the label  $\mathcal{C}_S$  in  $\{\mathcal{M}_E\}$
11. If  $|\{\mathcal{X}\}| > \mathcal{T} \times |\{\mathcal{S}\}|$
12. If  $|\{\mathcal{Y}\}| < \mathcal{K}$
13. For each query  $\mathcal{X}$  of  $\{\mathcal{X}\}$
14. Insert pair  $\langle \mathcal{C}_S, \mathcal{X} \rangle$  into output pairs  $\{\langle \mathcal{C}, \mathcal{I} \rangle\}$
15. Return pairs  $\{\langle \mathcal{C}, \mathcal{I} \rangle\}$

Figure 2: Acquisition of labeled sets of class instances

lowed by the generation of unlabeled clusters  $\{\mathcal{S}\}$  of distributionally similar queries, by clustering vectors of contextual features collected around the occurrences of queries  $\{\mathcal{Q}\}$  within documents  $\{\mathcal{D}\}$  (Steps 2 and 3). Finally, the intermediate data  $\{\mathcal{M}_E\}$  and  $\{\mathcal{S}\}$  is merged and filtered into smaller, more accurate labeled sets of instances (Steps 4 through 15).

Step 1 in Figure 2 applies lexico-syntactic patterns  $\{\mathcal{E}\}$  that aim at extracting Is-A pairs of an instance (e.g., *Google*) and an associated class label (e.g., *Internet search engines*) from text. The two patterns, which are inspired by (Hearst, 1992) and have been the de-facto extraction technique in previous work on extracting conceptual hierarchies from text (cf. (Ponzetto and Strube, 2007; Snow et al., 2006)), can be summarized as:

$\{[.] \mathcal{C} [\text{such as}|\text{including}] \mathcal{I} [\text{and},|,]\}$ ,

where  $\mathcal{I}$  is a potential instance (e.g., *Venezuelan equine encephalitis*) and  $\mathcal{C}$  is a potential class label for the instance (e.g., *zoonotic diseases*), for example in the sentence: “*The expansion of the farms increased the spread of zoonotic diseases such as Venezuelan equine encephalitis [.]*”.

During matching, all string comparisons are case-insensitive. In order for a pattern to match a sentence, two conditions must be met. First, the class

label  $\mathcal{C}$  from the sentence must be a non-recursive noun phrase whose last component is a plural-form noun (e.g., *zoonotic diseases* in the above sentence). Second, the instance  $\mathcal{I}$  from the sentence must also occur as a complete query somewhere in the query logs  $\{\mathcal{Q}\}$ , that is, a query containing the instance and nothing else. This heuristic acknowledges the difficulty of pinpointing complex entities within documents (Downey et al., 2007), and embodies the hypothesis that, if an instance is prominent, Web search users will eventually ask about it.

In Steps 4 through 14 from Figure 2, each cluster is inspected by scanning all labels attached to one or more queries from the cluster. For each label  $\mathcal{C}_S$ , if a)  $\{\mathcal{M}_E\}$  indicates that a large number of all queries from the cluster are attached to the label (as controlled by the parameter  $\mathcal{J}$  in Step 12); and b) those queries are a significant portion of all queries from all clusters attached to the same label in  $\{\mathcal{M}_E\}$  (as controlled by the parameter  $\mathcal{K}$  in Step 13), then the label  $\mathcal{C}_S$  and each query with that label are stored in the output pairs  $\{\langle \mathcal{C}, \mathcal{I} \rangle\}$  (Steps 13 and 14). The parameters  $\mathcal{J}$  and  $\mathcal{K}$  can be used to emphasize precision (higher  $\mathcal{J}$  and lower  $\mathcal{K}$ ) or recall (lower  $\mathcal{J}$  and higher  $\mathcal{K}$ ). The resulting pairs of an instance and a class label are arranged into sets of class instances (e.g.,  $\{\textit{rabies, west nile virus, leptospirosis, ...}\}$ ), each associated with a class label (e.g., *zoonotic diseases*), and returned in Step 15.

## 2.2 Open-Domain Class Attributes

The labeled classes of instances collected automatically from Web documents are passed as input to phase (2) from Figure 1, which acquires class attributes by mining a collection of Web search queries. The attributes capture properties that are relevant to the class. The extraction of attributes exploits the set of class instances rather than the associated class label, and consists of four stages:

- 1) identification of a noisy pool of candidate attributes, as remainders of queries that also contain one of the class instances. In the case of the class *movies*, whose instances include *jay and silent bob strike back* and *kill bill*, the query “*cast jay and silent bob strike back*” produces the candidate attribute *cast*;

- 2) construction of internal search-signature vector representations for each candidate attribute, based

on queries (e.g., “*cast selection for kill bill*”) that contain a candidate attribute (*cast*) and a class instance (*kill bill*). These vectors consist of counts tied to the frequency with which an attribute occurs with a given “templated” query. The latter replaces specific attributes and instances from the query with common placeholders, e.g., “*X for Y*”;

- 3) construction of a reference internal search-signature vector representation for a small set of seed attributes provided as input. A reference vector is the normalized sum of the individual vectors corresponding to the seed attributes;

- 4) ranking of candidate attributes with respect to each class (e.g., *movies*), by computing similarity scores between their individual vector representations and the reference vector of the seed attributes.

The result of the four stages is a ranked list of attributes (e.g.,  $[\textit{opening song, cast, characters, ...}]$ ) for each class (e.g., *movies*).

In a departure from previous work, the instances of each input class are automatically generated as described earlier, rather than manually assembled. Furthermore, the amount of supervision is limited to seed attributes being provided for only one of the classes, whereas (Paşca, 2007) requires seed attributes for each class. To this effect, the extraction includes modifications such that only one reference vector is constructed internally from the seed attributes during the third stage, rather one such vector for each class in (Paşca, 2007); and similarity scores are computed cross-class by comparing vector representations of individual candidate attributes against the only reference vector available during the fourth stage, rather than with respect to the reference vector of each class in (Paşca, 2007).

## 3 Evaluation

### 3.1 Textual Data Sources

The acquisition of open-domain knowledge, in the form of class instances, labels and attributes, relies on unstructured text available within Web documents maintained by, and search queries submitted to, the Google search engine.

The collection of queries is a random sample of fully-anonymized queries in English submitted by Web users in 2006. The sample contains approximately 50 million unique queries. Each query is

Found in WordNet?	Count	Pct.	Examples
Yes (original)	1931	42.2%	baseball players, endangered species
Yes (removal)	2614	57.0%	caribbean countries, fundamental rights
No	38	0.8%	agrochemicals, celebs, handhelds, mangas

Table 1: Class labels found in WordNet in original form, or found in WordNet after removal of leading words, or not found in WordNet at all

accompanied by its frequency of occurrence in the logs. The document collection consists of approximately 100 million Web documents in English, as available in a Web repository snapshot from 2006. The textual portion of the documents is cleaned of HTML, tokenized, split into sentences and part-of-speech tagged using the TnT tagger (Brants, 2000).

### 3.2 Evaluation of Labeled Classes of Instances

**Extraction Parameters:** The set of instances that can be potentially acquired by the extraction algorithm described in Section 2.1 is heuristically limited to the top five million queries with the highest frequency within the input query logs. In the extracted data, a class label (e.g., *search engines*) is associated with one or more instances (e.g., *google*). Similarly, an instance (e.g., *google*) is associated with one or more class labels (e.g., *search engines* and *internet search engines*). The values chosen for the weighting parameters  $\mathcal{J}$  and  $\mathcal{K}$  from Section 2.1 are 0.01 and 30 respectively. After discarding classes with fewer than 25 instances, the extracted set of classes consists of 4,583 class labels, each of them associated with 25 to 7,967 instances, with an average of 189 instances per class.

**Accuracy of Class Labels:** Built over many years of manual construction efforts, lexical gold standards such as WordNet (Fellbaum, 1998) provide wide-coverage upper ontologies of the English language. Built-in morphological normalization routines make it straightforward to verify whether a class label (e.g., *faculty members*) exists as a concept in WordNet (e.g., *faculty member*). When an extracted label (e.g., *central nervous system disorders*) is not found in WordNet, it is looked up again after iteratively removing its leading words (e.g., *nervous system dis-*

Class Label={Set of Instances}	Parent in WordNet	C?
american composers={aaron copland, eric ewazen, george gershwin,...}	composers	Y
modern appliances={built-in oven, ceramic hob, tumble dryer,...}	appliances	S
area hospitals={carolinas medical center, nyack hospital,...}	hospitals	S
multiple languages={chuukese, ladino, mandarin, us english,...}	languages	N

Table 2: Correctness judgments for extracted classes whose class labels are found in WordNet only after removal of their leading words (C=Correctness, Y=correct, S=subjectively correct, N=incorrect)

*orders, system disorders and disorders*).

As shown in Table 1, less than half of the 4,583 extracted class labels (e.g., *baseball players*) are found in their original forms in WordNet. The majority of the class labels (2,614 out of 4,583) can be found in WordNet only after removal of one or more leading words (e.g., *caribbean countries*), which suggests that many of the class labels correspond to finer-grained, automatically-extracted concepts that are not available in the manually-built WordNet. To test whether that is the case, a random sample of 200 class labels, out of the 2,614 labels found to be potentially-useful specific concepts, are manually annotated as correct, subjectively correct or incorrect, as shown in Table 2. A class label is: correct, if it captures a relevant concept although it could not be found in WordNet; subjectively correct, if it is relevant not in general but only in a particular context, either from a subjective viewpoint (e.g., *modern appliances*), or relative to a particular temporal anchor (e.g., *current players*), or in connection to a particular geographical area (e.g., *area hospitals*); or incorrect, if it does not capture any useful concept (e.g., *multiple languages*). The manual analysis of the sample of 200 class labels indicates that 154 (77%) are relevant concepts and 27 (13.5%) are subjectively relevant concepts, for a total of 181 (90.5%) relevant concepts, whereas 19 (9.5%) of the labels are incorrect. It is worth emphasizing the importance of automatically-collected classes judged as relevant and not present in WordNet: *caribbean countries, computer manufacturers, entertainment companies, market research firms* are arguably very useful and should probably be considered as part of

Total mapped: 37 out of 40 classes							-	-	<b>26.89</b>

Table 3: Comparison between manually-assembled instance sets of gold-standard classes ( $M$ ) and instance sets of automatically-extracted classes ( $E$ ). Each gold-standard class ( $M$ ) was manually mapped into an extracted class ( $E$ ), unless no relevant mapping was found. Ratios ( $\frac{M \cap E}{M}$ ) are shown as percentages

any refinements to hand-built hierarchies, including any future extensions of WordNet.

**Accuracy of Class Instances:** The computation of the precision of the extracted instances (e.g., *fifth element* and *kill bill* for the class label *movies*) relies on manual inspection of all instances associated to a sample of the extracted class labels. Rather than inspecting a random sample of classes, the evaluation validates the results against a reference set of 40 gold-standard classes that were manually assembled as part of previous work (Paşca, 2007). A class from the gold standard consists of a manually-created class label (e.g., *AircraftModel*) associated with a manually-assembled, and therefore high-precision, set of representative instances of the class.

To evaluate the precision of the extracted instances, the manual label of each gold-standard class (e.g., *SearchEngine*) is mapped into a class label extracted from text (e.g., *search engines*). As shown in the first two columns of Table 3, the mapping into extracted class labels succeeds for 37 of the 40 gold-standard classes. 28 of the 37 mappings involve linking an abstract class label (e.g., *SearchEngine*)

with the corresponding plural forms among the extracted class labels (e.g., *search engines*). The remaining 9 mappings link a manual class label with either an equivalent extracted class label (e.g., *SoccerClub* with *football clubs*), or a strongly-related class label (e.g., *NationalPark* with *parks*). No mapping is found for 3 out of the 40 classes, namely *AircraftModel*, *Hurricane* and *Skyscraper*, which are therefore removed from consideration.

The sizes of the instance sets available for each class in the gold standard are compared in the third through fifth columns of Table 3. In the table,  $M$  stands for manually-assembled instance sets, and  $E$  for automatically-extracted instance sets. For example, the gold-standard class *SearchEngine* contains 25 manually-collected instances, while the parallel class label *search engines* contains 133 automatically-extracted instances. The fifth column shows the percentage of manually-collected instances ( $M$ ) that are also extracted automatically ( $E$ ). In the case of the class *SearchEngine*, 16 of the 25 manually-collected instances are among the 133 automatically-extracted instances of the same class,

Label	Value	Examples of Attributes
vital	1.0	<i>investors</i> : investment strategies
okay	0.5	<i>religious leaders</i> : coat of arms
wrong	0.0	<i>designers</i> : stephanie

Table 4: Labels for assessing attribute correctness

which corresponds to a relative coverage of 64% of the manually-collected instance set. Some instances may occur within the manually-collected set but not the automatically-extracted set (e.g., *zoom-info* and *brainbot* for the class *SearchEngine*) or, more frequently, vice-versa (e.g., *surfwax*, *blinkx*, *entireweb*, *web wombat*, *exalead* etc.). Overall, the relative coverage of automatically-extracted instance sets with respect to manually-collected instance sets is 26.89%, as an average over the 37 gold-standard classes. More significantly, the size advantage of automatically-extracted instance sets is not the undesirable result of those sets containing many spurious instances. Indeed, the manual inspection of the automatically-extracted instances sets indicates an average accuracy of 79.3% over the 37 gold-standard classes retained in the experiments. To summarize, the method proposed in this paper acquires open-domain classes from unstructured text of arbitrary quality, without a-priori restrictions to specific domains of interest and with virtually no supervision (except for the ubiquitous Is-A extraction patterns), at accuracy levels of around 90% for class labels and 80% for class instances.

### 3.3 Evaluation of Class Attributes

**Extraction Parameters:** Given a target class specified as a set of instances and a set of five seed attributes for a class (e.g.,  $\{quality, speed, number\ of\ users, market\ share, reliability\}$  for *SearchEngine*), the method described in Section 2.2 extracts ranked lists of class attributes from the input query logs. Internally, the ranking uses Jensen-Shannon (Lee, 1999) to compute similarity scores between internal representations of seed attributes, on one hand, and each of the candidate attributes, on the other hand.

**Evaluation Procedure:** To remove any possible bias towards higher-ranked attributes during the assessment of class attributes, the ranked lists of attributes to be evaluated are sorted alphabetically into a merged list. Each attribute of the merged list is

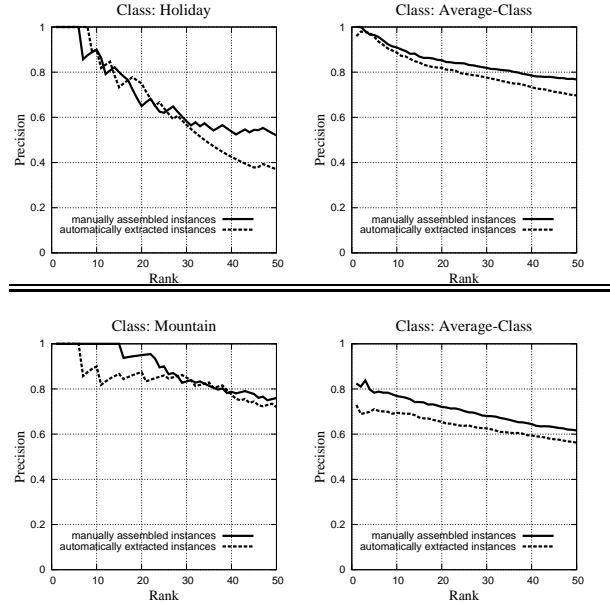

Figure 3: Accuracy of attributes extracted based on manually assembled, gold standard ( $M$ ) vs. automatically extracted ( $E$ ) instance sets, for a few target classes (left-most graphs) and as an average over all (37) target classes (right-most graphs). Seed attributes are provided as input for each target class (top graphs), or for only one target class (bottom graphs)

manually assigned a correctness label within its respective class. An attribute is *vital* if it must be present in an ideal list of attributes of the class; *okay* if it provides useful but non-essential information; and *wrong* if it is incorrect.

To compute the overall precision score over a ranked list of extracted attributes, the correctness labels are converted to numeric values as shown in Table 4. Precision at some rank  $N$  in the list is thus measured as the sum of the assigned values of the first  $N$  candidate attributes, divided by  $N$ .

**Accuracy of Class Attributes:** Figure 3 plots precision values for ranks 1 through 50 of the lists of attributes extracted through several runs over the 37 gold-standard classes described in the previous section. The runs correspond to different amounts of supervision, specified through a particular choice in the number of seed attributes, and in the source of instances passed as input to the system:

- number of input seed attributes: seed attributes are provided either for each of the 37 classes, for a total of  $5 \times 37 = 185$  attributes (the graphs at the top of Figure 3); or only for one class (namely, *Country*),

Class		Precision				Top Ten Extracted Attributes
#	Class Label={Set of Instances}	@5	@10	@15	@20	
1	accounting systems={flexcube, myob, oracle fi nancials, peachtree accounting, sybiz,...}	0.70	0.70	0.77	0.70	overview, architecture, interview questions, free downloads, canadian version, passwords, modules, crystal reports, property management, free trial
2	antimicrobials={azithromycin, chloramphenicol, fusidic acid, quinolones, sulfa drugs,...}	1.00	1.00	0.93	0.95	chemical formula, chemical structure, history, invention, inventor, defi nition, mechanism of action, side-effects, uses, shelf life
5	civilizations={ancient greece, chaldeans, etruscans, inca indians, roman republic,...}	1.00	1.00	0.93	0.90	social pyramid, climate, geography, flag, population, social structure, natural resources, family life, god, goddesses
9	farm animals={angora goats, burros, cattle, cows, donkeys, draft horses, mule, oxen,...}	1.00	0.80	0.83	0.80	digestive system, evolution, domestication, gestation period, scientifi c name, adaptations, coloring pages, p**, body parts, selective breeding
10	forages={alsike clover, rye grass, tall fescue, sericea lespedeza,...}	0.90	0.95	0.73	0.57	types, picture, weed control, planting, uses, information, herbicide, germination, care, fertilizer
Average-Class (25 classes)		<b>0.75</b>	<b>0.70</b>	<b>0.68</b>	<b>0.67</b>	

Table 5: Precision of attributes extracted for a sample of 25 classes. Seed attributes are provided for only one class.

for a total of 5 attributes over all classes (the graphs at the bottom of Figure 3);

- source of input instance sets: the instance sets for each class are either manually collected ( $M$  from Table 3), or automatically extracted ( $E$  from Table 3). The choices correspond to the two curves plotted in each graph in Figure 3.

The graphs in Figure 3 show the precision over individual target classes (leftmost graphs), and as an average over all 37 classes (rightmost graphs). As expected, the precision of the extracted attributes as an average over all classes is best when the input instance sets are hand-picked ( $M$ ), as opposed to automatically extracted ( $E$ ). However, the loss of precision from  $M$  to  $E$  is small at all measured ranks.

Table 5 offers an alternative view on the quality of the attributes extracted for a random sample of 25 classes out of the larger set of 4,583 classes acquired from text. The 25 classes are passed as input for attribute extraction without modifications. In particular, the instance sets are not manually post-filtered or otherwise changed in any way. To keep the time required to judge the correctness of all extracted attributes within reasonable limits, the evaluation considers only the top 20 (rather than 50) attributes extracted per class. As shown in Table 5, the method proposed in this paper acquires attributes for automatically-extracted, open-domain classes, without a-priori restrictions to specific domains of interest and relying on only five seed attributes specified

for only one class, at accuracy levels reaching 70% at rank 10, and 67% at rank 20.

## 4 Related Work

### 4.1 Acquisition of Classes of Instances

Although some researchers focus on re-organizing or extending classes of instances already available explicitly within manually-built resources such as Wikipedia (Ponzetto and Strube, 2007) or WordNet (Snow et al., 2006) or both (Suchanek et al., 2007), a large body of previous work focuses on compiling sets of instances, not necessarily labeled, from unstructured text. The extraction proceeds either iteratively by starting from a few seed extraction rules (Collins and Singer, 1999), or by mining named entities from comparable news articles (Shinyama and Sekine, 2004) or from multilingual corpora (Klementiev and Roth, 2006).

A bootstrapping method (Riloff and Jones, 1999) cautiously grows very small seed sets of five instances of the same class, to fewer than 300 items after 50 consecutive iterations, with a final precision varying between 46% and 76% depending on the type of semantic lexicon. Experimental results from (Feldman and Rosenfeld, 2006) indicate that named entity recognizers can boost the performance of weakly supervised extraction of class instances, but only for a few coarse-grained types such as *Person* and only if they are simpler to recognize in text (Feldman and Rosenfeld, 2006).

In (Cafarella et al., 2005), handcrafted extraction patterns are applied to a collection of 60 million Web documents to extract instances of the classes *Company* and *Country*. Based on the manual evaluation of samples of extracted instances, an estimated number of 1,116 instances of *Company* are extracted at a precision score of 90%. In comparison, the approach of this paper pursues a more aggressive goal, by extracting a larger and more diverse number of labeled classes, whose instances are often more difficult to extract than country names and most company names, at precision scores of almost 80%.

The task of extracting relevant labels to describe sets of documents, rather than sets of instances, is explored in (Treeratpituk and Callan, 2006). Given pre-existing sets of instances, (Pantel and Ravichandran, 2004) investigates the task of acquiring appropriate class labels to the sets from unstructured text. Various class labels are assigned to a total of 1,432 sets of instances. The accuracy of the class labels is computed over a sample of instances, by manually assessing the correctness of the top five labels returned by the system for each instance. The resulting mean reciprocal rank of 77% gives partial credit to labels of an evaluated instance, even if only the fourth or fifth assigned labels are correct. Our evaluation of the accuracy of class labels is stricter, as it considers only one class label of a given instance at a time, rather than a pool of the best candidate labels.

As a pre-requisite to extracting relations among pairs of classes, the method described in (Davidov et al., 2007) extracts class instances from unstructured Web documents, by submitting pairs of instances as queries and analyzing the contents of the top 1,000 documents returned by a Web search engine. For each target class, a small set of instances must be provided manually as seeds. As such, the method can be applied to the task of extracting a large set of open-domain classes only after manually enumerating through the entire set of target classes, and providing seed instances for each. Furthermore, no attempt is made to extract relevant class labels for the sets of instances. Comparatively, the open-domain classes extracted in our paper have an explicit label in addition to the sets of instances, and do not require identifying the range of the target classes in advance, or providing any seed instances as input. The evaluation methodology is also quite dif-

ferent, as the instance sets acquired based on the input seed instances in (Davidov et al., 2007) are only evaluated for three hand-picked classes, with precision scores of 90% for names of *countries*, 87% for *fish species* and 68% for instances of *constellations*. Our evaluation of the accuracy of class instances is again stricter, since the evaluation sample is larger, and includes more varied classes, whose instances are sometimes more difficult to identify in text.

## 4.2 Acquisition of Class Attributes

Previous work on the automatic acquisition of attributes for open-domain classes from text is less general than the extraction method and experiments presented in our paper. Indeed, previous evaluations were restricted to small sets of classes (forty classes in (Paşca, 2007)), whereas our evaluations also consider a random, more diverse sample of open-domain classes. More importantly, by dropping the requirement of manually providing a small set of seed attributes for each target class, and relying on only a few seed attributes specified for one reference class, we harvest class attributes without the need of first determining what the classes should be, what instances they should contain, and from which resources the instances should be collected.

## 5 Conclusion

In a departure from previous approaches to large-scale information extraction from unstructured text on the Web, this paper introduces a weakly-supervised extraction framework for mining useful knowledge from a combination of both documents and search query logs. In evaluations over labeled classes of instances extracted without a-priori restrictions to specific domains of interest and with very little supervision, the accuracy exceeds 90% for class labels, approaches 80% for class instances, and exceeds 70% (at rank 10) and 67% (at rank 20) for class attributes. Current work aims at expanding the number of instances within each class while retaining similar precision levels; extracting attributes with more consistent precision scores across classes from different domains; and introducing confidence scores in attribute extraction, allowing for the detection of classes for which it is unlikely to extract large numbers of useful attributes from text.

## Abstract

Traditional Information Extraction (IE) takes a relation name and hand-tagged examples of that relation as input. Open IE is a *relation-independent* extraction paradigm that is tailored to massive and heterogeneous corpora such as the Web. An Open IE system extracts a diverse set of relational tuples from text without *any* relation-specific input. How is Open IE possible? We analyze a sample of English sentences to demonstrate that numerous relationships are expressed using a compact set of relation-independent lexico-syntactic patterns, which can be learned by an Open IE system.

What are the tradeoffs between Open IE and traditional IE? We consider this question in the context of two tasks. First, when the number of relations is massive, and the relations themselves are not pre-specified, we argue that Open IE is necessary. We then present a new model for Open IE called O-CRF and show that it achieves increased precision and nearly double the recall than the model employed by TEXTRUNNER, the previous state-of-the-art Open IE system. Second, when the number of target relations is small, and their names are known in advance, we show that O-CRF is able to match the precision of a traditional extraction system, though at substantially lower recall. Finally, we show how to combine the two types of systems into a hybrid that achieves higher precision than a traditional extractor, with comparable recall.

## 1 Introduction

Relation Extraction (RE) is the task of recognizing the assertion of a particular relationship between two or more entities in text. Typically, the target relation (*e.g.*, seminar location) is given to the RE system as input along with hand-crafted extraction patterns or patterns learned from hand-labeled training examples (Brin, 1998; Riloff and Jones, 1999; Agichtein and Gravano, 2000). Such inputs are *specific* to the target relation. Shifting to a new relation requires a person to manually create new extraction patterns or specify new training examples. This manual labor scales linearly with the number of target relations.

In 2007, we introduced a new approach to the RE task, called Open Information Extraction (Open IE), which scales RE to the Web. An Open IE system extracts a diverse set of relational tuples without requiring *any* relation-specific human input. Open IE's extraction process is linear in the number of documents in the corpus, and constant in the number of relations. Open IE is ideally suited to corpora such as the Web, where the target relations are not known in advance, and their number is massive.

The relationship between standard RE systems and the new Open IE paradigm is analogous to the relationship between lexicalized and unlexicalized parsers. Statistical parsers are usually *lexicalized* (*i.e.* they make parsing decisions based on n-gram statistics computed for specific lexemes). However, Klein and Manning (2003) showed that *unlexicalized* parsers are more accurate than previously believed, and can be learned in an unsupervised manner. Klein and Manning analyze the tradeoffs be-

tween the two approaches to parsing and argue that state-of-the-art parsing will benefit from employing both approaches in concert. In this paper, we examine the tradeoffs between relation-specific (“lexicalized”) extraction and relation-independent (“unlexicalized”) extraction and reach an analogous conclusion.

Is it, in fact, possible to learn relation-independent extraction patterns? What do they look like? We first consider the task of open extraction, in which the goal is to extract relationships from text when their number is large and identity unknown. We then consider the targeted extraction task, in which the goal is to locate instances of a known relation. How does the precision and recall of Open IE compare with that of relation-specific extraction? Is it possible to combine Open IE with a “lexicalized” RE system to improve performance? This paper addresses the questions raised above and makes the following contributions:

- We present O-CRF, a new Open IE system that uses Conditional Random Fields, and demonstrate its ability to extract a variety of relations with a precision of 88.3% and recall of 45.2%. We compare O-CRF to O-NB, the extraction model previously used by *TEXTRUNNER* (Banko et al., 2007), a state-of-the-art Open IE system. We show that O-CRF achieves a relative gain in F-measure of 63% over O-NB.
- We provide a corpus-based characterization of how binary relationships are expressed in English to demonstrate that learning a relation-independent extractor is feasible, at least for the English language.
- In the targeted extraction case, we compare the performance of O-CRF to a traditional RE system and find that without any relation-specific input, O-CRF obtains the same precision with lower recall compared to a lexicalized extractor trained using hundreds, and sometimes thousands, of labeled examples per relation.
- We present H-CRF, an ensemble-based extractor that learns to combine the output of the lexicalized and unlexicalized RE systems and achieves a 10% relative increase in precision with comparable recall over traditional RE.

The remainder of this paper is organized as follows. Section 2 assesses the promise of relation-independent extraction for the English language by characterizing how a sample of relations is expressed in text. Section 3 describes O-CRF, a new Open IE system, as well as R1-CRF, a standard RE system; a hybrid RE system is then presented in Section 4. Section 5 reports on our experimental results. Section 6 considers related work, which is then followed by a discussion of future work.

## 2 The Nature of Relations in English

How are relationships expressed in English sentences? In this section, we show that many relationships are consistently expressed using a compact set of relation-independent lexico-syntactic patterns, and quantify their frequency based on a sample of 500 sentences selected at random from an IE training corpus developed by (Bunescu and Mooney, 2007).<sup>1</sup> This observation helps to explain the success of open relation extraction, which learns a relation-independent extraction model as described in Section 3.1.

Previous work has noted that distinguished relations, such as hypernymy (is-a) and meronymy (part-whole), are often expressed using a small number of lexico-syntactic patterns (Hearst, 1992). The manual identification of these patterns inspired a body of work in which this initial set of extraction patterns is used to seed a bootstrapping process that automatically acquires additional patterns for is-a or part-whole relations (Etzioni et al., 2005; Snow et al., 2005; Girju et al., 2006). It is quite natural then to consider whether the same can be done for *all* binary relationships.

To characterize how binary relationships are expressed, one of the authors of this paper carefully studied the labeled relation instances and produced a lexico-syntactic pattern that captured the relation for each instance. Interestingly, we found that 95% of the patterns could be grouped into the categories listed in Table 1. Note, however, that the patterns shown in Table 1 are greatly simplified by omitting the exact conditions under which they will reliably produce a correct extraction. For instance, while many relationships are indicated strictly by a verb,

<sup>1</sup>For simplicity, we restrict our study to binary relationships.

Relative Frequency	Category	Simplified Lexico-Syntactic Pattern
37.8	Verb	$E_1$ Verb $E_2$ <i>X established Y</i>
22.8	Noun+Prep	$E_1$ NP Prep $E_2$ <i>X settlement with Y</i>
16.0	Verb+Prep	$E_1$ Verb Prep $E_2$ <i>X moved to Y</i>
9.4	Infinitive	$E_1$ to Verb $E_2$ <i>X plans to acquire Y</i>
5.2	Modifier	$E_1$ Verb $E_2$ Noun <i>X is Y winner</i>
1.8	Coordinate <sub>n</sub>	$E_1$ (and , - :) $E_2$ NP <i>X-Y deal</i>
1.0	Coordinate <sub>v</sub>	$E_1$ (and ,) $E_2$ Verb <i>X, Y merge</i>
0.8	Appositive	$E_1$ NP (: ,)? $E_2$ <i>X hometown : Y</i>

Table 1: Taxonomy of Binary Relationships: Nearly 95% of 500 randomly selected sentences belongs to one of the eight categories above.

detailed contextual cues are required to determine, exactly which, if any, verb observed in the context of two entities is indicative of a relationship between them. In the next section, we show how we can use a Conditional Random Field, a model that can be described as a finite state machine with weighted transitions, to learn a model of how binary relationships are expressed in English.

### 3 Relation Extraction

Given a relation name, labeled examples of the relation, and a corpus, traditional Relation Extraction (RE) systems output instances of the given relation found in the corpus. In the open extraction task, relation names are not known in advance. The sole input to an Open IE system is a corpus, along with a small set of relation-independent heuristics, which are used to learn a general model of extraction for all relations at once.

The task of open extraction is notably more difficult than the traditional formulation of RE for several reasons. First, traditional RE systems do not attempt to extract the text that signifies a relation in a sentence, since the relation name is given. In con-

trast, an Open IE system has to locate both the set of entities believed to participate in a relation, and the salient textual cues that indicate the relation among them. Knowledge extracted by an open system takes the form of relational tuples  $(r, e_1, \dots, e_n)$  that contain two or more entities  $e_1, \dots, e_n$ , and  $r$ , the name of the relationship among them. For example, from the sentence, “Microsoft is headquartered in beautiful Redmond”, we expect to extract  $(is\ headquartered\ in, Microsoft, Redmond)$ . Moreover, following extraction, the system must identify exactly which relation strings  $r$  correspond to a general relation of interest. To ensure high-levels of coverage on a *per-relation* basis, we need, for example to deduce that “’s headquarters in”, “is headquartered in” and “is based in” are different ways of expressing HEADQUARTERS(X,Y).

Second, a relation-independent extraction process makes it difficult to leverage the full set of features typically used when performing extraction one relation at a time. For instance, the presence of the words *company* and *headquarters* will be useful in detecting instances of the HEADQUARTERS(X,Y) relation, but are not useful features for identifying relations in general. Finally, RE systems typically use named-entity types as a guide (e.g., the second argument to HEADQUARTERS should be a LOCATION). In Open IE, the relations are not known in advance, and neither are their argument types.

The unique nature of the open extraction task has led us to develop O-CRF, an open extraction system that uses the power of graphical models to identify relations in text. The remainder of this section describes O-CRF, and compares it to the extraction model employed by TEXTRUNNER, the first Open IE system (Banko et al., 2007). We then describe R1-CRF, a RE system that can be applied in a typical one-relation-at-a-time setting.

#### 3.1 Open Extraction with Conditional Random Fields

TEXTRUNNER initially treated Open IE as a classification problem, using a Naive Bayes classifier to predict whether heuristically-chosen tokens between two entities indicated a relationship or not. For the remainder of this paper, we refer to this model as O-NB. Whereas classifiers predict the label of a single variable, graphical models model multiple, in-

Figure 1: Relation Extraction as Sequence Labeling: A CRF is used to identify the relationship, *born in*, between *Kafka* and *Prague*

terdependent variables. Conditional Random Fields (CRFs) (Lafferty et al., 2001), are undirected graphical models trained to maximize the conditional probability of a finite set of labels  $Y$  given a set of input observations  $X$ . By making a first-order Markov assumption about the dependencies among the output variables  $Y$ , and arranging variables sequentially in a linear chain, RE can be treated as a sequence labeling problem. Linear-chain CRFs have been applied to a variety of sequential text processing tasks including named-entity recognition, part-of-speech tagging, word segmentation, semantic role identification, and recently relation extraction (Culotta et al., 2006).

### 3.1.1 Training

As with O-NB, O-CRF's training process is self-supervised. O-CRF applies a handful of relation-independent heuristics to the PennTreebank and obtains a set of labeled examples in the form of relational tuples. The heuristics were designed to capture dependencies typically obtained via syntactic parsing and semantic role labelling. For example, a heuristic used to identify positive examples is the extraction of noun phrases participating in a subject-verb-object relationship, e.g., "<Einstein> received <the Nobel Prize> in 1921." An example of a heuristic that locates negative examples is the extraction of objects that cross the boundary of an adverbial clause, e.g. "He studied <Einstein's work> when visiting <Germany>."

The resulting set of labeled examples are described using features that can be extracted without syntactic or semantic analysis and used to train a CRF, a sequence model that learns to identify spans of tokens believed to indicate explicit mentions of relationships between entities.

O-CRF first applies a phrase chunker to each document, and treats the identified noun phrases as candidate entities for extraction. Each pair of entities appearing no more than a maximum number of words apart and their surrounding context are considered as possible evidence for RE. The entity pair serves to anchor each end of a linear-chain CRF, and both entities in the pair are assigned a fixed label of ENT. Tokens in the surrounding context are treated as possible textual cues that indicate a relation, and can be assigned one of the following labels: B-REL, indicating the start of a relation, I-REL, indicating the continuation of a predicted relation, or O, indicating the token is not believed to be part of an explicit relationship. An illustration is given in Figure 1.

The set of features used by O-CRF is largely similar to those used by O-NB and other state-of-the-art relation extraction systems. They include part-of-speech tags (predicted using a separately trained maximum-entropy model), regular expressions (e.g. detecting capitalization, punctuation, etc.), context words, and conjunctions of features occurring in adjacent positions within six words to the left and six words to the right of the current word. A unique aspect of O-CRF is that O-CRF uses context words belonging only to *closed classes* (e.g. prepositions and determiners) but not function words such as verbs or nouns. Thus, unlike most RE systems, O-CRF does not try to recognize semantic classes of entities.

O-CRF has a number of limitations, most of which are shared with other systems that perform extraction from natural language text. First, O-CRF only extracts relations that are explicitly mentioned in the text; implicit relationships that could be inferred from the text would need to be inferred from O-CRF extractions. Second, O-CRF focuses on relationships that are primarily word-based, and not indicated solely from punctuation or document-level features. Finally, relations must occur between entity names within the same sentence.

O-CRF was built using the CRF implementation provided by MALLETT (McCallum, 2002), as well as part-of-speech tagging and phrase-chunking tools available from OPENNLP.<sup>2</sup>

<sup>2</sup><http://opennlp.sourceforge.net>

### 3.1.2 Extraction

Given an input corpus, O-CRF makes a single pass over the data, and performs entity identification using a phrase chunker. The CRF is then used to label instances relations for each possible entity pair, subject to the constraints mentioned previously.

Following extraction, O-CRF applies the RESOLVER algorithm (Yates and Etzioni, 2007) to find relation synonyms, the various ways in which a relation is expressed in text. RESOLVER uses a probabilistic model to predict if two strings refer to the same item, based on relational features, in an unsupervised manner. In Section 5.2 we report that RESOLVER boosts the recall of O-CRF by 50%.

### 3.2 Relation-Specific Extraction

To compare the behavior of open, or “unlexicalized,” extraction to relation-specific, or “lexicalized” extraction, we developed a CRF-based extractor under the traditional RE paradigm. We refer to this system as R1-CRF.

Although the graphical structure of R1-CRF is the same as O-CRF R1-CRF differs in a few ways. A given relation  $R$  is specified *a priori*, and R1-CRF is trained from hand-labeled positive and negative instances of  $R$ . The extractor is also permitted to use all lexical features, and is not restricted to closed-class words as is O-CRF. Since  $R$  is known in advance, if R1-CRF outputs a tuple at extraction time, the tuple is believed to be an instance of  $R$ .

## 4 Hybrid Relation Extraction

Since O-CRF and R1-CRF have complementary views of the extraction process, it is natural to wonder whether they can be combined to produce a more powerful extractor. In many machine learning settings, the use of an ensemble of diverse classifiers during prediction has been observed to yield higher levels of performance compared to individual algorithms. We now describe an ensemble-based or *hybrid* approach to RE that leverages the different views offered by open, self-supervised extraction in O-CRF, and lexicalized, supervised extraction in R1-CRF.

### 4.1 Stacking

*Stacked generalization*, or *stacking*, (Wolpert, 1992), is an ensemble-based framework in which the goal is learn a meta-classifier from the output of several base-level classifiers. The training set used to train the meta-classifier is generated using a leave-one-out procedure: for each base-level algorithm, a classifier is trained from all but one training example and then used to generate a prediction for the left-out example. The meta-classifier is trained using the predictions of the base-level classifiers as features, and the true label as given by the training data.

Previous studies (Ting and Witten, 1999; Zenko and Dzeroski, 2002; Sigletos et al., 2005) have shown that the probabilities of each class value as estimated by each base-level algorithm are effective features when training meta-learners. Stacking was shown to be consistently more effective than voting, another popular ensemble-based method in which the outputs of the base-classifiers are combined either through majority vote or by taking the class value with the highest average probability.

### 4.2 Stacked Relation Extraction

We used the stacking methodology to build an ensemble-based extractor, referred to as H-CRF. Treating the output of an O-CRF and R1-CRF as black boxes, H-CRF learns to predict which, if any, tokens found between a pair of entities ( $e_1, e_2$ ), indicates a relationship. Due to the sequential nature of our RE task, H-CRF employs a CRF as the meta-learner, as opposed to a decision tree or regression-based classifier.

H-CRF uses the probability distribution over the set of possible labels according to each O-CRF and R1-CRF as features. To obtain the probability at each position of a linear-chain CRF, the constrained forward-backward technique described in (Culotta and McCallum, 2004) is used. H-CRF also computes the Monge Elkan distance (Monge and Elkan, 1996) between the relations predicted by O-CRF and R1-CRF and includes the result in the feature set. An additional meta-feature utilized by H-CRF indicates whether either or both base extractors return “no relation” for a given pair of entities. In addition to these numeric features, H-CRF uses a subset of the base features used by O-CRF and R1-CRF. At each

Category	O-CRF			O-NB		
	P	R	F1	P	R	F1

Infinitive	95.7	46.8	62.9	100	25.5	40.6
Other	0	0	0	0	0	0
<b>All</b>	<b>88.3</b>	<b>45.2</b>	<b>59.8</b>	86.6	23.2	36.6

Table 2: Open Extraction by Relation Category. O-CRF outperforms O-NB, obtaining nearly double its recall and increased precision. O-CRF’s gains are partly due to its lower false positive rate for relationships categorized as “Other.”

given position  $i$  between  $e_1$  and  $e_2$ , the presence of the word observed at  $i$  as a feature, as well as the presence of the part-of-speech-tag at  $i$ .

## 5 Experimental Results

The following experiments demonstrate the benefits of Open IE for two tasks: open extraction and targeted extraction.

Section 5.1, assesses the ability of O-CRF to locate instances of relationships when the number of relationships is large and their identity is unknown. We show that without any relation-specific input, O-CRF extracts binary relationships with high precision and a recall that nearly doubles that of O-NB.

Sections 5.2 and 5.3 compare O-CRF to traditional and hybrid RE when the goal is to locate instances of a small set of known target relations. We find that while single-relation extraction, as embodied by R1-CRF, achieves comparatively higher levels of recall, it takes hundreds, and sometimes thousands, of labeled examples *per relation*, for R1-CRF to approach the precision obtained by O-CRF, which is self-trained without any relation-specific input. We also show that the combination of unlexicalized, open extraction in O-CRF and lexicalized, supervised extraction in R1-CRF improves precision and F-measure compared to a standalone RE system.

### 5.1 Open Extraction

This section contrasts the performance of O-CRF with that of O-NB on an Open IE task, and shows that O-CRF achieves both double the recall and increased precision relative to O-NB. For this exper-

iment, we used the set of 500 sentences<sup>3</sup> described in Section 2. Both IE systems were designed and trained prior to the examination of the sample sentences; thus the results on this sentence sample provide a fair measurement of their performance.

While the TEXTRUNNER system was previously found to extract over 7.5 million tuples from a corpus of 9 million Web pages, these experiments are the first to assess its true recall over a known set of relational tuples. As reported in Table 2, O-CRF extracts relational tuples with a precision of 88.3% and a recall of 45.2%. O-CRF achieves a relative gain in F1 of 63.4% over the O-NB model employed by TEXTRUNNER, which obtains a precision of 86.6% and a recall of 23.2%. The recall of O-CRF nearly doubles that of O-NB.

O-CRF is able to extract instances of the four most frequently observed relation types – Verb, Noun+Prep, Verb+Prep and Infinitive. Three of the four remaining types – Modifier, Coordinate<sub>n</sub> and Coordinate<sub>v</sub> – which comprise only 8% of the sample, are not handled due to simplifying assumptions made by both O-CRF and O-NB that tokens indicating a relation occur between entity mentions in the sentence.

### 5.2 O-CRF vs. R1-CRF Extraction

To compare performance of the extractors when a small set of target relationships is known in advance, we used labeled data for four different relations – corporate acquisitions, birthplaces, inventors of products and award winners. The first two datasets were collected from the Web, and made available by Bunescu and Mooney (2007). To augment the size of our corpus, we used the same technique to collect data for two additional relations, and manually labelled positive and negative instances by hand over all collections. For each of the four relations in our collection, we trained R1-CRF from labeled training data, and ran each of R1-CRF and O-CRF over the respective test sets, and compared the precision and recall of all tuples output by each system.

Table 3 shows that from the start, O-CRF achieves a high level of precision – 75.0% – without any

<b>All</b>	<b>75.0</b>	18.4	70.17	<b>60.7</b>	>4374

Table 4: For 4 relations, a minimum of 4374 hand-tagged examples is needed for R1-CRF to approximately match the precision of O-CRF for each relation. A “\*” indicates the use of all available training data; in these cases, R1-CRF was unable to match the precision of O-CRF.

relation-specific data. Using labeled training data, the R1-CRF system achieves a slightly lower precision of 73.9%.

Exactly how many training examples per relation does it take R1-CRF to achieve a comparable level of precision? We varied the number of training examples given to R1-CRF, and found that in 3 out of 4 cases it takes hundreds, if not thousands of labeled examples for R1-CRF to achieve acceptable levels of precision. In two cases – acquisitions and inventions – R1-CRF is unable to match the precision of O-CRF, even with many labeled examples. Table 4 summarizes these findings.

Using labeled data, R1-CRF obtains a recall of 58.4%, compared to O-CRF, whose recall is 18.4%. A large number of false negatives on the part of O-CRF can be attributed to its lack of lexical features, which are often crucial when part-of-speech tagging errors are present. For instance, in the sentence, “Yahoo To Acquire Inktomi”, “Acquire” is mistaken for a proper noun, and sufficient evidence of the existence of a relationship is absent. The lexicalized R1-CRF extractor is able to recover from this error; the presence of the word “Acquire” is enough to recog-

Relation	R1-CRF			Hybrid		
	P	R	F1	P	R	F1

<b>All</b>	73.9	<b>58.4</b>	65.2	<b>79.2</b>	56.9	<b>66.2</b>

Table 5: A hybrid extractor that uses O-CRF improves precision for all relations, at a small cost to recall.

nize the positive instance, despite the incorrect part-of-speech tag.

Another source of recall issues facing O-CRF is its ability to discover synonyms for a given relation. We found that while RESOLVER improves the relative recall of O-CRF by nearly 50%, O-CRF locates fewer synonyms per relation compared to its lexicalized counterpart. With RESOLVER, O-CRF finds an average of 6.5 synonyms per relation compared to R1-CRF’s 16.25.

In light of our findings, the relative tradeoffs of open versus traditional RE are as follows. Open IE automatically offers a high level of precision without requiring manual labor per relation, at the expense of recall. When relationships in a corpus are not known, or their number is massive, Open IE is essential for RE. When higher levels of recall are desirable for a small set of target relations, traditional RE is more appropriate. However, in this case, one must be willing to undertake the cost of acquiring labeled training data for each relation, either via a computational procedure such as bootstrapped learning or by the use of human annotators.

### 5.3 Hybrid Extraction

In this section, we explore the performance of H-CRF, an ensemble-based extractor that learns to perform RE for a set of known relations based on the individual behaviors of O-CRF and R1-CRF.

As shown in Table 5, the use of O-CRF as part of H-CRF, improves precision from 73.9% to 79.2% with only a slight decrease in recall. Overall, F1 improved from 65.2% to 66.2%.

One disadvantage of a stacking-based hybrid system is that labeled training data is still required. In the future, we would like to explore the development of hybrid systems that leverage Open IE methods,

like O-CRF, to reduce the number of training examples required per relation.

## 6 Related Work

TEXTRUNNER, the first Open IE system, is part of a body of work that reflects a growing interest in avoiding relation-specificity during extraction. Sekine (2006) developed a paradigm for “on-demand information extraction” in order to reduce the amount of effort involved when porting IE systems to new domains. Shinyama and Sekine’s “pre-emptive” IE system (2006) discovers relationships from sets of related news articles.

Until recently, most work in RE has been carried out on a per-relation basis. Typically, RE is framed as a binary classification problem: Given a sentence  $S$  and a relation  $R$ , does  $S$  assert  $R$  between two entities in  $S$ ? Representative approaches include (Zelenko et al., 2003) and (Bunescu and Mooney, 2005), which use support-vector machines fitted with language-oriented kernels to classify pairs of entities. Roth and Yih (2004) also described a classification-based framework in which they jointly learn to identify named entities and relations.

Culotta *et al.* (2006) used a CRF for RE, yet their task differs greatly from open extraction. RE was performed from biographical text in which the topic of each document was known. For every entity found in the document, their goal was to predict what relation, if any, it had relative to the page topic, from a set of given relations. Under these restrictions, RE became an instance of entity labeling, where the label assigned to an entity (*e.g.* *Father*) is its relation to the topic of the article.

Others have also found the stacking framework to yield benefits for IE. Freitag (2000) used linear regression to model the relationship between the confidence of several inductive learning algorithms and the probability that a prediction is correct. Over three different document collections, the combined method yielded improvements over the best individual learner for all but one relation. The efficacy of ensemble-based methods for extraction was further investigated by (Sigletos et al., 2005), who experimented with combining the outputs of a rule-based learner, a Hidden Markov Model and a wrapper-induction algorithm in five different domains. Of a

variety ensemble-based methods, stacking proved to consistently outperform the best base-level system, obtaining more precise results at the cost of somewhat lower recall. (Feldman et al., 2005) demonstrated that a hybrid extractor composed of a statistical and knowledge-based models outperform either in isolation.

## 7 Conclusions and Future Work

Our experiments have demonstrated the promise of relation-independent extraction using the Open IE paradigm. We have shown that binary relationships can be categorized using a compact set of lexico-syntactic patterns, and presented O-CRF, a CRF-based Open IE system that can extract different relationships with a precision of 88.3% and a recall of 45.2%<sup>4</sup>. Open IE is essential when the number of relationships of interest is massive or unknown.

Traditional IE is more appropriate for targeted extraction when the number of relations of interest is small and one is willing to incur the cost of acquiring labeled training data. Compared to traditional IE, the recall of our Open IE system is admittedly lower. However, in a targeted extraction scenario, Open IE can still be used to reduce the number of hand-labeled examples. As Table 4 shows, numerous hand-labeled examples (ranging from 50 for one relation to over 3,000 for another) are necessary to match the precision of O-CRF.

In the future, O-CRF’s recall may be improved by enhancements to its ability to locate the various ways in which a given relation is expressed. We also plan to explore the capacity of Open IE to automatically provide labeled training data, when traditional relation extraction is a more appropriate choice.

## Acknowledgments

This research was supported in part by NSF grants IIS-0535284 and IIS-0312988, ONR grant N00014-08-1-0431 as well as gifts from Google, and carried out at the University of Washington’s Turing Center. Doug Downey, Stephen Soderland and Dan Weld provided helpful comments on previous drafts.

<sup>4</sup>The TEXTRUNNER Open IE system now indexes extractions found by O-CRF from millions of Web pages, and is located at <http://www.cs.washington.edu/research/textrunner>

Charles University in Prague  
Malostranské nám. 25, 118 00 Prague 1, Czech Republic  
mirovsky@ufal.mff.cuni.cz

## Abstract

Linguistically annotated treebanks play an essential part in the modern computational linguistics. The more complex the treebanks become, the more sophisticated tools are required for using them, namely for searching in the data. We study linguistic phenomena annotated in the Prague Dependency Treebank 2.0 and create a list of requirements these phenomena set on a search tool, especially on its query language.

## 1 Introduction

Searching in a linguistically annotated treebank is a principal task in the modern computational linguistics. A search tool helps extract useful information from the treebank, in order to study the language, the annotation system or even to search for errors in the annotation.

The more complex the treebank is, the more sophisticated the search tool and its query language needs to be. The Prague Dependency Treebank 2.0 (Hajič et al. 2006) is one of the most advanced manually annotated treebanks. We study mainly the tectogrammatical layer of the Prague Dependency Treebank 2.0 (PDT 2.0), which is by far the most advanced and complex layer in the treebank, and show what requirements on a query language the annotated linguistic phenomena bring. We also add requirements set by lower layers of annotation.

In *section 1* (after this introduction) we mention related works on search languages for various

types of corpora. Afterwards, we very shortly introduce PDT 2.0, just to give a general picture of the principles and complexion of the annotation scheme.

In *section 2* we study the annotation manual for the tectogrammatical layer of PDT 2.0 (t-manual, Mikulová et al. 2006) and collect linguistic phenomena that bring special requirements on the query language. We also study lower layers of annotation and add their requirements.

In *section 3* we summarize the requirements in an extensive list of features required from a search language.

We conclude in *section 4*.

### 1.1 Related Work

In Lai, Bird 2004, the authors name seven linguistic queries they consider important representatives for checking a sufficiency of a query language power. They study several query tools and their query languages and compare them on the basis of their abilities to express these seven queries. In Bird et al. 2005, the authors use a revised set of seven key linguistic queries as a basis for forming a list of three expressive features important for linguistic queries. The features are: immediate precedence, subtree scoping and edge alignment. In Bird et al. 2006, another set of seven linguistic queries is used to show a necessity to enhance XPath (a standard query language for XML, Clark, DeRose 1999) to support linguistic queries.

Cassidy 2002 studies adequacy of XQuery (a search language based on XPath, Boag et al. 1999) for searching in hierarchically annotated data. Re-

quirements on a query language for annotation graphs used in speech recognition is also presented in Bird et al. 2000. A description of linguistic phenomena annotated in the Tiger Treebank, along with an introduction to a search tool TigerSearch, developed especially for this treebank, is given in Brants et al. 2002, nevertheless without a systematic study of the required features.

Laura Kallmeyer (Kallmeyer 2000) studies requirements on a query language based on two examples of complex linguistic phenomena taken from the NEGRA corpus and the Penn Treebank, respectively.

To handle alignment information, Merz and Volk 2005 study requirements on a search tool for parallel treebanks.

All the work mentioned above can be used as an ample source of inspiration, though it cannot be applied directly to PDT 2.0. A thorough study of the PDT 2.0 annotation is needed to form conclusions about requirements on a search tool for this dependency tree-based corpus, consisting of several layers of annotation and having an extremely complex annotation scheme, which we shortly describe in the next subsection.

## 1.2 The Prague Dependency Treebank 2.0

The Prague Dependency Treebank 2.0 is a manually annotated corpus of Czech. The texts are annotated on three layers – morphological, analytical and tectogrammatical.

On the morphological layer, each token of every sentence is annotated with a lemma (attribute `m/lemma`), keeping the base form of the token, and a tag (attribute `m/tag`), which keeps its morphological information.

The analytical layer roughly corresponds to the surface syntax of the sentence; the annotation is a single-rooted dependency tree with labeled nodes. Attribute `a/afun` describes the type of dependency between a dependent node and its governor. The order of the nodes from left to right corresponds exactly to the surface order of tokens in the sentence (attribute `a/ord`).

The tectogrammatical layer captures the linguistic meaning of the sentence in its context. Again, the annotation is a dependency tree with labeled nodes (Hajičová 1998). The correspondence of the nodes to the lower layers is often not 1:1 (Mírovský 2006).

Attribute `functor` describes the dependency between a dependent node and its governor. A tectogrammatical lemma (attribute `t_lemma`) is assigned to every node. 16 grammemes (prefixed `gram`) keep additional annotation (e.g. `gram/verbmod` for verbal modality).

Topic and focus (Hajičová et al. 1998) are marked (attribute `tfa`), together with so-called deep word order reflected by the order of nodes in the annotation (attribute `deepord`).

Coreference relations between nodes of certain category types are captured. Each node has a unique identifier (attribute `id`). Attributes `coref_text.rf` and `coref_gram.rf` contain ids of coreferential nodes of the respective types.

## 2 Phenomena and Requirements

We make a list of linguistic phenomena that are annotated in PDT 2.0 and that determine the necessary features of a query language.

Our work is focused on two structured layers of PDT 2.0 – the analytical layer and the tectogrammatical layer. For using the morphological layer exclusively and directly, a very good search tool Manatee/Bonito (Rychlý 2000) can be used. We intend to access the morphological information only from the higher layers, not directly. Since there is relation 1:1 among nodes on the analytical layer (but for the technical root) and tokens on the morphological layer, the morphological information can be easily merged into the analytical layer – the nodes only get additional attributes.

The tectogrammatical layer is by far the most complex layer in PDT 2.0, therefore we start our analysis with a study of the annotation manual for the tectogrammatical layer (`t-manual`, Mikulová et al. 2006) and focus also on the requirements on accessing lower layers with non-1:1 relation. Afterwards, we add some requirements on a query language set by the annotation of the lower layers – the analytical layer and the morphological layer.

During the studies, we have to keep in mind that we do not only want to search for a phenomenon, but also need to study it, which can be a much more complex task. Therefore, it is not sufficient e.g. to find a predicative complement, which is a trivial task, since attribute `functor` of the complement is set to value `COMPL`. In this particular example, we also need to be able to specify in the

query properties of the node the second dependency of the complement goes to, e.g. that it is an Actor.

A summary of the required features on a query language is given in the subsequent section.

## 2.1 The Tectogrammatical Layer

First, we focus on linguistic phenomena annotated on the tectogrammatical layer. T-manual has more than one thousand pages. Most of the manual describes the annotation of simple phenomena that only require a single-node query or a very simple structured query. We mostly focus on those phenomena that bring a special requirement on the query language.

### 2.1.1 Basic Principles

The basic unit of annotation on the tectogrammatical layer of PDT 2.0 is a sentence.

The representation of the tectogrammatical annotation of a sentence is a rooted dependency tree. It consists of a set of nodes and a set of edges. One of the nodes is marked as a root. Each node is a complex unit consisting of a set of pairs attribute-value (t-manual, page 1). The edges express dependency relations between nodes. The edges do not have their own attributes; attributes that logically belong to edges (e.g. type of dependency) are represented as node-attributes (t-manual, page 2).

It implies the first and most basic requirement on the query language: one result of the search is one sentence along with the tree belonging to it. Also, the query language should be able to express node evaluation and tree dependency among nodes in the most direct way.

### 2.1.2 Valency

Valency of semantic verbs, valency of semantic verbal nouns, valency of semantic nouns that represent the nominal part of a complex predicate and valency of some semantic adverbs are annotated fully in the trees (t-manual, pages 162-3). Since the valency of verbs is the most complete in the annotation and since the requirements on searching for valency frames of nouns are the same as of verbs, we will (for the sake of simplicity in expressions) focus on the verbs only. Every verb meaning is assigned a valency frame. Verbs usually have more than one meaning; each is assigned a separate va-

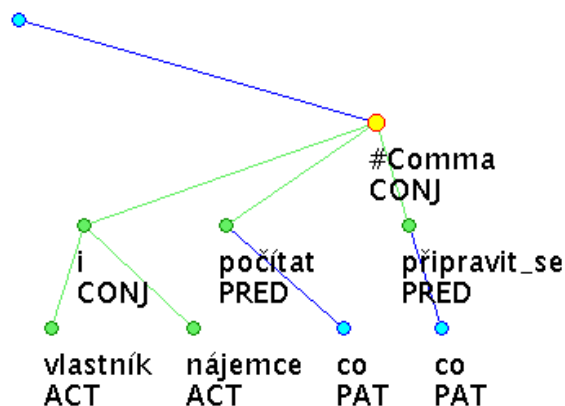

lency frame. Every verb has as many valency frames as it has meanings (t-manual, page 105).

Therefore, the query language has to be able to distinguish valency frames and search for each one of them, at least as long as the valency frames differ in their members and not only in their index. (Two or more identical valency frames may represent different verb meanings (t-manual, page 105).) The required features include a presence of a son, its non-presence, as well as controlling number of sons of a node.

### 2.1.3 Coordination and Apposition

Tree dependency is not always linguistic dependency (t-manual, page 9). Coordination and apposition are examples of such a phenomenon (t-manual, page 282). If a Predicate governs two coordinated Actors, these Actors technically depend on a coordinating node and this coordinating node depends on the Predicate. the query language should be able to skip such a coordinating node. In general, there should be a possibility to skip any type of node.

Skipping a given type of node helps but is not sufficient. The coordinated structure can be more complex, for example the Predicate itself can be coordinated too. Then, the Actors do not even belong to the subtree of any of the Predicates. In the following example, the two Predicates (PRED) are coordinated with conjunction (CONJ), as well as the two Actors (ACT). The linguistic dependencies go from each of the Actors to each of the Predicates but the tree dependencies are quite different:

In Czech: *S čím mohou vlastníci i nájemci počítat, na co by se měli připravit?*

In English: *What can owners and tenants expect, what they should get ready for?*

The query language should therefore be able to express the linguistic dependency directly. The information about the linguistic dependency is annotated in the treebank by the means of references, as well as many other phenomena (see below).

### 2.1.4 Idioms (Phrasemes) etc.

Idioms/phrasemes (idiomatic/phraseologic constructions) are combinations of two or more words with a fixed lexical content, which together constitute one lexical unit with a metaphorical meaning (which cannot be decomposed into meanings of its parts) (t-manual, page 308). Only expressions which are represented by at least two auto-semantic nodes in the tectogrammatical tree are captured as idioms (functor DPHR). One-node (one-auto-semantic-word) idioms are not represented as idioms in the tree. For example, in the combination “chlapec k pohledání” (“a boy to look for”), the prepositional phrase gets functor RSTR, and it is not indicated that it is an idiom.

Secondary prepositions are another example of a linguistic phenomenon that can be easily recognized in the surface form of the sentence but is difficult to find in the tectogrammatical tree.

Therefore, the query language should offer a basic searching in the linear form of the sentence, to allow searching for any idiom or phraseme, regardless of the way it is or is not captured in the tectogrammatical tree. It can even help in a situation when the user does not know how a certain linguistic phenomenon is annotated on the tectogrammatical layer.

### 2.1.5 Complex Predicates

A complex predicate is a multi-word predicate consisting of a semantically empty verb which expresses the grammatical meanings in a sentence, and a noun (frequently denoting an event or a state of affairs) which carries the main lexical meaning of the entire phrase (t-manual, page 345). Searching for a complex predicate is a simple task and does not bring new requirements on the query language. It is valency of complex predicates that requires our attention, especially dual function of a valency modification. The nominal and verbal components of the complex predicate are assigned the appropriate valency frame from the valency lexicon. By means of newly established nodes with `t_lemma` substitutes, those valency modification

positions not present at surface layer are filled. There are problematic cases where the expressed valency modification occurs in the same form in the valency frames of both components of the complex predicate (t-manual, page 362).

To study these special cases of valency, the query language has to offer a possibility to define that a valency member of the verbal part of a complex predicate is at the same time a valency member of the nominal part of the complex predicate, possibly with a different function. The identity of valency members is annotated again by the means of references, which is explained later.

### 2.1.6 Predicative Complement (Dual Dependency)

On the tectogrammatical layer, also cases of the so-called predicative complement are represented. The predicative complement is a non-obligatory free modification (adjunct) which has a dual semantic dependency relation. It simultaneously modifies a noun and a verb (which can be nominalized).

These two dependency relations are represented by different means (t-manual, page 376):

- the dependency on a verb is represented by means of an edge (which means it is represented in the same way like other modifications),
- the dependency on a (semantic) noun is represented by means of attribute `comp.pl.rf`, the value of which is the identifier of the modified noun.

In the following example, the predicative complement (COMPL) has one dependency on a verb (PRED) and another (dual) dependency on a noun (ACT):

In Czech: *Ze světové **recese** vyšly jako jednička Spojené státy.*

In English: *The United States **emerged** from the world **recession** as number one.*

The second form of dependency, represented once again with references (still see below), has to be expressible in the query language.

### 2.1.7 Coreferences

Two types of coreferences are annotated on the tectogrammatical layer:

- grammatical coreference
- textual coreference

The current way of representing coreference uses references (t-manual, page 996).

Let us finally explain what references are. References make use of the fact that every node of every tree has an identifier (the value of attribute `id`), which is unique within PDT 2.0. If coreference, dual dependency, or valency member identity is a link between two nodes (one node referring to another), it is enough to specify the identifier of the referred node in the appropriate attribute of the referring node. Reference types are distinguished by different referring attributes. Individual reference subtypes can be further distinguished by the value of another attribute.

The essential point in references (for the query language) is that at the time of forming a query, the value of the reference is unknown. For example, in the case of dual dependency of predicative complement, we know that the value of attribute `comp1.rf` of the complement must be the same as the value of attribute `id` of the governing noun, but the value itself differs tree from tree and therefore is unknown at the time of creating the query. The query language has to offer a possibility to bind these unknown values.

### 2.1.8 Topic-Focus Articulation

On the tectogrammatical layer, also the topic-focus articulation (TFA) is annotated. TFA annotation comprises two phenomena:

- contextual boundness, which is represented by values of attribute `tfa` for each node of the tectogrammatical tree.
- communicative dynamism, which is represented by the underlying order of nodes.

Annotated trees therefore contain two types of information - on the one hand the value of contextual boundness of a node and its relative ordering with respect to its brother nodes reflects its function within the topic-focus articulation of the sentence, on the other hand the set of all the TFA values in the tree and the relative ordering of subtrees reflect the overall functional perspective of the sentence, and thus enable to distinguish in the sentence the complex categories of topic and focus (however, these are not annotated explicitly) (t-manual, page 1118).

While contextual boundness does not bring any new requirement on the query language, communicative dynamism requires that the relative order of nodes in the tree from left to right can be expressed. The order of nodes is controlled by attribute `deepord`, which contains a non-negative real (usually natural) number that sets the order of the nodes from left to right. Therefore, we will again need to refer to a value of an attribute of another node but this time with relation other than “equal to”.

#### 2.1.8.1 Focus Proper

Focus proper is the most dynamic and communicatively significant contextually non-bound part of the sentence. Focus proper is placed on the rightmost path leading from the effective root of the tectogrammatical tree, even though it is at a different position in the surface structure. The node representing this expression will be placed rightmost in the tectogrammatical tree. If the focus proper is constituted by an expression represented as the effective root of the tectogrammatical tree (i.e. the governing predicate is the focus proper), there is no right path leading from the effective root (t-manual, page 1129).

#### 2.1.8.2 Quasi-Focus

Quasi-focus is constituted by (both contrastive and non-contrastive) contextually bound expressions, on which the focus proper is dependent. The focus proper can immediately depend on the quasi-focus, or it can be a more deeply embedded expression.

In the underlying word order, nodes representing the quasi-focus, although they are contextually bound, are placed to the right from their governing node. Nodes representing the quasi-focus are therefore contextually bound nodes on the rightmost

path in the tectogrammatical tree (t-manual, page 1130).

The ability of the query language to distinguish the rightmost node in the tree and the rightmost path leading from a node is therefore necessary.

### 2.1.8.3 Rhematizers

Rhematizers are expressions whose function is to signal the topic-focus articulation categories in the sentence, namely the communicatively most important categories - the focus and contrastive topic.

The position of rhematizers in the surface word order is quite loose, however they almost always stand right before the expressions they rhematize, i.e. the expressions whose being in the focus or contrastive topic they signal (t-manual, pages 1165-6).

The guidelines for positioning rhematizers in tectogrammatical trees are simple (t-manual, page 1171):

- a rhematizer (i.e. the node representing the rhematizer) is placed as the closest left brother (in the underlying word order) of the first node of the expression that is in its scope.
- if the scope of a rhematizer includes the governing predicate, the rhematizer is placed as the closest left son of the node representing the governing predicate.
- if a rhematizer constitutes the focus proper, it is placed according to the guidelines for the position of the focus proper - i.e. on the rightmost path leading from the effective root of the tectogrammatical tree.

Rhematizers therefore bring a further requirement on the query language – an ability to control the distance between nodes (in the terms of deep word order); at the very least, the query language has to distinguish an immediate brother and relative horizontal position of nodes.

### 2.1.8.4 (Non-)Projectivity

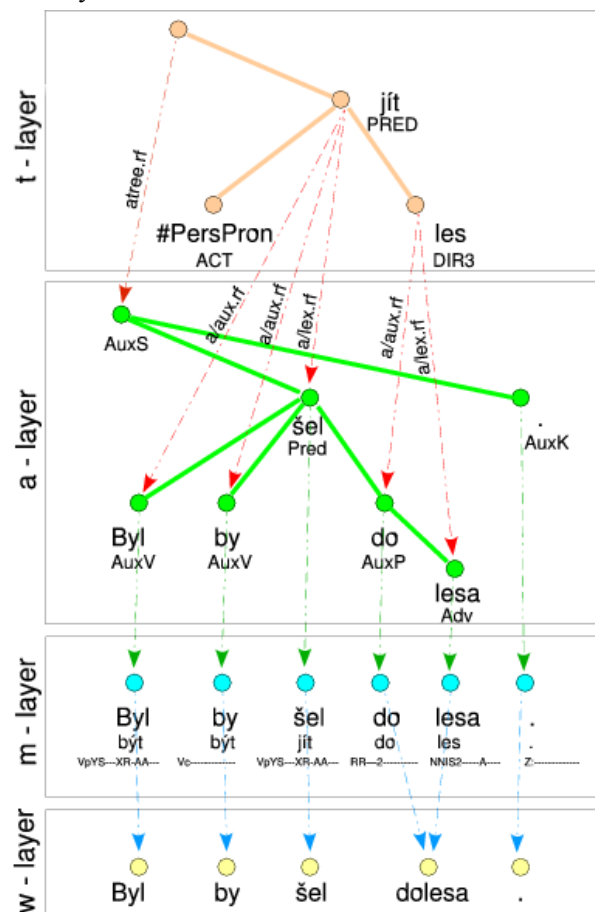

Projectivity of a tree is defined as follows: if two nodes B and C are connected by an edge and C is to the left from B, then all nodes to the right from B and to the left from C are connected with the root via a path that passes through at least one of the nodes B or C. In short: between a father and its son there can only be direct or indirect sons of the father (t-manual, page 1135).

The relative position of a node (node A) and an edge (nodes B, C) that together cause a non-projectivity forms four different configurations: (“B is on the left from C” or “B is on the right from C”) x (“A is on the path from B to the root” or “it is not”). Each of the configurations can be searched for using properties of the language that have been required so far by other linguistic phenomena. Four different queries search for four different configurations.

To be able to search for all configurations in one query, the query language should be able to combine several queries into one multi-query. We do not require that a general logical expression can be set above the single queries. We only require a general OR combination of the single queries.

### 2.1.9 Accessing Lower Layers

Studies of many linguistic phenomena require a multilayer access.

In Czech: *Byl by šel do lesa.*

In English (lit.): *He would have gone to the forest.*

For example, the query “find an example of Patient that is more dynamic than its governing Predicate (with greater `deepord`) but on the surface layer is on the left side from the Predicate” requires information both from the tectogrammatical layer and the analytical layer.

The picture above is taken from PDT 2.0 guide and shows the typical relation among layers of annotation for the sentence (the lowest w-layer is a technical layer containing only the tokenized original data).

The information from the lower layers can be easily compressed into the analytical layer, since there is relation 1:1 among the layers (with some rare exceptions like misprints in the w-layer). The situation between the tectogrammatical layer and the analytical layer is much more complex. Several nodes from the analytical layer may be (and often are) represented by one node on the tectogrammatical layer and new nodes without an analytical counterpart may appear on the tectogrammatical layer. It is necessary that the query language addresses this issue and allows access to the information from the lower layers.

## 2.2 The Analytical and Morphological Layer

The analytical layer is much less complex than the tectogrammatical layer. The basic principles are the same – the representation of the structure of a sentence is rendered in the form of a tree – a connected acyclic directed graph in which no more than one edge leads into a node, and whose nodes are labeled with complex symbols (sets of attributes). The edges are not labeled (in the technical sense). The information logically belonging to an edge is represented in attributes of the depending node. One node is marked as a root.

Here, we focus on linguistic phenomena annotated on the analytical and morphological layer that bring a new requirement on the query language (that has not been set in the studies of the tectogrammatical layer).

### 2.2.1 Morphological Tags

In PDT 2.0, morphological tags are positional. They consist of 15 characters, each representing a certain morphological category, e.g. the first position represents part of speech, the third position represents gender, the fourth position represents number, the fifth position represents case.

The query language has to offer a possibility to specify a part of the tag and leave the rest unspecified. It has to be able to set such conditions on the tag like “this is a noun”, or “this is a plural in fourth case”. Some conditions might include negation or enumeration, like “this is an adjective that is not in fourth case”, or “this is a noun either in third or fourth case”. This is best done with some sort of wild cards. The latter two examples suggest that such a strong tool like regular expressions may be needed.

### 2.2.2 Agreement

There are several cases of agreement in Czech language, like agreement in case, number and gender in attributive adjective phrase, agreement in gender and number between predicate and subject (though it may be complex), or agreement in case in apposition.

To study agreement, the query language has to allow to make a reference to only a part of value of attribute of another node, e.g. to the fifth position of the morphological tag for case.

### 2.2.3 Word Order

Word order is a linguistic phenomenon widely studied on the analytical layer, because it offers a perfect combination of a word order (the same like in the sentence) and syntactic relations between the words. The same technique like with the deep word order on the tectogrammatical layer can be used here. The order of words (tokens) ~ nodes in the analytical tree is controlled by attribute `ord`. Non-projective constructions are much more often and interesting here than on the tectogrammatical layer. Nevertheless, they appear also on the tectogrammatical layer and their contribution to the requirements on the query language has already been mentioned.

The only new requirement on the query language is an ability to measure the horizontal distance between words, to satisfy linguistic queries like “find trees where a preposition and the head of the noun phrase are at least five words apart”.

## 3 Summary of the Features

Here we summarize what features the query language has to have to suit PDT 2.0. We list the features from the previous section and also add some

obvious requirements that have not been mentioned so far but are very useful generally, regardless of a corpus.

### 3.1 Complex Evaluation of a Node

- multiple attributes evaluation (an ability to set values of several attributes at one node)
- alternative values (e.g. to define that `functor` of a node is either a disjunction or a conjunction)
- alternative nodes (alternative evaluation of the whole set of attributes of a node)
- wild cards (regular expressions) in values of attributes (e.g. `m/tag="N...4.*"` defines that the morphological tag of a node is a noun in accusative, regardless of other morphological categories)
- negation (e.g. to express "this node is not Actor")
- relations less than (`<=`) , greater than (`>=`) (for numerical attributes)

### 3.2 Dependencies Between Nodes (Vertical Relations)

- immediate, transitive dependency (existence, non-existence)
- vertical distance (from root, from one another)
- number of sons (zero for lists)

### 3.3 Horizontal Relations

- precedence, immediate precedence, horizontal distance (all both positive, negative)
- secondary edges, secondary dependencies, coreferences, long-range relations

### 3.4 Other Features

- multiple-tree queries (combined with general OR relation)
- skipping a node of a given type (for skipping simple types of coordination, apposition etc.)
- skipping multiple nodes of a given type (e.g. for recognizing the rightmost path)
- references (for matching values of attributes unknown at the time of creating the query)

- accessing several layers of annotation at the same time with non-1:1 relation (for studying relation between layers)
- searching in the surface form of the sentence

## 4 Conclusion

We have studied the Prague Dependency Treebank 2.0 tectogrammatical annotation manual and listed linguistic phenomena that require a special feature from any query tool for this corpus. We have also added several other requirements from the lower layers of annotation. We have summarized these features, along with general corpus-independent features, in a concise list.

## Abstract

This paper presents a comparative evaluation of several state-of-the-art English parsers based on different frameworks. Our approach is to measure the impact of each parser when it is used as a component of an information extraction system that performs protein-protein interaction (PPI) identification in biomedical papers. We evaluate eight parsers (based on dependency parsing, phrase structure parsing, or deep parsing) using five different parse representations. We run a PPI system with several combinations of parser and parse representation, and examine their impact on PPI identification accuracy. Our experiments show that the levels of accuracy obtained with these different parsers are similar, but that accuracy improvements vary when the parsers are re-trained with domain-specific data.

## 1 Introduction

Parsing technologies have improved considerably in the past few years, and high-performance syntactic parsers are no longer limited to PCFG-based frameworks (Charniak, 2000; Klein and Manning, 2003; Charniak and Johnson, 2005; Petrov and Klein, 2007), but also include dependency parsers (McDonald and Pereira, 2006; Nivre and Nilsson, 2005; Sagae and Tsujii, 2007) and deep parsers (Kaplan et al., 2004; Clark and Curran, 2004; Miyao and Tsujii, 2008). However, efforts to perform extensive comparisons of syntactic parsers based on different frameworks have been limited. The most popular method for parser comparison involves the direct measurement of the parser output accuracy in terms of metrics such as bracketing precision and recall, or

dependency accuracy. This assumes the existence of a gold-standard test corpus, such as the Penn Treebank (Marcus et al., 1994). It is difficult to apply this method to compare parsers based on different frameworks, because parse representations are often framework-specific and differ from parser to parser (Ringger et al., 2004). The lack of such comparisons is a serious obstacle for NLP researchers in choosing an appropriate parser for their purposes.

In this paper, we present a comparative evaluation of syntactic parsers and their output representations based on different frameworks: dependency parsing, phrase structure parsing, and deep parsing. Our approach to parser evaluation is to measure accuracy improvement in the task of identifying protein-protein interaction (PPI) information in biomedical papers, by incorporating the output of different parsers as statistical features in a machine learning classifier (Yakushiji et al., 2005; Katrenko and Adriaans, 2006; Erkan et al., 2007; Sætre et al., 2007). PPI identification is a reasonable task for parser evaluation, because it is a typical information extraction (IE) application, and because recent studies have shown the effectiveness of syntactic parsing in this task. Since our evaluation method is applicable to any parser output, and is grounded in a real application, it allows for a fair comparison of syntactic parsers based on different frameworks.

Parser evaluation in PPI extraction also illuminates domain portability. Most state-of-the-art parsers for English were trained with the Wall Street Journal (WSJ) portion of the Penn Treebank, and high accuracy has been reported for WSJ text; however, these parsers rely on lexical information to attain high accuracy, and it has been criticized that these parsers may overfit to WSJ text (Gildea, 2001;

Klein and Manning, 2003). Another issue for discussion is the portability of training methods. When training data in the target domain is available, as is the case with the GENIA Treebank (Kim et al., 2003) for biomedical papers, a parser can be re-trained to adapt to the target domain, and larger accuracy improvements are expected, if the training method is sufficiently general. We will examine these two aspects of domain portability by comparing the original parsers with the retrained parsers.

## 2 Syntactic Parsers and Their Representations

This paper focuses on eight representative parsers that are classified into three parsing frameworks: *dependency parsing*, *phrase structure parsing*, and *deep parsing*. In general, our evaluation methodology can be applied to English parsers based on any framework; however, in this paper, we chose parsers that were originally developed and trained with the Penn Treebank or its variants, since such parsers can be re-trained with GENIA, thus allowing for us to investigate the effect of domain adaptation.

### 2.1 Dependency parsing

Because the shared tasks of CoNLL-2006 and CoNLL-2007 focused on data-driven dependency parsing, it has recently been extensively studied in parsing research. The aim of dependency parsing is to compute a tree structure of a sentence where nodes are words, and edges represent the relations among words. Figure 1 shows a dependency tree for the sentence “IL-8 recognizes and activates CXCR1.” An advantage of dependency parsing is that dependency trees are a reasonable approximation of the semantics of sentences, and are readily usable in NLP applications. Furthermore, the efficiency of popular approaches to dependency parsing compare favorably with those of phrase structure parsing or deep parsing. While a number of approaches have been proposed for dependency parsing, this paper focuses on two typical methods.

**MST** McDonald and Pereira (2006)’s dependency parser,<sup>1</sup> based on the Eisner algorithm for projective dependency parsing (Eisner, 1996) with the second-order factorization.

<sup>1</sup><http://sourceforge.net/projects/mstparser>

Figure 1: CoNLL-X dependency tree

Figure 2: Penn Treebank-style phrase structure tree

**KSDEP** Sagae and Tsujii (2007)’s dependency parser,<sup>2</sup> based on a probabilistic shift-reduce algorithm extended by the pseudo-projective parsing technique (Nivre and Nilsson, 2005).

### 2.2 Phrase structure parsing

Owing largely to the Penn Treebank, the mainstream of data-driven parsing research has been dedicated to the phrase structure parsing. These parsers output Penn Treebank-style phrase structure trees, although function tags and empty categories are stripped off (Figure 2). While most of the state-of-the-art parsers are based on probabilistic CFGs, the parameterization of the probabilistic model of each parser varies. In this work, we chose the following four parsers.

**NO-RERANK** Charniak (2000)’s parser, based on a lexicalized PCFG model of phrase structure trees.<sup>3</sup> The probabilities of CFG rules are parameterized on carefully hand-tuned extensive information such as lexical heads and symbols of ancestor/sibling nodes.

**RERANK** Charniak and Johnson (2005)’s reranking parser. The reranker of this parser receives  $n$ -best<sup>4</sup> parse results from NO-RERANK, and selects the most likely result by using a maximum entropy model with manually engineered features.

**BERKELEY** Berkeley’s parser (Petrov and Klein, 2007).<sup>5</sup> The parameterization of this parser is op-

Figure 3: Predicate argument structure

timized automatically by assigning latent variables to each nonterminal node and estimating the parameters of the latent variables by the EM algorithm (Matsuzaki et al., 2005).

**STANFORD** Stanford’s unlexicalized parser (Klein and Manning, 2003).<sup>6</sup> Unlike NO-RERANK, probabilities are not parameterized on lexical heads.

### 2.3 Deep parsing

Recent research developments have allowed for efficient and robust deep parsing of real-world texts (Kaplan et al., 2004; Clark and Curran, 2004; Miyao and Tsujii, 2008). While deep parsers compute theory-specific syntactic/semantic structures, predicate argument structures (PAS) are often used in parser evaluation and applications. PAS is a graph structure that represents syntactic/semantic relations among words (Figure 3). The concept is therefore similar to CoNLL dependencies, though PAS expresses deeper relations, and may include reentrant structures. In this work, we chose the two versions of the Enju parser (Miyao and Tsujii, 2008).

**ENJU** The HPSG parser that consists of an HPSG grammar extracted from the Penn Treebank, and a maximum entropy model trained with an HPSG treebank derived from the Penn Treebank.<sup>7</sup>

**ENJU-GENIA** The HPSG parser adapted to biomedical texts, by the method of Hara et al. (2007). Because this parser is trained with both WSJ and GENIA, we compare it parsers that are retrained with GENIA (see section 3.3).

## 3 Evaluation Methodology

In our approach to parser evaluation, we measure the accuracy of a PPI extraction system, in which

<sup>6</sup><http://nlp.stanford.edu/software/lex-parser.shtml>

<sup>7</sup><http://www-tsujii.is.s.u-tokyo.ac.jp/enju/>

This study demonstrates that **IL-8** recognizes and activates **CXCR1**, **CXCR2**, and the **Duffy antigen** by distinct mechanisms.

The molar ratio of serum **retinol-binding protein (RBP)** to **transthyretin (TTR)** is not useful to assess vitamin A status during infection in hospitalised children.

Figure 4: Sentences including protein names

ENTITY1(IL-8)  $\xrightarrow{\text{SBJ}}$  recognizes  $\xleftarrow{\text{OBJ}}$  ENTITY2(CXCR1)

Figure 5: Dependency path

the parser output is embedded as statistical features of a machine learning classifier. We run a classifier with features of every possible combination of a parser and a parse representation, by applying conversions between representations when necessary. We also measure the accuracy improvements obtained by parser retraining with GENIA, to examine the domain portability, and to evaluate the effectiveness of domain adaptation.

### 3.1 PPI extraction

PPI extraction is an NLP task to identify protein pairs that are mentioned as interacting in biomedical papers. Because the number of biomedical papers is growing rapidly, it is impossible for biomedical researchers to read all papers relevant to their research; thus, there is an emerging need for reliable IE technologies, such as PPI identification.

Figure 4 shows two sentences that include protein names: the former sentence mentions a protein interaction, while the latter does not. Given a protein pair, PPI extraction is a task of binary classification; for example,  $\langle \text{IL-8}, \text{CXCR1} \rangle$  is a positive example, and  $\langle \text{RBP}, \text{TTR} \rangle$  is a negative example. Recent studies on PPI extraction demonstrated that dependency relations between target proteins are effective features for machine learning classifiers (Kartrenko and Adriaans, 2006; Erkan et al., 2007; Sætre et al., 2007). For the protein pair **IL-8** and **CXCR1** in Figure 4, a dependency parser outputs a dependency tree shown in Figure 1. From this dependency tree, we can extract a dependency path shown in Figure 5, which appears to be a strong clue in knowing that these proteins are mentioned as interacting.

```
(dep_path (SBJ (ENTITY1 recognizes))
  (rOBJ (recognizes ENTITY2)))
```

Figure 6: Tree representation of a dependency path

We follow the PPI extraction method of Sætne et al. (2007), which is based on SVMs with SubSet Tree Kernels (Collins and Duffy, 2002; Moschitti, 2006), while using different parsers and parse representations. Two types of features are incorporated in the classifier. The first is bag-of-words features, which are regarded as a strong baseline for IE systems. Lemmas of words before, between and after the pair of target proteins are included, and the linear kernel is used for these features. These features are commonly included in all of the models. Filtering by a stop-word list is not applied because this setting made the scores higher than Sætne et al. (2007)’s setting. The other type of feature is syntactic features. For dependency-based parse representations, a dependency path is encoded as a flat tree as depicted in Figure 6 (prefix “r” denotes reverse relations). Because a tree kernel measures the similarity of trees by counting common subtrees, it is expected that the system finds effective subsequences of dependency paths. For the PTB representation, we directly encode phrase structure trees.

### 3.2 Conversion of parse representations

It is widely believed that the choice of representation format for parser output may greatly affect the performance of applications, although this has not been extensively investigated. We should therefore evaluate the parser performance in multiple parse representations. In this paper, we create multiple parse representations by converting each parser’s default output into other representations when possible. This experiment can also be considered to be a comparative evaluation of parse representations, thus providing an indication for selecting an appropriate parse representation for similar IE tasks.

Figure 7 shows our scheme for representation conversion. This paper focuses on five representations as described below.

**CoNLL** The dependency tree format used in the 2006 and 2007 CoNLL shared tasks on dependency parsing. This is a representation format supported by several data-driven dependency parsers. This repre-

Figure 7: Conversion of parse representations

Figure 8: Head dependencies

sation is also obtained from Penn Treebank-style trees by applying constituent-to-dependency conversion<sup>8</sup> (Johansson and Nugues, 2007). It should be noted, however, that this conversion cannot work perfectly with automatic parsing, because the conversion program relies on function tags and empty categories of the original Penn Treebank.

**PTB** Penn Treebank-style phrase structure trees without function tags and empty nodes. This is the default output format for phrase structure parsers. We also create this representation by converting ENJU’s output by tree structure matching, although this conversion is not perfect because forms of PTB and ENJU’s output are not necessarily compatible.

**HD** Dependency trees of syntactic heads (Figure 8). This representation is obtained by converting PTB trees. We first determine lexical heads of nonterminal nodes by using Bikel’s implementation of Collins’ head detection algorithm<sup>9</sup> (Bikel, 2004; Collins, 1997). We then convert lexicalized trees into dependencies between lexical heads.

**SD** The Stanford dependency format (Figure 9). This format was originally proposed for extracting dependency relations useful for practical applications (de Marneffe et al., 2006). A program to convert PTB is attached to the Stanford parser. Although the concept looks similar to CoNLL, this representa-

<sup>8</sup><http://nlp.cs.lth.se/pennconverter/>

<sup>9</sup><http://www.cis.upenn.edu/~dbikel/software.html>

html

Figure 9: Stanford dependencies

tion does not necessarily form a tree structure, and is designed to express more fine-grained relations such as apposition. Research groups for biomedical NLP recently adopted this representation for corpus annotation (Pyysalo et al., 2007a) and parser evaluation (Clegg and Shepherd, 2007; Pyysalo et al., 2007b).

**PAS** Predicate-argument structures. This is the default output format for ENJU and ENJU-GENIA.

Although only CoNLL is available for dependency parsers, we can create four representations for the phrase structure parsers, and five for the deep parsers. Dotted arrows in Figure 7 indicate imperfect conversion, in which the conversion inherently introduces errors, and may decrease the accuracy. We should therefore take caution when comparing the results obtained by imperfect conversion. We also measure the accuracy obtained by the ensemble of two parsers/representations. This experiment indicates the differences and overlaps of information conveyed by a parser or a parse representation.

### 3.3 Domain portability and parser retraining

Since the domain of our target text is different from WSJ, our experiments also highlight the domain portability of parsers. We run two versions of each parser in order to investigate the two types of domain portability. First, we run the original parsers trained with WSJ<sup>10</sup> (39832 sentences). The results in this setting indicate the domain portability of the original parsers. Next, we run parsers re-trained with GENIA<sup>11</sup> (8127 sentences), which is a Penn Treebank-style treebank of biomedical paper abstracts. Accuracy improvements in this setting indicate the possibility of domain adaptation, and the portability of the training methods of the parsers. Since the parsers listed in Section 2 have programs for the training

<sup>10</sup>Some of the parser packages include parsing models trained with extended data, but we used the models trained with WSJ section 2-21 of the Penn Treebank.

<sup>11</sup>The domains of GENIA and AImed are not exactly the same, because they are collected independently.

with a Penn Treebank-style treebank, we use those programs as-is. Default parameter settings are used for this parser re-training.

In preliminary experiments, we found that dependency parsers attain higher dependency accuracy when trained only with GENIA. We therefore only input GENIA as the training data for the retraining of dependency parsers. For the other parsers, we input the concatenation of WSJ and GENIA for the retraining, while the reranker of RERANK was not re-trained due to its cost. Since the parsers other than NO-RERANK and RERANK require an external POS tagger, a WSJ-trained POS tagger is used with WSJ-trained parsers, and *geniatagger* (Tsuruoka et al., 2005) is used with GENIA-retrained parsers.

## 4 Experiments

### 4.1 Experiment settings

In the following experiments, we used AImed (Bunescu and Mooney, 2004), which is a popular corpus for the evaluation of PPI extraction systems. The corpus consists of 225 biomedical paper abstracts (1970 sentences), which are sentence-split, tokenized, and annotated with proteins and PPIs. We use gold protein annotations given in the corpus. Multi-word protein names are concatenated and treated as single words. The accuracy is measured by abstract-wise 10-fold cross validation and the one-answer-per-occurrence criterion (Giuliano et al., 2006). A threshold for SVMs is moved to adjust the balance of precision and recall, and the maximum f-scores are reported for each setting.

### 4.2 Comparison of accuracy improvements

Tables 1 and 2 show the accuracy obtained by using the output of each parser in each parse representation. The row “baseline” indicates the accuracy obtained with bag-of-words features. Table 3 shows the time for parsing the entire AImed corpus, and Table 4 shows the time required for 10-fold cross validation with GENIA-retrained parsers.

When using the original WSJ-trained parsers (Table 1), all parsers achieved almost the same level of accuracy — a significantly better result than the baseline. To the extent of our knowledge, this is the first result that proves that dependency parsing, phrase structure parsing, and deep parsing perform

Table 4: Evaluation time (sec.)

equally well in a real application. Among these parsers, RERANK performed slightly better than the other parsers, although the difference in the f-score is small, while it requires much higher parsing cost.

When the parsers are retrained with GENIA (Table 2), the accuracy increases significantly, demonstrating that the WSJ-trained parsers are not sufficiently domain-independent, and that domain adaptation is effective. It is an important observation that the improvements by domain adaptation are larger than the differences among the parsers in the previous experiment. Nevertheless, not all parsers had their performance improved upon retraining. Parser

retraining yielded only slight improvements for RERANK, BERKELEY, and STANFORD, while larger improvements were observed for MST, KSDEP, NO-RERANK, and ENJU. Such results indicate the differences in the portability of training methods. A large improvement from ENJU to ENJU-GENIA shows the effectiveness of the specifically designed domain adaptation method, suggesting that the other parsers might also benefit from more sophisticated approaches for domain adaptation.

While the accuracy level of PPI extraction is the similar for the different parsers, parsing speed

		RERANK			ENJU

	HD						57.1 (+0.5)	58.1 (+0.9)
	SD							58.3 (+1.1)

Table 5: Results of parser/representation ensemble (f-score)

differs significantly. The dependency parsers are much faster than the other parsers, while the phrase structure parsers are relatively slower, and the deep parsers are in between. It is noteworthy that the dependency parsers achieved comparable accuracy with the other parsers, while they are more efficient.

The experimental results also demonstrate that PTB is significantly worse than the other representations with respect to cost for training/testing and contributions to accuracy improvements. The conversion from PTB to dependency-based representations is therefore desirable for this task, although it is possible that better results might be obtained with PTB if a different feature extraction mechanism is used. Dependency-based representations are competitive, while CoNLL seems superior to HD and SD in spite of the imperfect conversion from PTB to CoNLL. This might be a reason for the high performances of the dependency parsers that directly compute CoNLL dependencies. The results for ENJU-CoNLL and ENJU-PAS show that PAS contributes to a larger accuracy improvement, although this does not necessarily mean the superiority of PAS, because two imperfect conversions, i.e., PAS-to-PTB and PTB-to-CoNLL, are applied for creating CoNLL.

### 4.3 Parser ensemble results

Table 5 shows the accuracy obtained with ensembles of two parsers/representations (except the PTB format). Bracketed figures denote improvements from the accuracy with a single parser/representation. The results show that the task accuracy significantly improves by parser/representation ensemble. Interestingly, the accuracy improvements are observed even for ensembles of different representations from the same parser. This indicates that a single parse representation is insufficient for expressing the true

potential of a parser. Effectiveness of the parser ensemble is also attested by the fact that it resulted in larger improvements. Further investigation of the sources of these improvements will illustrate the advantages and disadvantages of these parsers and representations, leading us to better parsing models and a better design for parse representations.

### 4.4 Comparison with previous results on PPI extraction

PPI extraction experiments on AImed have been reported repeatedly, although the figures cannot be compared directly because of the differences in data preprocessing and the number of target protein pairs (Sætre et al., 2007). Table 6 compares our best result with previously reported accuracy figures. Giuliano et al. (2006) and Mitsumori et al. (2006) do not rely on syntactic parsing, while the former applied SVMs with kernels on surface strings and the latter is similar to our baseline method. Bunescu and Mooney (2005) applied SVMs with subsequence kernels to the same task, although they provided only a precision-recall graph, and its f-score is around 50. Since we did not run experiments on protein-pair-wise cross validation, our system cannot be compared directly to the results reported by Erkan et al. (2007) and Katrenko and Adriaans

(2006), while Sætne et al. (2007) presented better results than theirs in the same evaluation criterion.

## 5 Related Work

Though the evaluation of syntactic parsers has been a major concern in the parsing community, and a couple of works have recently presented the comparison of parsers based on different frameworks, their methods were based on the comparison of the parsing accuracy in terms of a certain intermediate parse representation (Ringger et al., 2004; Kaplan et al., 2004; Briscoe and Carroll, 2006; Clark and Curran, 2007; Miyao et al., 2007; Clegg and Shepherd, 2007; Pyysalo et al., 2007b; Pyysalo et al., 2007a; Sagae et al., 2008). Such evaluation requires gold standard data in an intermediate representation. However, it has been argued that the conversion of parsing results into an intermediate representation is difficult and far from perfect.

The relationship between parsing accuracy and task accuracy has been obscure for many years. Quirk and Corston-Oliver (2006) investigated the impact of parsing accuracy on statistical MT. However, this work was only concerned with a single dependency parser, and did not focus on parsers based on different frameworks.

## 6 Conclusion and Future Work

We have presented our attempts to evaluate syntactic parsers and their representations that are based on different frameworks; dependency parsing, phrase structure parsing, or deep parsing. The basic idea is to measure the accuracy improvements of the PPI extraction task by incorporating the parser output as statistical features of a machine learning classifier. Experiments showed that state-of-the-art parsers attain accuracy levels that are on par with each other, while parsing speed differs significantly. We also found that accuracy improvements vary when parsers are retrained with domain-specific data, indicating the importance of domain adaptation and the differences in the portability of parser training methods.

Although we restricted ourselves to parsers trainable with Penn Treebank-style treebanks, our methodology can be applied to any English parsers. Candidates include RASP (Briscoe and Carroll,

2006), the C&C parser (Clark and Curran, 2004), the XLE parser (Kaplan et al., 2004), MINIPAR (Lin, 1998), and Link Parser (Sleator and Temperley, 1993; Pyysalo et al., 2006), but the domain adaptation of these parsers is not straightforward. It is also possible to evaluate unsupervised parsers, which is attractive since evaluation of such parsers with gold-standard data is extremely problematic.

A major drawback of our methodology is that the evaluation is indirect and the results depend on a selected task and its settings. This indicates that different results might be obtained with other tasks. Hence, we cannot conclude the superiority of parsers/representations only with our results. In order to obtain general ideas on parser performance, experiments on other tasks are indispensable.

# MAXSIM: A Maximum Similarity Metric for Machine Translation Evaluation

Yee Seng Chan and Hwee Tou Ng

Department of Computer Science

National University of Singapore

Law Link, Singapore 117590

{chanys, nght}@comp.nus.edu.sg

## Abstract

We propose an automatic machine translation (MT) evaluation metric that calculates a similarity score (based on precision and recall) of a pair of sentences. Unlike most metrics, we compute a similarity score between items across the two sentences. We then find a maximum weight matching between the items such that each item in one sentence is mapped to at most one item in the other sentence. This general framework allows us to use arbitrary similarity functions between items, and to incorporate different information in our comparison, such as n-grams, dependency relations, etc. When evaluated on data from the ACL-07 MT workshop, our proposed metric achieves higher correlation with human judgements than all 11 automatic MT evaluation metrics that were evaluated during the workshop.

## 1 Introduction

In recent years, machine translation (MT) research has made much progress, which includes the introduction of automatic metrics for MT evaluation. Since human evaluation of MT output is time consuming and expensive, having a robust and accurate automatic MT evaluation metric that correlates well with human judgement is invaluable.

Among all the automatic MT evaluation metrics, BLEU (Papineni et al., 2002) is the most widely used. Although BLEU has played a crucial role in the progress of MT research, it is becoming evident that BLEU does not correlate with human judgement

well enough, and suffers from several other deficiencies such as the lack of an intuitive interpretation of its scores.

During the recent ACL-07 workshop on statistical MT (Callison-Burch et al., 2007), a total of 11 automatic MT evaluation metrics were evaluated for correlation with human judgement. The results show that, as compared to BLEU, several recently proposed metrics such as Semantic-role overlap (Gimenez and Marquez, 2007), ParaEval-recall (Zhou et al., 2006), and METEOR (Banerjee and Lavie, 2005) achieve higher correlation.

In this paper, we propose a new automatic MT evaluation metric, MAXSIM, that compares a pair of system-reference sentences by extracting n-grams and dependency relations. Recognizing that different concepts can be expressed in a variety of ways, we allow matching across synonyms and also compute a score between two matching items (such as between two n-grams or between two dependency relations), which indicates their degree of similarity with each other.

Having weighted matches between items means that there could be many possible ways to match, or link items from a system translation sentence to a reference translation sentence. To match each system item to at most one reference item, we model the items in the sentence pair as nodes in a bipartite graph and use the Kuhn-Munkres algorithm (Kuhn, 1955; Munkres, 1957) to find a *maximum* weight matching (or alignment) between the items in polynomial time. The weights (from the edges) of the resulting graph will then be added to determine the final similarity score between the pair of sentences.

Although a maximum weight bipartite graph was also used in the recent work of (Taskar et al., 2005), their focus was on learning supervised models for single word alignment between sentences from a source and target language.

The contributions of this paper are as follows. Current metrics (such as BLEU, METEOR, Semantic-role overlap, ParaEval-recall, etc.) do not assign different weights to their matches: either two items match, or they don't. Also, metrics such as METEOR determine an alignment between the items of a sentence pair by using heuristics such as the least number of matching crosses. In contrast, we propose weighting different matches differently, and then obtain an optimal set of matches, or alignments, by using a maximum weight matching framework. We note that this framework is not used by any of the 11 automatic MT metrics in the ACL-07 MT workshop. Also, this framework allows for defining arbitrary similarity functions between two matching items, and we could match arbitrary concepts (such as dependency relations) gathered from a sentence pair. In contrast, most other metrics (notably BLEU) limit themselves to matching based only on the surface form of words. Finally, when evaluated on the datasets of the recent ACL-07 MT workshop (Callison-Burch et al., 2007), our proposed metric achieves higher correlation with human judgements than all of the 11 automatic MT evaluation metrics evaluated during the workshop.

In the next section, we describe several existing metrics. In Section 3, we discuss issues to consider when designing a metric. In Section 4, we describe our proposed metric. In Section 5, we present our experimental results. Finally, we outline future work in Section 6, before concluding in Section 7.

## 2 Automatic Evaluation Metrics

In this section, we describe BLEU, and the three metrics which achieved higher correlation results than BLEU in the recent ACL-07 MT workshop.

### 2.1 BLEU

BLEU (Papineni et al., 2002) is essentially a precision-based metric and is currently the standard metric for automatic evaluation of MT performance. To score a system translation, BLEU tabulates the

number of n-gram matches of the system translation against one or more reference translations. Generally, more n-gram matches result in a higher BLEU score.

When determining the matches to calculate precision, BLEU uses a *modified*, or *clipped* n-gram precision. With this, an n-gram (from both the system and reference translation) is considered to be exhausted or used after participating in a match. Hence, each system n-gram is "clipped" by the maximum number of times it appears in any reference translation.

To prevent short system translations from receiving too high a score and to compensate for its lack of a recall component, BLEU incorporates a brevity penalty. This penalizes the score of a system if the length of its entire translation output is shorter than the length of the reference text.

### 2.2 Semantic Roles

(Gimenez and Marquez, 2007) proposed using deeper linguistic information to evaluate MT performance. For evaluation in the ACL-07 MT workshop, the authors used the metric which they termed as  $SR-O_r-^*1$ . This metric first counts the number of lexical overlaps  $SR-O_r-t$  for all the different semantic roles  $t$  that are found in the system and reference translation sentence. A uniform average of the counts is then taken as the score for the sentence pair. In their work, the different semantic roles  $t$  they considered include the various core and adjunct arguments as defined in the PropBank project (Palmer et al., 2005). For instance,  $SR-O_r-A0$  refers to the number of lexical overlaps between the  $A0$  arguments. To extract semantic roles from a sentence, several processes such as lemmatization, part-of-speech tagging, base phrase chunking, named entity tagging, and finally semantic role tagging need to be performed.

### 2.3 ParaEval

The ParaEval metric (Zhou et al., 2006) uses a large collection of paraphrases, automatically extracted from parallel corpora, to evaluate MT performance. To compare a pair of sentences, ParaEval first locates paraphrase matches between the two

<sup>1</sup>Verified through personal communication as this is not evident in their paper.

sentences. Then, unigram matching is performed on the remaining words that are not matched using paraphrases. Based on the matches, ParaEval will then elect to use either unigram precision or unigram recall as its score for the sentence pair. In the ACL-07 MT workshop, ParaEval based on recall (ParaEval-recall) achieves good correlation with human judgements.

## 2.4 METEOR

Given a pair of strings to compare (a system translation and a reference translation), METEOR (Banerjee and Lavie, 2005) first creates a word alignment between the two strings. Based on the number of word or unigram matches and the amount of string fragmentation represented by the alignment, METEOR calculates a score for the pair of strings.

In aligning the unigrams, each unigram in one string is mapped, or linked, to at most one unigram in the other string. These word alignments are created incrementally through a series of stages, where each stage only adds alignments between unigrams which have not been matched in previous stages. At each stage, if there are multiple different alignments, then the alignment with the most number of mappings is selected. If there is a tie, then the alignment with the least number of unigram mapping crosses is selected.

The three stages of “exact”, “porter stem”, and “WN synonymy” are usually applied in sequence to create alignments. The “exact” stage maps unigrams if they have the same surface form. The “porter stem” stage then considers the remaining unmapped unigrams and maps them if they are the same after applying the Porter stemmer. Finally, the “WN synonymy” stage considers all remaining unigrams and maps two unigrams if they are synonyms in the WordNet sense inventory (Miller, 1990).

Once the final alignment has been produced, unigram precision  $P$  (number of unigram matches  $m$  divided by the total number of system unigrams) and unigram recall  $R$  ( $m$  divided by the total number of reference unigrams) are calculated and combined into a single parameterized harmonic mean (Rijsbergen, 1979):

$$F_{mean} = \frac{P \cdot R}{\alpha P + (1 - \alpha)R} \quad (1)$$

To account for longer matches and the amount of fragmentation represented by the alignment, METEOR groups the matched unigrams into as few *chunks* as possible and imposes a penalty based on the number of chunks. The METEOR score for a pair of sentences is:

$$score = \left[ 1 - \gamma \left( \frac{\text{no. of chunks}}{m} \right)^\beta \right] F_{mean}$$

where  $\gamma \left( \frac{\text{no. of chunks}}{m} \right)^\beta$  represents the fragmentation penalty of the alignment. Note that METEOR consists of three parameters that need to be optimized based on experimentation:  $\alpha$ ,  $\beta$ , and  $\gamma$ .

## 3 Metric Design Considerations

We first review some aspects of existing metrics and highlight issues that should be considered when designing an MT evaluation metric.

- **Intuitive interpretation:** To compensate for the lack of recall, BLEU incorporates a brevity penalty. This, however, prevents an intuitive interpretation of its scores. To address this, standard measures like precision and recall could be used, as in some previous research (Banerjee and Lavie, 2005; Melamed et al., 2003).
- **Allowing for variation:** BLEU only counts exact word matches. Languages, however, often allow a great deal of variety in vocabulary and in the ways concepts are expressed. Hence, using information such as synonyms or dependency relations could potentially address the issue better.
- **Matches should be weighted:** Current metrics either match, or don’t match a pair of items. We note, however, that matches between items (such as words, n-grams, etc.) should be weighted according to their *degree* of similarity.

## 4 The Maximum Similarity Metric

We now describe our proposed metric, Maximum Similarity (MAXSIM), which is based on precision and recall, allows for synonyms, and weights the matches found.

Given a pair of English sentences to be compared (a system translation against a reference translation), we perform tokenization<sup>2</sup>, lemmatization using WordNet<sup>3</sup>, and part-of-speech (POS) tagging with the MXPOST tagger (Ratnaparkhi, 1996). Next, we remove all non-alphanumeric tokens. Then, we match the unigrams in the system translation to the unigrams in the reference translation. Based on the matches, we calculate the recall and precision, which we then combine into a single  $F_{mean}$  unigram score using Equation 1. Similarly, we also match the bigrams and trigrams of the sentence pair and calculate their corresponding  $F_{mean}$  scores. To obtain a single similarity score  $score_s$  for this sentence pair  $s$ , we simply average the three  $F_{mean}$  scores. Then, to obtain a single similarity score  $sim-score$  for the entire system corpus, we repeat this process of calculating a  $score_s$  for each system-reference sentence pair  $s$ , and compute the average over all  $|S|$  sentence pairs:

$$sim-score = \frac{1}{|S|} \sum_{s=1}^{|S|} \left[ \frac{1}{N} \sum_{n=1}^N F_{mean_{s,n}} \right]$$

where in our experiments, we set  $N=3$ , representing calculation of unigram, bigram, and trigram scores. If we are given access to multiple references, we calculate an individual  $sim-score$  between the system corpus and *each* reference corpus, and then average the scores obtained.

#### 4.1 Using N-gram Information

In this subsection, we describe in detail how we match the n-grams of a system-reference sentence pair.

**Lemma and POS match** Representing each n-gram by its sequence of lemma and POS-tag pairs, we first try to perform an exact match in both lemma and POS-tag. In all our n-gram matching, each n-gram in the system translation can only match at most *one* n-gram in the reference translation.

Representing each unigram ( $l_i p_i$ ) at position  $i$  by its lemma  $l_i$  and POS-tag  $p_i$ , we count the number  $match_{uni}$  of system-reference unigram pairs where both their lemma and POS-tag match. To find matching pairs, we proceed in a left-to-right fashion

Figure 1: Bipartite matching.

(in both strings). We first compare the first system unigram to the first reference unigram, then to the second reference unigram, and so on until we find a match. If there is a match, we increment  $match_{uni}$  by 1 and remove this pair of system-reference unigrams from further consideration (removed items will not be matched again subsequently). Then, we move on to the second system unigram and try to match it against the reference unigrams, once again proceeding in a left-to-right fashion. We continue this process until we reach the last system unigram.

To determine the number  $match_{bi}$  of bigram matches, a system bigram ( $l_{s_i} p_{s_i}, l_{s_{i+1}} p_{s_{i+1}}$ ) matches a reference bigram ( $l_{r_i} p_{r_i}, l_{r_{i+1}} p_{r_{i+1}}$ ) if  $l_{s_i} = l_{r_i}$ ,  $p_{s_i} = p_{r_i}$ ,  $l_{s_{i+1}} = l_{r_{i+1}}$ , and  $p_{s_{i+1}} = p_{r_{i+1}}$ . For trigrams, we similarly determine  $match_{tri}$  by counting the number of trigram matches.

**Lemma match** For the remaining set of n-grams that are not yet matched, we now relax our matching criteria by allowing a match if their corresponding lemmas match. That is, a system unigram ( $l_{s_i} p_{s_i}$ ) matches a reference unigram ( $l_{r_i} p_{r_i}$ ) if  $l_{s_i} = l_{r_i}$ . In the case of bigrams, the matching conditions are  $l_{s_i} = l_{r_i}$  and  $l_{s_{i+1}} = l_{r_{i+1}}$ . The conditions for trigrams are similar. Once again, we find matches in a left-to-right fashion. We add the number of unigram, bigram, and trigram matches found during this phase to  $match_{uni}$ ,  $match_{bi}$ , and  $match_{tri}$  respectively.

**Bipartite graph matching** For the remaining n-grams that are not matched so far, we try to match them by constructing bipartite graphs. During this phase, we will construct three bipartite graphs, one

<sup>2</sup><http://www.cis.upenn.edu/~treebank/tokenizer.sed>

<sup>3</sup><http://wordnet.princeton.edu/man/morph.3WN>

each for the remaining set of unigrams, bigrams, and trigrams.

Using bigrams to illustrate, we construct a weighted complete bipartite graph, where each edge  $e$  connecting a pair of system-reference bigrams has a weight  $w(e)$ , indicating the degree of similarity between the bigrams connected. Note that, without loss of generality, if the number of system nodes and reference nodes (bigrams) are not the same, we can simply add dummy nodes with connecting edges of weight 0 to obtain a complete bipartite graph with equal number of nodes on both sides.

In an  $n$ -gram bipartite graph, the similarity score, or the weight  $w(e)$  of the edge  $e$  connecting a system  $n$ -gram  $(l_{s_1}p_{s_1}, \dots, l_{s_n}p_{s_n})$  and a reference  $n$ -gram  $(l_{r_1}p_{r_1}, \dots, l_{r_n}p_{r_n})$  is calculated as follows:

$$S_i = \frac{I(p_{s_i}, p_{r_i}) + \text{Syn}(l_{s_i}, l_{r_i})}{2}$$

$$w(e) = \frac{1}{n} \sum_{i=1}^n S_i$$

where  $I(p_{s_i}, p_{r_i})$  evaluates to 1 if  $p_{s_i} = p_{r_i}$ , and 0 otherwise. The function  $\text{Syn}(l_{s_i}, l_{r_i})$  checks whether  $l_{s_i}$  is a synonym of  $l_{r_i}$ . To determine this, we first obtain the set  $WN_{\text{syn}}(l_{s_i})$  of WordNet synonyms for  $l_{s_i}$  and the set  $WN_{\text{syn}}(l_{r_i})$  of WordNet synonyms for  $l_{r_i}$ . Then,

$$\text{Syn}(l_{s_i}, l_{r_i}) = \begin{cases} 1, & WN_{\text{syn}}(l_{s_i}) \cap WN_{\text{syn}}(l_{r_i}) \\ & \neq \emptyset \\ 0, & \text{otherwise} \end{cases}$$

In gathering the set  $WN_{\text{syn}}$  for a word, we gather all the synonyms for all its senses and do not restrict to a particular POS category. Further, if we are comparing bigrams or trigrams, we impose an additional condition:  $S_i \neq 0$ , for  $1 \leq i \leq n$ , else we will set  $w(e) = 0$ . This captures the intuition that in matching a system  $n$ -gram against a reference  $n$ -gram, where  $n > 1$ , we require each system token to have at least some degree of similarity with the corresponding reference token.

In the top half of Figure 1, we show an example of a complete bipartite graph, constructed for a set of three system bigrams  $(s_1, s_2, s_3)$  and three reference bigrams  $(r_1, r_2, r_3)$ , and the weight of the connecting edge between two bigrams represents their degree of similarity.

Next, we aim to find a *maximum* weight matching (or alignment) between the bigrams such that each system (reference) bigram is connected to exactly one reference (system) bigram. This *maximum weighted bipartite matching* problem can be solved in  $O(n^3)$  time (where  $n$  refers to the number of nodes, or vertices in the graph) using the Kuhn-Munkres algorithm (Kuhn, 1955; Munkres, 1957). The bottom half of Figure 1 shows the resulting maximum weighted bipartite graph, where the alignment represents the maximum weight matching, out of all possible alignments.

Once we have solved and obtained a maximum weight matching  $M$  for the bigram bipartite graph, we sum up the weights of the edges to obtain the weight of the matching  $M$ :  $w(M) = \sum_{e \in M} w(e)$ , and add  $w(M)$  to  $match_{bi}$ . From the unigram and trigram bipartite graphs, we similarly calculate their respective  $w(M)$  and add to the corresponding  $match_{uni}$  and  $match_{tri}$ .

Based on  $match_{uni}$ ,  $match_{bi}$ , and  $match_{tri}$ , we calculate their corresponding precision  $P$  and recall  $R$ , from which we obtain their respective  $F_{mean}$  scores via Equation 1. Using bigrams for illustration, we calculate its  $P$  and  $R$  as:

$$P = \frac{match_{bi}}{\text{no. of bigrams in system translation}}$$

$$R = \frac{match_{bi}}{\text{no. of bigrams in reference translation}}$$

## 4.2 Dependency Relations

Besides matching a pair of system-reference sentences based on the surface form of words, previous work such as (Gimenez and Marquez, 2007) and (Rajman and Hartley, 2002) had shown that deeper linguistic knowledge such as semantic roles and syntax can be usefully exploited.

In the previous subsection, we describe our method of using bipartite graphs for matching of  $n$ -grams found in a sentence pair. This use of bipartite graphs, however, is a very general framework to obtain an optimal alignment of the corresponding ‘‘information items’’ contained within a sentence pair. Hence, besides matching based on  $n$ -gram strings, we can also match other ‘‘information items’’, such as dependency relations.

Metric	Adequacy	Fluency	Rank	Constituent	Average
MAXSIM <sub>n+d</sub>	0.780	0.827	0.875	0.760	0.811
MAXSIM <sub>n</sub>	<b>0.804</b>	<b>0.845</b>	<b>0.893</b>	0.766	<b>0.827</b>
Semantic-role	0.774	0.839	0.804	0.742	0.790
ParaEval-recall	0.712	0.742	0.769	<b>0.798</b>	0.755
METEOR	0.701	0.719	0.746	0.670	0.709
BLEU	0.690	0.722	0.672	0.603	0.672

Table 1: Overall correlations on the Europarl and News Commentary datasets. The ‘Semantic-role overlap’ metric is abbreviated as ‘Semantic-role’. Note that each figure above represents 6 translation tasks: the Europarl and News Commentary datasets each with 3 language pairs (German-English, Spanish-English, French-English).

In our work, we train the MSTParser<sup>4</sup> (McDonald et al., 2005) on the Penn Treebank Wall Street Journal (WSJ) corpus, and use it to extract dependency relations from a sentence. Currently, we focus on extracting only two relations: *subject* and *object*. For each relation ( $ch, dp, pa$ ) extracted, we note the child lemma  $ch$  of the relation (often a noun), the relation type  $dp$  (either *subject* or *object*), and the parent lemma  $pa$  of the relation (often a verb). Then, using the system relations and reference relations extracted from a system-reference sentence pair, we similarly construct a bipartite graph, where each node is a relation ( $ch, dp, pa$ ). We define the weight  $w(e)$  of an edge  $e$  between a system relation ( $ch_s, dp_s, pa_s$ ) and a reference relation ( $ch_r, dp_r, pa_r$ ) as follows:

$$\frac{Syn(ch_s, ch_r) + I(dp_s, dp_r) + Syn(pa_s, pa_r)}{3}$$

where functions  $I$  and  $Syn$  are defined as in the previous subsection. Also,  $w(e)$  is non-zero only if  $dp_s = dp_r$ . After solving for the maximum weight matching  $M$ , we divide  $w(M)$  by the number of system relations extracted to obtain a precision score  $P$ , and divide  $w(M)$  by the number of reference relations extracted to obtain a recall score  $R$ .  $P$  and  $R$  are then similarly combined into a  $F_{mean}$  score for the sentence pair. To compute the similarity score when incorporating dependency relations, we average the  $F_{mean}$  scores for unigrams, bigrams, trigrams, and dependency relations.

## 5 Results

To evaluate our metric, we conduct experiments on datasets from the ACL-07 MT workshop and NIST

MT 2003 evaluation exercise.

### 5.1 ACL-07 MT Workshop

The ACL-07 MT workshop evaluated the translation quality of MT systems on various translation tasks, and also measured the correlation (with human judgement) of 11 automatic MT evaluation metrics. The workshop used a Europarl dataset and a News Commentary dataset, where each dataset consisted of English sentences (2,000 English sentences for Europarl and 2,007 English sentences for News Commentary) and their translations in various languages. As part of the workshop, correlations of the automatic metrics were measured for the tasks

of translating German, Spanish, and French into English. Hence, we will similarly measure the correlation of MAXSIM on these tasks.

### 5.1.1 Evaluation Criteria

For human evaluation of the MT submissions, four different criteria were used in the workshop: **Adequacy** (how much of the original meaning is expressed in a system translation), **Fluency** (the translation’s fluency), **Rank** (different translations of a single source sentence are compared and ranked from best to worst), and **Constituent** (some constituents from the parse tree of the source sentence are translated, and human judges have to rank these translations).

During the workshop, Kappa values measured for inter- and intra-annotator agreement for *rank* and *constituent* are substantially higher than those for *adequacy* and *fluency*, indicating that *rank* and *constituent* are more reliable criteria for MT evaluation.

### 5.1.2 Correlation Results

We follow the ACL-07 MT workshop process of converting the raw scores assigned by an automatic metric to ranks and then using the Spearman’s rank correlation coefficient to measure correlation.

During the workshop, only three automatic metrics (Semantic-role overlap, ParaEval-recall, and METEOR) achieve higher correlation than BLEU. We gather the correlation results of these metrics from the workshop paper (Callison-Burch et al., 2007), and show in Table 1 the overall correlations of these metrics over the Europarl and News Commentary datasets. In the table, MAXSIM<sub>n</sub> represents using only n-gram information (Section 4.1) for our metric, while MAXSIM<sub>n+d</sub> represents using both n-gram and dependency information. We also show the breakdown of the correlation results into the Europarl dataset (Table 2) and the News Commentary dataset (Table 3). In all our results for MAXSIM in this paper, we follow METEOR and use  $\alpha=0.9$  (weighing recall more than precision) in our calculation of  $F_{mean}$  via Equation 1, unless otherwise stated.

The results in Table 1 show that MAXSIM<sub>n</sub> and MAXSIM<sub>n+d</sub> achieve overall average (over the four criteria) correlations of 0.827 and 0.811 respectively. Note that these results are substantially

Metric	Adq	Flu	Avg
MAXSIM <sub>n+d</sub>	0.943	0.886	0.915
MAXSIM <sub>n</sub>	0.829	0.771	0.800
METEOR (optimized)	1.000	0.943	0.972
METEOR	0.943	0.886	0.915
BLEU	0.657	0.543	0.600

Table 4: Correlations on the NIST MT 2003 dataset.

higher than BLEU, and in particular higher than the *best* performing *Semantic-role overlap* metric in the ACL-07 MT workshop. Also, Semantic-role overlap requires more processing steps (such as base phrase chunking, named entity tagging, etc.) than MAXSIM. For future work, we could experiment with incorporating semantic-role information into our current framework. We note that the ParaEval-recall metric achieves higher correlation on the *constituent* criterion, which might be related to the fact that both ParaEval-recall and the *constituent* criterion are based on phrases: ParaEval-recall tries to match phrases, and the *constituent* criterion is based on judging translations of phrases.

## 5.2 NIST MT 2003 Dataset

We also conduct experiments on the test data (LDC2006T04) of NIST MT 2003 Chinese-English translation task. For this dataset, human judgements are available on *adequacy* and *fluency* for six system submissions, and there are four English reference translation texts.

Since implementations of the BLEU and METEOR metrics are publicly available, we score the system submissions using BLEU (version 11b with its default settings), METEOR, and MAXSIM, showing the resulting correlations in Table 4. For METEOR, when used with its originally proposed parameter values of ( $\alpha=0.9$ ,  $\beta=3.0$ ,  $\gamma=0.5$ ), which the METEOR researchers mentioned were based on some early experimental work (Banerjee and Lavie, 2005), we obtain an average correlation value of 0.915, as shown in the row “METEOR”. In the recent work of (Lavie and Agarwal, 2007), the values of these parameters were tuned to be ( $\alpha=0.81$ ,  $\beta=0.83$ ,  $\gamma=0.28$ ), based on experiments on the NIST 2003 and 2004 Arabic-English evaluation datasets. When METEOR was run with these new parameter values, it returned an average correlation value of

0.972, as shown in the row “METEOR (optimized)”.

MAXSIM using only n-gram information (MAXSIM<sub>n</sub>) gives an average correlation value of 0.800, while adding dependency information (MAXSIM<sub>n+d</sub>) improves the correlation value to 0.915. Note that so far, the parameters of MAXSIM are not optimized and we simply perform uniform averaging of the different n-grams and dependency scores. Under this setting, the correlation achieved by MAXSIM is comparable to that achieved by METEOR.

## 6 Future Work

In our current work, the parameters of MAXSIM are as yet un-optimized. We found that by setting  $\alpha=0.7$ , MAXSIM<sub>n+d</sub> could achieve a correlation of 0.972 on the NIST MT 2003 dataset. Also, we have barely exploited the potential of weighted similarity matching. Possible future directions include adding semantic role information, using the distance between item pairs based on the token position within each sentence as additional weighting consideration, etc. Also, we have seen that dependency relations help to improve correlation on the NIST dataset, but not on the ACL-07 MT workshop datasets. Since the accuracy of dependency parsers is not perfect, a possible future work is to identify when best to incorporate such syntactic information.

## 7 Conclusion

In this paper, we present MAXSIM, a new automatic MT evaluation metric that computes a similarity score between corresponding items across a sentence pair, and uses a bipartite graph to obtain an optimal matching between item pairs. This general framework allows us to use arbitrary similarity functions between items, and to incorporate different information in our comparison. When evaluated for correlation with human judgements, MAXSIM achieves superior results when compared to current automatic MT evaluation metrics.

# Contradictions and Justifications: Extensions to the Textual Entailment Task

Ellen M. Voorhees

National Institute of Standards and Technology  
Gaithersburg, MD 20899-8940, USA  
ellen.voorhees@nist.gov

## Abstract

The third PASCAL Recognizing Textual Entailment Challenge (RTE-3) contained an optional task that extended the main entailment task by requiring a system to make three-way entailment decisions (entails, contradicts, neither) and to justify its response. Contradiction was rare in the RTE-3 test set, occurring in only about 10% of the cases, and systems found accurately detecting it difficult. Subsequent analysis of the results shows a test set must contain many more entailment pairs for the three-way decision task than the traditional two-way task to have equal confidence in system comparisons. Each of six human judges representing eventual end users rated the quality of a justification by assigning “understandability” and “correctness” scores. Ratings of the same justification across judges differed significantly, signaling the need for a better characterization of the justification task.

## 1 Introduction

The PASCAL Recognizing Textual Entailment (RTE) workshop series (see [www.pascal-network.org/Challenges/RTE3/](http://www.pascal-network.org/Challenges/RTE3/)) has been a catalyst for recent research in developing systems that are able to detect when the content of one piece of text necessarily follows from the content of another piece of text (Dagan et al., 2006; Giampiccolo et al., 2007). This ability is seen as a fundamental component in the solutions for a variety of natural language problems such as question answering, summarization, and information extraction. In addition

to the main entailment task, the most recent Challenge, RTE-3, contained a second optional task that extended the main task in two ways. The first extension was to require systems to make three-way entailment decisions; the second extension was for systems to return a justification or explanation of how its decision was reached.

In the main RTE entailment task, systems report whether the *hypothesis* is entailed by the *text*. The system responds with YES if the hypothesis is entailed and NO otherwise. But this binary decision conflates the case when the hypothesis actually contradicts the text—the two could not both be true—with simple lack of entailment. The three-way entailment decision task requires systems to decide whether the hypothesis is entailed by the text (YES), contradicts the text (NO), or is neither entailed by nor contradicts the text (UNKNOWN).

The second extension required a system to explain why it reached its conclusion in terms suitable for an eventual end user (i.e., not system developer). Explanations are one way to build a user’s trust in a system, but it is not known what kinds of information must be conveyed nor how best to present that information. RTE-3 provided an opportunity to collect a diverse sample of explanations to begin to explore these questions.

This paper analyzes the extended task results, with the next section describing the three-way decision subtask and Section 3 the justification subtask. Contradiction was rare in the RTE-3 test set, occurring in only about 10% of the cases, and systems found accurately detecting it difficult. While the level of agreement among human annotators as to

the correct answer for an entailment pair was within expected bounds, the test set was found to be too small to reliably distinguish among systems’ three-way accuracy scores. Human judgments of the quality of a justification varied widely, signaling the need for a better characterization of the justification task. Comments from the judges did include some common themes. Judges prized conciseness, though they were uncomfortable with mathematical notation unless they had a mathematical background. Judges strongly disliked being shown system internals such as scores reported by various components.

## 2 The Three-way Decision Task

The extended task used the RTE-3 main task test set of entailment pairs as its test set. This test set contains 800 text and hypothesis pairs, roughly evenly split between pairs for which the text entails the hypothesis (410 pairs) and pairs for which it does not (390 pairs), as defined by the reference answer key released by RTE organizers.

RTE uses an “ordinary understanding” principle for deciding entailment. The hypothesis is considered entailed by the text if a human reading the text would most likely conclude that the hypothesis were true, even if there could exist unusual circumstances that would invalidate the hypothesis. It is explicitly acknowledged that ordinary understanding depends on a common human understanding of language as well as common background knowledge. The extended task also used the ordinary understanding principle for deciding contradictions. The hypothesis and text were deemed to contradict if a human would most likely conclude that the text and hypothesis could not both be true.

The answer key for the three-way decision task was developed at the National Institute of Standards and Technology (NIST) using annotators who had experience as TREC and DUC assessors. NIST assessors annotated all 800 entailment pairs in the test set, with each pair independently annotated by two different assessors. The three-way answer key was formed by keeping exactly the same set of YES answers as in the two-way key (regardless of the NIST annotations) and having NIST staff adjudicate assessor differences on the remainder. This resulted in a three-way answer key containing 410 (51%)

Reference Answer	Systems’ Responses			Totals
	YES	UNKN	NO	
YES	2449	2172	299	4920
UNKN	929	2345	542	3816
NO	348	415	101	864
Totals	3726	4932	942	9600

Table 1: Contingency table of responses over all 800 entailment pairs and all 12 runs.

YES answers, 319 (40%) UNKNOWN answers, and 72 (9%) NO answers.

### 2.1 System results

Eight different organizations participated in the three-way decision subtask submitting a total of 12 runs. A run consists of exactly one response of YES, NO, or UNKNOWN for each of the 800 test pairs. Runs were evaluated using accuracy, the percentage of system responses that match the reference answer.

Figure 1 shows both the overall accuracy of each of the runs (numbers running along the top of the graph) and the accuracy as conditioned on the reference answer (bars). The conditioned accuracy for YES answers, for example, is accuracy computed using just those test pairs for which YES is the reference answer. The runs are sorted by decreasing overall accuracy.

Systems were much more accurate in recognizing entailment than contradiction (black bars are greater than white bars). Since conditioned accuracy does not penalize for overgeneration of a response, the conditioned accuracy for UNKNOWN is excellent for those systems that used UNKNOWN as their default response. Run H never concluded that a pair was a contradiction, for example.

Table 1 gives another view of the relative difficulty of detecting contradiction. The table is a contingency table of the systems’ responses versus the reference answer summed over all test pairs and all runs. A reference answer is represented as a row in the table and a system’s response as a column. Since there are 800 pairs in the test set and 12 runs, there is a total of 9600 responses.

As a group the systems returned NO as a response 942 times, approximately 10% of the time. While 10% is a close match to the 9% of the test set for which NO is the reference answer, the systems detected contradictions for the wrong pairs: the table’s

Figure 1: Overall accuracy (top number) and accuracy conditioned by reference answer for three-way runs.

diagonal entry for NO is the smallest entry in both its row and its column. The smallest row entry means that systems were more likely to respond that the hypothesis was entailed than that it contradicted when it in fact contradicted. The smallest column entry means that when the systems did respond that the hypothesis contradicted, it was more often the case that the hypothesis was actually entailed than that it contradicted. The 101 correct NO responses represent 12% of the 864 possible correct NO responses. In contrast, the systems responded correctly for 50% (2449/4920) of the cases when YES was the reference answer and for 61% (2345/3816) of the cases when UNKNOWN was the reference answer.

## 2.2 Human agreement

Textual entailment is evaluated assuming that there is a single correct answer for each test pair. This is a simplifying assumption used to make the evaluation tractable, but as with most NLP phenomena it is not actually true. It is quite possible for two humans to have legitimate differences of opinions (i.e., to differ when neither is mistaken) about whether a hypothesis is entailed or contradicts, especially given annotations are based on ordinary understanding.

Since systems are given credit only when they respond with the reference answer, differences in annotators' opinions can clearly affect systems' accuracy scores. The RTE main task addressed this issue by including a candidate entailment pair in the test set only if multiple annotators agreed on its disposition (Giampiccolo et al., 2007). The test set also

Main Task	NIST Judge 1		
	YES	UNKN	NO
YES	378	27	5
NO	48	242	100
<i>conflated agreement = .90</i>			
Main Task	NIST Judge 2		
	YES	UNKN	NO
YES	383	23	4
NO	46	267	77
<i>conflated agreement = .91</i>			

Table 2: Agreement between NIST judges (columns) and main task reference answers (rows).

contains 800 pairs so an individual test case contributes only  $1/800 = 0.00125$  to the overall accuracy score. To allow the results from the two- and three-way decision tasks to be comparable (and to leverage the cost of creating the main task test set), the extended task used the same test set as the main task and used simple accuracy as the evaluation measure. The expectation was that this would be as effective an evaluation design for the three-way task as it is for the two-way task. Unfortunately, subsequent analysis demonstrates that this is not so.

Recall that NIST judges annotated all 800 entailment pairs in the test set, with each pair independently annotated twice. For each entailment pair, one of the NIST judges was arbitrarily assigned as the first judge for that pair and the other as the second judge. The agreement between NIST and RTE annotators is shown in Table 2. The top half of

the table shows the agreement between the two-way answer key and the annotations of the set of first judges; the bottom half is the same except using the annotations of the set of second judges. The NIST judges’ answers are given in the columns and the two-way reference answers in the rows. Each cell in the table gives the raw count before adjudication of the number of test cases that were assigned that combination of annotations. Agreement is then computed as the percentage of matches when a NIST judge’s NO or UNKNOWN annotation matched a NO two-way reference answer. Agreement is essentially identical for both sets of judges at 0.90 and 0.91 respectively.

Because the agreement numbers reflect the raw counts before adjudication, at least some of the differences may be attributable to annotator errors that were corrected during adjudication. But there do exist legitimate differences of opinion, even for the extreme cases of entails versus contradicts. Typical disagreements involve granularity of place names and amount of background knowledge assumed. Example disagreements concerned whether Hollywood was equivalent to Los Angeles, whether East Jerusalem was equivalent to Jerusalem, and whether members of the same political party who were at odds with one another were ‘opponents’.

RTE organizers reported an agreement rate of about 88% among their annotators for the two-way task (Giampiccolo et al., 2007). The 90% agreement rate between the NIST judges and the two-way answer key probably reflects a somewhat larger amount of disagreement since the test set already had RTE annotators’ disagreements removed. But it is similar enough to support the claim that the NIST annotators agree with other annotators as often as can be expected. Table 3 shows the three-way agreement between the two NIST annotators. As above, the table gives the raw counts before adjudication and agreement is computed as percentage of matching annotations. Three-way agreement is 0.83—smaller than two-way agreement simply because there are more ways to disagree.

Just as annotator agreement declines as the set of possible answers grows, the inherent stability of the accuracy measure also declines: accuracy and agreement are both defined as the percentage of exact matches on answers. The increased uncertainty

	YES	UNKN	NO
YES	381		
UNKN	82	217	
NO	11	43	66

*three-way agreement = .83*

Table 3: Agreement between NIST judges.

when moving from two-way to three-way decisions significantly reduces the power of the evaluation. With the given level of annotator agreement and 800 pairs in the test set, in theory accuracy scores could change by as much as  $136 \text{ (the number of test cases for which annotators disagreed)} \times 0.00125 = .17$  by using a different choice of annotator. The maximum difference in accuracy scores actually observed in the submitted runs was 0.063.

Previous analyses of other evaluation tasks such as document retrieval and question answering demonstrated that system rankings are stable despite differences of opinion in the underlying annotations (Voorhees, 2000; Voorhees and Tice, 2000). The differences in accuracy observed for the three-way task are large enough to affect system rankings, however. Compared to the system ranking of ABCDEFGHIJKL induced by the official three-way answer key, the ranking induced by the first set of judges’ raw annotations is BADCFEGKHLIJ. The ranking induced by the second set of judges’ raw annotations is much more similar to the official results, ABCDEFGHKIJL.

How then to proceed? Since the three-way decision task was motivated by the belief that distinguishing contradiction from simple non-entailment is important, reverting back to a binary decision task is not an attractive option. Increasing the size of the test set beyond 800 test cases will result in a more stable evaluation, though it is not known how big the test set needs to be. Defining new annotation rules in hopes of increasing annotator agreement is a satisfactory option only if those rules capture a characteristic of entailment that systems should actually embody. Reasonable people *do* disagree about entailment and it is unwise to enforce some arbitrary definition in the name of consistency. Using UNKNOWN as the reference answer for all entailment pairs on which annotators disagree may be a reasonable strategy: the disagreement itself is strong evidence that

neither of the other options holds. Creating balanced test sets using this rule could be difficult, however. Following this rule, the RTE-3 test set would have 360 (45%) YES answers, 64 (8%) NO answers, and 376 (47%) UNKNOWN answers, and would induce the ranking ABCDEHIJGKFL. (Runs such as H, I, and J that return UNKNOWN as a default response are rewarded using this annotation rule.)

### 3 Justifications

The second part of the extended task was for systems to provide explanations of how they reached their conclusions. The specification of a justification for the purposes of the task was deliberately vague—a collection of ASCII strings with no minimum or maximum size—so as to not preclude good ideas by arbitrary rules. A justification run contained all of the information from a three-way decision run plus the rationale explaining the response for each of the 800 test pairs in the RTE-3 test set. Six of the runs shown in Figure 1 (A, B, C, D, F, and H) are justification runs. Run A is a manual justification run, meaning there was some human tweaking of the justifications (but not the entailment decisions).

After the runs were submitted, NIST selected a subset of 100 test pairs to be used in the justification evaluation. The pairs were selected by NIST staff after looking at the justifications so as to maximize the informativeness of the evaluation set. All runs were evaluated on the same set of 100 pairs.

Figure 2 shows the justification produced by each run for pair 75 (runs D and F were submitted by the same organization and contained identical justifications for many pairs including pair 75). The text of pair 75 is *Muybridge had earlier developed an invention he called the Zoopraxiscope.*, and the hypothesis is *The Zoopraxiscope was invented by Muybridge.* The hypothesis is entailed by the text, and each of the systems correctly replied that it is entailed. Explanations for why the hypothesis is entailed differ widely, however, with some rationales of dubious validity.

Each of the six different NIST judges rated all 100 justifications. For a given justification, a judge first assigned an integer score between 1–5 on how understandable the justification was (with 1 as unintelligible and 5 as completely understandable). If the

understandability score assigned was 3 or greater, the judge then assigned a correctness score, also an integer between 1–5 with 5 the high score. This second score was interpreted as how compelling the argument contained in the justification was rather than simple correctness because justifications could be strictly correct but immaterial.

#### 3.1 System results

The motivation for the justification subtask was to gather data on how systems might best explain themselves to eventual end users. Given this goal and the exploratory nature of the exercise, judges were given minimal guidance on how to assign scores other than that it should be from a user’s, not a system developer’s, point of view. Judges used a system that displayed the text, hypothesis, and reference answer, and then displayed each submission’s justification in turn. The order in which the runs’ justifications were displayed was randomly selected for each pair; for a given pair, each judge saw the same order.

Figure 2 includes the scores assigned to each of the justifications of entailment pair 75. Each pair of numbers in brackets is a score pair assigned by one judge. The first number in the pair is the understandability score and the second the correctness score. The correctness score is omitted (‘-’) when the understandability score is 1 or 2 because no correctness score was assigned in that case. The scores from the different judges are given in the same order for each justification.

With 100 entailment pairs evaluated by each of 6 judges assigning 2 separate scores, each run had a total of 1200 numbers assigned to it. Figure 3 shows two views of these numbers: a histogram of the number of justifications in the run that were assigned a given score value summed over all judges and all test pairs, and the overall mean score for the run<sup>1</sup>. A correctness score that was not assigned because understandability was too poor is displayed as a score of 0 in the histogram and treated as a 0 in the computation of the mean. Understandability scores are shown toward the left in the figure and correctness scores toward the right.

The mean scores for correctness are fairly low

<sup>1</sup>Using the mean treats a score as an interval variable rather than an ordinal variable, a questionable treatment given a 5-point scale. A mean is a convenient summary, however.

<p>Run A:</p> <p>There is a relationship between Zoopraxiscope and Muybridge in both the text and hypothesis. The term "invention" is morphologically similar to "invented".</p> <p>Scores: [4,4] [4,4] [5,4] [4,1] [5,4], [3,2]</p>
<p>Run B:</p> <p>The text mentions 'Muybridge'. We can infer that Muybridge is inventor. From the fact that Muybridge is inventor, we can infer that Muybridge invented. We can conclude that the Zoopraxiscope was invented by Muybridge.</p> <p>Scores:[4,3] [3,3] [5,4] [5,1] [5,3] [3,2]</p>
<p>Run C:</p> <p>1: The Hypothesis could be precisely matched with content in the Text, with allowance for polarity and embedded contexts.</p> <p>2: Hypothesis words match well with words in the Text.</p> <p>3: text adjunct "called" of "invention" dropped on aligned hyp word "invented"</p> <p>Scores: [3,3] [4,4] [4,4] [2,-] [1,-] [2,-]</p>
<p>Runs D and F:</p> <p>The words in the hypothesis are all found, with the approximately all the exact same syntactic dependencies, also in the text. Therefore, I concluded that the given hypothesis:</p> <p style="padding-left: 2em;">The Zoopraxiscope was invented by Muybridge.</p> <p>is entailed by the given text</p> <p style="padding-left: 2em;">Muybridge had earlier developed an invention he called the Zoopraxiscope.</p> <p>Scores: [3,3] [4,3] [4,3] [5,1] [4,3] [2,-]</p>
<p>Run H:</p> <p>Yes!</p> <p>I have general knowledge that:</p> <p>IF Y is developed by X THEN Y is manufactured by X</p> <p>Here: X = Muybridge, Y = the invention</p> <p>Thus, here:</p> <p style="padding-left: 2em;">We are told in T: the invention is developed by Muybridge</p> <p style="padding-left: 2em;">Thus it follows that: the invention is manufactured by Muybridge</p> <p>In addition, I know:</p> <p style="padding-left: 2em;">"manufacture" and "invent" mean roughly the same thing</p> <p>Hence: The Zoopraxiscope was invented by Muybridge.</p> <p>Scores: [2,-] [4,1] [3,3] [3,1] [2,-] [1,-]</p>

Figure 2: Justification for entailment pair 75 from each justification run. Brackets contain the pair of scores assigned to the justification by one of the six human judges; the first number in the pair is the understandability score and the second is the correctness score.

for all runs. Recall, however, that the ‘correctness’ score was actually interpreted as compellingness. There were many justifications that were strictly correct but not very informative, and they received low correctness scores. For example, the low correctness scores for the justification from run A in Figure 2 were given because those judges did not feel that the fact that “invention and inventor are morphologically similar” was enough of an explanation. Mean

correctness scores were also affected by understandability. Since an unassigned correctness score was treated as a zero when computing the mean, systems with low understandability scores must have lower correctness scores. Nonetheless, it is also true that systems reached the correct entailment decision by faulty reasoning uncomfortably often, as illustrated by the justification from run H in Figure 2.

Figure 3: Number of justifications in a run that were assigned a particular score value summed over all judges and all test pairs. Brackets contain the overall mean understandability and correctness scores for the run. The starred run (A) is the manual run.

### 3.2 Human agreement

The most striking feature of the system results in Figure 3 is the variance in the scores. Not explicit in that figure, though illustrated in the example in Figure 2, is that different judges often gave widely different scores to the same justification. One systematic difference was immediately detected. The NIST judges have varying backgrounds with respect to mathematical training. Those with more training were more comfortable with, and often preferred, justifications expressed in mathematical notation; those with little training strongly disliked any mathematical notation in an explanation. This preference affected both the understandability and the correctness scores. Despite being asked to assign two separate scores, judges found it difficult to separate understandability and correctness. As a result, correctness scores were affected by presentation.

The scores assigned by different judges were sufficiently different to affect how runs compared to one another. This effect was quantified in the following way. For each entailment pair in the test set, the set of six runs was ranked by the scores assigned by

one assessor, with rank one assigned to the best run and rank six the worst run. If several systems had the same score, they were each assigned the mean rank for the tied set. (For example, if two systems had the same score that would rank them second and third, they were each assigned rank 2.5.) A run was then assigned its mean rank over the 100 justifications. Figure 4 shows how the mean rank of the runs varies by assessor. The x-axis in the figure shows the judge assigning the score and the y-axis the mean rank (remember that rank one is best). A run is plotted using its letter name consistent with previous figures, and lines connect the same system across different judges. Lines intersect demonstrating that different judges prefer different justifications.

After rating the 100 justifications, judges were asked to write a short summary of their impression of the task and what they looked for in a justification. These summaries did have some common themes. Judges prized conciseness and specificity, and expected (or at least hoped for) explanations in fluent English. Judges found “chatty” templates such as the one used in run H more annoying than engaging. Verbatim repetition of the text and hypothesis within

Figure 4: Relative effectiveness of runs as measured by mean rank.

the justification (as in runs D and F) was criticized as redundant. Generic phrases such as “there is a relation between” and “there is a match” were worse than useless: judges assigned no expository value to such assertions and penalized them as clutter.

Judges were also adverse to the use of system internals and jargon in the explanations. Some systems reported scores computed from WordNet (Fellbaum, 1998) or DIRT (Lin and Pantel, 2001). Such reports were penalized since the judges did not care what WordNet or DIRT are, and if they had cared, had no way to calibrate such a score. Similarly, linguistic jargon such as ‘polarity’ and ‘adjunct’ and ‘hyponym’ had little meaning for the judges.

Such qualitative feedback from the judges provides useful guidance to system builders on ways to explain system behavior. A broader conclusion from the justifications subtask is that it is premature for a quantitative evaluation of system-constructed explanations. The community needs a better understanding of the overall goal of justifications to develop a workable evaluation task. The relationships captured by many RTE entailment pairs are so obvious to humans (e.g., an inventor creates, a niece is a relative) that it is very unlikely end users would want explanations that include this level of detail. Having a true user task as a target would also provide needed direction as to the characteristics of those users, and thus allow judges to be more effective surrogates.

#### 4 Conclusion

The RTE-3 extended task provided an opportunity to examine systems’ abilities to detect contradiction and to provide explanations of their reasoning

when making entailment decisions. True contradiction was rare in the test set, accounting for approximately 10% of the test cases, though it is not possible to say whether this is a representative fraction for the text sources from which the test was drawn or simply a chance occurrence. Systems found detecting contradiction difficult, both missing it when it was present and finding it when it was not. Levels of human (dis)agreement regarding entailment and contradiction are such that test sets for a three-way decision task need to be substantially larger than for binary decisions for the evaluation to be both reliable and sensitive.

The justification task as implemented in RTE-3 is too abstract to make an effective evaluation task. Textual entailment decisions are at such a basic level of understanding for humans that human users don’t want explanations at this level of detail. User backgrounds have a profound effect on what presentation styles are acceptable in an explanation. The justification task needs to be more firmly situated in the context of a real user task so the requirements of the user task can inform the evaluation task.

#### Acknowledgements

The extended task of RTE-3 was supported by the Disruptive Technology Office (DTO) AQUAINT program. Thanks to fellow coordinators of the task, Chris Manning and Dan Moldovan, and to the participants for making the task possible.

# Cohesive Phrase-based Decoding for Statistical Machine Translation

Colin Cherry\*

One Microsoft Way

Redmond, WA, 98052

colinc@microsoft.com

## Abstract

Phrase-based decoding produces state-of-the-art translations with no regard for syntax. We add syntax to this process with a cohesion constraint based on a dependency tree for the source sentence. The constraint allows the decoder to employ arbitrary, non-syntactic phrases, but ensures that those phrases are translated in an order that respects the source tree's structure. In this way, we target the phrasal decoder's weakness in order modeling, without affecting its strengths. To further increase flexibility, we incorporate cohesion as a decoder feature, creating a soft constraint. The resulting cohesive, phrase-based decoder is shown to produce translations that are preferred over non-cohesive output in both automatic and human evaluations.

## 1 Introduction

Statistical machine translation (SMT) is complicated by the fact that words can move during translation. If one assumes arbitrary movement is possible, that alone is sufficient to show the problem to be NP-complete (Knight, 1999). **Syntactic cohesion**<sup>1</sup> is the notion that all movement occurring during translation can be explained by permuting children in a parse tree (Fox, 2002). Equivalently, one can say that phrases in the source, defined by subtrees in its parse, remain contiguous after translation. Early

methods for syntactic SMT held to this assumption in its entirety (Wu, 1997; Yamada and Knight, 2001). These approaches were eventually superseded by tree transducers and tree substitution grammars, which allow translation events to span subtree units, providing several advantages, including the ability to selectively produce uncohesive translations (Eisner, 2003; Graehl and Knight, 2004; Quirk et al., 2005). What may have been forgotten during this transition is that there is a reason it was once believed that a cohesive translation model would work: for some language pairs, cohesion explains nearly all translation movement. Fox (2002) showed that cohesion is held in the vast majority of cases for English-French, while Cherry and Lin (2006) have shown it to be a strong feature for word alignment. We attempt to use this strong, but imperfect, characterization of movement to assist a non-syntactic translation method: phrase-based SMT.

Phrase-based decoding (Koehn et al., 2003) is a dominant formalism in statistical machine translation. Contiguous segments of the source are translated and placed in the target, which is constructed from left to right. The process iterates within a beam search until each word from the source has been covered by exactly one phrasal translation. Candidate translations are scored by a linear combination of models, weighted according to Minimum Error Rate Training or MERT (Och, 2003). Phrasal SMT draws strength from being able to memorize non-compositional and context-specific translations, as well as local reorderings. Its primary weakness is in movement modeling; its default distortion model applies a flat penalty to any deviation from source

\*Work conducted while at the University of Alberta.

<sup>1</sup>We use the term "syntactic cohesion" throughout this paper to mean what has previously been referred to as "phrasal cohesion", because the non-linguistic sense of "phrase" has become so common in machine translation literature.

order, forcing the decoder to rely heavily on its language model. Recently, a number of data-driven distortion models, based on lexical features and relative distance, have been proposed to compensate for this weakness (Tillman, 2004; Koehn et al., 2005; Al-Onaizan and Papineni, 2006; Kuhn et al., 2006).

There have been a number of proposals to incorporate syntactic information into phrasal decoding. Early experiments with syntactically-informed phrases (Koehn et al., 2003), and syntactic re-ranking of  $K$ -best lists (Och et al., 2004) produced mostly negative results. The most successful attempts at syntax-enhanced phrasal SMT have directly targeted movement modeling: Zens et al. (2004) modified a phrasal decoder with ITG constraints, while a number of researchers have employed syntax-driven source reordering before decoding begins (Xia and McCord, 2004; Collins et al., 2005; Wang et al., 2007).<sup>2</sup> We attempt something between these two approaches: our constraint is derived from a linguistic parse tree, but it is used inside the decoder, not as a preprocessing step.

We begin in Section 2 by defining syntactic cohesion so it can be applied to phrasal decoder output. Section 3 describes how to add both hard and soft cohesion constraints to a phrasal decoder. Section 4 provides our results from both automatic and human evaluations. Sections 5 and 6 provide a qualitative discussion of cohesive output and conclude.

## 2 Cohesive Phrasal Output

Previous approaches to measuring the cohesion of a sentence pair have worked with a word alignment (Fox, 2002; Lin and Cherry, 2003). This alignment is used to project the spans of subtrees from the source tree onto the target sentence. If a modifier and its head, or two modifiers of the same head, have overlapping spans in the projection, then this indicates a cohesion violation. To check phrasal translations for cohesion violations, we need a way to project the source tree onto the decoder’s output.

Fortunately, each phrase used to create the target sentence can be tracked back to its original source phrase, providing an alignment between source and

target phrases. Since each source token is used exactly once during translation, we can transform this phrasal alignment into a word-to-phrase alignment, where each source token is linked to a target phrase. We can then project the source subtree spans onto the target phrase sequence. Note that we never consider individual tokens on the target side, as their connection to the source tree is obscured by the phrasal abstraction that occurred during translation.

Let  $e_1^m$  be the input source sentence, and  $\bar{f}_1^p$  be the output target phrase sequence. Our word-to-phrase alignment  $a_i \in [1, p]$ ,  $1 \leq i \leq m$ , maps a source token position  $i$  to a target phrase position  $a_i$ . Next, we introduce our source dependency tree  $T$ . Each source token  $e_i$  is also a node in  $T$ . We define  $T(e_i)$  to be the subtree of  $T$  rooted at  $e_i$ . We define a local tree to be a head node and its immediate modifiers. With this notation in place, we can define our projected spans. Following Lin and Cherry (2003), we define a head span to be the projection of a single token  $e_i$  onto the target phrase sequence:

$$\text{span}H(e_i, T, a_1^m) = [a_i, a_i]$$

and the subtree span to be the projection of the subtree rooted at  $e_i$ :

$$\text{span}S(e_i, T, a_1^m) = \left[ \min_{\{j|e_j \in T(e_i)\}} a_j, \max_{\{k|e_k \in T(e_i)\}} a_k \right]$$

Consider the simple phrasal translation shown in Figure 1 along with a dependency tree for the English source. If we examine the local tree rooted at *likes*, we get the following projected spans:

$$\begin{aligned} \text{span}S(\textit{nobody}, T, a) &= [1, 1] \\ \text{span}H(\textit{likes}, T, a) &= [1, 1] \\ \text{span}S(\textit{pay}, T, a) &= [1, 2] \end{aligned}$$

For any local tree, we consider only the head span of the head, and the subtree spans of any modifiers.

Typically, cohesion would be determined by checking these projected spans for intersection. However, at this level of resolution, avoiding intersection becomes highly restrictive. The monotone translation in Figure 1 would become non-cohesive: *nobody* intersects with both its sibling *pay* and with its head *likes* at phrase index 1. This complication stems from the use of multi-word phrases that

<sup>2</sup>While certainly both syntactic and successful, we consider Hiero (Chiang, 2007) to be a distinct approach, and not an extension to phrasal decoding’s left-to-right beam search.

Figure 1: An English source tree with translated French output. Segments are indicated with underlined spans.

do not correspond to syntactic constituents. Restricting phrases to syntactic constituents has been shown to harm performance (Koehn et al., 2003), so we tighten our definition of a violation to disregard cases where the only point of overlap is obscured by our phrasal resolution. To do so, we replace span intersection with a new notion of span **innersection**.

Assume we have two spans  $[u, v]$  and  $[x, y]$  that have been sorted so that  $[u, v] \leq [x, y]$  lexicographically. We say that the two spans **innersect** if and only if  $x < v$ . So,  $[1, 3]$  and  $[2, 4]$  innersect, while  $[1, 3]$  and  $[3, 4]$  do not. One can think of innersection as intersection, minus the cases where the two spans share only a single boundary point, where  $x = v$ . When two projected spans innersect, it indicates that the second syntactic constituent must begin before the first ends. If the two spans in question correspond to nodes in the same local tree, innersection indicates an unambiguous cohesion violation. Under this definition, the translation in Figure 1 is cohesive, as none of its spans innersect.

Our hope is that syntactic cohesion will help the decoder make smarter distortion decisions. An example with distortion is shown in Figure 2. In this case, we present two candidate French translations of an English sentence, assuming there is no entry in the phrase table for “voting session.” Because the proper French construction is “session of voting”, the decoder has to move *voting* after *session* using a distortion operation. Figure 2 shows two methods to do so, each using an equal numbers of phrases. The projected spans for the local tree rooted at *begins* in each candidate are shown in Table 1. Note the innersection between the head *begins* and its modifier *session* in (b). Thus, a cohesion-aware system would receive extra guidance to select (a), which maintains the original meaning much better than (b).

Span	(a)	(b)
$spanS(session, T, a)$	[1,3]	[1,3]*
$spanH(begins, T, a)$	[4,4]	[2,2]*
$spanS(tomorrow, T, a)$	[4,4]	[4,4]

Table 1: Spans of the local trees rooted at *begins* from Figures 2 (a) and (b). Innersection is marked with a “\*”.

## 2.1 K-best List Filtering

A first attempt at using cohesion to improve SMT output would be to apply our definition as a filter on  $K$ -best lists. That is, we could have a phrasal decoder output a 1000-best list, and return the highest-ranked cohesive translation to the user. We tested this approach on our English-French development set, and saw no improvement in BLEU score. Error analysis revealed that only one third of the uncohesive translations had a cohesive alternative in their 1000-best lists. In order to reach the remaining two thirds, we need to constrain the decoder’s search space to explore only cohesive translations.

## 3 Cohesive Decoding

This section describes a modification to standard phrase-based decoding, so that the system is constrained to produce only cohesive output. This will take the form of a check performed each time a hypothesis is extended, similar to the ITG constraint for phrasal SMT (Zens et al., 2004). To create a such a check, we need to detect a cohesion violation inside a partial translation hypothesis. We cannot directly apply our span-based cohesion definition, because our word-to-phrase alignment is not yet complete. However, we can still detect violations, and we can do so before the spans involved are completely translated.

Recall that when two projected spans  $a$  and  $b$  ( $a < b$ ) innersect, it indicates that  $b$  begins before  $a$  ends. We can say that the translation of  $b$  interrupts the translation of  $a$ . We can enforce cohesion by ensuring that these **interruptions** never happen. Because the decoder builds its translations from left to right, eliminating interruptions amounts to enforcing the following rule: once the decoder begins translating any part of a source subtree, it must cover all

Figure 2: Two candidate translations for the same parsed source. (a) is cohesive, while (b) is not.

the words under that subtree before it can translate anything outside of it.

For example, in Figure 2b, the decoder translates *the*, which is part of  $T(\textit{session})$  in  $\bar{f}_1$ . In  $\bar{f}_2$ , it translates *begins*, which is outside  $T(\textit{session})$ . Since we have yet to cover *voting*, we know that the projected span of  $T(\textit{session})$  will end at some index  $v > 2$ , creating an innersection. This eliminates the hypothesis after having proposed only the first two phrases.

### 3.1 Algorithm

In this section, we formally define an interruption, and present an algorithm to detect one during decoding. During both discussions, we represent each target phrase as a set that contains the English tokens used in its translation:  $\bar{f}_j = \{e_i | a_i = j\}$ . Formally, an interruption occurs whenever the decoder would add a phrase  $\bar{f}_{h+1}$  to the hypothesis  $\bar{f}_1^h$ , and:

$$\begin{aligned}
 &\exists r \in T && \text{such that:} \\
 &\exists e \in T(r) && \text{s.t. } e \in \bar{f}_1^h && \text{(a. Started)} \\
 &\exists e' \notin T(r) && \text{s.t. } e' \in \bar{f}_{h+1} && \text{(b. Interrupted)} \\
 &\exists e'' \in T(r) && \text{s.t. } e'' \notin \bar{f}_1^{h+1} && \text{(c. Unfinished)}
 \end{aligned} \tag{1}$$

The key to checking for interruptions quickly is knowing which subtrees  $T(r)$  to check for qualities (1:a,b,c). A naïve approach would check every subtree that has begun translation in  $\bar{f}_1^h$ . Figure 3a highlights the roots of all such subtrees for a hypothetical  $T$  and  $\bar{f}_1^h$ . Fortunately, with a little analysis that accounts for  $\bar{f}_{h+1}$ , we can show that at most two subtrees need to be checked.

For a given interruption-free  $\bar{f}_1^h$ , we call subtrees that have begun translation, but are not yet complete, **open** subtrees. Only open subtrees can lead to interruptions. We can focus our interruption check on  $\bar{f}_h$ , the last phrase in  $\bar{f}_1^h$ , as any open subtree  $T(r)$  must contain at least one  $e \in \bar{f}_h$ . If this were not the

---

#### Algorithm 1 Interruption check.

---

- Get the left and right-most tokens used to create  $\bar{f}_h$ , call them  $e_L$  and  $e_R$
  - For each of  $e \in \{e_L, e_R\}$ :
    - i.  $r' \leftarrow e, r \leftarrow \textit{null}$   
 While  $\exists e' \in \bar{f}_{h+1}$  such that  $e' \notin T(r')$ :  
 $r \leftarrow r', r' \leftarrow \textit{parent}(r)$
    - ii. If  $r \neq \textit{null}$  and  $\exists e'' \in T(r)$  such that  $e'' \notin \bar{f}_1^{h+1}$ , then  $\bar{f}_{h+1}$  interrupts  $T(r)$ .
- 

case, then the open  $T(r)$  must have begun translation somewhere in  $\bar{f}_1^{h-1}$ , and  $T(r)$  would be interrupted by the placement of  $\bar{f}_h$ . Since our hypothesis  $\bar{f}_1^h$  is interruption-free, this is impossible. This leaves the subtrees highlighted in Figure 3b to be checked. Furthermore, we need only consider subtrees that contain the left and right-most source tokens  $e_L$  and  $e_R$  translated by  $\bar{f}_h$ . Since  $\bar{f}_h$  was created from a contiguous string of source tokens, any distinct subtree between these two endpoints will be completed within  $\bar{f}_h$ . Finally, for each of these focus points  $e_L$  and  $e_R$ , only the highest containing subtree  $T(r)$  that does not completely contain  $\bar{f}_{h+1}$  needs to be considered. Anything higher would contain all of  $\bar{f}_{h+1}$ , and would not satisfy requirement (1:b) of our interruption definition. Any lower subtree would be a descendant of  $r$ , and therefore the check for the lower subtree is subsumed by the check for  $T(r)$ . This leaves only two subtrees, highlighted in our running example in Figure 3c.

With this analysis in place, an extension  $\bar{f}_{h+1}$  of the hypothesis  $\bar{f}_1^h$  can be checked for interruptions with Algorithm 1. Step (i) in this algorithm finds an ancestor  $r'$  such that  $T(r')$  completely contains

Figure 3: Narrowing down the source subtrees to be checked for completeness.

$\bar{f}_{h+1}$ , and then returns  $r$ , the highest node that **does not** contain  $\bar{f}_{h+1}$ . We know this  $r$  satisfies requirements (1:a,b). If there is no  $T(r)$  that does not contain  $\bar{f}_{h+1}$ , then  $e$  and its ancestors cannot lead to an interruption. Step (ii) then checks the coverage vector of the hypothesis<sup>3</sup> to make sure that  $T(r)$  is covered in  $\bar{f}_1^{h+1}$ . If  $T(r)$  is not complete in  $\bar{f}_1^{h+1}$ , then that satisfies requirement (1:c), which means an interruption has occurred.

For example, in Figure 2b, our first interruption occurs as we add  $\bar{f}_{h+1} = \bar{f}_2$  to  $\bar{f}_1^h = \bar{f}_1^1$ . The detection algorithm would first get the left and right boundaries of  $\bar{f}_1$ ; in this case, *the* is both  $e_L$  and  $e_R$ . Then, it would climb up the tree from *the* until it reached  $r' = \textit{begins}$  and  $r = \textit{session}$ . It would then check  $T(\textit{session})$  for coverage in  $\bar{f}_1^2$ . Since *voting*  $\in T(\textit{session})$  is not covered in  $\bar{f}_1^2$ , it would detect an interruption.

Walking up the tree takes at most linear time, and each check to see if  $T(r)$  contains all of  $\bar{f}_{h+1}$  can be performed in constant time, provided the source spans of each subtree have been precomputed. Checking to see if all of  $T(r)$  has been covered in Step (ii) takes at most linear time. This makes the entire process linear in the size of the source sentence.

### 3.2 Soft Constraint

Syntactic cohesion is not a perfect constraint for translation. Parse errors and systematic violations can create cases where cohesion works against the decoder. Fox (2002) demonstrated and counted cases where cohesion was not maintained in hand-aligned sentence-pairs, while Cherry and Lin (2006)

<sup>3</sup>This coverage vector is maintained by all phrasal decoders to track how much of the source sentence has been covered by the current partial translation, and to ensure that the same token is not translated twice.

showed that a soft cohesion constraint is superior to a hard constraint for word alignment. Therefore, we propose a soft version of our cohesion constraint. We perform our interruption check, but we do not invalidate any hypotheses. Instead, each hypothesis maintains a count of the number of extensions that have caused interruptions during its construction. This count becomes a feature in the decoder’s log-linear model, the weight of which is trained with MERT. After the first interruption, the exact meaning of further interruptions becomes difficult to interpret; but the interruption count does provide a useful estimate of the extent to which the translation is faithful to the source tree structure.

Initially, we were not certain to what extent this feature would be used by the MERT module, as BLEU is not always sensitive to syntactic improvements. However, trained with our French-English tuning set, the interruption count received the largest absolute feature weight, indicating, at the very least, that the feature is worth scaling to impact decoder.

### 3.3 Implementation

We modify the Moses decoder (Koehn et al., 2007) to translate head-annotated sentences. The decoder stores the flat sentence in the original sentence data structure, and the head-encoded dependency tree in an attached tree data structure. The tree structure caches the source spans corresponding to each of its subtrees. We then implement both a hard check for interruptions to be used before hypotheses are placed on the stack,<sup>4</sup> and a soft check that is used to calculate an interruption count feature.

<sup>4</sup>A hard cohesion constraint used in conjunction with a traditional distortion limit also requires a second linear-time check to ensure that all subtrees currently in progress can be finished under the constraints induced by the distortion limit.

Set	Cohesive	Uncohesive
Dev-Test	1170	330
Test	1563	437

Table 2: Number of sentences that receive cohesive translations from the baseline decoder. This property also defines our evaluation subsets.

## 4 Experiments

We have adapted the notion of syntactic cohesion so that it is applicable to phrase-based decoding. This results in a translation process that respects source-side syntactic boundaries when distorting phrases. In this section we will test the impact of such information on an English to French translation task.

### 4.1 Experimental Details

We test our cohesion-enhanced Moses decoder trained using 688K sentence pairs of Europarl French-English data, provided by the SMT 2006 Shared Task (Koehn and Monz, 2006). Word alignments are provided by GIZA++ (Och and Ney, 2003) with grow-diag-final combination, with infrastructure for alignment combination and phrase extraction provided by the shared task. We decode with Moses, using a stack size of 100, a beam threshold of 0.03 and a distortion limit of 4. Weights for the log-linear model are set using MERT, as implemented by Venugopal and Vogel (2005). Our tuning set is the first 500 sentences of the SMT06 development data. We hold out the remaining 1500 development sentences for development testing (dev-test), and the entirety of the provided 2000-sentence test set for blind testing (test). Since we require source dependency trees, all experiments test English to French translation. English dependency trees are provided by Minipar (Lin, 1994).

Our cohesion constraint directly targets sentences for which an unmodified phrasal decoder produces uncohesive output according to the definition in Section 2. Therefore, we present our results not only on each test set in its entirety, but also on the subsets defined by whether or not the baseline naturally produces a cohesive translation. The sizes of the resulting evaluation sets are given in Table 2.

Our development tests indicated that the soft and hard cohesion constraints performed somewhat sim-

ilarly, with the soft constraint providing more stable, and generally better results. We confirmed these trends on our test set, but to conserve space, we provide detailed results for only the soft constraint.

### 4.2 Automatic Evaluation

We first present our soft cohesion constraint’s effect on BLEU score (Papineni et al., 2002) for both our dev-test and test sets. We compare against an unmodified baseline decoder, as well as a decoder enhanced with a lexical reordering model (Tillman, 2004; Koehn et al., 2005). For each phrase pair in our translation table, the lexical reordering model tracks statistics on its reordering behavior as observed in our word-aligned training text. The lexical reordering model provides a good comparison point as a non-syntactic, and potentially orthogonal, improvement to phrase-based movement modeling. We use the implementation provided in Moses, with probabilities conditioned on bilingual phrases and predicting three orientation bins: straight, inverted and disjoint. Since adding features to the decoder’s log-linear model is straight-forward, we also experiment with a combined system that uses both the cohesion constraint and a lexical reordering model.

The results of our experiments are shown in Table 3, and reveal some interesting phenomena. First of all, looking across columns, we can see that there is a definite divide in BLEU score between our two evaluation subsets. Sentences with cohesive baseline translations receive much higher BLEU scores than those with uncohesive baseline translations. This indicates that the cohesive subset is easier to translate with a phrase-based system. Our definition of cohesive phrasal output appears to provide a useful feature for estimating translation confidence.

Comparing the baseline with and without the soft cohesion constraint, we see that cohesion has only a modest effect on BLEU, when measured on all sentence pairs, with improvements ranging between 0.2 and 0.5 absolute points. Recall that the majority of baseline translations are naturally cohesive. The cohesion constraint’s effect is much more pronounced on the more difficult uncohesive subsets, showing absolute improvements between 0.5 and 1.1 points.

Considering the lexical reordering model, we see that its effect is very similar to that of syntactic cohesion. Its BLEU scores are very similar, with lex-

System	Dev-Test			Test		
	All	Cohesive	Uncohesive	All	Cohesive	Uncohesive
base	32.04	33.80	27.46	32.35	33.78	28.73
lex	32.19	33.91	27.86	<b>32.71</b>	33.89	<b>29.66</b>
coh	32.22	33.82	<b>28.04</b>	<b>32.88</b>	<b>34.03</b>	<b>29.86</b>
lex+coh	<b>32.45</b>	34.12	<b>28.09</b>	<b>32.90</b>	34.04	<b>29.83</b>

Table 3: BLEU scores with an integrated soft cohesion constraint (coh) or a lexical reordering model (lex). Any system significantly better than base has been highlighted, as tested by bootstrap re-sampling with a 95% confidence interval.

ical reordering also affecting primarily the uncohesive subset. This similarity in behavior is interesting, as its data-driven, bilingual reordering probabilities are quite different from our cohesion flag, which is driven by monolingual syntax.

Examining the system that employs both movement models, we see that the combination (**lex+coh**) receives the highest score on the dev-test set. A large portion of the combined system’s gain is on the cohesive subset, indicating that the cohesion constraint may be enabling better use of the lexical reordering model on otherwise cohesive translations. Unfortunately, these same gains are not born out on the test set, where the lexical reordering model appears unable to improve upon the already strong performance of the cohesion constraint.

### 4.3 Human Evaluation

We also present a human evaluation designed to determine whether bilingual speakers prefer cohesive decoder output. Our comparison systems are the baseline decoder (**base**) and our soft cohesion constraint (**coh**). We evaluate on our dev-test set,<sup>5</sup> as it has our smallest observed BLEU-score gap, and we wish to determine if it is actually improving. Our experimental set-up is modeled after the human evaluation presented in (Collins et al., 2005). We provide two human annotators<sup>6</sup> a set of 75 English source sentences, along with a reference translation and a pair of translation candidates, one from each system. The annotators are asked to indicate which of the two system translations they prefer, or if they

<sup>5</sup>The cohesion constraint has no free parameters to optimize during development, so this does not create an advantage.

<sup>6</sup>Annotators were both native English speakers who speak French as a second language. Each has a strong comprehension of written French.

Annotator #1	Annotator #2			sum (#1)
	base	coh	equal	
base	<b>6</b>	7	1	14
coh	8	<b>35</b>	4	47
equal	7	4	<b>3</b>	14
sum (#2)	21	46	8	

Table 4: Confusion matrix from human evaluation.

consider them to be equal. To avoid bias, the competing systems were presented anonymously and in random order. Following (Collins et al., 2005), we provide the annotators with only short sentences: those with source sentences between 10 and 25 tokens long. Following (Callison-Burch et al., 2006), we conduct a targeted evaluation; we only draw our evaluation pairs from the uncohesive subset targeted by our constraint. All 75 sentences that meet these two criteria are included in the evaluation.

The aggregate results of our human evaluation are shown in the bottom row and right-most column of Table 4. Each annotator prefers **coh** in over 60% of the test sentences, and each prefers **base** in less than 30% of the test sentences. This presents strong evidence that we are having a consistent, positive effect on formerly non-cohesive translations. A complete confusion matrix indicating agreement between the two annotators is also given in Table 4. There are a few more off-diagonal points than one might expect, but it is clear that the two annotators are in agreement with respect to **coh**’s improvements. A combination annotator, which selects **base** or **coh** only when both human annotators agree and equal otherwise, finds **base** is preferred in only 8% of cases, compared to 47% for **coh**.

(1+)	creating structures that do not currently exist and reducing . . .

Table 5: A comparison of baseline and cohesion-constrained English-to-French translations, with English glosses.

## 5 Discussion

Examining the French translations produced by our cohesion constrained phrasal decoder, we can draw some qualitative generalizations. The constraint is used primarily to prevent distortion: it provides an intelligent estimate as to when source order must be respected. The resulting translations tend to be more literal than unconstrained translations. So long as the vocabulary present in our phrase table and language model supports a literal translation, cohesion tends to produce an improvement. Consider the first translation example shown in Table 5. In the baseline translation, the language model encourages the system to move the negation away from “exist” and toward “reduce.” The result is a tragic reversal of meaning in the translation. Our cohesion constraint removes this option, forcing the decoder to assemble the correct French construction for “does not yet exist.” The second example shows a case where our resources do not support a literal translation. In this case, we do not have a strong translation mapping to produce a French modifier equivalent to the English “banning.” Stuck with a noun form (“the ban”), the baseline is able to distort the sentence into something that is almost correct (the above gloss is quite generous). The cohesive system, even with a soft constraint, cannot reproduce the same movement, and returns a less grammatical translation.

We also examined cases where the decoder overrides the soft cohesion constraint and produces an uncohesive translation. We found this was done very rarely, and primarily to overcome parse errors. Only one correct syntactic construct repeatedly forced the

decoder to override cohesion: Minipar’s conjunction representation, which connects conjuncts in parent-child relationships, is at times too restrictive. A sibling representation, which would allow conjuncts to be permuted arbitrarily, may work better.

## 6 Conclusion

We have presented a definition of syntactic cohesion that is applicable to phrase-based SMT. We have used this definition to develop a linear-time algorithm to detect cohesion violations in partial decoder hypotheses. This algorithm was used to implement a soft cohesion constraint for the Moses decoder, based on a source-side dependency tree.

Our experiments have shown that roughly 1/5 of our baseline English-French translations contain cohesion violations, and these translations tend to receive lower BLEU scores. This suggests that cohesion could be a strong feature in estimating the confidence of phrase-based translations. Our soft constraint produced improvements ranging between 0.5 and 1.1 BLEU points on sentences for which the baseline produces uncohesive translations. A human evaluation showed that translations created using a soft cohesion constraint are preferred over uncohesive translations in the majority of cases.

## Abstract

In this work, the problem of extracting phrase translation is formulated as an information retrieval process implemented with a log-linear model aiming for a balanced precision and recall. We present a generic phrase training algorithm which is parameterized with feature functions and can be optimized jointly with the translation engine to directly maximize the end-to-end system performance. Multiple data-driven feature functions are proposed to capture the quality and confidence of phrases and phrase pairs. Experimental results demonstrate consistent and significant improvement over the widely used method that is based on word alignment matrix only.

## 1 Introduction

Phrase has become the standard basic translation unit in Statistical Machine Translation (SMT) since it naturally captures context dependency and models internal word reordering. In a phrase-based SMT system, the phrase translation table is the defining component which specifies alternative translations and their probabilities for a given source phrase. In learning such a table from parallel corpus, two related issues need to be addressed (either separately or jointly): which pairs are considered valid translations and how to assign weights, such as probabilities, to them. The first problem is referred to as phrase pair extraction, which identifies phrase pairs that are supposed to be translations of each other. Methods have been proposed, based on syntax, that take advantage of linguistic constraints and alignment of grammatical structure, such as in Yamada

and Knight (2001) and Wu (1995). The most widely used approach derives phrase pairs from word alignment matrix (Och and Ney, 2003; Koehn et al., 2003). Other methods do not depend on word alignments only, such as directly modeling phrase alignment in a joint generative way (Marcu and Wong, 2002), pursuing information extraction perspective (Venugopal et al., 2003), or augmenting with model-based phrase pair posterior (Deng and Byrne, 2005).

Using relative frequency as translation probability is a common practice to measure goodness of a phrase pair. Since most phrases appear only a few times in training data, a phrase pair translation is also evaluated by lexical weights (Koehn et al., 2003) or term weighting (Zhao et al., 2004) as additional features to avoid overestimation. The translation probability can also be discriminatively trained such as in Tillmann and Zhang (2006).

The focus of this paper is the phrase pair extraction problem. As in information retrieval, precision and recall issues need to be addressed with a right balance for building a phrase translation table. High precision requires that identified translation candidates are accurate, while high recall wants as much valid phrase pairs as possible to be extracted, which is important and necessary for online translation that requires coverage. In the word-alignment derived phrase extraction approach, precision can be improved by filtering out most of the entries by using a statistical significance test (Johnson et al., 2007). On the other hand, there are valid translation pairs in the training corpus that are not learned due to word alignment errors as shown in Deng and Byrne (2005).

We would like to improve phrase translation accuracy and at the same time extract as many as possible valid phrase pairs that are missed due to incorrect word alignments. One approach is to leverage underlying word alignment quality such as in Ayan and Dorr (2006). In this work, we present a generic discriminative phrase pair extraction framework that can integrate multiple features aiming to identify correct phrase translation candidates. A significant deviation from most other approaches is that the framework is parameterized and can be optimized jointly with the decoder to maximize translation performance on a development set. Within the general framework, the main work is on investigating useful metrics. We employ features based on word alignment models and alignment matrix. We also propose information metrics that are derived from both bilingual and monolingual perspectives. All these features are data-driven and independent of languages. The proposed phrase extraction framework is general to apply linguistic features such as semantic, POS tags and syntactic dependency.

## 2 A Generic Phrase Training Procedure

Let  $\mathbf{e} = e_1^I$  denote an English sentence and  $\mathbf{f} = f_1^J$  denote its translation in a foreign language, say Chinese. Phrase extraction begins with sentence-aligned parallel corpora  $\{(\mathbf{e}_i, \mathbf{f}_i)\}$ . We use  $E = e_{i_b}^{i_e}$  and  $F = f_{j_b}^{j_e}$  to denote an English and foreign phrases respectively, where  $i_b(j_b)$  is the position in the sentence of the beginning word of the English(foreign) phrase and  $i_e(j_e)$  is the position of the ending word of the phrase.

We first train word alignment models and will use them to evaluate the goodness of a phrase and a phrase pair. Let  $f_k(E, F), k = 1, 2, \dots, K$  be  $K$  feature functions to be used to measure the quality of a given phrase pair  $(E, F)$ . The generic phrase extraction procedure is an evaluation, ranking, filtering, estimation and tuning process, presented in Algorithm 1.

Step 1 (line 1) is the preparation stage. Beginning with a flat lexicon, we train IBM Model-1 word alignment model with 10 iterations for each translation direction. We then train HMM word alignment models (Vogel et al., 1996) in two directions simultaneously by merging statistics collected in the

- 1: Train Model-1 and HMM word alignment models
  - 2: **for all** sentence pair  $(\mathbf{e}, \mathbf{f})$  **do**
  - 3:   Identify candidate phrases on each side
  - 4:   **for all** candidate phrase pair  $(E, F)$  **do**
  - 5:     Calculate its feature function values  $f_k$
  - 6:     Obtain the score  $q(E, F) = \sum_{k=1}^K \lambda_k f_k(E, F)$
  - 7:   **end for**
  - 8:   Sort candidate phrase pairs by their final scores  $q$
  - 9:   Find the maximum score  $qm = \max q(E, F)$
  - 10:   **for all** candidate phrase pair  $(E, F)$  **do**
  - 11:     If  $q(E, F) \geq qm - \tau$ , dump the pair into the pool
  - 12:   **end for**
  - 13: **end for**
  - 14: Built a phrase translation table from the phrase pair pool
  - 15: Discriminatively train feature weights  $\lambda_k$  and threshold  $\tau$
- 

E-step from two directions motivated by Zens et al. (2004) with 5 iterations. We use these models to define the feature functions of candidate phrase pairs such as phrase pair posterior distribution. More details will be given in Section 3.

Step 2 (line 2) consists of phrase pair evaluation, ranking and filtering. Usually all n-grams up to a pre-defined length limit are considered as candidate phrases. This is also the place where linguistic constraints can be applied, say to avoid non-compositional phrases (Lin, 1999). Each normalized feature score derived from word alignment models or language models will be log-linearly combined to generate the final score. Phrase pair filtering is simply thresholding on the final score by comparing to the maximum within the sentence pair. Note that under the log-linear model, applying threshold for filtering is equivalent to comparing the “likelihood” ratio.

Step 3 (line 14) pools all candidate phrase pairs that pass the threshold testing and estimates the final phrase translation table by maximum likelihood criterion. For each candidate phrase pair which is above the threshold, we assign HMM-based phrase pair posterior as its soft count when dumping them into the global phrase pair pool. Other possibilities for the weighting include assigning constant one or the exponential of the final score etc.

One of the advantages of the proposed phrase training algorithm is that it is a parameterized procedure that can be optimized jointly with the trans-

lation engine to minimize the final translation errors measured by automatic metrics such as BLEU (Papineni et al., 2002). In the final step 4 (line 15), parameters  $\{\lambda_k, \tau\}$  are discriminatively trained on a development set using the downhill simplex method (Nelder and Mead, 1965).

This phrase training procedure is general in the sense that it is configurable and trainable with different feature functions and their parameters. The commonly used phrase extraction approach based on word alignment heuristics (referred as *ViterbiExtract* algorithm for comparison in this paper) as described in (Och, 2002; Koehn et al., 2003) is a special case of the algorithm, where candidate phrase pairs are restricted to those that respect word alignment boundaries.

We rely on multiple feature functions that aim to describe the quality of candidate phrase translations and the generic procedure to figure out the best way of combining these features. A good feature function pops up valid translation pairs and pushes down incorrect ones.

### 3 Features

Now we present several feature functions that we investigated to help extracting correct phrase translations. All these features are data-driven and defined based on models, such as statistical word alignment model or language model.

#### 3.1 Model-based Phrase Pair Posterior

In a statistical generative word alignment model (Brown et al., 1993), it is assumed that (i) a random variable  $\mathbf{a}$  specifies how each target word  $f_j$  is generated by (therefore aligned to) a source<sup>1</sup> word  $e_{a_j}$ ; and (ii) the likelihood function  $f(\mathbf{f}, \mathbf{a}|\mathbf{e})$  specifies a generative procedure from the source sentence to the target sentence. Given a phrase pair in a sentence pair, there will be many generative paths that align the source phrase to the target phrase. The likelihood of those generative procedures can be accumulated to get the likelihood of the phrase pair (Deng and Byrne, 2005). This is implemented as the summation of the likelihood function over all valid hidden word alignments.

<sup>1</sup>The word *source* and *target* are in the sense of word alignment direction, not as in the source-channel formulation.

More specifically, let  $A_{(i_1, i_2)}^{(j_1, j_2)}$  be the set of word alignment  $\mathbf{a}$  that aligns the source phrase  $e_{i_1}^{j_1}$  to the target phrase  $f_{j_1}^{j_2}$  (links to NULL word are ignored for simplicity):

$$A_{(i_1, i_2)}^{(j_1, j_2)} = \{\mathbf{a} : a_j \in [i_1, i_2] \text{ iff } j \in [j_1, j_2]\}$$

The alignment set given a phrase pair ignores those pairs with word links across the phrase boundary. Consequently, the phrase-pair posterior distribution is defined as

$$P_{\theta}(e_{i_1}^{j_1} \rightarrow f_{j_1}^{j_2} | \mathbf{e}, \mathbf{f}) = \frac{\sum_{\mathbf{a} \in A_{(i_1, i_2)}^{(j_1, j_2)}} f(\mathbf{a}, \mathbf{f} | \mathbf{e}; \theta)}{\sum_{\mathbf{a}} f(\mathbf{a}, \mathbf{f} | \mathbf{e}; \theta)} \quad (1)$$

Switching the source and the target, we can obtain the posterior distribution in another translation direction. This distribution is applicable to all word alignment models that follow assumptions (i) and (ii). However, the complexity of the likelihood function could make it impractical to calculate the summations in Equation 1 unless an approximation is applied.

Several feature functions will be defined on top of the posterior distribution. One of them is based on HMM word alignment model. We use the geometric mean of posteriors in two translation directions as a symmetric metric for phrase pair quality evaluation function under HMM alignment models. Table 1 shows the phrase pair posterior matrix of the example.

Replacing the word alignment model with IBM Model-1 is another feature function that we added. IBM Model-1 is simple yet has been shown to be effective in many applications (Och et al., 2004). There is a close form solution to calculate the phrase pair posterior under Model-1. Moreover, word to word translation table under HMM is more concentrated than that under Model-1. Therefore, the posterior distribution evaluated by Model-1 is smoother and potentially it can alleviate the overestimation problem in HMM especially when training data size is small.

#### 3.2 Bilingual Information Metric

Trying to find phrase translations for any possible n-gram is not a good idea for two reasons. First, due to data sparsity and/or alignment model’s capability, there would exist n-grams that cannot be aligned

	$e_1^1$	$e_1^2$	$e_2^2$	$H_{BL}(f_{j_1}^{j_2})$
$f_1^1$	0.0006	0.012	0.89	0.08

Table 1: Phrase pair posterior distribution for the example

well, for instance, n-grams that are part of a paraphrase translation or metaphorical expression. To give an example, the unigram ‘tomorrow’ in ‘the day after tomorrow’ whose Chinese translation is a single word ‘后天’. Extracting candidate translations for such kind of n-grams for the sake of improving coverage (recall) might hurt translation quality (precision). We will define a confidence metric to estimate how reliably the model can align an n-gram in one side to a phrase on the other side given a parallel sentence. Second, some n-grams themselves carry no linguistic meaning; their phrase translations can be misleading, for example non-compositional phrases (Lin, 1999). We will address this in section 3.3.

Given a sentence pair, the basic assumption is that if the HMM word alignment model can align an English phrase well to a foreign phrase, the posterior distribution of the English phrase generating all foreign phrases on the other side is significantly biased. For instance, the posterior of one foreign phrase is far larger than that of the others. We use the entropy of the posterior distribution as the confidence metric:

$$H_{BL}(e_{i_1}^{i_2} | \mathbf{e}, \mathbf{f}) = H(\hat{P}_{\theta_{HMM}}(e_{i_1}^{i_2} \rightarrow *)) \quad (2)$$

where  $H(P) = -\sum_x P(x) \log P(x)$  is the entropy of a distribution  $P(x)$ ,  $\hat{P}_{\theta_{HMM}}(e_{i_1}^{i_2} \rightarrow *)$  is the normalized probability (sum up to 1) of the posterior  $P_{\theta_{HMM}}(e_{i_1}^{i_2} \rightarrow *)$  as defined in Equation 1. Low entropy signals a high confidence that the English phrase can be aligned correctly. On the other hand, high entropy implies ambiguity presented in discriminating the correct foreign phrase from the others from the viewpoint of the model.

Similarly we calculate the confidence metric of aligning a foreign phrase correctly with the word alignment model in foreign to English direction. Table 1 shows the entropy of phrases. The unigram of foreign side  $f_2^2$  is unlikely to survive with such high ambiguity. Adding the entropy in two directions defines the bilingual information metric as another feature function, which describes the reliability of aligning each phrase correctly by the model. Note that we used HMM word alignment model to find the posterior distribution. Other models such as Model-1 can be applied in the same way. This feature function quantitatively captures the goodness of phrases. During phrase pair ranking, it can help to move upward phrases that can be aligned well and push downward phrases that are difficult for the model to find correct translations.

### 3.3 Monolingual Information Metric

Now we turn to monolingual resources to evaluate the quality of an n-gram being a good phrase. A phrase in a sentence is specified by its boundaries. We assume that the boundaries of a good phrase should be the “right” place to break. More generally, we want to quantify how effective a word boundary is as a phrase boundary. One would perform say NP-chunking or parsing to avoid splitting a linguistic constituent. We apply a language model (LM) to describe the predictive uncertainty (PU) between words in two directions.

Given a history  $w_1^{n-1}$ , a language model specifies a conditional distribution of the future word being predicted to follow the history. We can find the entropy of such pdf:  $H_{LM}(w_1^{n-1}) = H(P(\cdot | w_1^{n-1}))$ . So given a sentence  $w_1^N$ , the PU of the boundary between word  $w_i$  and  $w_{i+1}$  is established by two-way entropy sum using a forward and backward language model:  $PU(w_1^N, i) = H_{LMF}(w_1^i) + H_{LMB}(w_N^{i+1})$

We assume that the higher the predictive uncertainty is, the more likely the left or right part of the word boundary can be “cut-and-pasted” to form another reasonable sentence. So a good phrase is characterized with high PU values on the boundaries. For example, in ‘we want to have a table near the window’, the PU value of the point after ‘table’ is 0.61, higher than that between ‘near’ and ‘the’ 0.3, using trigram LMs.

With this, the feature function derived from

monolingual clue for a phrase pair can be defined as the product of  $PU$ s of the four word boundaries.

### 3.4 Word Alignments Induced Metric

The widely used ViterbiExtract algorithm relies on word alignment matrix and no-crossing-link assumption to extract phrase translation candidates. Practically it has been proved to work well. However, discarding correct phrase pairs due to incorrect word links leaves room for improving recall. This is especially true for not significantly large training corpora. Provided with a word alignment matrix, we define within phrase pair consistency ratio (WPPCR) as another feature function. WPPCR was used as one of the scores in (Venugopal et al., 2003) for phrase extraction. It is defined as the number of consistent word links associated with any words within the phrase pair divided by the number of all word links associated with any words within the phrase pair. An inconsistent link connects a word within the phrase pair to a word outside the phrase pair. For example, the WPPCR for  $(e_1^2, f_1^2)$  in Table 1 is  $2/3$ . As a special case, the ViterbiExtract algorithm extracts only phrase pairs with WPPCR is 1.

To further discriminate the pairs with higher WPPCR from those with lower ratio, we apply a Bi-Linear Transform (BLT) (Oppenheim and Schafer, 1989) mapping. BLT is commonly used in signal processing to attenuate the low frequency parts. When used to map WPPCR, it exaggerates the difference between phrase pairs with high WPPCR and those with low WPPCR, making the pairs with low ratio more unlikely to be selected as translation candidates. One of the nice properties of BLT is that there is a parameter that can be changed to adjust the degree of attenuation, which provides another dimension for system optimization.

## 4 Experimental Results

We evaluate the effect of the proposed phrase extraction algorithm with translation performance. We do experiments on IWSLT (Paul, 2006) 2006 Chinese-English corpus. The task is to translate Chinese utterances in travel domain into English. We report only text (speech transcription) translation results.

The training corpus consists of 40K Chinese-English parallel sentences in travel domain with to-

Eval Set	04dev	04test	05test	06dev	06test
# of sentences	506	500	506	489	500
# of words	2808	2906	3209	5214	5550
# of refs	16	16	16	7	7

Table 2: Dev/test set statistics

tal 306K English words and 295K Chinese words. In the data processing step, Chinese characters are segmented into words. English text are normalized and lowercased. All punctuation is removed.

There are five sets of evaluation sentences in tourism domain for development and test. Their statistics are shown in Table 2. We will tune training and decoding parameters on 06dev and report results on other sets.

### 4.1 Training and Translation Setup

Our decoder is a phrase-based multi-stack implementation of the log-linear model similar to Pharaoh (Koehn et al., 2003). Like other log-linear model based decoders, active features in our translation engine include translation models in two directions, lexicon weights in two directions, language model, lexicalized distortion models, sentence length penalty and other heuristics. These feature weights are tuned on the dev set to achieve optimal translation performance using downhill simplex method. The language model is a statistical trigram model estimated with Modified Kneser-Ney smoothing (Chen and Goodman, 1996) using only English sentences in the parallel training data.

Starting from the collection of parallel training sentences, we build word alignment models in two translation directions, from English to Chinese and from Chinese to English, and derive two sets of Viterbi alignments. By combining word alignments in two directions using heuristics (Och and Ney, 2003), a single set of static word alignments is then formed. Based on alignment models and word alignment matrices, we compare different approaches of building a phrase translation table and show the final translation results. We measure translation performance by the BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) scores with multiple translation references.

BLEU Scores					
Table	04dev	04test	05test	06dev	06test
HMM	0.367	0.407	0.473	0.200	0.190
Model-4	0.380	0.403	0.485	0.210	0.204
New	0.411	0.427	0.500	0.216	0.208

METEOR Scores					
Table	04dev	04test	05test	06dev	06test
HMM	0.532	0.586	0.675	0.482	0.471
Model-4	0.540	0.593	0.682	0.492	0.480
New	0.568	0.614	0.691	0.505	0.487

Table 3: Translation Results

## 4.2 Translation Results

Our baseline phrase table training method is the ViterbiExtract algorithm. All phrase pairs with respect to the word alignment boundary constraint are identified and pooled to build phrase translation tables with the Maximum Likelihood criterion. We prune phrase translation entries by their probabilities. The maximum number of words in Chinese and English phrases is set to 8 and 25 respectively for all conditions<sup>2</sup>. We perform online style phrase training, i.e., phrase extraction is not particular for any evaluation set.

Two different word alignment models are trained as the baseline, one is symmetric HMM word alignment model, the other is IBM Model-4 as implemented in the GIZA++ toolkit (Och and Ney, 2003). The translation results as measured by BLEU and METEOR scores are presented in Table 3. We notice that Model-4 based phrase table performs roughly 1% better in terms of both BLEU and METEOR scores than that based on HMM.

We follow the generic phrase training procedure as described in section 2. The most time consuming part is calculating posteriors, which is carried out in parallel with 30 jobs in less than 1.5 hours.

We use the Viterbi word alignments from HMM to define within phrase pair consistency ratio as discussed in section 3.4. Although Table 3 implies that Model-4 word alignment quality is better than that of HMM, we did not get benefits by switching to Model-4 to compute word alignments based feature values.

In estimating phrase translation probability, we use accumulated HMM-based phrase pair posteriors

<sup>2</sup>We chose large numbers for phrase length limit to build a strong baseline and to avoid impact of longer phrase length.

as their ‘soft’ frequencies and then the final translation probability is the relative frequency. HMM-based posterior was shown to be better than treating each occurrence as count one.

Once we have computed all feature values for all phrase pairs in the training corpus, we discriminatively train feature weights  $\lambda_k$ s and the threshold  $\tau$  using the downhill simplex method to maximize the BLEU score on 06dev set. Since the translation engine implements a log-linear model, the discriminative training of feature weights in the decoder should be embedded in the whole end-to-end system jointly with the discriminative phrase table training process. This is globally optimal but computationally demanding. As a compromise, we fix the decoder feature weights and put all efforts on optimizing phrase training parameters to find out the best phrase table.

The translation results with the discriminatively trained phrase table are shown as the row of ‘‘New’’ in Table 3. We observe that the new approach is consistently better than the baseline ViterbiExtract algorithm with either Model-4 or HMM word alignments on all sets. Roughly, it has 0.5% higher BLEU score on 2006 sets and 1.5% to 3% higher on other sets than Model-4 based ViterbiExtract method. Similar superior results are observed when measured with METEOR score.

## 5 Discussions

The generic phrase training algorithm follows an information retrieval perspective as in (Venugopal et al., 2003) but aims to improve both precision and recall with the trainable log-linear model. A clear advantage of the proposed approach over the widely used ViterbiExtract method is trainability. Under the general framework, one can put as many features as possible together under the log-linear model to evaluate the quality of a phrase and a phrase pair. The phrase table extracting procedure is trainable and can be optimized jointly with the translation engine.

Another advantage is flexibility, which is provided partially by the threshold  $\tau$ . As the figure 1 shows, when we increase the threshold by allowing more candidate phrase pair hypothesized as valid translation, we observe the phrase table size increases monotonically. On the other hand, we notice

Figure 1: Thresholding effects on translation performance and phrase table size

that the translation performance improves gradually. After reaching its peak, the BLEU score drops as the threshold  $\tau$  increases. When  $\tau$  is large enough, the translation performance is not changing much but still worse than the peak value. It implies a balancing process between precision and recall. The final optimal threshold  $\tau$  is around 5.

The flexibility is also enabled by multiple configurable features used to evaluate the quality of a phrase and a phrase pair. Ideally, a perfect combination of feature functions divides the correct and incorrect candidate phrase pairs within a parallel sentence into two ordered separate sets. We use feature functions to decide the order and the threshold  $\tau$  to locate the boundary guided with a development set.

So the main issue to investigate now is which features are important and valuable in ranking candidate phrase pairs. We propose several information metrics derived from posterior distribution, language model and word alignments as feature functions. The ViterbiExtract is a special case where a single binary feature function defined from word alignments is used. Its good performance (as shown in Table 3) suggests that word alignments are very indicative of phrase pair quality. So we design comparative experiments to capture word alignment impact only. We start with basic features that include model-based posterior, bilingual and monolingual information metrics. Its results on different test sets are presented in the “basic” row of Table 4. We add word alignment feature (“+align” row), and

Features	04dev	04test	05test	06dev	06test
basic	0.393	0.406	0.496	0.205	0.199
+align	0.401	0.429	0.502	0.208	0.196
+align_BLT	0.411	0.427	0.500	0.216	0.208

Table 4: Translation Results (BLEU) of discriminative phrase training approach using different features

Features	04dev	04test	05test	06dev	06test
PP2	0.380	0.395	0.480	0.207	0.202
PP1+PP2	0.380	0.403	0.485	0.210	0.204
PP2+PP3	0.411	0.427	0.500	0.216	0.208
PP1+PP2+PP3	0.412	0.432	0.500	0.217	0.214

Table 5: Translation Results (BLEU) of Different Phrase Pair Combination

then apply bilinear transform to the consistency ratio WPPCR as described in section 3.4 (“+align\_BLT” row). The parameter controlling the degree of attenuation in BLT is also optimized together with other feature weights.

With the basic features, the new phrase extraction approach performs better than the baseline method with HMM word alignment models but similar to the baseline method with Model-4. With the word alignment based feature WPPCR, we obtain a 2% improvement on 04test set but not much on other sets except slight degradation on 06test. Finally, applying BLT transform to WPPCR leads to additional 0.8 BLEU point on 06dev set and 1.2 point on 06test set. This confirms the effectiveness of word alignment based features.

Now we compare the phrase table using the proposed method to that extracted using the baseline ViterbiExtract method with Model-4 word alignments. The Venn diagram in Table 5 shows how the two phrase tables overlap with each other and size of each part. As expected, they have a large number of common phrase pairs (PP2). The new method is able to extract more phrase pairs than the baseline with Model-4. PP1 is the set of phrase pairs found by Model-4 alignments. Removing PP1 from the baseline phrase table (comparing the first group of scores) or adding PP1 to the new phrase table

(the second group of scores) overall results in no or marginal performance change. On the other hand, adding phrase pairs extracted by the new method only (PP3) can lead to significant BLEU score increases (comparing row 1 vs. 3, and row 2 vs. 4).

## 6 Conclusions

In this paper, the problem of extracting phrase translation is formulated as an information retrieval process implemented with a log-linear model aiming for a balanced precision and recall. We have presented a generic phrase translation extraction procedure which is parameterized with feature functions. It can be optimized jointly with the translation engine to directly maximize the end-to-end translation performance. Multiple feature functions were investigated. Our experimental results on IWSLT Chinese-English corpus have demonstrated consistent and significant improvement over the widely used word alignment matrix based extraction method.<sup>3</sup>

## Abstract

Measure words in Chinese are used to indicate the count of nouns. Conventional statistical machine translation (SMT) systems do not perform well on measure word generation due to data sparseness and the potential long distance dependency between measure words and their corresponding head words. In this paper, we propose a statistical model to generate appropriate measure words of nouns for an English-to-Chinese SMT system. We model the probability of measure word generation by utilizing lexical and syntactic knowledge from both source and target sentences. Our model works as a post-processing procedure over output of statistical machine translation systems, and can work with any SMT system. Experimental results show our method can achieve high precision and recall in measure word generation.

## 1 Introduction

In linguistics, *measure words* (MW) are words or morphemes used in combination with numerals or demonstrative pronouns to indicate the count of nouns<sup>1</sup>, which are often referred to as *head words* (HW).

Chinese measure words are grammatical units and occur quite often in real text. According to our survey on the measure word distribution in the Chinese Penn Treebank and the test datasets distributed by Linguistic Data Consortium (LDC) for Chinese-to-English machine translation evaluation, the average occurrence is 0.505 and 0.319 measure

words per sentence respectively. Unlike in Chinese, there is no special set of measure words in English. Measure words are usually used for mass nouns and any semantically appropriate nouns can function as the measure words. For example, in the phrase *three bottles of water*, the word *bottles* acts as a measure word. Countable nouns are almost never modified by measure words<sup>2</sup>. Numerals and indefinite articles are directly followed by countable nouns to denote the quantity of objects.

Therefore, in the English-to-Chinese machine translation task we need to take additional efforts to generate the missing measure words in Chinese. For example, when translating the English phrase *three books* into the Chinese phrases “三本书”, where *three* corresponds to the numeral “三” and *books* corresponds to the noun “书”, the Chinese measure word “本” should be generated between the numeral and the noun.

In most statistical machine translation (SMT) models (Och et al., 2004; Koehn et al., 2003; Chiang, 2005), some of measure words can be generated without modification or additional processing. For example, in above translation, the phrase translation table may suggest the word *three* be translated into “三”, “三本”, “三只”, etc, and the word *books* into “书”, “书本”, “名册” (scroll), etc. Then the SMT model selects the most likely combination “三本书” as the final translation result. In this example, a measure word candidate set consisting of “本” and “只” can be generated by bilingual phrases (or synchronous translation rules), and the best measure word “本” from the measure

<sup>1</sup> The uncommon cases of verbs are not considered.

<sup>2</sup> There are some exceptional cases, such as “100 head of cattle”. But they are very uncommon.

Figure 1. Example of long distance dependency between MW and its modified HW

word candidate set can be selected by the SMT decoder. However, as we will show below, existing SMT systems do not deal well with the measure word generation in general due to data sparseness and long distance dependencies between measure words and their corresponding head words.

Due to the limited size of bilingual corpora, many measure words, as well as the collocations between a measure and its head word, cannot be well covered by the phrase translation table in an SMT system. Moreover, Chinese measure words often have a long distance dependency to their head words which makes language model ineffective in selecting the correct measure words from the measure word candidate set. For example, in Figure 1 the distance between the measure word “项” and its head word “工程” (undertaking) is 15. In this case, an  $n$ -gram language model with  $n < 15$  cannot capture the MW-HW collocation. Table 1 shows the relative position’s distribution of head words around measure words in the Chinese Penn Treebank, where a negative position indicates that the head word is to the left of the measure word and a positive position indicates that the head word is to the right of the measure word. Although lots of measure words are close to the head words they modify, more than sixteen percent of measure words are far away from their corresponding head words (the absolute distance is more than 5).

To overcome the disadvantage of measure word generation in a general SMT system, this paper proposes a dedicated statistical model to generate measure words for English-to-Chinese translation.

We model the probability of measure word generation by utilizing rich lexical and syntactic knowledge from both source and target sentences. Three steps are involved in our method to generate measure words: Identifying the positions to gener-

ate measure words, collecting the measure word candidate set and selecting the best measure word. Our method is performed as a post-processing procedure of the output of SMT systems. The advantage is that it can be easily integrated into any SMT system. Experimental results show our method can significantly improve the quality of measure word generation. We also compared the performance of our model based on different contextual information, and show that both large-scale monolingual data and parallel bilingual data can be helpful to generate correct measure words.

Position	Occurrence	Position	Occurrence
1	39.5%	-1	0
2	15.7%	-2	0
3	4.7%	-3	8.7%
4	1.4%	-4	6.8%
5	2.1%	-5	4.3%
>5	8.8%	<-5	8.0%

Table 1. Position distribution of head words

## 2 Our Method

### 2.1 Measure word generation in Chinese

In Chinese, measure words are obligatory in certain contexts, and the choice of measure word usually depends on the head word’s semantics (e.g., shape or material). The set of Chinese measure words is a relatively close set and can be classified into two categories based on whether they have a corresponding English translation. Those not having an English counterpart need to be generated during translation. For those having English translations, such as “米” (meter), “吨” (ton), we just use the translation produced by the SMT system itself. According to our survey, about 70.4% of measure words in the Chinese Penn Treebank need

to be explicitly generated during the translation process.

In Chinese, there are generally stable linguistic collocations between measure words and their head words. Once the head word is determined, the collocated measure word can usually be selected accordingly. However, there is no easy way to identify head words in target Chinese sentences since for most of the time an SMT output is not a well formed sentence due to translation errors. Mistake of head word identification may cause low quality of measure word generation. In addition, sometimes the head word itself is not enough to determine the measure word. For example, in Chinese sentences “他家有 5 口人” (there are five people in his family) and “总共有 5 个人参加了会议” (a total of five people attended the meeting), where “人” (people) is the head word collocated with two different measure words “口” and “个”, we cannot determine the measure word just based on the head word “人”.

## 2.2 Framework

In our framework, a statistical model is used to generate measure words. The model is applied to SMT system outputs as a post-processing procedure. Given an English source sentence, an SMT decoder produces a target Chinese translation, in which positions for measure word generation are identified. Based on contextual information contained in both input source sentence and SMT system’s output translation, a measure word candidate set  $M$  is constructed. Then a measure word selection model is used to select the best one from  $M$ . Finally, the selected measure word is inserted into previously determined measure word slot in the SMT system’s output, yielding the final translation result.

## 2.3 Measure word position identification

To identify where to generate measure words in the SMT outputs, all positions after numerals are marked at first since measure words often follow numerals. For other cases in which measure words do not follow numerals (e.g., “许多/台/电脑” (many computers), where “台” is a measure word and “电脑” (computers) is its head word), we just mine the set of words which can be followed by measure words from training corpus. Most of

words in the set are pronouns such as “该” (this), “那” (that) and “若干” (several). In the SMT output, the positions after these words are also identified as candidate positions to generate measure words.

## 2.4 Candidate measure word generation

To avoid high computation cost, the measure word candidate set only consists of those measure words which can form valid MW-HW collocations with their head words. We assume that all the surrounding words within a certain window size centered on the given position to generate a measure word are potential head words, and require that a measure word candidate must collocate with at least one of the surrounding words. Valid MW-HW collocations are mined from the training corpus and a separate lexicon resource.

There is a possibility that the real head word is outside the window of given size. To address this problem, we also use a source window centered on the position  $p_s$ , which is aligned to the target measure word position  $p_t$ . The link between  $p_s$  and  $p_t$  can be inferred from SMT decoding result. Thus, the chance of capturing the best measure word increases with the aid of words located in the source window. For example, given the window size of 10, although the target head word “工程” (undertaking) in Figure 1 is located outside the target window, its corresponding source head word *undertaking* can be found in the source window. Based on this source head word, the best measure word “项” will be included into the candidate measure word set. This example shows how bilingual information can enrich the measure word candidate set.

Another special word {NULL} is always included in the measure word candidate set. {NULL} represents those measure words having a corresponding English translation as mentioned in Section 2.1. If {NULL} is selected, it means that we need not generate any measure word at the current position. Thus, no matter what kinds of measure words they are, we can handle the issue of measure word generation in a unified framework.

## 2.5 Measure word selection model

After obtaining the measure word candidate set  $M$ , a measure word selection model is employed to select the best one from  $M$ . Given the contextual information  $C$  in both source window and target

window, we model the measure word selection as finding the measure word  $m^*$  with highest posterior probability given  $C$ :

$$m^* = \operatorname{argmax}_{m \in M} P(m|C) \quad (1)$$

To leverage the collocation knowledge between measure words and head words, we extend (1) by introducing a hidden variable  $h$  where  $H$  represents all candidate head words located within the target window:

$$\begin{aligned} m^* &= \operatorname{argmax}_{m \in M} \sum_{h \in H} P(m, h|C) \\ &= \operatorname{argmax}_{m \in M} \sum_{h \in H} P(h|C)P(m|h, C) \end{aligned} \quad (2)$$

In (2),  $P(h|C)$  is the head word selection probability and is empirically estimated according to the position distribution of head words in Table 1.  $P(m|h, C)$  is the conditional probability of  $m$  given both  $h$  and  $C$ . We use maximum entropy model to compute  $P(m|h, C)$ :

$$P(m|h, C) = \frac{\exp(\sum_i \lambda_i f_i(m, C))}{\sum_{m' \in M} \exp(\sum_i \lambda_i f_i(m', C))} \quad (3)$$

Based on the different features used in the computation of  $P(m|h, C)$ , we can train two sub-models – a monolingual model (*Mo-ME*) which only uses monolingual (Chinese) features and a bilingual model (*Bi-ME*) which integrates bilingual features. The advantage of the Mo-ME model is that it can employ an unlimited monolingual target training corpora, while the Bi-ME model leverages rich features including both the source and target information and may improve the precision. Compared to the Mo-ME model, the Bi-ME model suffers from small scale of parallel training data. To leverage advantages of both models, we use a combined model *Co-ME*, by linearly combing the monolingual and bilingual sub-models:

$$m^* = \operatorname{argmax}_{m \in M} \lambda P_{Mo-ME} + (1 - \lambda) P_{Bi-ME}$$

where  $\lambda \in [0, 1]$  is a free parameter that can be optimized on held-out data and it was set to 0.39 in our experiments.

## 2.6 Features

The computation of Formula (3) involves the features listed in Table 2 where the Mo-ME model only employs target features and the Bi-ME model leverages both target features and source features.

For target features,  $n$ -gram language model score is defined as the sum of  $\log n$ -gram probabilities within the target window after the measure

word is filled into the measure word slot. The MW-HW collocation feature is defined to be a function  $f_1$  to capture the collocation between a measure word and a head word. For features of surrounding words, the feature function  $f_2$  is defined as 1 if a certain word exists at a certain position, otherwise 0. For example,  $f_2(\text{人}, -2) = 1$  means the second word on the left is “人”.  $f_2(\text{书}, 3) = 1$  means the third word on the right is “书”. For punctuation position feature function  $f_3$ , the feature value is 1 when there is a punctuation following the measure word, which indicates the target head word may appear to the left of measure word. Otherwise, it is 0. In practice, we can also ignore the position part, i.e., a word appears anywhere within the window is viewed as the same feature.

Target features	Source features
$n$ -gram language model score	MW-HW collocation
MW-HW collocation	surrounding words
surrounding words	source head word
punctuation position	POS tags

Table 2. Features used in our model

For source language side features, MW-HW collocation and surrounding words are used in a similar way as does with target features. The source head word feature is defined to be a function  $f_4$  to indicate whether a word  $e_i$  is the source head word in English according to a parse tree of the source sentence. Similar to the definition of lexical features, we also use a set of features based on POS tags of source language.

## 3 Model Training and Application

### 3.1 Training

We parsed English and Chinese sentences to get training samples for measure word generation model. Based on the source syntax parse tree, for each measure word, we identified its head word by using a toolkit from (Chiang and Bikel, 2002) which can heuristically identify head words for sub-trees. For the bilingual corpus, we also perform word alignment to get correspondences between source and target words. Then, the collocation between measure words and head words and their surrounding contextual information are extracted to train the measure word selection models. According to word alignment results, we classify

measure words into two classes based on whether they have non-null translations. We map Chinese measure words having non-null translations to a unified symbol {NULL} as mentioned in Section 2.4, indicating that we need not generate these kind of measure words since they can be translated from English.

In our work, the Berkeley parser (Petrov and Klein, 2007) was employed to extract syntactic knowledge from the training corpus. We ran GIZA++ (Och and Ney, 2000) on the training corpus in both directions with IBM model 4, and then applied the refinement rule described in (Koehn et al., 2003) to obtain a many-to-many word alignment for each sentence pair. We used the SRI Language Modeling Toolkit (Stolcke, 2002) to train a five-gram model with modified Kneser-Ney smoothing (Chen and Goodman, 1998). The Maximum Entropy training toolkit from (Zhang, 2006) was employed to train the measure word selection model.

### 3.2 Measure word generation

As mentioned in previous sections, we apply our measure word generation module into SMT output as a post-processing step. Given a translation from an SMT system, we first determine the position  $p_t$  at which to generate a Chinese measure word. Centered on  $p_t$ , a surrounding word window with specified size is determined. From translation alignments, the corresponding source position  $p_s$  aligned to  $p_t$  can be referred. In the same way, a source window centered on  $p_s$  is determined as well. Then, contextual information within the windows in the source and the target sentence is extracted and fed to the measure word selection model. Meanwhile, the candidate set is obtained based on words in both windows. Finally, each measure word in the candidate set is inserted to the position  $p_t$ , and its score is calculated based on the models presented in Section 2.5. The measure word with the highest probability will be chosen.

There are two reasons why we perform measure word generation for SMT systems as a post-processing step. One is that in this way our method can be easily applied to any SMT system. The other is that we can leverage both source and target information during the measure word generation process. We do not integrate our measure word generation module into the SMT decoder since there is only little target contextual information available during SMT decoding. Moreover, as we

will show in experiment section, a pre-processing method does not work well when only source information is available.

## 4 Experiments

### 4.1 Data

In the experiments, the language model is a Chinese 5-gram language model trained with the Chinese part of the LDC parallel corpus and the Xinhua part of the Chinese Gigaword corpus with about 27 million words. We used an SMT system similar to Chiang (2005), in which FBIS corpus is used as the bilingual training data. The training corpus for Mo-ME model consists of the Chinese Peen Treebank and the Chinese part of the LDC parallel corpus with about 2 million sentences. The Bi-ME model is trained with FBIS corpus, whose size is smaller than that used in Mo-ME model training.

We extracted both development and test data set from years of NIST Chinese-to-English evaluation data by filtering out sentence pairs not containing measure words. The development set is extracted from NIST evaluation data from 2002 to 2004, and the test set consists of sentence pairs from NIST evaluation data from 2005 to 2006. There are 759 testing cases for measure word generation in our test data consisting of 2746 sentence pairs. We use the English sentences in the data sets as input to the SMT decoder, and apply our proposed method to generate measure words for the output from the decoder. Measure words in Chinese sentences of the development and test sets are used as references. When there are more than one measure words acceptable at some places, we manually augment the references with multiple acceptable measure words.

### 4.2 Baseline

Our baseline is the SMT output where measure words are generated by a Hiero-like SMT decoder as discussed in Section 1. Due to noises in the Chinese translations introduced by the SMT system, we cannot correctly identify all the positions to generate measure words. Therefore, besides precision we examine recall in our experiments.

### 4.3 Evaluation over SMT output

Table 3 and Table 4 show the precision and recall of our measure word generation method. From the

experimental results, the Mo-ME, Bi-ME and Co-ME models all outperform the baseline. Compared with the baseline, the Mo-ME method takes advantage of a large size monolingual training corpus and reduces the data sparseness problem. The advantage of the Bi-ME model is being able to make full use of rich knowledge from both source and target sentences. Also as shown in Table 3 and Table 4, the Co-ME model always achieve the best results when using the same window size since it leverages the advantage of both the Mo-ME and the Bi-ME models.

Wsize	Baseline	Mo-ME	Bi-ME	Co-ME
6	54.82%	64.29%	67.15%	67.66%
8		64.93%	68.50%	69.00%
10		64.72%	69.40%	69.58%
12		65.46%	69.40%	69.76%
14		65.61%	69.69%	70.03%

Table 3. Precision over SMT output

Wsize	Baseline	Mo-ME	Bi-ME	Co-ME
6	45.61%	51.48%	53.69%	54.09%
8		51.98%	54.75%	55.14%
10		51.81%	55.44%	55.58%
12		52.38%	55.44%	55.72%
14		52.50%	55.67%	55.93%

Table 4. Recall over SMT output

We can see that the Bi-ME model can achieve better results than the Mo-ME model in both recall and precision metrics although only a small sized bilingual corpus is used for Bi-ME model training. The reason is that the Mo-ME model cannot correctly handle the cases where head words are located outside the target window. However, due to word order differences between English and Chinese, when target head words are outside the target window, their corresponding source head words might be within the source window. The capacity of capturing head words is improved when both source and target windows are used, which demonstrates that bilingual knowledge is useful for measure word generation.

We compare the results for each model with different window sizes. Larger window size can lead to better results as shown in Table 3 and Table 4 since more contextual knowledge is used to model measure word generation. However, enlarging the window size does not bring significant improvements, The major reason is that even a small win-

dow size is already able to cover most of measure word collocations, as indicated by the position distribution of head words in Table 1.

The quality of the SMT output also affects the quality of measure word generation since our method is performed in a post-processing step over the SMT output. Although translation errors degrade the measure word generation accuracy, we achieve about 15% improvement in precision and a 10% increase in recall over baseline. We notice that the recall is relatively lower. Part of the reason is some positions to generate measure words are not successfully identified due to translation errors. In addition to precision and recall, we also evaluate the Bleu score (Papineni et al., 2002) changes before and after applying our measure word generation method to the SMT output. For our test data, we only consider sentences containing measure words for Bleu score evaluation. Our measure word generation step leads to a Bleu score improvement of 0.32 where the window size is set to 10, which shows that it can improve the translation quality of an English-to-Chinese SMT system.

#### 4.4 Evaluation over reference data

To isolate the impact of the translation errors in SMT output on the performance of our measure word generation model, we conducted another experiment with reference bilingual sentences in which measure words in Chinese sentences are manually removed. This experiment can show the performance upper bound of our method without interference from an SMT system. Table 5 shows the results. Compared to the results in Table 3, the precision improvement in the Mo-ME model is larger than that in the Bi-ME model, which shows that noisy translation of the SMT system has more serious influence on the Mo-ME model than the Bi-ME model. This also indicates that source information without noises is helpful for measure word generation.

Wsize	Mo-ME	Bi-ME	Co-ME
6	71.63%	74.92%	75.72%
8	73.80%	75.48%	76.20%
10	73.80%	74.76%	75.48%
12	73.80%	75.24%	75.96%
14	73.56%	75.48%	76.44%

Table 5. Results over reference data

## 4.5 Impacts of features

In this section, we examine the contribution of both target language based features and source language based features in our model. Table 6 and Table 7 show the precision and recall when using different features. The window size is set to 10. In the tables, *Lm* denotes the *n*-gram language model feature, *Tmh* denotes the feature of collocation between target head words and the candidate measure word, *Smh* denotes the feature of collocation between source head words and the candidate measure word, *Hs* denotes the feature of source head word selection, *Punc* denotes the feature of target punctuation position, *Tlex* denotes surrounding word features in translation, *Slex* denotes surrounding word features in source sentence, and *Pos* denotes Part-Of-Speech feature.

Feature setting	Precision	Recall
Baseline	54.82%	45.61%
<i>Lm</i>	51.11%	41.24%
+ <i>Tmh</i>	61.43%	49.22%
+ <i>Punc</i>	62.54%	50.08%
+ <i>Tlex</i>	64.80%	51.87%

Table 6. Feature contribution in Mo-ME model

Feature setting	Precision	Recall
Baseline	54.82%	45.61%
<i>Lm</i>	51.11%	41.24%
+ <i>Tmh</i> + <i>Smh</i>	64.50%	51.64%
+ <i>Hs</i>	65.32%	52.26%
+ <i>Punc</i>	66.29%	53.10%
+ <i>Pos</i>	66.53%	53.25%
+ <i>Tlex</i>	67.50%	54.02%
+ <i>Slex</i>	69.52%	55.54%

Table 7. Feature contribution in Bi-ME model

The experimental results show that all the features can bring incremental improvements. The method with only *Lm* feature performs worse than the baseline. However, with more features integrated, our method outperforms the baseline, which indicates each kind of features we selected is useful for measure word generation. According to the results, the feature of MW-HW collocation has much contribution to reducing the selection error of measure words given head words. The contribution of *Slex* feature explains that other surrounding words in source sentence are also helpful since head word determination in source language

might be incorrect due to errors in English parse trees. Meanwhile, the contribution from *Smh*, *Hs* and *Slex* features demonstrates that bilingual knowledge can play an important role for measure word generation. Compared with lexicalized features, we do not get much benefit from the *Pos* features.

## 4.6 Error analysis

We conducted an error analysis on 100 randomly selected sentences from the test data. There are four major kinds of errors as listed in Table 8. Most errors are caused by failures in finding positions to generate measure words. The main reason for this is some hint information used to identify measure word positions is missing in the noisy output of SMT systems. Two kinds of errors are introduced by incomplete head word and MW-HW collocation coverage, which can be solved by enlarging the size of training corpus. There are also head word selection errors due to incorrect syntax parsing.

Error type	Ratio
unseen head word	32.14%
unseen MW-HW collocation	10.71%
missing MW position	39.29%
incorrect HW selection	10.71%
others	7.14%

Table 8. Error distribution

## 4.7 Comparison with other methods

In this section we compare our statistical methods with the pre-processing method and the rule-based methods for measure word generation in a translation task.

In pre-processing method, only source language information is available. Given a source sentence, the corresponding syntax parse tree  $T_s$  is first constructed with an English parser. Then the pre-processing method chooses the source head word  $h_s$  based on  $T_s$ . The candidate measure word with the highest probability collocated with  $h_s$  is selected as the best result, where the measure word candidate set corresponding to each head word is mined over a bilingual training corpus in advance. We achieved precision 58.62% and recall 49.25%, which are worse than the results of our post-processing based methods. The weakness of the pre-processing method is twofold. One problem is data sparseness with respect to collocations be-

tween English head words and Chinese measure words. The other problem comes from the English head word selection error introduced by using source parse trees.

We also compared our method with a well-known rule-based machine translation system – SYSTRAN<sup>3</sup>. We translated our test data with SYSTRAN’s English-to-Chinese translation engine. The precision and recall are 63.82% and 51.09% respectively, which are also lower than our method.

## 5 Related Work

Most existing rule-based English-to-Chinese MT systems have a dedicated module handling measure word generation. In general a rule-based method uses manually constructed rule patterns to predict measure words. Like most rule based approaches, this kind of system requires lots of human efforts of experienced linguists and usually cannot easily be adapted to a new domain. The most relevant work based on statistical methods to our research might be statistical technologies employed to model issues such as morphology generation (Minkov et al., 2007).

## 6 Conclusion and Future Work

In this paper we propose a statistical model for measure word generation for English-to-Chinese SMT systems, in which contextual knowledge from both source and target sentences is involved. Experimental results show that our method not only achieves high precision and recall for generating measure words, but also improves the quality of English-to-Chinese SMT systems.

In the future, we plan to investigate more features and enlarge coverage to improve the quality of measure word generation, especially reduce the errors found in our experiments.

## Abstract

We combine the strengths of Bayesian modeling and synchronous grammar in unsupervised learning of basic translation phrase pairs. The structured space of a synchronous grammar is a natural fit for phrase pair probability estimation, though the search space can be prohibitively large. Therefore we explore efficient algorithms for pruning this space that lead to empirically effective results. Incorporating a sparse prior using Variational Bayes, biases the models toward generalizable, parsimonious parameter sets, leading to significant improvements in word alignment. This preference for sparse solutions together with effective pruning methods forms a phrase alignment regimen that produces better end-to-end translations than standard word alignment approaches.

## 1 Introduction

Most state-of-the-art statistical machine translation systems are based on large phrase tables extracted from parallel text using word-level alignments. These word-level alignments are most often obtained using Expectation Maximization on the conditional generative models of Brown et al. (1993) and Vogel et al. (1996). As these word-level alignment models restrict the word alignment complexity by requiring each target word to align to zero or one source words, results are improved by aligning both source-to-target as well as target-to-source,

then heuristically combining these alignments. Finally, the set of phrases consistent with the word alignments are extracted from every sentence pair; these form the basis of the decoding process. While this approach has been very successful, poor word-level alignments are nonetheless a common source of error in machine translation systems.

A natural solution to several of these issues is unite the word-level and phrase-level models into one learning procedure. Ideally, such a procedure would remedy the deficiencies of word-level alignment models, including the strong restrictions on the form of the alignment, and the strong independence assumption between words. Furthermore it would obviate the need for heuristic combination of word alignments. A unified procedure may also improve the identification of non-compositional phrasal translations, and the attachment decisions for unaligned words.

In this direction, Expectation Maximization at the phrase level was proposed by Marcu and Wong (2002), who, however, experienced two major difficulties: computational complexity and controlling overfitting. Computational complexity arises from the exponentially large number of decompositions of a sentence pair into phrase pairs; overfitting is a problem because as EM attempts to maximize the likelihood of its training data, it prefers to directly explain a sentence pair with a single phrase pair.

In this paper, we attempt to address these two issues in order to apply EM above the word level.

We attack computational complexity by adopting the polynomial-time Inversion Transduction Grammar framework, and by only learning small *non-compositional* phrases. We address the tendency of EM to overfit by using Bayesian methods, where sparse priors assign greater mass to parameter vectors with fewer non-zero values therefore favoring shorter, more frequent phrases. We test our model by extracting longer phrases from our model’s alignments using traditional phrase extraction, and find that a phrase table based on our system improves MT results over a phrase table extracted from traditional word-level alignments.

## 2 Phrasal Inversion Transduction Grammar

We use a phrasal extension of Inversion Transduction Grammar (Wu, 1997) as the generative framework. Our ITG has two nonterminals:  $X$  and  $C$ , where  $X$  represents compositional phrase pairs that can have recursive structures and  $C$  is the pre-terminal over terminal phrase pairs. There are three rules with  $X$  on the left-hand side:

$$\begin{aligned} X &\rightarrow [X X], \\ X &\rightarrow \langle X X \rangle, \\ X &\rightarrow C. \end{aligned}$$

The first two rules are the straight rule and inverted rule respectively. They split the left-hand side constituent which represents a phrase pair into two smaller phrase pairs on the right-hand side and order them according to one of the two possible permutations. The rewriting process continues until the third rule is invoked.  $C$  is our unique pre-terminal for generating terminal multi-word pairs:

$$C \rightarrow \mathbf{e}/\mathbf{f}.$$

We parameterize our probabilistic model in the manner of a PCFG: we associate a multinomial distribution with each nonterminal, where each outcome in this distribution corresponds to an expansion of that nonterminal. Specifically, we place one multinomial distribution  $\theta_X$  over the three expansions of the nonterminal  $X$ , and another multinomial distribution  $\theta_C$  over the expansions of  $C$ . Thus, the parameters in our model can be listed as

$$\theta_{\mathbf{X}} = (P_{\diamond}, P_{\square}, P_C),$$

where  $P_{\diamond}$  is for the inverted rule,  $P_{\square}$  for the straight rule,  $P_C$  for the third rule, satisfying  $P_{\diamond} + P_{\square} + P_C = 1$ , and

$$\theta_{\mathbf{C}} = (P(\mathbf{e}/\mathbf{f}), P(\mathbf{e}'/\mathbf{f}'), \dots),$$

where  $\sum_{\mathbf{e}/\mathbf{f}} P(\mathbf{e}/\mathbf{f}) = 1$  is a multinomial distribution over phrase pairs.

This is our model in a nutshell. We can train this model using a two-dimensional extension of the inside-outside algorithm on bilingual data, assuming every phrase pair that can appear as a leaf in a parse tree of the grammar a valid candidate. However, it is easy to show that the maximum likelihood training will lead to the saturated solution where  $P_C = 1$  — each sentence pair is generated by a single phrase spanning the whole sentence. From the computational point of view, the full EM algorithm runs in  $O(n^6)$  where  $n$  is the average length of the two input sentences, which is too slow in practice.

The key is to control the number of parameters, and therefore the size of the set of candidate phrases. We deal with this problem in two directions. First we change the objective function by incorporating a prior over the phrasal parameters. This has the effect of preferring parameter vectors in  $\theta_{\mathbf{C}}$  with fewer non-zero values. Our second approach was to constrain the search space using simpler alignment models, which has the further benefit of significantly speeding up training. First we train a lower level word alignment model, then we place hard constraints on the phrasal alignment space using confident word links from this simpler model. Combining the two approaches, we have a staged training procedure going from the simplest unconstrained word based model to a constrained Bayesian word-level ITG model, and finally proceeding to a constrained Bayesian phrasal model.

## 3 Variational Bayes for ITG

Goldwater and Griffiths (2007) and Johnson (2007) show that modifying an HMM to include a sparse prior over its parameters and using Bayesian estimation leads to improved accuracy for unsupervised part-of-speech tagging. In this section, we describe a Bayesian estimator for ITG: we select parameters that optimize the probability of the data given a prior. The traditional estimation method for word

alignment models is the EM algorithm (Brown et al., 1993) which iteratively updates parameters to maximize the likelihood of the data. The drawback of maximum likelihood is obvious for phrase-based models. If we do not put any constraint on the distribution of phrases, EM overfits the data by memorizing every sentence pair. A sparse prior over a multinomial distribution such as the distribution of phrase pairs may bias the estimator toward skewed distributions that generalize better. In the context of phrasal models, this means learning the more representative phrases in the space of all possible phrases.

The Dirichlet distribution, which is parameterized by a vector of real values often interpreted as pseudo-counts, is a natural choice for the prior, for two main reasons. First, the Dirichlet is *conjugate* to the multinomial distribution, meaning that if we select a Dirichlet prior and a multinomial likelihood function, the posterior distribution will again be a Dirichlet. This makes parameter estimation quite simple. Second, Dirichlet distributions with small, non-zero parameters place more probability mass on multinomials on the edges or faces of the probability simplex, distributions with fewer non-zero parameters. Starting from the model from Section 2, we propose the following Bayesian extension, where  $A \sim \text{Dir}(B)$  means the random variable  $A$  is distributed according to a Dirichlet with parameter  $B$ :

$$\begin{aligned} \theta_{\mathbf{X}} \mid \alpha_X &\sim \text{Dir}(\alpha_X), \\ \theta_C \mid \alpha_C &\sim \text{Dir}(\alpha_C), \\ \left. \begin{array}{c} [X \ X] \\ \langle X \ X \rangle \\ C \end{array} \right| X &\sim \text{Multi}(\theta_{\mathbf{X}}), \\ \mathbf{e}/\mathbf{f} \mid C &\sim \text{Multi}(\theta_C). \end{aligned}$$

The parameters  $\alpha_X$  and  $\alpha_C$  control the sparsity of the two distributions in our model. One is the distribution of the three possible branching choices. The other is the distribution of the phrase pairs.  $\alpha_C$  is crucial, since the multinomial it is controlling has a high dimension. By adjusting  $\alpha_C$  to a very small number, we hope to place more posterior mass on parsimonious solutions with fewer but more confident and general phrase pairs.

Having defined the Bayesian model, it remains to decide the inference procedure. We chose Variational Bayes, for its procedural similarity to EM and ease of implementation. Another potential option would be Gibbs sampling (or some other sampling technique). However, in experiments in unsupervised POS tag learning using HMM structured models, Johnson (2007) shows that VB is more effective than Gibbs sampling in approaching distributions that agree with the Zipf’s law, which is prominent in natural languages.

Kurihara and Sato (2006) describe VB for PCFGs, showing the only need is to change the M step of the EM algorithm. As in the case of maximum likelihood estimation, Bayesian estimation for ITGs is very similar to PCFGs, which follows due to the strong isomorphism between the two models. Specific to our ITG case, the M step becomes:

$$\begin{aligned} \tilde{P}_{\square}^{(l+1)} &= \frac{\exp(\psi(E(X \rightarrow [X \ X]) + \alpha_X))}{\exp(\psi(E(X) + s\alpha_X))}, \\ \tilde{P}_{\langle \rangle}^{(l+1)} &= \frac{\exp(\psi(E(X \rightarrow \langle X \ X \rangle) + \alpha_X))}{\exp(\psi(E(X) + s\alpha_X))}, \\ \tilde{P}_C^{(l+1)} &= \frac{\exp(\psi(E(X \rightarrow C) + \alpha_X))}{\exp(\psi(E(X) + s\alpha_X))}, \\ \tilde{P}^{(l+1)}(\mathbf{e}/\mathbf{f}) &= \frac{\exp(\psi(E(\mathbf{e}/\mathbf{f}) + \alpha_C))}{\exp(\psi(E(C) + m\alpha_C))}, \end{aligned}$$

where  $\psi$  is the *digamma function* (Beal, 2003),  $s = 3$  is the number of right-hand-sides for  $X$ , and  $m$  is the number of observed phrase pairs in the data. The sole difference between EM and VB with a sparse prior  $\alpha$  is that the raw fractional counts  $c$  are replaced by  $\exp(\psi(c + \alpha))$ , an operation that resembles smoothing. As pointed out by Johnson (2007), in effect this expression adds to  $c$  a small value that asymptotically approaches  $\alpha - 0.5$  as  $c$  approaches  $\infty$ , and 0 as  $c$  approaches 0. For small values of  $\alpha$  the net effect is the opposite of typical smoothing, since it tends to redistribute probably mass away from unlikely events onto more likely ones.

## 4 Bitext Pruning Strategy

ITG is slow mainly because it considers every pair of spans in two sentences as a possible chart element. In reality, the set of useful chart elements is much

smaller than the possible  $\text{script}O(n^4)$ , where  $n$  is the average sentence length. Pruning the span pairs (bitext cells) that can participate in a tree (either as terminals or non-terminals) serves to not only speed up ITG parsing, but also to provide a kind of initialization hint to the training procedures, encouraging it to focus on promising regions of the alignment space.

Given a bitext cell defined by the four boundary indices  $(i, j, l, m)$  as shown in Figure 1a, we prune based on a figure of merit  $V(i, j, l, m)$  approximating the utility of that cell in a full ITG parse. The figure of merit considers the Model 1 scores of not only the words inside a given cell, but also all the words not included in the source and target spans, as in Moore (2003) and Vogel (2005). Like Zhang and Gildea (2005), it is used to prune bitext cells rather than score phrases. The total score is the product of the Model 1 probabilities for each column; “inside” columns in the range  $[l, m]$  are scored according to the sum (or maximum) of Model 1 probabilities for  $[i, j]$ , and “outside” columns use the sum (or maximum) of all probabilities not in the range  $[i, j]$ .

Our pruning differs from Zhang and Gildea (2005) in two major ways. First, we perform pruning using both directions of the IBM Model 1 scores; instead of a single figure of merit  $V$ , we have two:  $V_F$  and  $V_B$ . Only those spans that pass the pruning threshold in both directions are kept. Second, we allow whole spans to be pruned. The figure of merit for a span is  $V_F(i, j) = \max_{l, m} V_F(i, j, l, m)$ . Only spans that are within some threshold of the unrestricted Model 1 scores  $V_F$  and  $V_B$  are kept:

$$\frac{V_F(i, j)}{V_F} \geq \tau_s \text{ and } \frac{V_B(l, m)}{V_B} \geq \tau_s.$$

Amongst those spans retained by this first threshold, we keep only those bitext cells satisfying both

$$\frac{V_F(i, j, l, m)}{V_F(i, j)} \geq \tau_b \text{ and } \frac{V_B(i, j, l, m)}{V_B(l, m)} \geq \tau_b.$$

#### 4.1 Fast Tic-tac-toe Pruning

The tic-tac-toe pruning algorithm (Zhang and Gildea, 2005) uses dynamic programming to compute the product of inside and outside scores for all cells in  $\mathcal{O}(n^4)$  time. However, even this can be slow for large values of  $n$ . Therefore we describe an

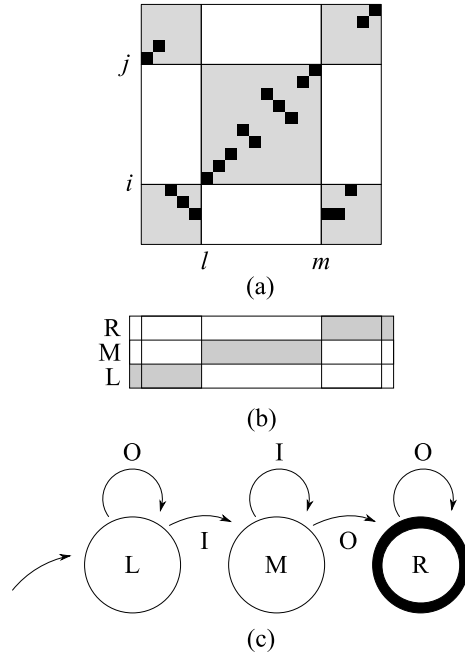

Figure 1: (a) shows the original tic-tac-toe score for a bitext cell  $(i, j, l, m)$ . (b) demonstrates the finite state representation using the machine in (c), assuming a fixed source span  $(i, j)$ .

improved algorithm with best case  $n^3$  performance. Although the worst case performance is also  $\mathcal{O}(n^4)$ , in practice it is significantly faster.

To begin, let us restrict our attention to the forward direction for a fixed source span  $(i, j)$ . Pruning bitext spans and cells requires  $V_F(i, j)$ , the score of the best bitext cell within a given span, as well as all cells within a given threshold of that best score. For a fixed  $i$  and  $j$ , we need to search over the starting and ending points  $l$  and  $m$  of the inside region. Note that there is an isomorphism between the set of spans and a simple finite state machine: any span  $(l, m)$  can be represented by a sequence of  $l$  OUTSIDE columns, followed by  $m - l + 1$  INSIDE columns, followed by  $n - m + 1$  OUTSIDE columns. This simple machine has the restricted form described in Figure 1c: it has three states,  $L$ ,  $M$ , and  $R$ ; each transition generates either an OUTSIDE column  $O$  or an INSIDE column  $I$ . The cost of generating an OUTSIDE at position  $a$  is  $O(a) = P(t_a|\text{NULL}) + \sum_{b \notin [i, j]} P(t_a|s_b)$ ; likewise the cost of generating an INSIDE column is  $I(a) = P(t_a|\text{NULL}) + \sum_{b \in [i, j]} P(t_a|s_b)$ , with

$O(0) = O(n + 1) = 1$  and  $I(0) = I(n + 1) = 0$ .

Directly computing  $O$  and  $I$  would take time  $\mathcal{O}(n^2)$  for each source span, leading to an overall runtime of  $\mathcal{O}(n^4)$ . Luckily there are faster ways to find the inside and outside scores. First we can pre-compute following arrays in  $\mathcal{O}(n^2)$  time and space:

$$\begin{aligned} \text{pre}[0, l] &:= P(t_l|\text{NULL}) \\ \text{pre}[i, l] &:= \text{pre}[i - 1, l] + P(t_l|s_i) \\ \text{suf}[n + 1, l] &:= 0 \\ \text{suf}[i, l] &:= \text{suf}[i + 1, l] + P(t_l|s_i) \end{aligned}$$

Then for any  $(i, j)$ ,  $O(a) = P(t_a|\text{NULL}) + \sum_{b \notin [i, j]} P(t_a|s_b) = \text{pre}[i - 1, a] + \text{suf}[j + 1, a]$ .  $I(a)$  can be incrementally updated as the source span varies: when  $i = j$ ,  $I(a) = P(t_a|\text{NULL}) + P(t_a|s_i)$ . As  $j$  is incremented, we add  $P(t_a|s_j)$  to  $I(a)$ . Thus we have linear time updates for  $O$  and  $I$ .

We can then find the best scoring sequence using the familiar Viterbi algorithm. Let  $\delta[a, \sigma]$  be the cost of the best scoring sequence ending in state  $\sigma$  at time  $a$ :

$$\begin{aligned} \delta[0, \sigma] &:= 1 \text{ if } \sigma = L; 0 \text{ otherwise} \\ \delta[a, L] &:= \delta[a - 1, L] \cdot O(a) \\ \delta[a, M] &:= \max_{\sigma \in L, M} \{\delta[a - 1, \sigma]\} \cdot I(a) \\ \delta[a, R] &:= \max_{\sigma \in M, R} \{\delta[a - 1, \sigma]\} \cdot O(a) \end{aligned}$$

Then  $V_F(i, j) = \delta[n + 1, R]$ , using the isomorphism between state sequences and spans. This linear time algorithm allows us to compute span pruning in  $\mathcal{O}(n^3)$  time. The same algorithm may be performed using the backward figure of merit after transposing rows and columns.

Having cast the problem in terms of finite state automata, we can use finite state algorithms for pruning. For instance, fixing a source span we can enumerate the target spans in decreasing order by score (Soong and Huang, 1991), stopping once we encounter the first span below threshold. In practice the overhead of maintaining the priority queue outweighs any benefit, as seen in Figure 2.

An alternate approach that avoids this overhead is to enumerate spans by position. Note that  $\delta[m, R] \cdot \prod_{a=m+1}^n O(a)$  is within threshold iff there is a span with right boundary  $m' < m$  within threshold. Furthermore if  $\delta[m, M] \cdot \prod_{a=m+1}^n O(a)$  is

Figure 2: Speed comparison of the  $\mathcal{O}(n^4)$  tic-tac-toe pruning algorithm, the A\* top- $x$  algorithm, and the fast tic-tac-toe pruning. All produce the same set of bitext cells, those within threshold of the best bitext cell.

within threshold, then  $m$  is the right boundary within threshold. Using these facts, we can gradually sweep the right boundary  $m$  from  $n$  toward 1 until the first condition fails to hold. For each value where the second condition holds, we pause to search for the set of left boundaries within threshold.

Likewise for the left edge,  $\delta[l, M] \cdot \prod_{a=l+1}^m I(a) \cdot \prod_{a=m+1}^n O(a)$  is within threshold iff there is some  $l' < l$  identifying a span  $(l', m)$  within threshold. Finally if  $V(i, j, l, m) = \delta[l - 1, L] \cdot \prod_{a=l}^m I(a) \cdot \prod_{a=m+1}^n O(a)$  is within threshold, then  $(i, j, l, m)$  is a bitext cell within threshold. For right edges that are known to be within threshold, we can sweep the left edges leftward until the first condition no longer holds, keeping only those spans for which the second condition holds.

The filtering algorithm behaves extremely well. Although the worst case runtime is still  $\mathcal{O}(n^4)$ , the best case has improved to  $n^3$ ; empirically it seems to significantly reduce the amount of time spent exploring spans. Figure 2 compares the speed of the fast tic-tac-toe algorithm against the algorithm in Zhang and Gildea (2005).

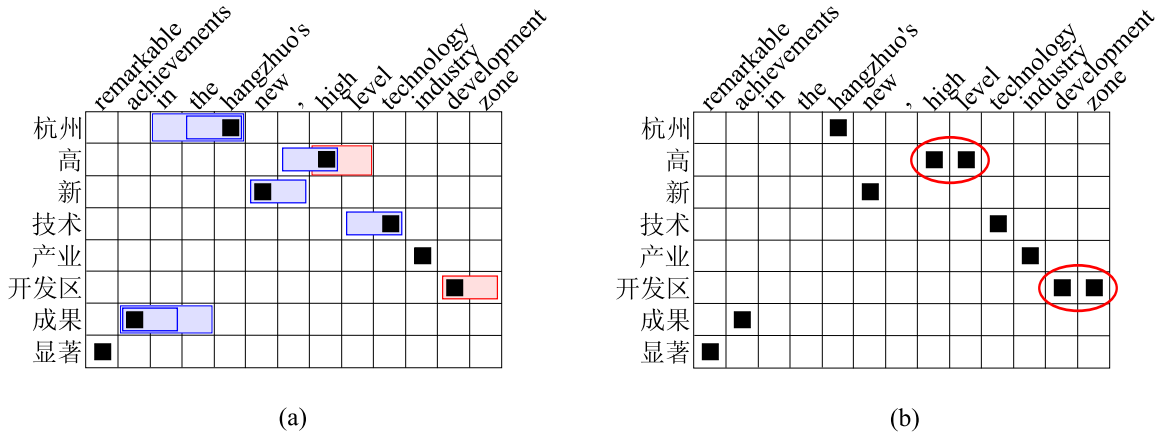

Figure 3: Example output from the ITG using non-compositional phrases. (a) is the Viterbi alignment from the word-based ITG. The shaded regions indicate phrasal alignments that are allowed by the non-compositional constraint; all other phrasal alignments will not be considered. (b) is the Viterbi alignment from the phrasal ITG, with the multi-word alignments highlighted.

## 5 Bootstrapping Phrasal ITG from Word-based ITG

This section introduces a technique that bootstraps candidate phrase pairs for phrase-based ITG from word-based ITG Viterbi alignments. The word-based ITG uses the same expansions for the non-terminal  $X$ , but the expansions of  $C$  are limited to generate only 1-1, 1-0, and 0-1 alignments:

$$\begin{aligned} C &\rightarrow e/f, \\ C &\rightarrow e/\epsilon, \\ C &\rightarrow \epsilon/f \end{aligned}$$

where  $\epsilon$  indicates that no word was generated. Broadly speaking, the goal of this section is the same as the previous section, namely, to limit the set of phrase pairs that needs to be considered in the training process. The tic-tac-toe pruning relies on IBM model 1 for scoring a given aligned area. In this part, we use word-based ITG alignments as anchor points in the alignment space to pin down the potential phrases. The scope of iterative phrasal ITG training, therefore, is limited to determining the boundaries of the phrases anchored on the given one-to-one word alignments.

The heuristic method is based on the Non-Compositional Constraint of Cherry and Lin (2007). Cherry and Lin (2007) use GIZA++ intersections which have high precision as anchor points in the

bitext space to constraint ITG phrases. We use ITG Viterbi alignments instead. The benefit is two-fold. First of all, we do not have to run a GIZA++ aligner. Second, we do not need to worry about non-ITG word alignments, such as the (2, 4, 1, 3) permutation patterns. GIZA++ does not limit the set of permutations allowed during translation, so it can produce permutations that are not reachable using an ITG.

Formally, given a word-based ITG alignment, the bootstrapping algorithm finds all the phrase pairs according to the definition of Och and Ney (2004) and Chiang (2005) with the additional constraint that each phrase pair contains at most one word link. Mathematically, let  $e(i, j)$  count the number of word links that are emitted from the substring  $e_{i\dots j}$ , and  $f(l, m)$  count the number of word links emitted from the substring  $f_{l\dots m}$ . The non-compositional phrase pairs satisfy

$$e(i, j) = f(l, m) \leq 1.$$

Figure 3 (a) shows all possible non-compositional phrases given the Viterbi word alignment of the example sentence pair.

## 6 Summary of the Pipeline

We summarize the pipeline of our system, demonstrating the interactions between the three main contributions of this paper: Variational Bayes, tic-tac-toe pruning, and word-to-phrase bootstrapping. We

start from sentence-aligned bilingual data and run IBM Model 1 in both directions to obtain two translation tables. Then we use the efficient bidirectional tic-tac-toe pruning to prune the bitext space within each of the sentence pairs; ITG parsing will be carried out on only this sparse set of bitext cells. The first stage of training is word-based ITG, using the standard iterative training procedure, except VB replaces EM to focus on a sparse prior. After several training iterations, we obtain the Viterbi alignments on the training data according to the final model. Now we transition into the second stage – the phrasal training. Before the training starts, we apply the non-compositional constraints over the pruned bitext space to further constrain the space of phrase pairs. Finally, we run phrasal ITG iterative training using VB for a certain number of iterations. In the end, a Viterbi pass for the phrasal ITG is executed to produce the non-compositional phrasal alignments. From this alignment, phrase pairs are extracted in the usual manner, and a phrase-based translation system is trained.

## 7 Experiments

The training data was a subset of 175K sentence pairs from the NIST Chinese-English training data, automatically selected to maximize character-level overlap with the source side of the test data. We put a length limit of 35 on both sides, producing a training set of 141K sentence pairs. 500 Chinese-English pairs from this set were manually aligned and used as a gold standard.

### 7.1 Word Alignment Evaluation

First, using evaluations of alignment quality, we demonstrate the effectiveness of VB over EM, and explore the effect of the prior.

Figure 4 examines the difference between EM and VB with varying sparse priors for the word-based model of ITG on the 500 sentence pairs, both after 10 iterations of training. Using EM, because of overfitting, AER drops first and increases again as the number of iterations varies from 1 to 10. The lowest AER using EM is achieved after the second iteration, which is .40. At iteration 10, AER for EM increases to .42. On the other hand, using VB, AER decreases monotonically over the 10 iterations and

Figure 4: AER drops as  $\alpha_C$  approaches zero; a more sparse solution leads to better results.

stabilizes at iteration 10. When  $\alpha_C$  is  $1e - 9$ , VB gets AER close to .35 at iteration 10.

As we increase the bias toward sparsity, the AER decreases, following a long slow plateau. Although the magnitude of improvement is not large, the trend is encouraging.

These experiments also indicate that a very sparse prior is needed for machine translation tasks. Unlike Johnson (2007), who found optimal performance when  $\alpha$  was approximately  $10^{-4}$ , we observed monotonic increases in performance as  $\alpha$  dropped. The dimensionality of this MT problem is significantly larger than that of the sequence problem, though, therefore it may take a stronger push from the prior to achieve the desired result.

### 7.2 End-to-end Evaluation

Given an unlimited amount of time, we would tune the prior to maximize end-to-end performance, using an objective function such as BLEU. Unfortunately these experiments are very slow. Since we observed monotonic increases in alignment performance with smaller values of  $\alpha_C$ , we simply fixed the prior at a very small value ( $10^{-100}$ ) for all translation experiments. We do compare VB against EM in terms of final BLEU scores in the translation experiments to ensure that this sparse prior has a sig-

nificant impact on the output.

We also trained a baseline model with GIZA++ (Och and Ney, 2003) following a regimen of 5 iterations of Model 1, 5 iterations of HMM, and 5 iterations of Model 4. We computed Chinese-to-English and English-to-Chinese word translation tables using five iterations of Model 1. These values were used to perform tic-tac-toe pruning with  $\tau_b = 1 \times 10^{-3}$  and  $\tau_s = 1 \times 10^{-6}$ . Over the pruned charts, we ran 10 iterations of word-based ITG using EM or VB. The charts were then pruned further by applying the non-compositional constraint from the Viterbi alignment links of that model. Finally we ran 10 iterations of phrase-based ITG over the residual charts, using EM or VB, and extracted the Viterbi alignments.

For translation, we used the standard phrasal decoding approach, based on a re-implementation of the Pharaoh system (Koehn, 2004). The output of the word alignment systems (GIZA++ or ITG) were fed to a standard phrase extraction procedure that extracted all phrases of length up to 7 and estimated the conditional probabilities of source given target and target given source using relative frequencies. Thus our phrasal ITG learns only the minimal non-compositional phrases; the standard phrase-extraction algorithm learns larger combinations of these minimal units. In addition the phrases were annotated with lexical weights using the IBM Model 1 tables. The decoder also used a trigram language model trained on the target side of the training data, as well as word count, phrase count, and distortion penalty features. Minimum Error Rate training (Och, 2003) over BLEU was used to optimize the weights for each of these models over the development test data.

We used the NIST 2002 evaluation datasets for tuning and evaluation; the 10-reference development set was used for minimum error rate training, and the 4-reference test set was used for evaluation. We trained several phrasal translation systems, varying only the word alignment (or phrasal alignment) method.

Table 1 compares the four systems: the GIZA++ baseline, the ITG word-based model, the ITG multiword model using EM training, and the ITG multiword model using VB training. ITG-mwm-VB is our best model. We see an improvement of nearly

	<i>Development</i>	<i>Test</i>
GIZA++	37.46	28.24
ITG-word	35.47	26.55
ITG-mwm (VB)	39.21	<b>29.02</b>
ITG-mwm (EM)	39.15	28.47

Table 1: Translation results on Chinese-English, using the subset of training data (141K sentence pairs) that have length limit 35 on both sides. (No length limit in translation.)

2 points dev set and nearly 1 point of improvement on the test set. We also observe the consistent superiority of VB over EM. The gain is especially large on the test data set, indicating VB is less prone to overfitting.

## 8 Conclusion

We have presented an improved and more efficient method of estimating phrase pairs directly. By both changing the objective function to include a bias toward sparser models and improving the pruning techniques and efficiency, we achieve significant gains on test data with practical speed. In addition, these gains were shown without resorting to external models, such as GIZA++. We have shown that VB is both practical and effective for use in MT models.

However, our best system does not apply VB to a single probability model, as we found an appreciable benefit from bootstrapping each model from simpler models, much as the IBM word alignment models are usually trained in succession. We find that VB alone is not sufficient to counteract the tendency of EM to prefer analyses with smaller trees using fewer rules and longer phrases. Both the tic-tac-toe pruning and the non-compositional constraint address this problem by reducing the space of possible phrase pairs. On top of these hard constraints, the sparse prior of VB helps make the model less prone to overfitting to infrequent phrase pairs, and thus improves the quality of the phrase pairs the model learns.

## Abstract

We propose a language model based on a precise, linguistically motivated grammar (a hand-crafted Head-driven Phrase Structure Grammar) and a statistical model estimating the probability of a parse tree. The language model is applied by means of an N-best rescoring step, which allows to directly measure the performance gains relative to the baseline system without rescoring. To demonstrate that our approach is feasible and beneficial for non-trivial broad-domain speech recognition tasks, we applied it to a simplified German broadcast-news transcription task. We report a significant reduction in word error rate compared to a state-of-the-art baseline system.

## 1 Introduction

It has repeatedly been pointed out that N-grams model natural language only superficially: an Nth-order Markov chain is a very crude model of the complex dependencies between words in an utterance. More accurate statistical models of natural language have mainly been developed in the field of statistical parsing, e.g. Collins (2003), Charniak (2000) and Ratnaparkhi (1999). Other linguistically inspired language models like Chelba and Jelinek (2000) and Roark (2001) have been applied to continuous speech recognition.

These models have in common that they explicitly or implicitly use a context-free grammar induced from a treebank, with the exception of Chelba and Jelinek (2000). The probability of a rule expansion or parser operation is conditioned on various contextual information and the derivation history. An

important reason for the success of these models is the fact that they are lexicalized: the probability distributions are also conditioned on the actual words occurring in the utterance, and not only on their parts of speech. Most statistical parsers achieve a high robustness with respect to out-of-grammar sentences by allowing for arbitrary derivations and rule expansions. On the other hand, they are not suited to reliably decide on the grammaticality of a given phrase, as they do not accurately model the linguistic constraints inherent in natural language.

We take a completely different position. In the first place, we want our language model to reliably distinguish between grammatical and ungrammatical phrases. To this end, we have developed a precise, linguistically motivated grammar. To distinguish between common and uncommon phrases, we use a statistical model that estimates the probability of a phrase based on the syntactic dependencies established by the parser. We achieve some degree of robustness by letting the grammar accept arbitrary sequences of words and phrases. To keep the grammar restrictive, such sequences are penalized by the statistical model.

Accurate hand-crafted grammars have been applied to speech recognition before, e.g. Kiefer et al. (2000) and van Noord et al. (1999). However, they primarily served as a basis for a speech understanding component and were applied to narrow-domain tasks such as appointment scheduling or public transport information. We are mainly concerned with speech recognition performance on broad-domain recognition tasks.

Beutler et al. (2005) pursued a similar approach.

However, their grammar-based language model did not make use of a probabilistic component, and it was applied to a rather simple recognition task (dictation texts for pupils read and recorded under good acoustic conditions, no out-of-vocabulary words). Besides proposing an improved language model, this paper presents experimental results for a much more difficult and realistic task and compares them to the performance of a state-of-the-art baseline system.

In the following Section, we will first describe our grammar-based language model. Next, we will turn to the linguistic components of the model, namely the grammar, the lexicon and the parser. We will point out some of the challenges arising from the broad-domain speech recognition application and propose ways to deal with them. Finally, we will describe our experiments on broadcast news data and discuss the results.

## 2 Language Model

### 2.1 The General Approach

Speech recognizers choose the word sequence  $\hat{W}$  which maximizes the posterior probability  $P(W|O)$ , where  $O$  is the acoustic observation. This is achieved by optimizing

$$\hat{W} = \underset{W}{\operatorname{argmax}} P(O|W) \cdot P(W)^\lambda \cdot ip^{|W|} \quad (1)$$

The language model weight  $\lambda$  and the word insertion penalty  $ip$  lead to a better performance in practice, but they have no theoretical justification. Our grammar-based language model is incorporated into the above expression as an additional probability  $P_{gram}(W)$ , weighted by a parameter  $\mu$ :

$$\hat{W} = \underset{W}{\operatorname{argmax}} P(O|W) \cdot P(W)^\lambda \cdot P_{gram}(W)^\mu \cdot ip^{|W|} \quad (2)$$

$P_{gram}(W)$  is defined as the probability of the most likely parse tree of a word sequence  $W$ :

$$P_{gram}(W) = \max_{T \in \text{parses}(W)} P(T) \quad (3)$$

To determine  $P_{gram}(W)$  is an expensive operation as it involves parsing. For this reason, we pursue an N-best rescoring approach. We first produce the N best hypotheses according to the criterion in equation (1). From these hypotheses we then choose the final recognition result according to equation (2).

### 2.2 The Probability of a Parse Tree

The parse trees produced by our parser are binary-branching and rather deep. In order to compute the probability of a parse tree, it is transformed to a flat dependency tree similar to the syntax graph representation used in the TIGER treebank Brants et al (2002). An inner node of such a dependency tree represents a constituent or phrase. Typically, it directly connects to a leaf node representing the most important word of the phrase, the *head child*. The other children represent phrases or words directly depending on the head child. To give an example, the immediate children of a sentence node are the finite verb (the head child), the adverbials, the subject and the all other (verbal and non-verbal) complements.

This flat structure has the advantage that the information which is most relevant for the head child is represented within the locality of an inner node. Assuming statistical independence between the internal structures of the inner nodes  $n_i$ , we can factor  $P(T)$  much like it is done for probabilistic context-free grammars:

$$P(T) \approx \prod_{n_i} P(\text{childtags}(n_i) | \text{tag}(n_i)) \quad (4)$$

In the above equation,  $\text{tag}(n_i)$  is simply the label assigned to the tree node  $n_i$ , and  $\text{childtags}(n_i)$  denotes the tags assigned to the child nodes of  $n_i$ .

Our statistical model for German sentences distinguishes between eight different tags. Three tags are used for different types of noun phrases: pronominal NPs, non-pronominal NPs and pronominal genitives. Pronominal genitives were given a dedicated tag because they are much more restricted than ordinary NPs. Another two tags were used to distinguish between clauses with sentence-initial finite verbs (main clauses) and clauses with sentence-final finite verbs (subordinate clauses). Finally, there are specific tags for infinitive verb phrases, adjective phrases and prepositional phrases.

$P$  was modeled by means of a dedicated probability distribution for each conditioning tag. The probability of the internal structure of a sentence was modeled as the trigram probability of the corresponding tag sequence (the sequence of the sentence node's child tags). The probability of an adjective phrase was decomposed into the probability

of the adjective type (participle or non-participle and attributive, adverbial or predicative) and the probability of its length in words given the adjective type. This allows the model to directly penalize long adjective phrases, which are very rare. The model for noun phrases is based on the joint probability of the head type (either noun, adjective or proper name), the presence of a determiner and the presence of pre- and postnominal modifiers. The probabilities of various other events are conditioned on those four variables, namely the number of prepositional phrases, relative clauses and adjectives, as well as the presence of appositions and prenominal or postnominal genitives.

The resulting probability distributions were trained on the German TIGER treebank which consists of about 50000 sentences of newspaper text.

### 2.3 Robustness Issues

A major problem of grammar-based approaches to language modeling is how to deal with out-of-grammar utterances. Obviously, the utterance to be recognized may be ungrammatical, or it could be grammatical but not covered by the given grammar. But even if the utterance is both grammatical and covered by the grammar, the correct word sequence may not be among the  $N$  best hypotheses due to out-of-vocabulary words or bad acoustic conditions. In all these cases, the best hypothesis available is likely to be out-of-grammar, but the language model should nevertheless prefer it to competing hypotheses. To make things worse, it is not unlikely that some of the competing hypotheses are grammatical.

It is therefore important that our language model is robust with respect to out-of-grammar sentences. In particular this means that it should provide a reasonable parse tree for any possible word sequence  $W$ . However, our approach is to use an accurate, linguistically motivated grammar, and it is undesirable to weaken the constraints encoded in the grammar. Instead, we allow the parser to attach any sequence of words or correct phrases to the root node, where each attachment is penalized by the probabilistic model  $P(T)$ . This can be thought of as adding two probabilistic context-free rules:

$$\begin{aligned} S &\longrightarrow S' S && \text{with probability } q \\ S &\longrightarrow S' && \text{with probability } 1-q \end{aligned}$$

In order to guarantee that all possible word sequences are parseable,  $S'$  can produce both saturated phrases and arbitrary words. To include such a productive set of rules into the grammar would lead to serious efficiency problems. For this reason, these rules were actually implemented as a dynamic programming pass: after the parser has identified all correct phrases, the most probable sequence of phrases or words is computed.

### 2.4 Model Parameters

Besides the distributions required to specify  $P(T)$ , our language model has three parameters: the language model weight  $\mu$ , the attachment probability  $q$  and the number of hypotheses  $N$ . The parameters  $\mu$  and  $q$  are considered to be task-dependent. For instance, if the utterances are well-covered by the grammar and the acoustic conditions are good, it can be expected that  $\mu$  is relatively large and that  $q$  is relatively small. The choice of  $N$  is restricted by the available computing power. For our experiments, we chose  $N = 100$ . The influence of  $N$  on the word error rate is discussed in the results section.

## 3 Linguistic Resources

### 3.1 Particularities of the Recognizer Output

The linguistic resources presented in this Section are partly influenced by the form of the recognizer output. In particular, the speech recognizer does not always transcribe numbers, compounds and acronyms as single words. For instance, the word “*einundzwanzig*” (twenty-one) is transcribed as “*ein und zwanzig*”, “*Kriegspläne*” (war plans) as “*Kriegs Pläne*” and “*BMW*” as “*B. M. W.*” These transcription variants are considered to be correct by our evaluation scheme. Therefore, the grammar should accept them as well.

### 3.2 Grammar and Parser

We used the Head-driven Phrase Structure Grammar (HPSG, see Pollard and Sag (1994)) formalism to develop a precise large-coverage grammar for German. HPSG is an unrestricted grammar (Chomsky type 0) which is based on a context-free skeleton and the unification of complex feature structures. There are several variants of HPSG which mainly differ in the formal tools they provide for stating lin-

guistic constraints. Our particular variant requires that constituents (phrases) be continuous, but it provides a mechanism for dealing with discontinuities as present e.g. in the German main clause, see Kaufmann and Pfister (2007). HPSG typically distinguishes between *immediate dominance schemata* (rough equivalents of phrase structure rules, but making no assumptions about constituent order) and *linear precedence rules* (constraints on constituent order). We do not make this distinction but rather let immediate dominance schemata specify constituent order. Further, the formalism allows to express complex linguistic constraints by means of *predicates* or *relational constraints*. At parse time, predicates are backed by program code that can perform arbitrary computations to check or specify feature structures.

We have implemented an efficient Java parser for our variant of the HPSG formalism. The parser supports ambiguity packing, which is a technique for merging constituents with different derivational histories but identical syntactic properties. This is essential for parsing long and ambiguous sentences.

Our grammar incorporates many ideas from existing linguistic work, e.g. Müller (2007), Müller (1999), Crysmann (2005), Crysmann (2003). In addition, we have modeled a few constructions which occur frequently but are often neglected in formal syntactic theories. Among them are prenominal and postnominal genitives, expressions of quantity and expressions of date and time. Further, we have implemented dedicated subgrammars for analyzing written numbers, compounds and acronyms that are written as separate words. To reduce ambiguity, only noun-noun compounds are covered by the grammar. Noun-noun compounds are by far the most productive compound type.

The grammar consists of 17 rules for general linguistic phenomena (e.g. subcategorization, modification and extraction), 12 rules for modeling the German verbal complex and another 13 construction-specific rules (relative clauses, genitive attributes, optional determiners, nominalized adjectives, etc.). The various subgrammars (expressions of date and time, written numbers, noun-noun compounds and acronyms) amount to a total of 43 rules.

The grammar allows the derivation of “intermediate products” which cannot be regarded as complete phrases. We consider complete phrases to be

sentences, subordinate clauses, relative and interrogative clauses, noun phrases, prepositional phrases, adjective phrases and expressions of date and time.

### 3.3 Lexicon

The lexicon was created manually based on a list of more than 5000 words appearing in the N-best lists of our experiment. As the domain of our recognition task is very broad, we attempted to include any possible reading of a given word. Our main source of dictionary information was Duden (1999).

Each word was annotated with precise morphological and syntactic information. For example, the roughly 2700 verbs were annotated with over 7000 valency frames. We distinguish 86 basic valency frames, for most of which the complement types can be further specified.

A major difficulty was the acquisition of *multi-word lexemes*. Slightly deviating from the common notion, we use the following definition: A syntactic unit consisting of two or more words is a multi-word lexeme, if the grammar cannot derive it from its parts. English examples are idioms like “*by and large*” and phrasal verbs such as “*to call sth off*”. Such multi-word lexemes have to be entered into the lexicon, but they cannot directly be identified in the word list. Therefore, they have to be extracted from supplementary resources. For our work, we used a newspaper text corpus of 230M words (Frankfurter Rundschau and Neue Zürcher Zeitung). This corpus included only articles which are dated before the first broadcast news show used in the experiment. In the next few paragraphs we will discuss some types of multiword lexemes and our methods of extracting them.

There is a large and very productive class of German prefix verbs whose prefixes can appear separated from the verb, similar to English phrasal verbs. For example, the prefix of the verb “*untergehen*” (to sink) is separated in “*das Schiff geht unter*” (the ship sinks) and attached in “*weil das Schiff untergeht*” (because the ship sinks). The set of possible valency frames of a prefix verb has to be looked up in a dictionary as it cannot be derived systematically from its parts. Exploiting the fact that prefixes are attached to their verb under certain circumstances, we extracted a list of prefix verbs from the above newspaper text corpus. As the number of prefix verbs is

very large, a candidate prefix verb was included into the lexicon only if there is a recognizer hypothesis in which both parts are present. Note that this procedure does not amount to optimizing on test data: when parsing a hypothesis, the parser chart contains only those multiword lexemes for which all parts are present in the hypothesis.

Other multi-word lexemes are fixed word clusters of various types. For instance, some prepositional phrases appearing in support verb constructions lack an otherwise mandatory determiner, e.g. “*unter Beschuss*” (under fire). Many multi-word lexemes are adverbials, e.g. “*nach wie vor*” (still), “*auf die Dauer*” (in the long run). To extract such word clusters we used suffix arrays proposed in Yamamoto and Church (2001) and the pointwise mutual information measure, see Church and Hanks (1990). Again, it is feasible to consider only those clusters appearing in some recognizer hypothesis. The list of candidate clusters was reduced using different filter heuristics and finally checked manually.

For our task, split compounds are to be considered as multi-word lexemes as well. As our grammar only models noun-noun compounds, other compounds such as “*unionsgeführt*” (led by the union) have to be entered into the lexicon. We applied the decompounding algorithm proposed in Adda-Decker (2003) to our corpus to extract such compounds. The resulting candidate list was again filtered manually.

We observed that many proper nouns (e.g. personal names and geographic names) are identical to some noun, adjective or verb form. For example, about 40% of the nouns in our lexicon share inflected forms with personal names. Proper nouns considerably contribute to ambiguity, as most of them do not require a determiner. Therefore, a proper noun which is a homograph of an open-class word was entered only if it is “relevant” for our task. The “relevant” proper nouns were extracted automatically from our text corpus. We used small databases of unambiguous given names and forms of address to spot personal names in significant bigrams. Relevant geographic names were extracted by considering capitalized words which significantly often follow certain local prepositions.

The final lexicon contains about 2700 verbs (including 1900 verbs with separable prefixes), 3500

nouns, 450 adjectives, 570 closed-class words and 220 multiword lexemes. All lexicon entries amount to a total of 137500 full forms. Noun-noun compounds are not included in these numbers, as they are handled in a morphological analysis component.

## 4 Experiments

### 4.1 Experimental Setup

The experiment was designed to measure how much a given speech recognition system can benefit from our grammar-based language model. To this end, we used a baseline speech recognition system which provided the  $N$  best hypotheses of an utterance along with their respective scores. The grammar-based language model was then applied to the  $N$  best hypotheses as described in Section 2.1, yielding a new best hypothesis. For a given test set we could then compare the word error rate of the baseline system with that of the extended system employing the grammar-based language model.

### 4.2 Data and Preprocessing

Our experiments are based on word lattice output from the LIMSI German broadcast news transcription system (McTait and Adda-Decker, 2003), which employs 4-gram backoff language models. From the experiment reported in McTait and Adda-Decker (2003), we used the first three broadcast news shows<sup>1</sup> which corresponds to a signal length of roughly 50 minutes.

Rather than applying our model to the original broadcast-news transcription task, we used the above data to create an artificial recognition task with manageable complexity. Our primary aim was to design a task which allows us to investigate the properties of our grammar-based approach and to compare its performance with that of a competitive baseline system.

As a first simplification, we assumed perfect sentence segmentation. We manually split the original word lattices at the sentence boundaries and merged them where a sentence crossed a lattice boundary. This resulted in a set of 636 lattices (sentences). Second, we classified the sentences with respect to content type and removed those classes with an excep-

<sup>1</sup>The 8 o'clock broadcasts of the “Tagesschau” from the 14<sup>th</sup> of April, 21<sup>st</sup> of April and 7<sup>th</sup> of Mai 2002.

tionally high baseline word error rate. These classes are interviews (a word error rate of 36.1%), sports reports (28.4%) and press conferences (25.7%). The baseline word error rate of the remaining 447 lattices (sentences) is 11.8%.

From each of these 447 lattices, the 100 best hypotheses were extracted. We next compiled a list containing all words present in the recognizer hypotheses. These words were entered into the lexicon as described in Section 3.3. Finally, all extracted recognizer hypotheses were parsed. Only 25 of the 44000 hypotheses<sup>2</sup> caused an early termination of the parser due to the imposed memory limits. However, the inversion of ambiguity packing (see Section 3.2) turned out to be a bottleneck. As  $P(T)$  does not directly apply to parse trees, all possible readings have to be unpacked. For 24 of the 447 lattices, some of the  $N$  best hypotheses contained phrases with more than 1000 readings. For these lattices the grammar-based language model was simply switched off in the experiment, as no parse trees were produced for efficiency reasons.

To assess the difficulty of our task, we inspected the reference transcriptions, the word lattices and the N-best lists for the 447 selected utterances. We found that for only 59% of the utterances the correct transcription is among the 100-best hypotheses. The first-best hypothesis is completely correct for 34% of the utterances. The out-of-vocabulary rate (estimated from the number of reference transcription words which do not appear in any of the lattices) is 1.7%. The first-best word error rate is 11.79%, and the 100-best oracle word error rate is 4.8%.

We further attempted to judge the grammaticality of the reference transcriptions. We considered only 1% of the sentences to be clearly ungrammatical. 19% of the remaining sentences were found to contain general grammatical constructions which are not handled by our grammar. Some of these constructions (most notably ellipses, which are omnipresent in broadcast-news reports) are notoriously difficult as they would dramatically increase ambiguity when implemented in a grammar. About 45% of the reference sentences were correctly analyzed by the grammar.

---

<sup>2</sup>Some of the word lattices contain less than 100 different hypotheses.

### 4.3 Training and Testing

The parameter  $N$ , the maximum number of hypotheses to be considered, was set to 100 (the effect of choosing different values of  $N$  will be discussed in section 4.4). The remaining parameters  $\mu$  and  $q$  were trained using the leave-one-out cross-validation method: each of the 447 utterances served as the single test item once, whereas the remaining 446 utterances were used for training. As the error landscape is complex and discrete, we could not use gradient-based optimization methods. Instead, we chose  $\mu$  and  $q$  from 500 equidistant points within the intervals  $[0, 20]$  and  $[0, 0.25]$ , respectively. The word error rate was evaluated for each possible pair of parameter values.

The evaluation scheme was taken from McTait and Adda-Decker (2003). It ignores capitalization, and written numbers, compounds and acronyms need not be written as single words.

### 4.4 Results

As shown in Table 1, the grammar-based language model reduced the word error rate by 9.2% relative over the baseline system. This improvement is statistically significant on a level of  $< 0.1\%$  for both the Matched Pairs Sentence-Segment Word Error test (MAPSSWE) and McNemar’s test (Gillick and Cox, 1989). If the parameters are optimized on all 447 sentences (i.e. on the test data), the word error rate is reduced by 10.7% relative.

For comparison, we redefined the probabilistic model as  $P(T) = (1 - q)q^{k-1}$ , where  $k$  is the number of phrases attached to the root node. This reduced model only considers the grammaticality of a phrase, completely ignoring the probability of its internal structure. It achieved a relative word error reduction of 5.9%, which is statistically significant on a level of  $< 0.1\%$  for both tests. The improvement of the full model compared to the reduced model is weakly significant on a level of 2.6% for the MAPSSWE test.

For both models, the optimal value of  $q$  was 0.001 for almost all training runs. The language model weight  $\mu$  of the reduced model was about 60% smaller than the respective value for the full model, which confirms that the full model provides more reliable information.

experiment	word error rate
<b>baseline</b>	<b>11.79%</b>
grammar, no statistics	11.09% (-5.9% rel.)
<b>grammar</b>	<b>10.70%</b> (-9.2% rel.)
grammar, cheating	10.60% (-10.7% rel.)
100-best oracle	4.80%

Table 1: The impact of the grammar-based language model on the word error rate. For comparison, the results for alternative experiments are shown. In the experiment “*grammar, cheating*”, the parameters were optimized on test data.

Figure 1 shows the effect of varying  $N$  (the maximum number of hypotheses) on the word error rate both for leave-one-out training and for optimizing the parameters on test data. The similar shapes of the two curves suggest that the observed variations are partly due to the problem structure. In fact, if  $N$  is increased and new hypotheses with a high value of  $P_{gram}(W)$  appear, the benefit of the grammar-based language model can increase (if the hypotheses are predominantly good with respect to word error rate) or decrease (if they are bad). This horizon effect tends to be reduced with increasing  $N$  (with the exception of  $89 \leq N \leq 93$ ) because hypotheses with high ranks need a much higher  $P_{gram}(W)$  in order to compensate for their lower value of  $P(O|W) \cdot P(W)^\lambda$ . For small  $N$ , the parameter estimation is more severely affected by the rather accidental horizon effects and therefore is prone to overfitting.

## 5 Conclusions and Outlook

We have presented a language model based on a precise, linguistically motivated grammar, and we have successfully applied it to a difficult broad-domain task.

It is a well-known fact that natural language is highly ambiguous: a correct and seemingly unambiguous sentence may have an enormous number of readings. A related – and for our approach even more relevant – phenomenon is that many weird-looking and seemingly incorrect word sequences are in fact grammatical. This obviously reduces the benefit of pure grammaticality information. A solution is to use additional information to assess how “natural” a reading of a word sequence is. We have done a

Figure 1: The word error rate as a function of the maximum number of best hypotheses  $N$ .

first step in this direction by estimating the probability of a parse tree. However, our model only looks at the structure of a parse tree and does not take the actual words into account. As N-grams and statistical parsers demonstrate, word information can be very valuable. It would therefore be interesting to investigate ways of introducing word information into our grammar-based model.

## Acknowledgements

This work was supported by the Swiss National Science Foundation. We cordially thank Jean-Luc Gauvain of LIMSI for providing us with word lattices from their German broadcast news transcription system.

## Abstract

Written documents created through dictation differ significantly from a true verbatim transcript of the recorded speech. This poses an obstacle in automatic dictation systems as speech recognition output needs to undergo a fair amount of editing in order to turn it into a document that complies with the customary standards. We present an approach that attempts to perform this edit from recognized words to final document automatically by learning the appropriate transformations from example documents. This addresses a number of problems in an integrated way, which have so far been studied independently, in particular automatic punctuation, text segmentation, error correction and disfluency repair. We study two different learning methods, one based on rule induction and one based on a probabilistic sequence model. Quantitative evaluation shows that the probabilistic method performs more accurately.

## 1 Introduction

Large vocabulary speech recognition today achieves a level of accuracy that makes it useful in the production of written documents. Especially in the medical and legal domains large volumes of text are traditionally produced by means of dictation. Here document creation is typically a “back-end” process. The author dictates all necessary information into a telephone handset or a portable recording device and is not concerned with the actual production of the document any further. A transcriptionist will then

listen to the recorded dictation and produce a well-formed document using a word processor. The goal of introducing speech recognition in this process is to create a draft document automatically, so that the transcriptionist only has to verify the accuracy of the document and to fix occasional recognition errors. We observe that users try to spend as little time as possible dictating. They usually focus only on the content and rely on the transcriptionist to compose a readable, syntactically correct, stylistically acceptable and formally compliant document. For this reason there is a considerable discrepancy between the final document and what the speaker has said literally. In particular in medical reports we see differences of the following kinds:

- Punctuation marks are typically not verbalized.
- No instructions on the formatting of the report are dictated. Section headings are not identified as such.
- Frequently section headings are only implied. (“vitals are” → “PHYSICAL EXAMINATION: VITAL SIGNS:”)
- Enumerated lists. Typically speakers use phrases like “number one . . . next number . . .”, which need to be turned into “1. . . 2. . .”
- The dictation usually begins with a preamble (e.g. “This is doctor Xyz ...”) which does not appear in the report. Similarly there are typical phrases at the end of the dictation which should not be transcribed (e.g. “End of dictation. Thank you.”)

- There are specific standards regarding the use of medical terminology. Transcriptionists frequently expand dictated abbreviations (e.g. “CVA” → “cerebrovascular accident”) or otherwise use equivalent terms (e.g. “nonicteric sclerae” → “no scleral icterus”).
- The dictation typically has a more narrative style (e.g. “She has no allergies.”, “I examined him”). In contrast, the report is normally more impersonal and structured (e.g. “ALLERGIES: None.”, “he was examined”).
- For the sake of brevity, speakers frequently omit function words. (“patient” → “the patient”, “denies fever pain” → “he denies any fever or pain”)
- As the dictation is spontaneous, disfluencies are quite frequent, in particular false starts, corrections and repetitions. (e.g. “22-year-old female, sorry, male 22-year-old male” → “22-year-old male”)
- Instruction to the transcriptionist and so-called normal reports, pre-defined text templates invoked by a short phrase like “This is a normal chest x-ray.”
- In addition to the above, speech recognition output has the usual share of recognition errors some of which may occur systematically.

These phenomena pose a problem that goes beyond the speech recognition task which has traditionally focused on correctly identifying speech utterances. Even with a perfectly accurate verbatim transcript of the user’s utterances, the transcriptionist would need to perform a significant amount of editing to obtain a document conforming to the customary standards. We need to look for what the user wants rather than what he says.

Natural language processing research has addressed a number of these issues as individual problems: automatic punctuation (Liu et al., 2005), text segmentation (Beeferman et al., 1999; Matusov et al., 2003) disfluency repair (Heeman et al., 1996) and error correction (Ringger and Allen, 1996; Strzalkowski and Brandow, 1997; Peters and Drexel,

2004). The method we present in the following attempts to address all this by a unified transformation model. The goal is simply stated as transforming the recognition output into a text document. We will first describe the general framework of learning transformations from example documents. In the following two sections we will discuss a rule-induction-based and a probabilistic transformation method respectively. Finally we present experimental results in the context of medical transcription and conclude with an assessment of both methods.

## 2 Text transformation

In dictation and transcription management systems corresponding pairs of recognition output and edited and corrected documents are readily available. The idea of transformation modeling, outlined in figure 1, is to learn to emulate the transcriptionist. To this end we first process archived dictations with the speech recognizer to create approximate verbatim transcriptions. For each document this yields the spoken or *source* word sequence  $S = s_1 \dots s_M$ , which is supposed to be a word-by-word transcription of the user’s utterances, but which may actually contain recognition errors. The corresponding final reports are cleaned (removal of page headers etc.), tagged (identification of section headings and enumerated lists) and tokenized, yielding the text or *target* token sequence  $T = t_1 \dots t_N$  for each document. Generally, the token sequence corresponds to the spoken form. (E.g. “25mg” is tokenized as “twenty five milligrams”.) Tokens can be ordinary words or special symbols representing line breaks, section headings, etc. Specifically, we represent each section heading by a single indivisible token, even if the section name consists of multiple words. Enumerations are represented by special tokens, too. Different techniques can be applied to learn and execute the actual transformation from  $S$  to  $T$ . Two options are discussed in the following.

With the transformation model at hand, a draft for a new document is created in three steps. First the speech recognizer processes the audio recording and produces the source word sequence  $S$ . Next, the transformation step converts  $S$  into the target sequence  $T$ . Finally the transformation output  $T$  is formatted into a text document. Formatting is the

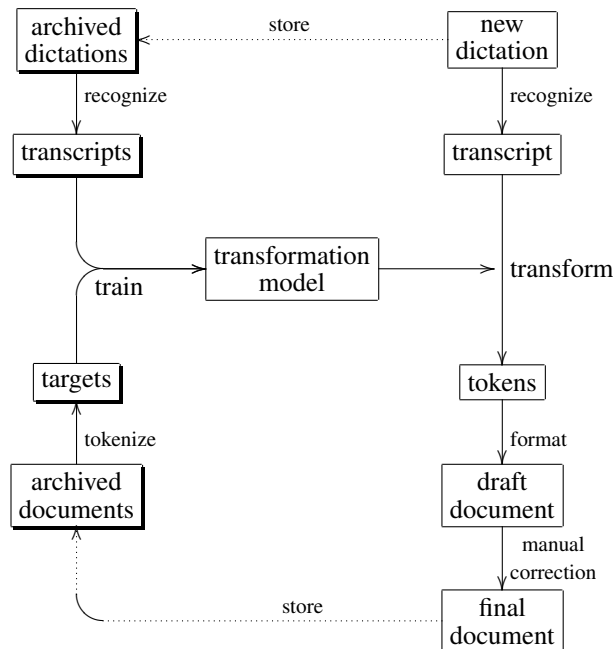

Figure 1: Illustration of how text transformation is integrated into a speech-to-text system.

inverse of tokenization and includes conversion of number words to digits, rendition of paragraphs and section headings, etc.

Before we turn to concrete transformation techniques, we can make two general statements about this problem. Firstly, in the absence of observations to the contrary, it is reasonable to leave words unchanged. So, a priori the mapping should be the identity. Secondly, the transformation is mostly monotonous. Out-of-order sections do occur but are the exception rather than the rule.

### 3 Transformation based learning

Following Strzalkowski and Brandow (1997) and Peters and Drexel (2004) we have implemented a *transformation-based learning* (TBL) algorithm (Brill, 1995). This method iteratively improves the match (as measured by token error rate) of a collection of corresponding source and target token sequences by positing and applying a sequence of *substitution rules*. In each iteration the source and target tokens are aligned using a minimum edit distance criterion. We refer to maximal contiguous subsequences of non-matching tokens as *error re-*

*gions*. These consist of paired sequences of source and target tokens, where either sequence may be empty. Each error region serves as a candidate substitution rule. Additionally we consider refinements of these rules with varying amounts of contiguous context tokens on either side. Deviating from Peters and Drexel (2004), in the special case of an empty target sequence, i.e. a deletion rule, we consider deleting all (non-empty) contiguous subsequences of the source sequence as well. For each candidate rule we accumulate two counts: the number of exactly matching error regions and the number of false alarms, i.e. when its left-hand-side matches a sequence of already correct tokens. Rules are ranked by the difference in these counts scaled by the number of errors corrected by a single rule application, which is the length of the corresponding error region. This is an approximation to the total number of errors corrected by a rule, ignoring rule interactions and non-local changes in the minimum edit distance alignment. A subset of the top-ranked non-overlapping rules satisfying frequency and minimum impact constraints are selected and the source sequences are updated by applying the selected rules. Again deviating from Peters and Drexel (2004), we consider two rules as overlapping if the left-hand-side of one is a contiguous subsequence of the other. This procedure is iterated until no additional rules can be selected. The initial rule set is populated by a small sequence of hand-crafted rules (e.g. “impression colon” → “IMPRESSION:”). A user-independent baseline rule set is generated by applying the algorithm to data from a collection of users. We construct speaker-dependent models by initializing the algorithm with the speaker-independent rule set and applying it to data from the given user.

### 4 Probabilistic model

The canonical approach to text transformation following statistical decision theory is to maximize the text document posterior probability given the spoken document.

$$T^* = \operatorname{argmax}_T p(T|S) \quad (1)$$

Obviously, the global model  $p(T|S)$  must be constructed from smaller scale observations on the cor-

responsiveness between source and target words. We use a 1-to-n alignment scheme. This means each source word is assigned to a sequence of zero, one or more target words. We denote the target words assigned to source word  $s_i$  as  $\tau_i$ . Each replacement  $\tau_i$  is a possibly empty sequence of target words. A source word together with its replacement sequence will be called a *segment*. We constrain the set of possible transformations by selecting a relatively small set of allowable replacements  $A(s)$  to each source word. This means we require  $\tau_i \in A(s_i)$ . We use the usual  $m$ -gram approximation to model the joint probability of a transformation:

$$p(S, T) = \prod_{i=1}^M p(s_i, \tau_i | s_{i-m+1}, \tau_{i-m+1}, \dots, s_{i-1}, \tau_{i-1}) \quad (2)$$

The work of Ringger and Allen (1996) is similar in spirit to this method, but uses a factored source-channel model. Note that the decision rule (1) is over whole documents. Therefore we process complete documents at a time without prior segmentation into sentences.

To estimate this model we first align all training documents. That is, for each document, the target word sequence is segmented into  $M$  segments  $T = \tau_1 \cup \dots \cup \tau_M$ . The criterion for this alignment is to maximize the likelihood of a segment unigram model. The alignment is performed by an expectation maximization algorithm. Subsequent to the alignment step,  $m$ -gram probabilities are estimated by standard language modeling techniques. We create speaker-specific models by linearly interpolating an  $m$ -gram model based on data from the user with a speaker-independent background  $m$ -gram model trained on data pooled from a collection of users.

To select the allowable replacements for each source word we count how often each particular target sequence is aligned to it in the training data. A source target pair is selected if it occurs twice or more times. Source words that were not observed in training are immutable, i.e. the word itself is its only allowable replacement  $A(s) = \{s\}$ . As an example suppose “patient” was deleted 10 times, left unchanged 105 times, replaced by “the patient” 113 times and once replaced by “she”. The word patient would then have three allowables:  $A(\text{patient}) = \{(), (\text{patient}), (\text{the, patient})\}$ .

The decision rule (1) minimizes the document error rate. A more appropriate loss function is the number of source words that are replaced incorrectly. Therefore we use the following *minimum word risk* (MWR) decision strategy, which minimizes source word loss.

$$T^* = (\operatorname{argmax}_{\tau_1 \in A(s_1)} p(\tau_1 | S)) \cup \dots \cup (\operatorname{argmax}_{\tau_M \in A(s_M)} p(\tau_M | S)) \quad (3)$$

This means for each source sequence position we choose the replacement that has the highest posterior probability  $p(\tau_i | S)$  given the entire source sequence. To compute the posterior probabilities, first a graph is created representing alternatives “around” the most probable transform using beam search. Then the forward-backward algorithm is applied to compute edge posterior probabilities. Finally edge posterior probabilities for each source position are accumulated.

## 5 Experimental evaluation

The methods presented were evaluated on a set of real-life medical reports dictated by 51 doctors. For each doctor we use 30 reports as a test set. Transformation models are trained on a disjoint set of reports that predated the evaluation reports. The typical document length is between one hundred and one thousand words. All dictations were recorded via telephone. The speech recognizer works with acoustic models that are specifically adapted for each user, not using the test data, of course. It is hard to quote the verbatim word error rate of the recognizer, because this would require a careful and time-consuming manual transcription of the test set. The recognition output is auto-punctuated by a method similar in spirit to the one proposed by Liu et al. (2005) before being passed to the transformation model. This was done because we considered the auto-punctuation output as the status quo ante which transformation modeling was to be compared to. Neither of both transformation methods actually relies on having auto-punctuated input. The auto-punctuation step only inserts periods and commas and the document is not explicitly segmented into sentences. (The transformation step always applies to entire documents and the interpretation of a period as a sentence boundary is left to the human

Table 1: Experimental evaluation of different text transformation techniques with different amounts of user-specific data. Precision, recall, deletion, insertion and error rate values are given in percent and represent the average of 51 users, where the results for each user are the ratios of sums over 30 reports.

3-gram without MWR	100	81.39	64.23	79.01	71.52	11.55	10.92	27.29

reader of the document.) For each doctor a background transformation model was constructed using 100 reports from each of the *other* users. This is referred to as the speaker-independent (SI) model. In the case of the probabilistic model, all models were 3-gram models. User-specific models were created by augmenting the SI model with 25, 50 or 100 reports. One report from the test set is shown as an example in the appendix.

## 5.1 Evaluation metric

The output of the text transformation is aligned with the corresponding tokenized report using a minimum edit cost criterion. Alignments between section headings and non-section headings are not permitted. Likewise no alignment of punctuation and non-punctuation tokens is allowed. Using the alignment we compute precision and recall for sections headings and punctuation marks as well as the overall token error rate. It should be noted that the so derived error rate is not comparable to word error rates usually reported in speech recognition research. All missing or erroneous section headings, punctuation marks and line breaks are counted as errors. As pointed out in the introduction the reference texts do not represent a literal transcript of the dictation. Furthermore the data were not cleaned manually. There are, for example, instances of letter heads or page numbers that were not correctly removed when the text was extracted from the word processor’s file for-

mat. The example report shown in the appendix features some of the typical differences between the produced draft and the final report that may or may not be judged as errors. (For example, the date of the report was not given in the dictation, the section names “laboratory data” and “laboratory evaluation” are presumably equivalent and whether “stable” is preceded by a hyphen or a period in the last section might not be important.) Nevertheless, the numbers reported do permit a quantitative comparison between different methods.

## 5.2 Results

Results are stated in table 1. In the baseline setup no transformation is applied to the auto-punctuated recognition output. Since many parts of the source data do not need to be altered, this constitutes the reference point for assessing the benefit of transformation modeling. For obvious reasons precision and recall of section headings are zero. A high rate of insertion errors is observed which can largely be attributed to preambles. Both transformation methods reduce the discrepancy between the draft document and the final corrected document significantly. With 100 training documents per user the mean token error rate is reduced by up to 40% relative by the probabilistic model. When user specific data is used, the probabilistic approach performs consistently better than TBL on all accounts. In particular it always has much lower insertion rates reflecting its supe-

rior ability to remove utterances that are not typically part of the report. On the other hand the probabilistic model suffers from a slightly higher deletion rate due to being overzealous in this regard. In speaker independent mode, however, the deletion rate is excessively high and leads to inferior overall performance. Interestingly the precision of the automatic punctuation is increased by the transformation step, without compromising on recall, at least when enough user specific training data is available. The minimum word risk criterion (3) yields slightly better results than the simpler document risk criterion (1).

## 6 Conclusions

Automatic text transformation brings speech recognition output much closer to the end result desired by the user of a back-end dictation system. It automatically punctuates, sections and rephrases the document and thereby greatly enhances transcriptionist productivity. The holistic approach followed here is simpler and more comprehensive than a cascade of more specialized methods. Whether or not the holistic approach is also more accurate is not an easy question to answer. Clearly the outcome would depend on the specifics of the specialized methods one would compare to, as well as the complexity of the integrated transformation model one applies. The simple models studied in this work admittedly have little provisions for targeting specific transformation problems. For example the typical length of a section is not taken into account. However, this is not a limitation of the general approach. We have observed that a simple probabilistic sequence model performs consistently better than the transformation-based learning approach. Even though neither of both methods is novel, we deem this an important finding since none of the previous publications we know of in this domain allow this conclusion. While the present experiments have used a separate auto-punctuation step, future work will aim to eliminate it by integrating the punctuation features into the transformation step. In the future we plan to integrate additional knowledge sources into our statistical method in order to more specifically address each of the various phenomena encountered in spontaneous dictation.

Media Laboratory  
dkroy@media.mit.edu

## Abstract

Grounded language models represent the relationship between words and the non-linguistic context in which they are said. This paper describes how they are learned from large corpora of unlabeled video, and are applied to the task of automatic speech recognition of sports video. Results show that grounded language models improve perplexity and word error rate over text based language models, and further, support video information retrieval better than human generated speech transcriptions.

## 1 Introduction

Recognizing speech in broadcast video is a necessary precursor to many multimodal applications such as video search and summarization (Snoek and Worring, 2005;). Although performance is often reasonable in controlled environments (such as studio news rooms), automatic speech recognition (ASR) systems have significant difficulty in noisier settings (such as those found in live sports broadcasts) (Wactlar et al., 1996). While many researches have examined how to compensate for such noise using acoustic techniques, few have attempted to leverage information in the visual stream to improve speech recognition performance (for an exception see Murkherjee and Roy, 2003).

In many types of video, however, visual context can provide valuable clues as to what has been said. For example, in video of Major League Baseball games, the likelihood of the phrase “home run” increases dramatically when a home run has actually been hit. This paper describes a method for incorporating such visual information in an ASR system for sports video. The method is based on the use of *grounded language models* to repre-

sent the relationship between words and the non-linguistic context to which they refer (Fleischman and Roy, 2007).

Grounded language models are based on research from cognitive science on grounded models of meaning. (for a review see Roy, 2005, and Roy and Reiter, 2005). In such models, the meaning of a word is defined by its relationship to representations of the language users’ environment. Thus, for a robot operating in a laboratory setting, words for colors and shapes may be grounded in the outputs of its computer vision system (Roy & Pentland, 2002); while for a simulated agent operating in a virtual world, words for actions and events may be mapped to representations of the agent’s plans or goals (Fleischman & Roy, 2005).

This paper extends previous work on grounded models of meaning by learning a grounded language model from naturalistic data collected from broadcast video of Major League Baseball games. A large corpus of unlabeled sports videos is collected and paired with closed captioning transcriptions of the announcers’ speech.<sup>1</sup> This corpus is used to train the grounded language model, which like traditional language models encode the prior probability of words for an ASR system. Unlike traditional language models, however, grounded language models represent the probability of a word conditioned not only on the previous word(s), but also on features of the non-linguistic context in which the word was uttered.

Our approach to learning grounded language models operates in two phases. In the first phase, events that occur in the video are represented using hierarchical temporal pattern automatically mined

---

<sup>1</sup> Closed captioning refers to human transcriptions of speech embedded in the video stream primarily for the hearing impaired. Closed captioning is reasonably accurate (although not perfect) and available on some, but not all, video broadcasts.

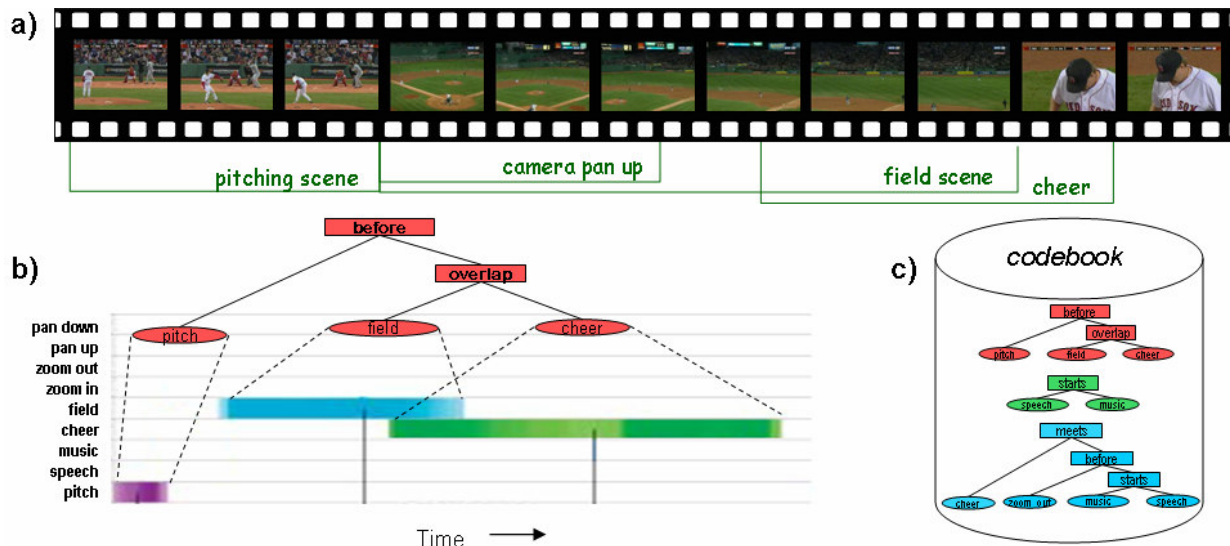

Figure 1. Representing events in video. a) Events are represented by first abstracting the raw video into visual context, camera motion, and audio context features. b) Temporal data mining is then used to discover hierarchical temporal patterns in the parallel streams of features. c) Temporal patterns found significant in each iteration are stored in a codebook that is used to represent high level events in video.

from low level features. In the second phase, a conditional probability distribution is estimated that describes the probability that a word was uttered given such event representations. In the following sections we describe these two aspects of our approach and evaluate the performance of our grounded language model on a speech recognition task using video highlights from Major League Baseball games. Results indicate improved performance using three metrics: perplexity, word error rate, and precision on an information retrieval task.

## 2 Representing Events in Sports Video

Recent work in video surveillance has demonstrated the benefit of representing complex events as temporal relations between lower level sub-events (Hongen et al., 2004). Thus, to represent events in the sports domain, we would ideally first represent the basic sub events that occur in sports video (e.g., hitting, throwing, catching, running, etc.) and then build up complex events (such as *home run*) as a set of temporal relations between these basic events. Unfortunately, due to the limitations of computer vision techniques, reliably identifying such basic events in video is not feasible. However, sports video does have characteristics that can be exploited to effectively represent complex events.

Like much broadcast video, sports video is highly produced, exploiting many different camera angles and a human director who selects which camera is most appropriate given what is happening on the field. The styles that different directors employ are extremely consistent within a sport and make up a “language of film” which the machine can take advantage of in order to represent the events taking place in the video.

Thus, even though it is not easy to automatically identify a player hitting a ball in video, it is easy to detect features that correlate with hitting, e.g., when a scene focusing on the pitching mound immediately jumps to one zooming in on the field (see Figure 1). Although these correlations are not perfect, experiments have shown that baseball events can be classified using such features (Fleischman et al., 2007).

We exploit the language of film to represent events in sports video in two phases. First, low level features that correlate with basic events in sports are extracted from the video stream. Then, temporal data mining is used to find patterns within this low level event stream.

### 2.1 Feature Extraction

We extract three types of features: visual context features, camera motion features, and audio context features.

## Visual Context Features

Visual context features encode general properties of the visual scene in a video segment. Supervised classifiers are trained to identify these features, which are relatively simple to classify in comparison to high level events (like home runs) that require more training data and achieve lower accuracy. The first step in classifying visual context features is to segment the video into shots (or scenes) based on changes in the visual scene due to editing (e.g. jumping from a close up to a wide shot of the field). Shot detection and segmentation is a well studied problem; in this work we use the method of Tardini et al. (2005).

After the video is segmented into shots, individual frames (called key frames) are selected and represented as a vector of low level features that describe the key frame's color distribution, entropy, etc. (see Fleischman and Roy, 2007 for the full list of low level features used). The WEKA machine learning package is used to train a boosted decision tree to classify these frames into one of three categories: *pitching-scene*, *field-scene*, *other* (Witten and Frank, 2005). Those shots whose key frames are classified as *field-scenes* are then sub-categorized (using boosted decision trees) into one of the following categories: *infield*, *outfield*, *wall*, *base*, *running*, and *misc*. Performance of these classification tasks is approximately 96% and 90% accuracy respectively.

## Camera Motion Features

In addition to visual context features, we also examine the camera motion that occurs within a video. Unlike visual context features, which provide information about the global situation that is being observed, camera motion features represent more precise information about the actions occurring in a video. The intuition here is that the camera is a stand in for a viewer's focus of attention. As actions occur in a video, the camera moves to follow it; this camera motion thus mirrors the actions themselves, providing informative features for event representation.

Like shot boundary detection, detecting the motion of the camera in a video (i.e., the amount it pans left to right, tilts up and down, and zooms in and out) is a well-studied problem. We use the system of Bouthemy et al. (1999) which computes the camera motion using the parameters of a two-

dimensional affine model to fit every pair of sequential frames in a video. A 15 state 1<sup>st</sup> order Hidden Markov Model, implemented with the Graphical Modeling Toolkit,<sup>2</sup> then converts the output of the Bouthemy system into a stream of clustered characteristic camera motions (e.g. state 12 clusters together motions of zooming in fast while panning slightly left).

## Audio Context

The audio stream of a video can also provide useful information for representing non-linguistic context. We use boosted decision trees to classify audio into segments of *speech*, *excited\_speech*, *cheering*, and *music*. Classification operates on a sequence of overlapping 30 ms frames extracted from the audio stream. For each frame, a feature vector is computed using, MFCCs (often used in speaker identification and speech detection tasks), as well as energy, the number of zero crossings, spectral entropy, and relative power between different frequency bands. The classifier is applied to each frame, producing a sequence of class labels. These labels are then smoothed using a dynamic programming cost minimization algorithm (similar to those used in Hidden Markov Models). Performance of this system achieves between 78% and 94% accuracy.

## 2.2 Temporal Pattern Mining

Given a set of low level features that correlate with the basic events in sports, we can now focus on building up representations of complex events. Unlike previous work (Hongen et al., 2005) in which representations of the temporal relations between low level events are built up by hand, we employ temporal data mining techniques to automatically discover such relations from a large corpus of unannotated video.

As described above, ideal basic events (such as hitting and catching) cannot be identified easily in sports video. By finding temporal patterns between audio, visual and camera motion features, however, we can produce representations that are highly correlated with sports events. Importantly, such temporal patterns are not strictly sequential, but rather, are composed of features that can occur

---

<sup>2</sup> <http://ssli.ee.washington.edu/~bilmes/gmtk/>

in complex and varied temporal relations to each other.

To find such patterns automatically, we follow previous work in video content classification in which temporal data mining techniques are used to discover event patterns within streams of lower level features. The algorithm we use is fully unsupervised and proceeds by examining the relations that occur between features in multiple streams within a moving time window. Any two features that occur within this window must be in one of seven temporal relations with each other (e.g. *before*, *during*, *etc.*) (Allen, 1984). The algorithm keeps track of how often each of these relations is observed, and after the entire video corpus is analyzed, uses chi-square analyses to determine which relations are significant. The algorithm iterates through the data, and relations between individual features that are found significant in one iteration (e.g. [OVERLAP, *field-scene*, *cheer*]), are themselves treated as individual features in the next. This allows the system to build up higher-order nested relations in each iteration (e.g. [BEFORE, [OVERLAP, *field-scene*, *cheer*], *field scene*]).

The temporal patterns found significant in this way make up a codebook which can then be used as a basis for representing a video. The term codebook is often used in image analysis to describe a set of features (stored in the codebook) that are used to encode raw data (images or video). Such codebooks are used to represent raw video using features that are more easily processed by the computer.

Our framework follows a similar approach in which raw video is encoded (using a codebook of temporal patterns) as follows. First, the raw video is abstracted into the visual context, camera motion, and audio context feature streams (as described in Section 2.1). These feature streams are then scanned, looking for any temporal patterns (and nested sub-patterns) that match those found in the codebook. For each pattern, the duration for which it occurs in the feature streams is treated as the value of an element in the vector representation for that video.

Thus, a video is represented as an  $n$  length vector, where  $n$  is the total number of temporal patterns in the codebook. The value of each element of this vector is the duration for which the pattern associated with that element was observed in the video. So, if a pattern was not observed in a video

at all, it would have a value of 0, while if it was observed for the entire length of the video, it would have a value equal to the number of frames present in that video.

Given this method for representing the non-linguistic context of a video, we can now examine how to model the relationship between such context and the words used to describe it.

### 3 Linguistic Mapping

Modeling the relationship between words and non-linguistic context assumes that the speech uttered in a video refers consistently (although not exclusively) to the events being represented by the temporal pattern features. We model this relationship, much like traditional language models, using conditional probability distributions. Unlike traditional language models, however, our grounded language models condition the probability of a word not only on the word(s) uttered before it, but also on the temporal pattern features that describe the non-linguistic context in which it was uttered. We estimate these conditional distributions using a framework similar that used for training acoustic models in ASR and translation models in Machine Translation (MT).

We generate a training corpus of utterances paired with representations of the non-linguistic context in which they were uttered. The first step in generating this corpus is to generate the low level features described in Section 2.1 for each video in our training set. We then segment each video into a set of independent events based on the visual context features we have extracted. We follow previous work in sports video processing (Gong et al., 2004) and define an event in a baseball video as any sequence of shots starting with a *pitching-scene* and continuing for four subsequent shots. This definition follows from the fact that the vast majority of events in baseball start with a pitch and do not last longer than four shots. For each of these events in our corpus, a temporal pattern feature vector is generated as described in section 2.2. These events are then paired with all the words from the closed captioning transcription that occur during each event (plus or minus 10 seconds). Because these transcriptions are not necessarily time synched with the audio, we use the method described in Hauptmann and Witbrock

(1998) to align the closed captioning to the announcers’ speech.

Previous work has examined applying models often used in MT to the paired corpus described above (Fleischman and Roy, 2006). Recent work in automatic image annotation (Barnard et al., 2003; Blei and Jordan, 2003) and natural language processing (Steyvers et al., 2004), however, have demonstrated the advantages of using hierarchical Bayesian models for related tasks. In this work we follow closely the Author-Topic (AT) model (Steyvers et al., 2004) which is a generalization of Latent Dirichlet Allocation (LDA) (Blei et al., 2005).<sup>3</sup>

LDA is a technique that was developed to model the distribution of topics discussed in a large corpus of documents. The model assumes that every document is made up of a mixture of topics, and that each word in a document is generated from a probability distribution associated with one of those topics. The AT model generalizes LDA, saying that the mixture of topics is not dependent on the document itself, but rather on the authors who wrote it. According to this model, for each word (or phrase) in a document, an author is chosen uniformly from the set of the authors of the document. Then, a topic is chosen from a distribution of topics associated with that particular author. Finally, the word is generated from the distribution associated with that chosen topic. We can express the probability of the words in a document ( $W$ ) given its authors ( $A$ ) as:

$$p(W | A) = \prod_{m \in W} \frac{1}{A_d} \sum_{x \in A} \sum_{z \in T} p(m | z) p(z | x) \quad (1)$$

where  $T$  is the set of latent topics that are induced given a large set of training data.

We use the AT model to estimate our grounded language model by making an analogy between documents and events in video. In our framework, the words in a document correspond to the words in the closed captioning transcript associated with an event. The authors of a document correspond to the temporal patterns representing the non-

linguistic context of that event. We modify the AT model slightly, such that, instead of selecting from

<sup>3</sup> In the discussion that follows, we describe a method for estimating unigram grounded language models. Estimating bigram and trigram models can be done by processing on word pairs or triples, and performing normalization on the resulting conditional distributions.

a uniform distribution (as is done with authors of documents), we select patterns from a multinomial distribution based upon the duration of the pattern. The intuition here is that patterns that occur for a longer duration are more salient and thus, should be given greater weight in the generative process. We can now rewrite (1) to give the probability of words during an event ( $W$ ) given the vector of observed temporal patterns ( $P$ ) as:

$$p(W | P) = \prod_{m \in W} \sum_{x \in P} \sum_{z \in T} p(m | z) p(z | x) p(x) \quad (2)$$

In the experiments described below we follow Steyver et al., (2004) and train our AT model using Gibbs sampling, a Markov Chain Monte Carlo technique for obtaining parameter estimates. We run the sampler on a single chain for 200 iterations. We set the number of topics to 15, and normalize the pattern durations first by individual pattern across all events, and then for all patterns within an event. The resulting parameter estimates are smoothed using a simple add  $N$  smoothing technique, where  $N=1$  for the word by topic counts and  $N=.01$  for the pattern by topic counts.

## 4 Evaluation

In order to evaluate our grounded language modeling approach, a parallel data set of 99 Major League Baseball games with corresponding closed captioning transcripts was recorded from live television. These games represent data totaling approximately 275 hours and 20,000 distinct events from 25 teams in 23 stadiums, broadcast on five different television stations. From this set, six games were held out for testing (15 hours, 1200 events, nine teams, four stations). From this test set, baseball highlights (i.e., events which terminate with the player either *out* or *safe*) were hand annotated for use in evaluation, and manually transcribed in order to get clean text transcriptions for gold standard comparisons. Of the 1200 events in the test set, 237 were highlights with a total word count of 12,626 (vocabulary of 1800 words).

The remaining 93 unlabeled games are used to train unigram, bigram, and trigram grounded language models. Only unigrams, bigrams, and trigrams that are not proper names, appear greater than three times, and are not composed only of stop words were used. These grounded language models are then combined in a backoff strategy

with traditional unigram, bigram, and trigram language models generated from a combination of the closed captioning transcripts of all training games and data from the switchboard corpus (see below). This backoff is necessary to account for the words not included in the grounded language model itself (i.e. stop words, proper names, low frequency words). The traditional text-only language models (which are also used below as baseline comparisons) are generated with the SRI language modeling toolkit (Stolcke, 2002) using Chen and Goodman's modified Kneser-Ney discounting and interpolation (Chen and Goodman, 1998). The backoff strategy we employ here is very simple: if the ngram appears in the GLM then it is used, otherwise the traditional LM is used. In future work we will examine more complex backoff strategies (Hsu, in review).

We evaluate our grounded language modeling approach using 3 metrics: perplexity, word error rate, and precision on an information retrieval task.

#### 4.1 Perplexity

Perplexity is an information theoretic measure of how well a model predicts a held out test set. We use perplexity to compare our grounded language model to two baseline language models: a language model generated from the switchboard corpus, a commonly used corpus of spontaneous speech in the telephony domain (3.65M words; 27k vocab); and a language model that interpolates (with equal weight given to both) between the switchboard model and a language model trained only on the baseball-domain closed captioning (1.65M words; 17k vocab). The results of calculating perplexity on the test set highlights for these three models is presented in Table 1 (lower is better).

Not surprisingly, the switchboard language model performs far worse than both the interpolated text baseline and the grounded language model. This is due to the large discrepancy between both the style and vocabulary of language about sports compared to the domain of telephony sampled by the switchboard corpus. Of more interest is the decrease in perplexity seen when using the grounded language model compared to the interpolated model. Note that these two language models are generated using the same speech transcriptions, i.e. the closed captioning from the training games and the switchboard corpus. However,

whereas the baseline model remains the same for each of the 237 test highlights, the grounded language model generates different word distributions for each highlight depending on the event features extracted from the highlight video.

	Switchboard	Interpolated (Switch+CC)	Grounded
ppl	1404	145.27	83.88

Table 1. Perplexity measures for three different language models on a held out test set of baseball highlights (12,626 words). We compare the grounded language model to two text based language models: one trained on the switchboard corpus alone; and interpolated with one trained on closed captioning transcriptions of baseball video.

#### 4.2 Word Accuracy and Error Rate

Word error rate (WER) is a normalized measure of the number of word insertions, substitutions, and deletions required to transform the output transcription of an ASR system to a human generated gold standard transcription of the same utterance. Word accuracy is simply the number of words in the gold standard that they system correctly recognized. Unlike perplexity which only evaluates the performance of language models, examining word accuracy and error rate requires running an entire ASR system, i.e. both the language and acoustic models.

We use the Sphinx system to train baseball specific acoustic models using parallel acoustic/text data automatically mined from our training set. Following Jang and Hauptman (1999), we use an off the shelf acoustic model (the hub4 model) to generate an extremely noisy speech transcript of each game in our training set, and use dynamic programming to align these noisy outputs to the closed captioning stream for those same games. Given these two transcriptions, we then generate a paired acoustic/text corpus by sampling the audio at the time codes where the ASR transcription matches the closed captioning transcription.

For example, if the ASR output contains the term sequence "... and farther *home run for David* forty says..." and the closed captioning contains the sequence "...another *home run for David* Ortiz....," the matched phrase "*home run for David*" is assumed a correct transcription for the audio at the time codes given by the ASR system. Only looking at sequences of three words or more,

Figure 3. Word accuracy and error rates for ASR systems using a grounded language model, a text based language model trained on the switchboard corpus, and the switchboard model interpolated with a text based model trained on baseball closed captions.

we extract approximately 18 hours of clean paired data from our 275 hour training corpus. A continuous acoustic model with 8 gaussians and 6000 ties states is trained on this data using the Sphinx speech recognizer.<sup>4</sup>

Figure 3 shows the WERs and accuracy for three ASR systems run using the Sphinx decoder with the acoustic model described above and either the grounded language model or the two baseline models described in section 4.1. Note that performance for all of these systems is very poor due to limited acoustic data and the large amount of background crowd noise present in sports video (and particularly in sports highlights). Even with this noise, however, results indicate that the word accuracy and error rates when using the grounded language model is significantly better than both the switchboard model (absolute WER reduction of 13%; absolute accuracy increase of 15.2%) and the switchboard interpolated with the baseball specific text based language model (absolute WER reduction of 3.7%; absolute accuracy increase of 5.9%).

<sup>4</sup> <http://cmusphinx.sourceforge.net/html/cmusphinx.php>

Drawing conclusions about the usefulness of grounded language models using word accuracy or error rate alone is difficult. As it is defined, these measures penalizes a system that mistakes “a” for “uh” as much as one that mistakes “run” for “rum.” When using ASR to support multimedia applications (such as search), though, such substitutions are not of equal importance. Further, while visual information may be useful for distinguishing the latter error, it is unlikely to assist with the former. Thus, in the next section we examine an extrinsic evaluation in which grounded language models are judged not directly on their effect on word accuracy or error rate, but based on their ability to support video information retrieval.

### 4.3 Precision of Information Retrieval

One of the most commonly used applications of ASR for video is to support information retrieval (IR). Such video IR systems often use speech transcriptions to index segments of video in much the same way that words are used to index text documents (Wactlar et al., 1996). For example, in the domain of baseball, if a video IR system were issued the query “home run,” it would typically return a set of video clips by searching its database for events in which someone uttered the phrase “home run.” Because such systems rely on ASR output to search video, the performance of a video IR system gives an indirect evaluation of the ASR’s quality. Further, unlike the case with word accuracy or error rate, such evaluations highlight a systems ability to recognize the more relevant content words without being distracted by the more common stop words.

Our metric for evaluation is the precision with which baseball highlights are returned in a video IR system. We examine three systems: one that uses ASR with the grounded language model, a baseline system that uses ASR with the text only interpolated language model, and finally a system that uses human produced closed caption transcriptions to index events.

For each system, all 1200 events from the test set (not just the highlights) are indexed. Queries are generated artificially using a method similar to Berger and Lafferty (1999) and used in Fleischman and Roy (2007). First, each highlight is labeled with the event’s type (e.g. *fly ball*), the event’s location (e.g. *left field*) and the event’s result (e.g. *double play*): 13 labels total. Log likelihood ratios

are then used to find the phrases (unigram, trigram, and bigram) most indicative of each label (e.g. “fly ball” for category *fly ball*). For each label, the three most indicative phrases are issued as queries to the system, which ranks its results using the language modeling approach of Ponte and Croft (1998). Precision is measured on how many of the top five returned events are of the correct category.

Figure 4 shows the precision of the video IR systems based on ASR with the grounded language model, ASR with the text-only interpolated language model, and closed captioning transcriptions. As with our previous evaluations, the IR results show that the system using ASR with the grounded language model performed better than the one using ASR with the text-only language model (5.1% absolute improvement). More notably, though, Figure 4 shows that the system using the grounded language model performed better than the system using the hand generated closed captioning transcriptions (4.6% absolute improvement). Although this is somewhat counterintuitive given that hand transcriptions are typically considered gold standards, these results follow from a limitation of using text-based methods to index video.

Unlike the case with text documents, the occurrence of a query term in a video is often not enough to assume the video’s relevance to that query. For example, when searching through video of baseball games, returning all clips in which the phrase “home run” occurs, results primarily in video of events where a home run does not actually occur. This follows from the fact that in sports, as in life, people often talk not about what is currently happening, but rather, they talk about what did, might, or will happen in the future.

By taking into account non-linguistic context during speech recognition, the grounded language model system indirectly circumvents some of these false positive results. This follows from the fact that an effect of using the grounded language model is that when an announcer utters a phrase (e.g., “fly ball”), the system is more likely to recognize that phrase correctly if the event it refers to is actually occurring (e.g. if someone actually hit a fly ball). Because the grounded language model system is biased to recognize phrases that describe what is currently happening, it returns fewer false positives and gets higher precision.

Figure 4. Precision of top five results of a video IR system based on speech transcriptions. Three different transcriptions are compared: ASR-LM uses ASR with a text-only interpolated language model (trained on baseball closed captioning and the switchboard corpus); ASR-GLM uses ASR with a grounded language model; CC uses human generated closed captioning transcriptions (i.e., no ASR).

## 5 Conclusions

We have described a method for improving speech recognition in video. The method uses grounded language modeling, an extension of traditional language modeling in which the probability of a word is conditioned not only on the previous word(s) but also on the non-linguistic context in which the word is uttered. Context is represented using hierarchical temporal patterns of low level features which are mined automatically from a large unlabeled video corpus. Hierarchical Bayesian models are then used to map these representations to words. Initial results show grounded language models improve performance on measures of perplexity, word accuracy and error rate, and precision on an information retrieval task.

In future work, we will examine the ability of grounded language models to improve performance for other natural language tasks that exploit text based language models, such as Machine Translation. Also, we are examining extending this approach to other sports domains such as American football. In theory, however, our approach is applicable to any domain in which there is discussion of the here-and-now (e.g., cooking shows, etc.). In future work, we will examine the strengths and limitations of grounded language modeling in these domains.

mfleck@cs.uiuc.edu

## Abstract

This paper presents a new unsupervised algorithm (WordEnds) for inferring word boundaries from transcribed adult conversations. Phone ngrams before and after observed pauses are used to bootstrap a simple discriminative model of boundary marking. This fast algorithm delivers high performance even on morphologically complex words in English and Arabic, and promising results on accurate phonetic transcriptions with extensive pronunciation variation. Expanding training data beyond the traditional miniature datasets pushes performance numbers well above those previously reported. This suggests that WordEnds is a viable model of child language acquisition and might be useful in speech understanding.

## 1 Introduction

Words are essential to most models of language and speech understanding. Word boundaries define the places at which speakers can fluently pause, and limit the application of most phonological rules. Words are a key constituent in structural analyses: the output of morphological rules and the constituents in syntactic parsing. Most speech recognizers are word-based. And, words are entrenched in the writing systems of many languages.

Therefore, it is generally accepted that children learning their first language must learn how to segment speech into a sequence of words. Similar, but more limited, learning occurs when adults hear speech containing unfamiliar words. These words must be accurately delimited, so that they can be

added to the lexicon and nearby familiar words recognized correctly. Current speech recognizers typically misinterpret such speech.

This paper will consider algorithms which segment phonetically transcribed speech into words. For example, Figure 1 shows a transcribed phrase from the Buckeye corpus (Pitt et al., 2005; Pitt et al., 2007) and the automatically segmented output. Like almost all previous researchers, I use human-transcribed input to work around the limitations of current speech recognizers.

In most available datasets, words are transcribed using standard dictionary pronunciations (henceforth “dictionary transcriptions”). These transcriptions are approximately phonemic and, more importantly, assign a constant form to each word. I will also use one dataset with accurate phonetic transcriptions, including natural variation in the pronunciation of words. Handling this variation is an important step towards eventually using phone lattices or features produced by real speech recognizers.

This paper will focus on segmentation of speech between adults. This is the primary input for speech recognizers. Moreover, understanding such speech is the end goal of child language acquisition. Models tested only on simplified child-directed speech are incomplete without an algorithm for upgrading the understander to handle normal adult speech.

## 2 The task in more detail

This paper uses a simple model of the segmentation task, which matches prior work and the available datasets. Possible enhancements to the model are discussed at the end.

```

"all the kids in there      # are people that have kids # or that are having kids"
IN  REAL: ohlThikidsinner   # ahrpiyp@lThA?HAvkids    # ohrThADurHAViynqkids
    DICT: ahlThiykidzinTher # ahrpiyp@lThAtHAvkidz    # owrThAtahrHAVinqkidz
OUT REAL: ohl Thi kids inner # ahr piyp@l ThA? HAV kids # ohr ThADur HAViynq kids
    DICT: ahl Thiy kidz in Ther # ahr piyp@l ThAt HAV kidz # owr ThAt ahr HAVinq kidz

```

Figure 1: Part of Buckeye corpus dialog 2101a, in accurate phonetic transcription (REAL) and dictionary pronunciations (DICT). Both use modified arpabet, with # marking pauses. Notice the two distinct pronunciations of “that” in the accurate transcription. Automatically inserted word boundaries are shown at bottom.

## 2.1 The input data

This paper considers only languages with an established tradition of words, e.g. not Chinese. I assume that the authors of each corpus have given us reasonable phonetic transcriptions and word boundaries. The datasets are informal conversations in which debatable word segmentations are rare.

The transcribed data is represented as a sequence of phones, with neither prosodic/stress information nor feature representations for the phones. These phone sequences are presented to segmentation algorithms as strings of ASCII characters. Large phonesets may be represented using capital letters and punctuation or, more readably, using multi-character phone symbols. Well-designed (e.g. easily decodable) multi-character codes do not affect the algorithms or evaluation metrics in this paper. Testing often also uses orthographic datasets.

Finally, the transcriptions are divided into “phrases” at pauses in the speech signal (silences, breaths, etc). These pause phrases are **not** necessarily syntactic or prosodic constituents. Disfluencies in conversational speech create pauses where you might not expect them, e.g. immediately following the definite article (Clark and Wasow, 1998; Fox Tree and Clark, 1997). Therefore, I have chosen corpora in which pauses have been marked carefully.

## 2.2 Affixes and syllables

A theory of word segmentation must explain how affixes differ from free-standing function words. For example, we must explain why English speakers consider “the” to be a word, but “-ing” to be an affix, although neither occurs by itself in fluent prepared English. We must also explain why the Arabic determiner “Al-” is not a word, though its syntactic and semantic role seems similar to English “the”.

Viewed another way, we must show how to esti-

mate the average word length. Conversational English has short words (about 3 phones), because most grammatical morphemes are free-standing. Languages with many affixes have longer words, e.g. my Arabic data averages 5.6 phones per word.

Pauses are vital for deciding what is an affix. Attempts to segment transcriptions without pauses, e.g. (Christiansen et al., 1998), have worked poorly. Claims that humans can extract words without pauses seem to be based on psychological experiments such as (Saffran, 2001; Jusczyk and Aslin, 1995) which conflate words and morphemes. Even then, explicit boundaries seem to improve performance (Seidl and Johnson, 2006).

Another significant part of this task is finding syllable boundaries. For English, many phone strings have multiple possible syllabifications. Because words average only 1.26 syllables, segmenting pre-syllabified input has a very high baseline: 100% precision and 80% recall of boundary positions.

## 2.3 Algorithm testing

Unsupervised algorithms are presented with the transcription, divided only at phrase boundaries. Their task is to infer the phrase-internal word boundaries. The primary worry in testing is that development may have biased the algorithm towards a particular language, speaking style, and/or corpus size. Addressing this requires showing that different corpora can be handled with a common set of parameter settings. Therefore a test/training split within one corpus serves little purpose and is not standard.

Supervised algorithms are given training data with all word boundaries marked, and must infer word boundaries in a separate test set. Simple supervised algorithms perform extremely well (Cairns et al., 1997; Teahan et al., 2000), but don’t address our main goal: **learning** how to segment.

Notice that phrase boundaries are not randomly

selected word boundaries. Syntactic and communicative constraints make pauses more likely at certain positions than others. Therefore, the “supervised” algorithms for this task train on a representative set of word boundaries whereas “unsupervised” algorithms train on a biased set of word boundaries. Moreover, supplying **all** the word boundaries for even a small amount of data effectively tells the supervised algorithms the average word length, a parameter which is otherwise not easy to estimate.

Standard evaluation metrics include the precision, recall and F-score <sup>1</sup> of the phrase-internal boundaries (BP, BR, BF), of the extracted word tokens (WP, WR, WF), and of the resulting lexicon of word types (LP, LR, LF). Outputs don’t look good until BF is at least 90%.

### 3 Previous work

Learning to segment words is an old problem, with extensive prior work surveyed in (Batchelder, 2002; Brent and Cartwright, 1996; Cairns et al., 1997; Goldwater, 2006; Hockema, 2006; Rytting, 2007). There are two major approaches. *Phonotactic* methods model which phone sequences are likely within words and which occur primarily across or adjacent to word boundaries. *Language modelling* methods build word ngram models, like those used in speech recognition. Statistical criteria define the “best” model fitting the input data. In both cases, details are complex and variable.

#### 3.1 Phonotactic Methods

Supervised phonotactic methods date back at least to (Lamel and Zue, 1984), see also (Harrington et al., 1989). Statistics of phone trigrams provide sufficient information to segment adult conversational speech (dictionary transcriptions with simulated phonology) with about 90% precision and 93% recall (Cairns et al., 1997), see also (Hockema, 2006). Teahan et al.’s compression-based model (2000) achieves BF over 99% on orthographic English. Segmentation by adults is sensitive to phonotactic constraints (McQueen, 1998; Weber, 2000).

To build unsupervised algorithms, Brent and Cartwright suggested (1996) inferring phonotactic constraints from phone sequences observed at

<sup>1</sup> $F = \frac{2PR}{P+R}$  where  $P$  is the precision and  $R$  is the recall.

phrase boundaries. However, experimental results are poor. Early results using neural nets by Cairns et al. (1997) and Christiansen et al (1998) are discouraging. Rytting (2007) seems to have the best result: 61.0% boundary recall with 60.3% precision <sup>2</sup> on 26K words of modern Greek data, average word length 4.4 phones. This algorithm used mutual information plus phrase-final 2-phone sequences. He obtained similar results (Rytting, 2004) using phrase-final 3-phone sequences.

Word segmentation experiments by Christiansen and Allen (1997) and Harrington et al. (1989). simulated the effects of pronunciation variation and/or recognizer error. Rytting (2007) uses actual speech recognizer output. These experiments broke useful new ground, but poor algorithm performance (BF  $\leq$  50% even on dictionary transcriptions) makes it hard to draw conclusions from their results.

#### 3.2 Language modelling methods

So far, language modelling methods have been more effective. Brent (1999) and Venkataraman (2001) present incremental splitting algorithms with BF about 82% <sup>3</sup> on the Bernstein-Ratner (BR87) corpus of infant-directed English with disfluencies and interjections removed (Bernstein Ratner, 1987; Brent, 1999). Batchelder (2002) achieved almost identical results using a clustering algorithm. The most recent algorithm (Goldwater, 2006) achieves a BF of 85.8% using a Dirichlet Process bigram model, estimated using a Gibbs sampling algorithm.<sup>4</sup>

Language modelling methods incorporate a bias towards re-using hypothesized words. This suggests they should systematically segment morphologically complex words, so as to exploit the structure they share with other words. Goldwater, the only author to address this issue explicitly, reports that her algorithm breaks off common affixes (e.g. “ing”, “s”). Batchelder reports a noticeable drop in performance on Japanese data, which might relate to its more complex words (average 4.1 phones).

<sup>2</sup>These numbers have been adjusted so as not to include boundaries between phrases.

<sup>3</sup>Numbers are from Goldwater’s (2006) replication.

<sup>4</sup>Goldwater numbers are from the December 2007 version of her code, with its suggested parameter values:  $\alpha_0 = 3000$ ,  $\alpha_1 = 300$ ,  $p\# = 0.2$ .

## 4 The new approach

Previous algorithms have modelled either whole words or very short (e.g. 2-3) phone sequences. The new approach proposed in this paper, “lexicalized phonotactics,” models extended sequences of phones at the starts and ends of word sequences. This allows a new algorithm, called WordEnds, to successfully mark word boundaries with a simple local classifier.

### 4.1 The idea

This method models sequences of phones that start or end at a word boundary. When words are long, such a sequence may cover only part of the word e.g. a group of suffixes or a suffix plus the end of the stem. A sequence may also include parts of multiple short words, capturing some simple bits of syntax.

These longer sequences capture not only purely phonotactic constraints, but also information about the inventory of lexical items. This improves handling of complex, messy inputs. (Cf. Ando and Lee’s (2000) kanji segmenter.)

On the other hand, modelling only partial words helps the segmenter handle long, infrequent words. Long words are typically created by productive morphology and, thus, often start and end just like other words. Only 32% of words in Switchboard occur both before and after pauses, but many of the other 68% have similar-looking beginnings or endings.

Given an inter-character position in a phrase, its *right and left contexts* are the character sequences to its right and left. By convention, phrases input to WordEnds are padded with a single blank at each end. So the middle position of the phrase “afunjoke” has right context “joke□” and left context “□afun.” Since this is a word boundary, the right context looks like the start of a real word sequence, and the left context looks like the end of one. This is not true for the immediately previous position, which has right context “njoke□” and left context “□afu.”

Boundaries will be marked where the right and left contexts look like what we have observed at the starts and ends of phrases.

### 4.2 Statistical model

To formalize this, consider a fixed inter-character position in a phrase. It may be a word boundary ( $b$ )

or not ( $-b$ ). Let  $r$  and  $l$  be its right and left contexts. The input data will (see Section 4.3) give us  $P(b|r)$  and  $P(b|l)$ . Deciding whether to mark a boundary at this position requires estimating  $P(b|r, l)$ .

To express  $P(b|r, l)$  in terms of  $P(b|l)$  and  $P(b|r)$ , I will assume that  $r$  and  $l$  are conditionally independent given  $b$ . This corresponds roughly to a unigram language model. Let  $P(b)$  be the probability of a boundary at a random inter-character position. I will assume that the average word length, and therefore  $P(b)$ , is not absurdly small or large.

$P(b|r, l)$  is  $\frac{P(r, l|b)P(b)}{P(r, l)}$ . Conditional independence implies that this is  $\frac{P(r|b)P(l|b)P(b)}{P(r, l)}$ , which is  $\frac{P(r)P(b|r)P(l)P(b|l)}{P(b)P(r, l)}$ . This is  $\frac{P(b|r)P(b|l)}{QP(b)}$  where  $Q = \frac{P(r, l)}{P(r)P(l)}$ .  $Q$  is typically not 1, because a right and left context often co-occur simply because they both tend to occur at boundaries.

To estimate  $Q$ , write  $P(r, l)$  as  $P(r, l, b) + P(r, l, -b)$ . Then  $P(r, l, b)$  is  $\frac{P(r)P(b|r)P(l)P(b|l)}{P(b)}$ . If we assume that  $r$  and  $l$  are also conditionally independent given  $-b$ , then a similar equation holds for  $P(r, l, -b)$ . So  $Q = \frac{P(b|r)P(b|l)}{P(b)} + \frac{P(-b|r)P(-b|l)}{P(-b)}$

Contexts that occur primarily inside words (e.g. not at a syllable boundary) often restrict the adjacent context, violating conditional independence given  $-b$ . However, in these cases,  $P(b|r)$  and/or  $P(b|l)$  will be very low, so  $P(b|r, l)$  will be very low. So (correctly) no boundary will be marked.

Thus, we can compute  $P(b|r, l)$  from  $P(b|r)$ ,  $P(b|l)$ , and  $P(b)$ . A boundary is marked if  $P(b|r, l) \geq 0.5$ .

### 4.3 Estimating context probabilities

Estimation of  $P(b|r)$  and  $P(b|l)$  uses a simple ngram backoff algorithm. The details will be shown for  $P(b|l)$ .  $P(b|r)$  is similar.

Suppose for the moment that word boundaries are marked. The left context  $l$  might be very long and unusual. So we will estimate its statistics using a shorter lefthand neighborhood  $l'$ .  $P(b|l)$  is then estimated as the number of times  $l'$  occurs before a boundary, divided by the total number of times  $l'$  occurs in the corpus.

The suffix  $l'$  is chosen to be the longest suffix of  $l$  which occurs at least 10 times in the corpus, i.e. often enough for a reliable estimate in the presence

corpus	language	transcription	sm size	med size	lg size	pho/wd	wd/phr	hapax
BR87	English	dictionary	33K	–	–	2.9	3.4	31.7
Switchboard	English	dictionary	34K	409K	3086K	3.1	5.9	33.8
Switchboard	English	orthographic	34K	409K	3086K	[3.8]	5.9	34.2
Buckeye	English	dictionary	32K	290K	–	3.1	5.9	41.9
Buckeye	English	phonetic	32K	290K	–	2.9	5.9	66.0
Arabic	Arabic	dictionary	30K	405K	–	5.6	5.9	60.3
Spanish	Spanish	dictionary	37K	200K	–	3.7	8.4	49.1

Table 1: Key parameters for each test dataset include the language, transcription method, number of words (small, medium, large subsets), average phones per word, average words per phrase, and percent of word types that occur only once (hapax). Phones/word is replaced by characters/word for the orthographic corpus.

of noise.<sup>5</sup>  $l'$  may cross word boundaries and, if our position is near a pause, may contain the blank at the lefthand end of the phrase. The length of  $l'$  is limited to  $N_{max}$  characters to reduce overfitting.

Unfortunately, our input data has boundaries only at pauses (#). So applying this method to the raw input data produces estimates of  $P(\#|r)$  and  $P(\#|l)$ . Because phrase boundaries are not a representative selection of word boundaries,  $P(\#|r)$  and  $P(\#|l)$  are not good estimates of  $P(b|r)$  and  $P(b|l)$ . Moreover, initially, we don't know  $P(b)$ .

Therefore, WordEnds bootstraps the estimation using a binary model of the relationship between word and phrase boundaries. To a first approximation, an ngram occurs at the end of a phrase if and only if it can occur at the end of a word. Since the magnitude of  $P(\#, l)$  isn't helpful, we simply check whether it is zero and, accordingly, set  $P(b|l)$  to either zero or a constant, very high value.

In fact, real data contains phrase endings corrupted by disfluencies, foreign words, etc. So WordEnds actually sets  $P(b|l)$  high only if  $P(\#|l)$  is above a threshold (currently 0.003) chosen to reflect the expected amount of corruption.

In the equations from Section 4.2, if either  $P(b|r)$  or  $P(b|l)$  is zero, then  $P(b|r, l)$  is zero. If both values are very high, then  $Q$  is  $\frac{P(b|r)P(b|l)}{P(b)} + \epsilon$ , with  $\epsilon$  very small. So  $P(b|r, l)$  is close to 1. So, in the bootstrapping phase, the test for marking a boundary is independent of  $P(b)$  and reduces to testing whether  $P(\#|r)$  and  $P(\#|l)$  are both over threshold.

So, WordEnds estimates  $P(\#|r)$  and  $P(\#|l)$  from the input data, then uses this bootstrapping

<sup>5</sup>A single character is used if no suffix occurs 10 times.

method ( $N_{max} = 5$ )<sup>6</sup> to infer preliminary word boundaries. The preliminary boundaries are used to estimate  $P(b)$  and to re-estimate  $P(b|r)$  and  $P(b|l)$ , using  $N_{max} = 4$ . Final boundaries are then marked.

## 5 Mini-morph

In a full understanding system, output of the word segmenter would be passed to morphological and local syntactic processing. Because the segmenter is myopic, certain errors in its output would be easier to fix with the wider perspective available to this later processing. Because standard models of morphological learning don't address the interaction with word segmentation, WordEnds does a simple version of this repair process using a placeholder algorithm called Mini-morph.

Mini-morph fixes two types of defects in the segmentation. Short fragments are created when two nearby boundaries represent alternative reasonable segmentations rather than parts of a common segmentation. For example, "treestake" has potential boundaries both before and after the s. This issue was noted by Harrington et al. (1988) who used a list of known very short words to detect these cases. See also (Cairns et al., 1997). Also, surrounding words sometimes mislead WordEnds into undersegmenting a phone sequence which has an "obvious" analysis using well-established component words.

Mini-morph classifies each word in the segmentation as a fragment, a word that is reliable enough to use in subdividing other words, or unknown status.

<sup>6</sup>Values for  $N_{max}$  were chosen empirically. They could be adjusted for differences in entropy rate, but this is very similar across the datasets in this paper.

Because it has only a feeble model of morphology, Mini-morph has been designed to be cautious: most words are classified as unknown.

To classify a word, we compare its frequency  $w$  as a word in the segmentation to the frequencies  $p$  and  $s$  with which it occurs as a prefix and suffix of words in the segmentation (including itself). The word's fragment ratio  $f$  is  $\frac{2w}{p+s}$ .

Values of  $f$  are typically over 0.8 for freely occurring words, under 0.1 for fragments and strongly-attached affixes, and intermediate for clitics, some affixes, and words with restricted usage. However, most words haven't been seen enough times for  $f$  to be reliable. So a word is classified as a fragment if  $p + s \geq 1000$  and  $f \leq 0.2$ . It is classified as a reliable word if  $p + s \geq 50$  and  $f \geq 0.5$ .

To revise the input segmentation of the corpus, Mini-morph merges each fragment with an adjacent word if the newly-created merged word occurred at least 10 times in the input segmentation. When mergers with both adjacent words are possible, the algorithm alternates which to prefer. Each word is then subdivided into a sequence of reliable words, when possible. Because words are typically short and reliable words rare, a simple recursive algorithm is used, biased towards using shorter words.<sup>7</sup>

WordEnds calls Mini-morph twice, once to revise the preliminary segmentation produced by the bootstrapping phase and a second time to revise the final segmentation.

## 6 Test corpora

WordEnds was tested on a diverse set of seven corpora, summarized in Table 1. Notice that the Arabic dataset has much longer words than those used by previous authors. Subsets were extracted from the larger corpora, to control for training set size. Goldwater's algorithm, the best performing of previous methods, was also tested on the small versions.<sup>8</sup>

The first three corpora all use dictionary transcriptions with 1-character phone symbols. The Bernstein-Ratner (BR87) corpus was described above (Section 3.2). The Arabic corpus was created by removing punctuation and word boundaries from the Buckwalter version of the LDC's transcripts of

Gulf Arabic Conversational Telephone Speech (Apen, 2006). Filled pauses and foreign words were kept as is. Word fragments were kept, but the telltale hyphens were removed. The Spanish corpus was produced in a similar way from the Callhome Spanish dataset (Wheatley, 1996), removing all accents. Orthographic forms were used for words without pronunciations (e.g. foreign, fragments)

The other two English dictionary transcriptions were produced in a similar way from the Buckeye corpus (Pitt et al., 2005; Pitt et al., 2007) and Mississippi State's corrected version of the LDC's Switchboard transcripts (Godfrey and Holliman, 1994; Deshmukh et al., 1998). These use a "readable phonetic" version of arpabet. Each phone is represented with a 1–2 character code, chosen to look like English orthography and to ensure that character sequences decode uniquely into phone sequences. Buckeye does not provide dictionary pronunciations for word fragments, so these were transcribed as "X". Switchboard was also transcribed using standard English orthography.

The Buckeye corpus also provides an accurate phonetic transcription of its data, showing allophonic variation (e.g. glottal stop, dental/nasal flaps), segment deletions, quality shifts/uncertainty, and nasalization. Some words are "massively" reduced (Johnson, 2003), going well beyond standard phonological rules. We represented its 64 phones using codes with 1–3 characters.

## 7 Test results

Table 2 presents test results for the small corpora. The numbers for the four English dictionary and orthographic transcriptions are very similar. This confirms the finding of Batchelder (2002) that variations in transcription method have only minor impacts on segmenter performance. Performance seems to be largely determined by structural and lexical properties (e.g. word length, pause frequency).

For the English dictionary datasets, the primary overall evaluation numbers (BF and WF) for the two algorithms differ less than the variation created by tweaking parameters or re-running Goldwater's (randomized) algorithm. Both degrade similarly on the phonetic version of Buckeye. The most visible overall difference is speed. WordEnds processes

<sup>7</sup>Subdivision is done only once for each word type.

<sup>8</sup>It is too slow to run on the larger ones.

Table 3: Results for WordEnds on the medium and large datasets, also on the medium dataset without Mini-morph. See Table 1 for dataset sizes.

each small dataset in around 30-40 seconds. Goldwater requires around 2000 times as long: 14.5-32 hours, depending on the dataset.

However, WordEnds keeps affixes on words whereas Goldwater’s algorithm removes them. This creates a systematic difference in the balance between boundary recall and precision. It also causes Goldwater’s LF values to drop dramatically between the child-directed BR87 corpus and the adult-directed speech. For the same reason, WordEnds maintains good performance on the Arabic dataset, but Goldwater’s performance (especially LF) is much worse. It is quite likely that Goldwater’s algorithm is finding morphemes rather than words.

Datasets around 30K words are traditional for this task. However, a child learner has access to much more data, e.g. Weijer (1999) measured 1890 words per hour spoken near an infant. WordEnds performs much better when more data is available (Table 3). Numbers for even the harder datasets (Buckeye phonetic, Spanish) are starting to look promising. The Spanish results show that data with infrequent pauses can be handled in two very different ways: aggressive model-based segmentation (Gold-

water) or feeding more data to a more cautious segmenter (WordEnds).

The two calls to Mini-morph sometimes make almost no difference, e.g. on the Arabic data. But it can make large improvements, e.g. BF +6.9%, WF +10.5%, LF +5.8% on the BR corpus. Table 3 shows details for the medium datasets. Its contribution seems to diminish as the datasets get bigger, e.g. improvements of BF +4.7%, WF +9.3%, LF +3.7% on the small dictionary Switchboard corpus but only BF +1.3%, WF +3.3%, LF +3.4% on the large one.

## 8 Some specifics of performance

Examining specific mistakes confirms that WordEnds does not systematically remove affixes on English dictionary data. On the large Switchboard corpus, “-ed” is never removed from its stem and “-ing” is removed only 16 times. The Mini-morph post-processor misclassifies, and thus segments off, some affixes that are homophonous with free-standing words, such as “-en”/“in” and “-es”/“is”. A smarter model of morphology and local syntax could probably avoid this.

There is a visible difference between English “the” and the Arabic determiner “Al-”. The English determiner is almost always segmented off. From the medium-sized Switchboard corpus, only 434 lexical items are posited with “the” attached to a following word. Arabic “Al” is sometimes attached and sometimes segmented off. In the medium Arabic dataset, the correct and computed lexicons contain similar numbers of words starting with Al (4873 and 4608), but there is only partial overlap (2797 words). Some of this disagreement involves foreign language nouns, which the markup in the original corpus separates from the determiner.<sup>9</sup>

Mistakes on twenty specific items account for 24% of the errors on the large Switchboard corpus. The first two items, accounting for over 11% of the mistakes, involve splitting “uhhuh” and “umhum”. Most of the rest involve merging common collocations (e.g. “a lot”) or splitting common compounds that have a transparent analysis (e.g. “something”).

## 9 Discussion and conclusions

Performance of WordEnds is much stronger than previous reported results, including good results on Arabic and promising results on accurate phonetic transcriptions. This is partly due to good algorithm design and partly due to using more training data. This sets a much higher standard for models of child language acquisition and also suggests that it is not crazy to speculate about inserting such an algorithm into the speech recognition pipeline.

Performance would probably be improved by better models of morphology and/or phonology. An ngram model of morpheme sequences (e.g. like Goldwater uses) might avoid some of the mistakes mentioned in Section 8. Feature-based or gestural phonology (Browman and Goldstein, 1992) might help model segmental variation. Finite-state models (Belz, 2000) might be more compact. Prosody, stress, and other sub-phonemic cues might disambiguate some problem situations (Hockema, 2006; Rytting, 2007; Salverda et al., 2003).

However, it is not obvious which of these approaches will actually improve performance. Additional phonetic features may not be easy to detect

<sup>9</sup>The author does not read Arabic and, thus, is not in a position to explain why the annotators did this.

reliably, e.g. marking lexical stress in the presence of contrastive stress and utterance-final lengthening. The actual phonology of fast speech may not be quite what we expect, e.g. performance on the phonetic version of Buckeye was slightly **improved** by merging nasal flap with n, and dental flap with d and glottal stop. The sets of word initial and final segments may not form natural phonological classes, because they are partly determined by morphological and lexical constraints (Rytting, 2007).

Moreover, the strong performance from the basic segmental model makes it hard to rule out the possibility that high performance could be achieved, even on data with phonetic variation, by throwing enough training data at a simple segmental algorithm.

Finally, the role of child-directed speech needs to be examined more carefully. Child-directed speech displays helpful features such as shorter phrases and fewer reductions (Bernstein Ratner, 1996; van de Weijer, 1999). These features may make segmentation easier to learn, but the strong results presented here for adult-directed speech make it trickier to argue that this help is necessary for learning.

Moreover, it is not clear how learning to segment child-directed speech might make it easier to learn to segment speech directed at adults or older children. It’s possible that learning child-directed speech makes it easier to learn the basic principles of phonology, semantics, or higher-level linguistic structure. This might somehow feed back into learning segmentation. However, it’s also possible that its only *raison d’être* is social: enabling earlier communication between children and adults.

## Abstract

Query expansion is an effective technique to improve the performance of information retrieval systems. Although hand-crafted lexical resources, such as WordNet, could provide more reliable related terms, previous studies showed that query expansion using only WordNet leads to very limited performance improvement. One of the main challenges is how to assign appropriate weights to expanded terms. In this paper, we re-examine this problem using recently proposed axiomatic approaches and find that, with appropriate term weighting strategy, we are able to exploit the information from lexical resources to significantly improve the retrieval performance. Our empirical results on six TREC collections show that query expansion using only hand-crafted lexical resources leads to significant performance improvement. The performance can be further improved if the proposed method is combined with query expansion using co-occurrence-based resources.

## 1 Introduction

Most information retrieval models (Salton et al., 1975; Fuhr, 1992; Ponte and Croft, 1998; Fang and Zhai, 2005) compute relevance scores based on matching of terms in queries and documents. Since various terms can be used to describe a same concept, it is unlikely for a user to use a query term that is exactly the same term as used in relevant documents. Clearly, such vocabulary gaps make the retrieval performance non-optimal. Query expansion (Voorhees, 1994; Mandala et al., 1999a; Fang and

Zhai, 2006; Qiu and Frei, 1993; Bai et al., 2005; Cao et al., 2005) is a commonly used strategy to bridge the vocabulary gaps by expanding original queries with related terms. Expanded terms are often selected from either co-occurrence-based thesauri (Qiu and Frei, 1993; Bai et al., 2005; Jing and Croft, 1994; Peat and Willett, 1991; Smeaton and van Rijsbergen, 1983; Fang and Zhai, 2006) or hand-crafted thesauri (Voorhees, 1994; Liu et al., 2004) or both (Cao et al., 2005; Mandala et al., 1999b).

Intuitively, compared with co-occurrence-based thesauri, hand-crafted thesauri, such as WordNet, could provide more reliable terms for query expansion. However, previous studies failed to show any significant gain in retrieval performance when queries are expanded with terms selected from WordNet (Voorhees, 1994; Stairmand, 1997). Although some researchers have shown that combining terms from both types of resources is effective, the benefit of query expansion using only manually created lexical resources remains unclear. The main challenge is how to assign appropriate weights to the expanded terms.

In this paper, we re-examine the problem of query expansion using lexical resources with the recently proposed axiomatic approaches (Fang and Zhai, 2006). The major advantage of axiomatic approaches in query expansion is to provide guidance on how to weight related terms based on a given term similarity function. In our previous study, a co-occurrence-based term similarity function was proposed and studied. In this paper, we study several term similarity functions that exploit various information from two lexical resources, i.e., WordNet

and dependency-thesaurus constructed by Lin (Lin, 1998), and then incorporate these similarity functions into the axiomatic retrieval framework. We conduct empirical experiments over several TREC standard collections to systematically evaluate the effectiveness of query expansion based on these similarity functions. Experiment results show that all the similarity functions improve the retrieval performance, although the performance improvement varies for different functions. We find that the most effective way to utilize the information from WordNet is to compute the term similarity based on the overlap of synset definitions. Using this similarity function in query expansion can significantly improve the retrieval performance. According to the retrieval performance, the proposed similarity function is significantly better than simple mutual information based similarity function, while it is comparable to the function proposed in (Fang and Zhai, 2006). Furthermore, we show that the retrieval performance can be further improved if the proposed similarity function is combined with the similarity function derived from co-occurrence-based resources.

The main contribution of this paper is to re-examine the problem of query expansion using lexical resources with a new approach. Unlike previous studies, we are able to show that query expansion using only manually created lexical resources can significantly improve the retrieval performance.

The rest of the paper is organized as follows. We discuss the related work in Section 2, and briefly review the studies of query expansion using axiomatic approaches in Section 3. We then present our study of using lexical resources, such as WordNet, for query expansion in Section 4, and discuss experiment results in Section 5. Finally, we conclude in Section 6.

## 2 Related Work

Although the use of WordNet in query expansion has been studied by various researchers, the improvement of retrieval performance is often limited. Voorhees (Voorhees, 1994) expanded queries using a combination of synonyms, hypernyms and hyponyms *manually* selected from WordNet, and achieved limited improvement (i.e., around  $-2\%$  to

$+2\%$ ) on short verbose queries. Stairmand (Stairmand, 1997) used WordNet for query expansion, but they concluded that the improvement was restricted by the coverage of the WordNet and no empirical results were reported.

More recent studies focused on combining the information from both co-occurrence-based and hand-crafted thesauri. Mandala et. al. (Mandala et al., 1999a; Mandala et al., 1999b) studied the problem in vector space model, and Cao et. al. (Cao et al., 2005) focused on extending language models. Although they were able to improve the performance, it remains unclear whether using only information from hand-crafted thesauri would help to improve the retrieval performance.

Another way to improve retrieval performance using WordNet is to disambiguate word senses. Voorhees (Voorhees, 1993) showed that using WordNet for word sense disambiguation degrade the retrieval performance. Liu et. al. (Liu et al., 2004) used WordNet for both sense disambiguation and query expansion and achieved reasonable performance improvement. However, the computational cost is high and the benefit of query expansion using only WordNet is unclear. Ruch et. al. (Ruch et al., 2006) studied the problem in the domain of biology literature and proposed an argumentative feedback approach, where expanded terms are selected from only sentences classified into one of four disjunct argumentative categories.

The goal of this paper is to study whether query expansion using only manually created lexical resources could lead to the performance improvement. The main contribution of our work is to show query expansion using only hand-crafted lexical resources is effective in the recently proposed axiomatic framework, which has not been shown in the previous studies.

## 3 Query Expansion in Axiomatic Retrieval Model

Axiomatic approaches have recently been proposed and studied to develop retrieval functions (Fang and Zhai, 2005; Fang and Zhai, 2006). The main idea is to search for a retrieval function that satisfies all the desirable retrieval constraints, i.e., axioms. The underlying assumption is that a retrieval function sat-

isfying all the constraints would perform well empirically. Unlike other retrieval models, axiomatic retrieval models directly model the relevance with term level retrieval constraints.

In (Fang and Zhai, 2005), several axiomatic retrieval functions have been derived based on a set of basic formalized retrieval constraints and an inductive definition of the retrieval function space. The derived retrieval functions are shown to perform as well as the existing retrieval functions with less parameter sensitivity. One of the components in the inductive definition is primitive weighting function, which assigns the retrieval score to a single term document  $\{d\}$  for a single term query  $\{q\}$  based on

$$S(\{q\}, \{d\}) = \begin{cases} \omega(q) & q = d \\ 0 & q \neq d \end{cases} \quad (1)$$

where  $\omega(q)$  is a term weighting function of  $q$ . A limitation of the primitive weighting function described in Equation 1 is that it can not bridge vocabulary gaps between documents and queries.

To overcome this limitation, in (Fang and Zhai, 2006), we proposed a set of semantic term matching constraints and modified the previously derived axiomatic functions to make them satisfy these additional constraints. In particular, the primitive weighting function is generalized as

$$S(\{q\}, \{d\}) = \omega(q) \times f(s(q, d)),$$

where  $s(q, d)$  is a semantic similarity function between two terms  $q$  and  $d$ , and  $f$  is a monotonically increasing function defined as

$$f(s(q, d)) = \begin{cases} 1 & q = d \\ \frac{s(q, d)}{s(q, q)} \times \beta & q \neq d \end{cases} \quad (2)$$

where  $\beta$  is a parameter that regulates the weighting of the original query terms and the semantically similar terms. We have shown that the proposed generalization can be implemented as a query expansion method. Specifically, the expanded terms are selected based on a term similarity function  $s$  and the weight of an expanded term  $t$  is determined by its term similarity with a query term  $q$ , i.e.,  $s(q, t)$ , as well as the weight of the query term, i.e.,  $\omega(q)$ . Note that the weight of an expanded term  $t$  is  $\omega(t)$  in traditional query expansion methods.

In our previous study (Fang and Zhai, 2006), term similarity function  $s$  is derived based on the mutual information of terms over collections that are constructed under the guidance of a set of term semantic similarity constraints. The focus of this paper is to study and compare several term similarity functions exploiting the information from lexical resources, and evaluate their effectiveness in the axiomatic retrieval models.

## 4 Term Similarity based on Lexical Resources

In this section, we discuss a set of term similarity functions that exploit the information stored in two lexical resources: WordNet (Miller, 1990) and dependency-based thesaurus (Lin, 1998).

The most commonly used lexical resource is WordNet (Miller, 1990), which is a hand-crafted lexical system developed at Princeton University. Words are organized into four taxonomies based on different parts of speech. Every node in the WordNet is a synset, i.e., a set of synonyms. The definition of a synset, which is referred to as *gloss*, is also provided. For a query term, all the synsets in which the term appears can be returned, along with the definition of the synsets. We now discuss six possible term similarity functions based on the information provided by WordNet.

Since the definition provides valuable information about the semantic meaning of a term, we can use the definitions of the terms to measure their semantic similarity. The more common words the definitions of two terms have, the more similar these terms are (Banerjee and Pedersen, 2005). Thus, we can compute the term semantic similarity based on synset definitions in the following way:

$$s_{def}(t_1, t_2) = \frac{|D(t_1) \cap D(t_2)|}{|D(t_1) \cup D(t_2)|},$$

where  $D(t)$  is the concatenation of the definitions for all the synsets containing term  $t$  and  $|D|$  is the number of words of the set  $D$ .

Within a taxonomy, synsets are organized by their lexical relations. Thus, given a term, related terms can be found in the synsets related to the synsets containing the term. In this paper, we consider the following five word relations.

- **Synonym(Syn)**: X and Y are synonyms if they are interchangeable in some context.
- **Hypernym(Hyper)**: Y is a hypernym of X if X is a (kind of) Y.
- **Hyponym(Hypo)**: X is a hyponym of Y if X is a (kind of) Y.
- **Holonym(Holo)**: Y is a holonym of X if X is a part of Y.
- **Meronym(Mero)**: X is a meronym of Y if X is a part of Y.

Since these relations are binary, we define the term similarity functions based on these relations in the following way.

$$s_R(t_1, t_2) = \begin{cases} \alpha_R & t_1 \in T_R(t_2) \\ 0 & t_1 \notin T_R(t_2) \end{cases}$$

where  $R \in \{syn, hyper, hypo, holo, mero\}$ ,  $T_R(t)$  is a set of words that are related to term  $t$  based on the relation  $R$ , and  $\alpha$ s are non-zero parameters to control the similarity between terms based on different relations. However, since the similarity values for all term pairs are same, the values of these parameters can be ignored when we use Equation 2 in query expansion.

Another lexical resource we study in the paper is the dependency-based thesaurus provided by Lin<sup>1</sup> (Lin, 1998). The thesaurus provides term similarities that are automatically computed based on dependency relationships extracted from a parsed corpus. We define a similarity function that can utilize this thesaurus as follows:

$$s_{Lin}(t_1, t_2) = \begin{cases} L(t_1, t_2) & (t_1, t_2) \in TP_{Lin} \\ 0 & (t_1, t_2) \notin TP_{Lin} \end{cases}$$

where  $L(t_1, t_2)$  is the similarity of terms stored in the dependency-based thesaurus and  $TP_{Lin}$  is a set of all the term pairs stored in the thesaurus. The similarity of two terms would be assigned to zero if we can not find the term pair in the thesaurus.

Since all the similarity functions discussed above capture different perspectives of term relations, we

propose a simple strategy to combine these similarity functions so that the similarity of a term pair is the highest similarity value of these two terms of all the above similarity functions, which is shown as follows.

$$s_{combined}(t_1, t_2) = \max_{R \in Rset}(s_R(t_1, t_2)),$$

where

$$Rset = \{def, syn, hyper, hypo, holo, mero, Lin\}.$$

In summary, we have discussed eight possible similarity functions that exploit the information from the lexical resources. We then incorporate these similarity functions into the axiomatic retrieval models based on Equation 2, and perform query expansion based on the procedure described in Section 3. The empirical results are reported in Section 5.

## 5 Experiments

In this section, we experimentally evaluate the effectiveness of query expansion with the term similarity functions discussed in Section 4 in the axiomatic framework. Experiment results show that the similarity function based on synset definitions is most effective. By incorporating this similarity function into the axiomatic retrieval models, we show that query expansion using the information from only WordNet can lead to significant improvement of retrieval performance, which has not been shown in the previous studies (Voorhees, 1994; Stairmand, 1997).

### 5.1 Experiment Design

We conduct three sets of experiments. First, we compare the effectiveness of term similarity functions discussed in Section 4 in the context of query expansion. Second, we compare the best one with the term similarity functions derived from co-occurrence-based resources. Finally, we study whether the combination of term similarity functions from different resources can further improve the performance.

All experiments are conducted over six TREC collections: ap88-89, doe, fr88-89, wt2g, trec7 and trec8. Table 1 shows some statistics of the collections, including the description, the collection size,

<sup>1</sup>Available at <http://www.cs.ualberta.ca/~lindek/downloads.htm>

Table 1: Statistics of Test Collections

Collection	Description	Size	# Voc.	# Doc.	#query
ap88-89	news articles	491MB	361K	165K	150
doe	technical reports	184MB	163K	226K	35
fr88-89	government documents	469MB	204K	204K	42
trec7	ad hoc data	2GB	908K	528K	50
trec8	ad hoc data	2GB	908K	528K	50
wt2g	web collections	2GB	1968K	247K	50

the vocabulary size, the number of documents and the number of queries. The preprocessing only involves stemming with Porter’s stemmer.

We use WordNet 3.0 <sup>2</sup>, Lemur Toolkit <sup>3</sup> and TrecWN library <sup>4</sup> in experiments. The results are evaluated with both MAP (mean average precision) and gMAP (geometric mean average precision) (Voorhees, 2005), which emphasizes the performance of difficulty queries.

There is one parameter  $\beta$  in the query expansion method presented in Section 3. We tune the value of  $\beta$  and report the best performance. The parameter sensitivity is similar to the observations described in (Fang and Zhai, 2006) and will not be discussed in this paper. In all the result tables, ‡ and † indicate that the performance difference is statistically significant according to Wilcoxon signed rank test at the level of 0.05 and 0.1 respectively.

We now explain the notations of different methods. *BL* is the baseline method without query expansion. In this paper, we use the best performing function derived in axiomatic retrieval models, i.e, F2-EXP in (Fang and Zhai, 2005) with a fixed parameter value ( $b = 0.5$ ).  $QE_X$  is the query expansion method with term similarity function  $s_X$ , where  $X$  could be *Def.*, *Syn.*, *Hyper.*, *Hypo.*, *Mero.*, *Holo.*, *Lin* and *Combined*.

Furthermore, we examine the query expansion method using co-occurrence-based resources. In particular, we evaluate the retrieval performance using the following two similarity functions:  $s_{MIBL}$  and  $s_{MIImp}$ . Both functions are based on the mutual information of terms in a set of documents.  $s_{MIBL}$  uses the collection itself to compute the mutual information, while  $s_{MIImp}$  uses the working sets con-

structed based on several constraints (Fang and Zhai, 2006). The mutual information of two terms  $t_1$  and  $t_2$  in collection  $C$  is computed as follow (van Rijsbergen, 1979):

$$I(X_{t_1}, X_{t_2}) = \sum p(X_{t_1}, X_{t_2}) \log \frac{p(X_{t_1}, X_{t_2})}{p(X_{t_1})p(X_{t_2})}$$

$X_{t_i}$  is a binary random variable corresponding to the presence/absence of term  $t_i$  in each document of collection  $C$ .

## 5.2 Effectiveness of Lexical Resources

We first compare the retrieval performance of query expansion with different similarity functions using short keyword (i.e., title-only) queries, because query expansion techniques are often more effective for shorter queries (Voorhees, 1994; Fang and Zhai, 2006). The results are presented in Table 2. It is clear that query expansion with these functions can improve the retrieval performance, although the performance gains achieved by different functions vary a lot. In particular, we make the following observations.

First, the similarity function based on synset definitions is the most effective one.  $QE_{def}$  significantly improves the retrieval performance for all the data sets. For example, in trec7, it improves the performance from 0.186 to 0.216. As far as we know, none of the previous studies showed such significant performance improvement by using only WordNet as query expansion resource.

Second, the similarity functions based on term relations are less effective compared with definition-based similarity function. We think that the worse performance is related to the following two reasons: (1) The similarity functions based on relations are binary, which is not a good way to model term similarities. (2) The relations are limited by the part

of speech of the terms, because two terms in WordNet are related only when they have the same part of speech tags. However, definition-based similarity function does not have such a limitation.

Third, the similarity function based on Lin’s thesaurus is more effective than those based on term relations from the WordNet, while it is less effective compared with the definition-based similarity function, which might be caused by its smaller coverage.

Finally, combining different WordNet-based similarity functions does not help, which may indicate that the expanded terms selected by different functions are overlapped.

### 5.3 Comparison with Co-occurrence-based Resources

As shown in Table 2, the similarity function based on synset definitions, i.e.,  $s_{def}$ , is most effective. We now compare the retrieval performance of using this similarity function with that of using the mutual information based functions, i.e.,  $s_{MIBL}$  and  $s_{MIImp}$ . The experiments are conducted over two types of queries, i.e. short keyword (keyword title) and short verbose (one sentence description) queries.

The results for short keyword queries are shown in Table 3. The retrieval performance of query expansion based on  $s_{def}$  is significantly better than that based on  $s_{MIBL}$  on almost all the data sets, while it is slightly worse than that based on  $s_{MIImp}$  on some data sets. We can make the similar observation from the results for short verbose queries as shown in Table 4. One advantage of  $s_{def}$  over  $s_{MIImp}$  is the computational cost, because  $s_{def}$  can be computed offline in advance while  $s_{MIImp}$  has to be computed online from query-dependent working sets which takes much more time. The low computa-

tional cost and high retrieval performance make  $s_{def}$  more attractive in the real world applications.

### 5.4 Additive Effect

Since both types of similarity functions are able to improve retrieval performance, we now study whether combining them could lead to better performance. Table 5 shows the retrieval performance of combining both types of similarity functions for short keyword queries. The results for short verbose queries are similar. Clearly, combining the similarity functions from different resources could further improve the performance.

## 6 Conclusions

Query expansion is an effective technique in information retrieval to improve the retrieval performance, because it often can bridge the vocabulary gaps between queries and documents. Intuitively, hand-crafted thesaurus could provide reliable related terms, which would help improve the performance. However, none of the previous studies is able to show significant performance improvement through query expansion using information only from manually created lexical resources.

In this paper, we re-examine the problem of query expansion using lexical resources in recently proposed axiomatic framework and find that we are able to significantly improve retrieval performance through query expansion using only hand-crafted lexical resources. In particular, we first study a few term similarity functions exploiting the information from two lexical resources: WordNet and dependency-based thesaurus created by Lin. We then incorporate the similarity functions with the query expansion method in the axiomatic retrieval

models. Systematical experiments have been conducted over six standard TREC collections and show promising results. All the proposed similarity functions improve the retrieval performance, although the degree of improvement varies for different similarity functions. Among all the functions, the one based on synset definition is most effective and is able to significantly and consistently improve retrieval performance for all the data sets. This similarity function is also compared with some similarity functions using mutual information. Furthermore, experiment results show that combining similarity functions from different resources could further improve the performance.

Unlike previous studies, we are able to show that query expansion using only manually created thesauri can lead to significant performance improvement. The main reason is that the axiomatic approach provides guidance on how to appropriately assign weights to expanded terms.

There are many interesting future research directions based on this work. First, we will study the same problem in some specialized domain, such as biology literature, to see whether the proposed approach could be generalized to the new domain. Second, the fact that using axiomatic approaches to incorporate linguistic information can improve retrieval performance is encouraging. We plan to extend the axiomatic approach to incorporate more linguistic information, such as phrases and word

senses, into retrieval models to further improve the performance.

## Abstract

Query expansion by word alterations (alternative forms of a word) is often used in Web search to replace word stemming. This allows users to specify particular word forms in a query. However, if many alterations are added, query traffic will be greatly increased. In this paper, we propose methods to select only a few useful word alterations for query expansion. The selection is made according to the appropriateness of the alteration to the query context (using a bigram language model), or according to its expected impact on the retrieval effectiveness (using a regression model). Our experiments on two TREC collections will show that both methods only select a few expansion terms, but the retrieval effectiveness can be improved significantly.

## 1 Introduction

Word stemming is a basic NLP technique used in most of Information Retrieval (IR) systems. It transforms words into their root forms so as to increase the chance to match similar words/terms that are morphological variants. For example, with stemming, “controlling” can match “controlled” because both have the same root “control”. Most stemmers, such as the Porter stemmer (Porter, 1980) and Krovetz stemmer (Krovetz, 1993), deal with stemming by stripping word suffixes according to a set of morphological rules. Rule-based approaches are intuitive and easy to implement. However, while in general, most words can be stemmed correctly; there is often erroneous stemming that unifies unrelated words. For instance,

“jobs” is stemmed to “job” in both “find jobs in Apple” and “Steve Jobs at Apple”. This is particularly problematic in Web search, where users often use special or new words in their queries. A standard stemmer such as Porter’s will wrongly stem them.

To better determine stemming rules, Xu and Croft (1998) propose a selective stemming method based on corpus analysis. They refine the Porter stemmer by means of word clustering: words are first clustered according to their co-occurrences in the text collection. Only word variants belonging to the same cluster will be conflated.

Despite this improvement, the basic idea of word stemming is to transform words in both documents and queries to a standard form. Once this is done, there is no means for users to require a specific word form in a query – the word form will be automatically transformed, otherwise, it will not match documents. This approach does not seem to be appropriate for Web search, where users often specify particular word forms in their queries. An example of this is a quoted query such as “Steve Jobs”, or “US Policy”. If documents are stemmed, many pages about job offerings or US police may be returned (“policy” conflates with “police” in Porter stemmer). Another drawback of stemming is that it usually enhances recall, but may hurt precision (Kraaij and Pohlmann, 1996). However, general Web search is basically a precision-oriented task.

One alternative approach to word stemming is to do query expansion at query time. The original query terms are expanded by their related forms having the same root. All expansions can be combined by the Boolean operator “OR”. For example,

the query “*controlling acid rain*” can be expanded to “(*control OR controlling OR controller OR controlled OR controls*) (*acid OR acidic OR acidify*) (*rain OR raining OR rained OR rains*)”. We will call each such expansion term an *alteration* to the original query term. Once a set of possible alterations is determined, the simplest approach to perform expansion is to add all possible alterations. We call this approach *Naive Expansion*. One can easily show that stemming at indexing time is equivalent to *Naive Expansion* at retrieval time. This approach has been adopted by most commercial search engines (Peng et al., 2007). However, the expansion approaches proposed previously can have several serious problems: First, they usually do not consider expansion ambiguity – each query term is usually expanded independently. However, some expansion terms may not be appropriate. The case of “Steve Jobs” is one such example, for which the word “job” can be proposed as an expansion term. Second, as each query term may have several alterations, the naïve approach using all the alterations will create a very long query. As a consequence, query traffic (the time required for the evaluation of a query) is greatly increased. Query traffic is a critical problem, as each search engine serves millions of users at the same time. It is important to limit the query traffic as much as possible.

In practice, we can observe that some word alterations are irrelevant and undesirable (as in the “Steve Jobs” case), and some other alterations have little impact on the retrieval effectiveness (for example, if we expand a word by a rarely used word form). In this study, we will address these two problems. Our goal is to select only appropriate word alterations to be used in query expansion. This is done for two purposes: On the one hand, we want to limit query traffic as much as possible when query expansion is performed. On the other hand, we also want to remove irrelevant expansion terms so that fewer irrelevant documents will be retrieved, thereby improve the retrieval effectiveness.

To deal with the two problems we mentioned above, we will propose two methods to select alterations. In the first method, we make use of the query context to select only the alterations that fit the query. The query context is modeled by a bigram language model. To reduce query traffic, we select only one alteration for each query term,

which is the most coherent with the bigram model. We call this model *Bigram Expansion*. Despite the fact that this method adds far fewer expansion terms than the naïve expansion, our experiments will show that we can achieve comparable or even better retrieval effectiveness.

Both the Naive Expansion and the Bigram Expansion determine word alterations solely according to general knowledge about the language (bigram model or morphological rules), and no consideration about the possible effect of the expansion term is made. In practice, some alterations will have virtually no impact on retrieval effectiveness. They can be ignored. Therefore, in our second method, we will try to predict whether an alteration will have some positive impact on retrieval effectiveness. Only the alterations with positive impact will be retained. In this paper, we will use a regression model to predict the impact on retrieval effectiveness. Compared to the bigram expansion method, the regression method results in even fewer alterations, but experiments show that the retrieval effectiveness is even better.

Experiments will be conducted on two TREC collections, Gov2 data for Web Track and TREC6&7&8 for ad-hoc retrieval. The results show that the two methods we propose both outperform the original queries significantly with less than two alterations per query on average. Compared to the *Naive Expansion* method, the two methods can perform at least equally well, while query traffic is dramatically reduced.

In the following section, we provide a brief review of related work. Section 3 shows how to generate alteration candidates using a similar approach to Xu and Croft’s corpus analysis (1998). In section 4 and 5, we describe the Bigram Expansion method and Regression method respectively. Section 6 presents some experiments on TREC benchmarks to evaluate our methods. Section 7 concludes this paper and suggests some avenues for future work.

## 2 Related Work

Many stemmers have been implemented and used as standard processing in IR. Among them, the Porter stemmer (Porter, 1980) is the most widely used. It strips term suffixes step-by-step according to a set of morphological rules. However, the Porter stemmer sometimes wrongly transforms a term into an unrelated root. For example, it will unify

“news” and “new”, “execute” and “executive”. On the other hand, it may miss some confluences, such as “mice” and “mouse”, “europe” and “european”. Krovetz (1993) developed another stemmer, which uses a machine-readable dictionary, to improve the Porter stemmer. It avoids some of the Porter stemmer’s wrong stripping, but does not produce consistent improvement in IR experiments.

Both stemmers use generic rules for English to strip each word in isolation. In practice, the required stemming may vary from one text collection to another. Therefore, attempts have been made to use corpus analysis to improve existing rule-based stemmers. Xu and Croft (1998) create equivalence clusters of words which are morphologically similar and occur in similar contexts.

As we stated earlier, the stemming-based IR approaches are not well suited to Web search. Query expansion has been used as an alternative (Peng et al. 2007). To limit the number of expansion terms, and thus the query traffic, Peng et al. only use alterations for some of the query words: They segment each query into phrases and only the head word in each phrase is expanded. The assumptions are: 1) Queries issued in Web search often consist of noun phrases. 2) Only the head word in the noun phrase varies in form and needs to be expanded. However, both assumptions may be questionable. Their experiments did not show that the two assumptions hold.

Stemming is related to query expansion or query reformulation (Jones et al., 2006; Anick, 2003; Xu and Croft, 1996), although the latter is not limited to word variants. If the expansion terms used are those that are variant forms of a word, then query expansion can produce the same effect as word stemming. However, if we add all possible word alterations, query expansion/reformulation will run the risk of adding many unrelated terms to the original query, which may result in both heavy traffic and topic drift. Therefore, we need a way to select the most appropriate expansion terms. In (Peng et al. 2007), a bigram language model is used to determine the alteration of the head word that best fits the query. In this paper, one of the proposed methods will also use a bigram language model of the query to determine the appropriate alteration candidates. However, in our approach, alterations are not limited to head words. In addition, we will also propose a supervised learning

method to predict if an alteration will have a positive impact on retrieval effectiveness. To our knowledge, no previous method uses the same approach.

In the following sections, we will describe our approach, which consists of two steps: the generation of alteration candidates, and the selection of appropriate alterations for a query. The first step is query-independent using corpus analysis, while the second step is query-dependent. The selected word alterations will be *OR*-ed with the original query words.

### 3 Generating Alteration Candidates

Our method to generate alteration candidates can be described as follows. First, we do word clustering using a Porter stemmer. All words in the vocabulary sharing the same root form are grouped together. Then we do corpus analysis to filter out the words which are clustered incorrectly, according to word distributional similarity, following (Xu and Croft, 1998; Lin 1998). The rationale behind this is that words sharing the same meaning tend to occur in the same contexts.

The context of each word in the vocabulary is represented by a vector containing the frequencies of the context words which co-occur with the word within a predefined window in a training corpus. The window size is set empirically at 3 words and the training corpus is about 1/10 of the GOV2 corpus (see section 5 for details about the collection). Similarity is measured by the cosine distance between two vectors. For each word, we select at most 5 similar words as alteration candidates.

In the next sections, we will further consider ways to select appropriate alterations according to the query.

### 4 Bigram Expansion Model for Alteration Selection

In this section, we try to select the most suitable alterations according to the query context. The query context is modeled by a bigram language model as in (Peng et al. 2007).

Given a query described by a sequence of words, we consider each of the query word as representing a concept  $c_i$ . In addition to the given word form,  $c_i$  can also be expressed by other alternative forms. However, the appropriate alterations do not only depend on the original word of  $c_i$ , but also on other query words or their alterations.

Figure 1: Considering all Combinations to Calculate the Plausibility of Alterations

Accordingly, a confidence weight is determined for each alteration candidate. For example, in the query “Steve Jobs at Apple”, the alteration “job” of “jobs” should have a low confidence; while in the query “finding jobs in Apple”, it should have a high confidence.

One way to measure the confidence of an alteration is the plausibility of its appearing in the query. Since each concept may be expressed by several alterations, we consider all the alterations of context concepts when calculating the plausibility of a given word. Suppose we have the query “controlling acid rain”. The second concept has two alterations - “acidify” and “acidic”. For each of the alterations, our method will consider all the combinations with other words, as illustrated in figure 1, where each combination is shown as a path. More precisely, for a query of  $n$  words (or their corresponding concepts), let  $e_{ij} \in c_i$ ,  $j=1,2,\dots,|c_i|$  be the alterations of concept  $c_i$ . Then we have:

$$P(e_{ij}) = \sum_{1,j_1=1}^{|c_1|} \sum_{2,j_2=1}^{|c_2|} \dots \sum_{i-1,j_{i-1}=1}^{|c_{i-1}|} \sum_{i+1,j_{i+1}=1}^{|c_{i+1}|} \dots \sum_{n,j_n=1}^{|c_n|} P(e_{1,j_1}, e_{2,j_2}, \dots, e_{i,j_i}, \dots, e_{n,j_n}) \quad (1)$$

In equation 1,  $e_{1,j_1}, e_{2,j_2}, \dots, e_{i,j_i}, \dots, e_{n,j_n}$  is a path passing through  $e_{i,j}$ . For simplicity, we abbreviate it as  $e_1 e_2 \dots e_i \dots e_n$ . In this work, we used bigram language model to calculate the probability of each path. Then we have:

$$P(e_1, e_2, \dots, e_i, \dots, e_n) = P(e_1) \prod_{k=2}^n P(e_k | e_{k-1}) \quad (2)$$

$P(e_k | e_{k-1})$  is estimated with a back-off bigram language model (Goodman, 2001). In the experiments with TREC6&7&8, we train the model with all text collections; while in the experiments with Gov2 data, we only used about 1/10 of the GOV2 data to train the bigram model because the whole Gov2 collection is too large.

Directly calculating  $P(e_{ij})$  by summing the probabilities of all paths passing through  $e_{ij}$  is an NP problem (Rabiner, 1989), and is intractable if the query is long. Therefore, we use the forward-backward algorithm (Bishop, 2006) to calculate  $P(e_{ij})$  in a more efficient way. After calculating  $P(e_{ij})$  for each  $c_i$ , we select one alteration which has the highest probability. We limit the number of additional alterations to 1 in order to limit query traffic. Our experiments will show that this is often sufficient.

## 5 Regression Model for Alteration Selection

None of the previous selection methods considers how well an alteration would perform in retrieval. The Bigram Expansion model assumes that the query replaced with better alterations should have a higher likelihood. This approach belongs to the family of unsupervised learning. In this section, we introduce a method belonging to supervised learning family. This method develops a regression model from a set of training data, and it is capable of predicting the expected change in performance when the original query is augmented by this alteration. The performance change is measured by the difference in the Mean Average Precision (MAP) between the augmented and the original query. The training instances are defined by the original query string, an original query term under consideration and one alteration to the query term. A set of features will be used, which will be defined later in this section.

### 5.1 Linear Regression Model

The goal of the regression model is to predict the performance change when a query term is augmented with an alteration. There are several regression models, ranging from the simplest linear regression model to non-linear alternatives, such as a neural network (Duda et al., 2001), a Regression SVM (Bishop, 2006). For simplicity, we use linear regression model here. We denote an instance in the feature space as  $X$ , and the weights of features are denoted as  $W$ . Then the linear regression model is defined as:

$$f(X) = W^T X \quad (3)$$

where  $W^T$  is the transpose of  $W$ . However, we will have a technical problem if we set the target value to the performance change directly: The range of

values of  $f(X)$  is  $(-\infty, +\infty)$ , while the range of performance change is  $[-1, 1]$ . The two value ranges do not match. This inconsistency may result in severe problems when the scales of feature values vary dramatically (Duda et al., 2001). To solve this problem, we do a simple transformation on the performance change. Let the change be  $y \in [-1, 1]$ , then the transformed performance change is:

$$\varphi(y) = \log \frac{1+y+\gamma}{1-y+\gamma} \quad y \in [-1, 1] \quad (4)$$

where  $\gamma$  is a very small positive real number (set to be  $1e-37$  in the experiments), which acts as a smoothing factor. The value of  $\varphi(y)$  can be an arbitrary real number.  $\varphi(y)$  is a monotonic function defined in the range of  $[-1, 1]$ . Moreover, the fixed point of  $\varphi(y)$  is 0, i.e.,  $\varphi(y) = y$  when  $y=0$ . This property is nice; it means that the expansion brings positive improvement if and only if  $f(X) > 0$ , which makes it easy to determine which alteration is better.

We train the regression model by minimizing the mean square error. Suppose there are training instances  $X_1, X_2, \dots, X_m$ , and the corresponding performance change is  $y_i, i=1, 2, \dots, m$ . We calculate the mean square error with the following equation:

$$err(W) = \sum_{i=1}^m (W^T X_i - \varphi(y_i))^2 \quad (5)$$

Then the optimal weight is defined as:

$$W^* = \arg \min_W err(W) \quad (6)$$

$$= \arg \min_W \sum_{i=1}^m (W^T X_i - \varphi(y_i))^2$$

Because  $err(W)$  is a convex function of  $W$ , it has a global minimum and obtains its minimum when the gradient is zero (Bazaraa et al., 2006). Then we have:

$$\frac{\partial err(W^*)}{\partial W^*} = \sum_{i=1}^m (W^T X_i - \varphi(y_i)) X_i^T = 0$$

$$\text{So, } W^{*T} \sum_{i=1}^m X_i X_i^T = \sum_{i=1}^m \varphi(y_i) X_i^T$$

In fact,  $\sum_{i=1}^m X_i X_i^T$  is a square matrix, we denote it as  $XX^T$ . Then we have:

$$W^* = (XX^T)^{-1} \left[ \sum_{i=1}^m \varphi(y_i) X_i^T \right] \quad (7)$$

The matrix  $XX^T$  is an  $l \times l$  square matrix, where  $l$  is the number of features. In our experiments, we only use three features. Therefore the optimal weights can be calculated efficiently even we have a large number of training instances.

## 5.2 Constructing Training Data

As a supervised learning method, the regression model is trained with a set of training data. We illustrate here the procedure to generate training instances with an example.

Given a query “controlling acid rain”, we obtain the MAP of the original query at first. Then we augment the query with an alteration to the original term (one term at a time) at each time. We retain the MAP of the augmented query and compare it with the original query to obtain the performance change. For this query, we expand “controlling” by “control” and get an augmented query “(controlling OR control) acid rain”. We can obtain the difference between the MAP of the augmented query and that of the original query. By doing this, we can generate a series of training instances consisting of the original query string, the original query term under consideration, its alteration and the performance change, for example:

*<controlling acid rain, controlling, control, 0.05>*

Note that we use MAP to measure performance, but we could well use other metrics such as NDCG (Peng et al., 2007) or P@N (precision at top-N documents).

## 5.3 Features Used for Regression Model

Three features are used. The first feature reflects to what degree an alteration is coherent with the other terms. For example, for the query “controlling acid rain”, the coherence of the alteration “acidic” is measured by the logarithm of its co-occurrence with the other query terms within a predefined window (90 words) in the corpus. That is:

$\log(\text{count}(\text{controlling} \dots \text{acidic} \dots \text{rain} | \text{window}) + 0.5)$  where “...” means there may be some words between two query terms. Word order is ignored.

The second feature is an extension to point-wise mutual information (Rijsbergen, 1979), defined as follows:

$$\log \left( \frac{P(\text{controlling} \dots \text{acidic} \dots \text{rain} | \text{window})}{P(\text{controlling})P(\text{acidic})P(\text{rain})} \right)$$

where  $P(\text{controlling} \dots \text{acidic} \dots \text{rain} | \text{window})$  is the co-occurrence probability of the trigram containing acidic within a predefined window (50 words).  $P(\text{controlling})$ ,  $p(\text{acidic})$ ,  $P(\text{rain})$  are probabilities of the three words in the collection. The three words are defined as: the term under consideration, the first term to the left of that term, and the first term to the right. If a query contains less than 3

terms or the term under consideration is the beginning/ending term in the query, we will set the probability of the missed term/terms to be 1. Therefore, it becomes point-wise mutual information when the query contains only two terms. In fact, this feature is supplemental to the first feature. When the query is very long and the first feature always obtains a value of  $\log(0.5)$ , so it does not have any discriminative ability. On the other hand, the second feature helps because it can capture some co-occurrence information no matter how long the query is.

The last feature is the bias, whose value is always set to be 1.0.

The regression model is trained in a leave-one-out cross-validation manner on three collections; each of them is used in turn as a test collection while the two others are used for training. For each incoming query, the regression model predicts the expected performance change when one alteration is used. For each query term, we only select the alteration with the largest positive performance change. If none of its alterations produce a positive performance change, we do not expand the query term. This selection is therefore more restrictive than the Bigram Expansion Model. Nevertheless, our experiments show that it improves retrieval effectiveness further.

## 6 Experiments

### 6.1 Experiment Settings

In this section, our aim is to evaluate the two context-sensitive word alteration selection methods. The ideal evaluation corpus should be composed of some Web data. Unfortunately, such data are not publicly available and the results also could not be compared with other published results. Therefore, we use two TREC collections. The first one is the ad-hoc retrieval test collections used for TREC6&7& 8. This collection is relative small and homogeneous. The second one is the Gov2 data. It is obtained by crawling the entire .gov domain and has been used for three TREC Terabyte tracks (TREC2004-2006). Table 1 shows some statistics of the two collections. For each collection, we use 150 queries. Since the Regression model needs some data for training, we divided the queries into three parts, each containing 50 queries. We then use leave-one-out cross-validation. The evaluation metrics shown below are the average value of the

Name	Description	Size (GB)	#Doc	Query
<b>TREC6 &amp;7&amp;8</b>	TREC disk4&5, Newspapers	1.7	500,447	301-450
<b>Gov2</b>	2004 crawl of entire .gov domain	427	25,205,179	701-850

Table1: Overview of Test Collections

three-fold cross-validation. Because the queries in Web are usually very short, we use only the title field of each query.

To correspond to Web search practice, both documents and queries are not stemmed. We do not filter the stop words either.

Two main metrics are used: the Mean Average Precision (MAP) for the top 1000 documents to measure retrieval effectiveness, and the number of terms in the query to reflect query traffic. In addition, we also provide precision for the top 30 documents (P@30) to show the impact on top ranked documents. We also conducted t-tests to determine whether the improvement is statistically significant.

The Indri 2.5 search engine (Strohman et al., 2004) is used as our basic retrieval system. It provides for a rich query language allowing disjunctive combinations of words in queries.

### 6.2 Experimental Results

The first baseline method we compare with only uses the original query, which is named *Original*. In addition to this, we also compare with the following methods:

*Naïve Exp*: The Naïve expansion model expands each query term with all terms in the vocabulary sharing the same root with it. This model is equivalent to the traditional stemming method.

*UMASS*: This is the result reported in (Metzler et al., 2006) using Porter stemming for both document and query terms. This reflects a state-of-the-art result using Porter stemming.

*Similarity*: We select the alterations (at most 5) with the highest similarity to the original term. This is the method described in section 3.

The two methods we propose in this paper are the following ones:

*Bigram Exp*: the alteration is chosen by a Bigram Expansion model.

*Regression*: the alteration is chosen by a Regression model.

<b>Regression</b>	0.3220	187	0.2144	21.88**

Table7: Results of Query 401-450 over TREC6&7&8

Tables 2, 3, 4 show the results of Gov2 data while table 5, 6, 7 show the results of the TREC6&7&8 collection. In the tables, the \* mark indicates that the improvement over the original

model is statistically significant with  $p\text{-value} < 0.05$ , and \*\* means the  $p\text{-values} < 0.01$ .

From the tables, we see that both word stemming (UMASS) and expansion with word alterations can improve MAP for all six tasks. In most cases (except in table 4 and 6), it also improve the precision of top ranked documents. This shows the usefulness of word stemming or word alteration expansion for IR.

We can make several additional observations:

- 1). Stemming Vs Expansion. UMASS uses document and query stemming while *Naive Exp* uses expansion by word alteration. We stated that both approaches are equivalent. The equivalence is confirmed by our experiment results: for all Gov2 collections, these approaches perform equivalently.
- 2). The Similarity model performs very well. Compared with the Naïve Expansion model, it produces quite similar retrieval effectiveness, while the query traffic is dramatically reduced. This approach is similar to the work of Xu and Croft (1998), and can be considered as another state-of-the-art result.
- 3). In comparison, the Bigram Expansion model performs better than the Similarity model. This shows that it is useful to consider query context in selecting word alterations.
- 4). The Regression model performs the best of all the models. Compared with the Original query, it adds fewer than 2 alterations for each query on average (since each group has 50 queries); nevertheless we obtained improvements on all the six collections. Moreover, the improvements on five collections are statistically significant. It also performs slightly better than the Similarity and Bigram Expansion methods, but with fewer alterations. This shows that the supervised learning approach, if used in the correct way, is superior to an unsupervised approach. Another advantage over the two other models is that the Regression model can reduce the number of alterations further. Because the Regression model selects alterations according to their expected improvement, the improvement of the alterations to one query term can be compared with that of the alterations to other query terms. Therefore, we can select at most one optimal alteration for the whole query. However, with the Similarity or Bigram Expansion models, the selection value, either similarity or query likelihood, cannot be

compared across the query terms. As a consequence, more alterations need to be selected, leading to heavier query traffic.

## 7 Conclusion

Traditional IR approaches stem terms in both documents and queries. This approach is appropriate for general purpose IR, but is ill-suited for the specific retrieval needs in Web search such as quoted queries or queries with a specific word form that should not be stemmed. The current practice in Web search is not to stem words in index, but rather to perform a form of expansion using word alteration.

However, a naïve expansion will result in many alterations and this will increase the query traffic. This paper has proposed two alternative methods to select precise alterations by considering the query context. We seek to produce similar or better improvements in retrieval effectiveness, while limiting the query traffic.

In the first method proposed – the Bigram Expansion model, query context is modeled by a bigram language model. For each query term, the selected alteration is the one which maximizes the query likelihood. In the second method - Regression model, we fit a regression model to calculate the expected improvement when the original query is expanded by an alteration. Only the alteration that is expected to yield the largest improvement to retrieval effectiveness is added.

The proposed methods were evaluated on two TREC benchmarks: the ad-hoc retrieval test collection for TREC6&7&8 and the Gov2 data. Our experimental results show that both proposed methods perform significantly better than the original queries. Compared with traditional word stemming or the naïve expansion approach, our methods can not only improve retrieval effectiveness, but also greatly reduce the query traffic.

This work shows that query expansion with word alterations is a reasonable alternative to word stemming. It is possible to limit the query traffic by a query-dependent selection of word alterations. Our work shows that both unsupervised and supervised learning can be used to perform alteration selection.

Our methods can be further improved in several aspects. For example, we could integrate other features in the regression model, and use other non-linear regression models, such as Bayesian regres-

sion models (e.g. Gaussian Process regression) (Rasmussen and Williams, 2006). The additional advantage of these models is that we can not only obtain the expected improvement in retrieval effectiveness for an alteration, but also the probability of obtaining an improvement (i.e. the robustness of the alteration).

Finally, it would be interesting to test the approaches using real Web data.

## Abstract

This paper is concerned with the problem of question search. In question search, given a question as query, we are to return questions semantically equivalent or close to the queried question. In this paper, we propose to conduct question search by identifying question topic and question focus. More specifically, we first summarize questions in a data structure consisting of question topic and question focus. Then we model question topic and question focus in a language modeling framework for search. We also propose to use the MDL-based tree cut model for identifying question topic and question focus automatically. Experimental results indicate that our approach of identifying question topic and question focus for search significantly outperforms the baseline methods such as Vector Space Model (VSM) and Language Model for Information Retrieval (LMIR).

## 1 Introduction

Over the past few years, online services have been building up very large archives of questions and their answers, for example, traditional FAQ services and emerging community-based Q&A services (e.g., Yahoo! Answers<sup>1</sup>, Live QnA<sup>2</sup>, and Baidu Zhidao<sup>3</sup>).

To make use of the large archives of questions and their answers, it is critical to have functionality facilitating users to search previous answers. Typically, such functionality is achieved by first retrieving questions expected to have the same answers as a queried question and then returning the related answers to users. For example, given question *Q1* in Table 1, question *Q2* can be re-

turned and its answer will then be used to answer *Q1* because the answer of *Q2* is expected to partially satisfy the queried question *Q1*. This is what we called *question search*. In question search, returned questions are *semantically equivalent or close* to the queried question.

<b>Query:</b> <i>Q1: Any cool clubs in Berlin or Hamburg?</i>
<b>Expected:</b> <i>Q2: What are the best/most fun clubs in Berlin?</i>
<b>Not Expected:</b> <i>Q3: Any nice hotels in Berlin or Hamburg?</i> <i>Q4: How long does it take to Hamburg from Berlin?</i> <i>Q5: Cheap hotels in Berlin?</i>

Table 1. An Example on Question Search

Many methods have been investigated for tackling the problem of question search. For example, Jeon et al. have compared the uses of four different retrieval methods, i.e. vector space model, Okapi, language model, and translation-based model, within the setting of question search (Jeon et al., 2005b). However, all the existing methods treat questions just as plain texts (without considering question structure). For example, obviously, *Q2* can be considered semantically closer to *Q1* than *Q3-Q5* although all questions (*Q2-Q5*) are related to *Q1*. The existing methods are not able to tell the difference between question *Q2* and questions *Q3*, *Q4*, and *Q5* in terms of their relevance to question *Q1*. We will clarify this in the following.

In this paper, we propose to conduct question search by identifying question topic and question focus.

The question topic usually represents the major context/constraint of a question (e.g., Berlin, Hamburg) which characterizes users' interests. In contrast, question focus (e.g., cool club, cheap hotel) presents certain aspect (or descriptive features) of the question topic. For the aim of retrieving semantically equivalent (or close) questions, we need to

<sup>1</sup> <http://answers.yahoo.com>

<sup>2</sup> <http://qna.live.com>

<sup>3</sup> <http://zhidao.baidu.com>

assure that returned questions are related to the queried question with respect to both question topic and question focus. For example, in Table 1,  $Q2$  preserves certain useful information of  $Q1$  in the aspects of both question topic (Berlin) and question focus (fun club) although it loses some useful information in question topic (Hamburg). In contrast, questions  $Q3$ - $Q5$  are not related to  $Q1$  in question focus (although being related in question topic, e.g. Hamburg, Berlin), which makes them unsuitable as the results of question search.

We also propose to use the MDL-based (Minimum Description Length) tree cut model for automatically identifying question topic and question focus. Given a question as query, a structure called *question tree* is constructed over the question collection including the queried question and all the related questions, and then the MDL principle is applied to find a *cut* of the question tree specifying the question topic and the question focus of each question.

In a summary, we summarize questions in a data structure consisting of *question topic* and *question focus*. On the basis of this, we then propose to model question topic and question focus in a language modeling framework for search. To the best of our knowledge, none of the existing studies addressed question search by modeling both question topic and question focus.

We empirically conduct the question search with questions about ‘travel’ and ‘computers & internet’. Both kinds of questions are from Yahoo! Answers. Experimental results show that our approach can significantly improve traditional methods (e.g. VSM, LMIR) in retrieving relevant questions.

The rest of the paper is organized as follow. In Section 2, we present our approach to question search which is based on identifying question topic and question focus. In Section 3, we empirically verify the effectiveness of our approach to question search. In Section 4, we employ a translation-based retrieval framework for extending our approach to fix the issue called ‘lexical chasm’. Section 5 surveys the related work. Section 6 concludes the paper by summarizing our work and discussing the future directions.

## 2 Our Approach to Question Search

Our approach to question search consists of two steps: (a) summarize questions in a data structure consisting of question topic and question focus; (b)

model question topic and question focus in a language modeling framework for search.

In the step (a), we employ the MDL-based (Minimum Description Length) tree cut model for automatically identifying question topic and question focus. Thus, this section will begin with a brief review of the MDL-based tree cut model and then follow that by an explanation of steps (a) and (b).

### 2.1 The MDL-based tree cut model

Formally, a tree cut model  $M$  (Li and Abe, 1998) can be represented by a pair consisting of a tree cut  $\Gamma$ , and a probability parameter vector  $\theta$  of the same length, that is,

$$M = (\Gamma, \theta) \quad (1)$$

where  $\Gamma$  and  $\theta$  are

$$\Gamma = [C_1, C_2, \dots, C_k], \quad (2)$$

$$\theta = [p(C_1), p(C_2), \dots, p(C_k)]$$

where  $C_1, C_2, \dots, C_k$  are classes determined by a cut in the tree and  $\sum_{i=1}^k p(C_i) = 1$ . A ‘cut’ in a tree is any set of nodes in the tree that defines a partition of all the nodes, viewing each node as representing the set of child nodes as well as itself. For example, the cut indicated by the dash line in Figure 1 corresponds to three classes:  $[n_0, n_{11}], [n_{13}, n_{24}]$ , and  $[n_{12}, n_{21}, n_{22}, n_{23}]$ .

Figure 1. An Example on the Tree Cut Model

A straightforward way for determining a cut of a tree is to collapse the nodes of less frequency into their parent nodes. However, the method is too heuristic for it relies much on manually tuned frequency threshold. In our practice, we turn to use a theoretically well-motivated method based on the MDL principle. MDL is a principle of data compression and statistical estimation from information theory (Rissanen, 1978).

Given a sample  $S$  and a tree cut  $\Gamma$ , we employ MLE to estimate the parameters of the corresponding tree cut model  $\hat{M} = (\Gamma, \hat{\theta})$ , where  $\hat{\theta}$  denotes the estimated parameters.

According to the MDL principle, the description length (Li and Abe, 1998)  $L(\hat{M}, S)$  of the tree cut model  $\hat{M}$  and the sample  $S$  is the sum of the model

description length  $L(\Gamma)$ , the parameter description length  $L(\hat{\theta}|\Gamma)$ , and the data description length  $L(S|\Gamma, \hat{\theta})$ , i.e.

$$L(\hat{M}, S) = L(\Gamma) + L(\hat{\theta}|\Gamma) + L(S|\Gamma, \hat{\theta}) \quad (3)$$

The model description length  $L(\Gamma)$  is a subjective quantity which depends on the coding scheme employed. Here, we simply assume that each tree cut model is equally likely *a priori*.

The parameter description length  $L(\hat{\theta}|\Gamma)$  is calculated as

$$L(\hat{\theta}|\Gamma) = \frac{k}{2} \times \log |S| \quad (4)$$

where  $|S|$  denotes the sample size and  $k$  denotes the number of free parameters in the tree cut model, i.e.  $k$  equals the number of nodes in  $\Gamma$  minus one.

The data description length  $L(S|\Gamma, \hat{\theta})$  is calculated as

$$L(S|\Gamma, \hat{\theta}) = -\sum_{n \in S} \log \hat{p}(n) \quad (5)$$

where

$$\hat{p}(n) = \frac{1}{|C|} \times \frac{f(C)}{|S|} \quad (6)$$

where  $C$  is the class that  $n$  belongs to and  $f(C)$  denotes the total frequency of instances in class  $C$  in the sample  $S$ .

With the description length defined as (3), we wish to select a tree cut model with the minimum description length and output it as the result. Note that the model description length  $L(\Gamma)$  can be ignored because it is the same for all tree cut models.

The MDL-based tree cut model was originally introduced for handling the problem of generalizing case frames using a thesaurus (Li and Abe, 1998). To the best of our knowledge, no existing work utilizes it for question search. This may be partially because of the unavailability of the resources (e.g., thesaurus) which can be used for embodying the questions in a tree structure. In Section 2.2, we will introduce a tree structure called *question tree* for representing questions.

## 2.2 Identifying question topic and question focus

In principle, it is possible to identify *question topic* and *question focus* of a question by only parsing the question itself (for example, utilizing a syntactic parser). However, such a method requires accurate parsing results which cannot be obtained from the noisy data from online services.

Instead, we propose using the MDL-based tree cut model which identifies question topics and

question foci for a set of questions together. More specifically, the method consists of two phases:

- 1) Constructing a *question tree*: represent the queried question and all the related questions in a tree structure called *question tree*;
- 2) Determining a *tree cut*: apply the MDL principle to the *question tree*, which yields the cut specifying *question topic* and *question focus*.

### 2.2.1 Constructing a question tree

In the following, with a series of definitions, we will describe how a *question tree* is constructed from a collection of questions.

Let's begin with explaining the representation of a question. A straightforward method is to represent a question as a bag-of-words (possibly ignoring stop words). However, this method cannot discern 'the hotels in Paris' from 'the Paris hotel'. Thus, we turn to use the linguistic units carrying on more semantic information. Specifically, we make use of two kinds of units: BaseNP (Base Noun Phrase) and WH-ngram. A BaseNP is defined as a simple and non-recursive noun phrase (Cao and Li, 2002). A WH-ngram is an ngram beginning with WH-words. The WH-words that we consider include 'when', 'what', 'where', 'which', and 'how'. We refer to these two kinds of units as '*topic terms*'. With 'topic terms', we represent a question as a *topic chain* and a set of questions as a *question tree*.

**Definition 1 (Topic Profile)** The *topic profile*  $\theta_t$  of a topic term  $t$  in a categorized question collection is a probability distribution of categories  $\{p(c|t)\}_{c \in C}$  where  $C$  is a set of categories.

$$p(c|t) = \frac{\text{count}(c,t)}{\sum_{c \in C} \text{count}(c,t)} \quad (7)$$

where  $\text{count}(c,t)$  is the frequency of the topic term  $t$  within category  $c$ . Clearly, we have  $\sum_{c \in C} p(c|t) = 1$ .

By 'categorized questions', we refer to the questions that are organized in a tree of taxonomy. For example, at Yahoo! Answers, the question "How do I install my wireless router" is categorized as "Computers & Internet  $\rightarrow$  Computer Networking". Actually, we can find categorized questions at other online services such as FAQ sites, too.

**Definition 2 (Specificity)** The *specificity*  $s(t)$  of a topic term  $t$  is the inverse of the entropy of the topic profile  $\theta_t$ . More specifically,

$$s(t) = 1 / (-\sum_{c \in C} p(c|t) \log p(c|t) + \varepsilon) \quad (8)$$

where  $\varepsilon$  is a smoothing parameter used to cope with the topic terms whose entropy is 0. In our experiments, the value of  $\varepsilon$  was set 0.001.

We use the term *specificity* to denote how specific a topic term is in characterizing information needs of users who post questions. A topic term of high specificity (e.g., Hamburg, Berlin) usually specifies the *question topic* corresponding to the main context of a question because it tends to occur only in a few categories. A topic term of low specificity is usually used to represent the *question focus* (e.g., cool club, where to see) which is relatively volatile and might occur in many categories.

**Definition 3 (Topic Chain)** A topic chain  $q^c$  of a question  $q$  is a sequence of ordered topic terms  $t_1 \rightarrow t_2 \rightarrow \dots \rightarrow t_m$  such that

- 1)  $t_i$  is included in  $q$ ,  $1 \leq i \leq m$ ;
- 2)  $s(t_k) > s(t_l)$ ,  $1 \leq k < l \leq m$ .

For example, the topic chain of “any cool clubs in Berlin or Hamburg?” is “Hamburg  $\rightarrow$  Berlin  $\rightarrow$  cool club” because the *specificities* for ‘Hamburg’, ‘Berlin’, and ‘cool club’ are 0.99, 0.62, and 0.36.

**Definition 4 (Question Tree)** A question tree of a question set  $Q = \{q_i\}_{i=1}^N$  is a prefix tree built over the topic chains  $Q^c = \{q_i^c\}_{i=1}^N$  of the question set  $Q$ . Clearly, if a question set contains only one question, its question tree will be exactly same as the topic chain of the question.

Note that the root node of a question tree is associated with *empty string* as the definition of prefix tree requires (Fredkin, 1960).

Figure 2. An Example of a Question Tree

Given the topic chains with respect to the questions in Table 1 as follow,

- $Q1$ : Hamburg  $\rightarrow$  Berlin  $\rightarrow$  cool club
- $Q2$ : Berlin  $\rightarrow$  fun club
- $Q3$ : Hamburg  $\rightarrow$  Berlin  $\rightarrow$  nice hotel

- $Q4$ : Hamburg  $\rightarrow$  Berlin  $\rightarrow$  how long does it take
- $Q5$ : Berlin  $\rightarrow$  cheap hotel

we can have the question tree presented in Figure 2.

### 2.2.2 Determining the tree cut

According to the definition of a *topic chain*, the topic terms in a topic chain of a question are ordered by their specificity values. Thus, a cut of a topic chain naturally separates the topic terms of low specificity (representing question focus) from the topic terms of high specificity (representing question topic). Given a topic chain of a question consisting of  $m$  topic terms, there exist  $(m - 1)$  possible cuts. The question is: which cut is the best?

We propose using the MDL-based tree cut model for the search of the best cut in a topic chain. Instead of dealing with each topic chain individually, the proposed method handles a set of questions together. Specifically, given a queried question, we construct a question tree consisting of both the queried question and the related questions, and then apply the MDL principle to select the best cut of the question tree. For example, in Figure 2, we hope to get the cut indicated by the dashed line. The topic terms on the left of the dashed line represent the question topic and those on the right of the dashed line represent the question focus. Note that the tree cut yields a cut for each individual topic chain (each path) within the question tree accordingly.

A cut of a topic chain  $q^c$  of a question  $q$  separates the topic chain in two parts: HEAD and TAIL. HEAD (denoted as  $H(q^c)$ ) is the subsequence of the original topic chain  $q^c$  before the cut. TAIL (denoted as  $T(q^c)$ ) is the subsequence of  $q^c$  after the cut. Thus,  $q^c = H(q^c) \rightarrow T(q^c)$ . For instance, given the tree cut specified in Figure 2, for the topic chain of  $Q1$  “Hamburg  $\rightarrow$  Berlin  $\rightarrow$  cool club”, the HEAD and TAIL are “Hamburg  $\rightarrow$  Berlin” and “cool club” respectively.

### 2.3 Modeling question topic and question focus for search

We employ the framework of language modeling (for information retrieval) to develop our approach to question search.

In the language modeling approach to information retrieval, the relevance of a targeted question  $\tilde{q}$  to a queried question  $q$  is given by the probability  $p(q|\tilde{q})$  of generating the queried question  $q$

from the language model formed by the targeted question  $\tilde{q}$ . The targeted question  $\tilde{q}$  is from a collection  $C$  of questions.

Following the framework, we propose a mixture model for modeling question structure (namely, question topic and question focus) within the process of searching questions:

$$p(q|\tilde{q}) = \lambda \cdot p(H(q)|H(\tilde{q})) + (1 - \lambda) \cdot p(T(q)|T(\tilde{q})) \quad (9)$$

In the mixture model, it is assumed that the process of generating question topics and the process of generating question foci are independent from each other.

In traditional language modeling, a single multinomial model  $p(t|\tilde{q})$  over terms is estimated for each targeted question  $\tilde{q}$ . In our case, two multinomial models  $p(t|H(\tilde{q}))$  and  $p(t|T(\tilde{q}))$  need to be estimated for each targeted question  $\tilde{q}$ .

If unigram document language models are used, the equation (9) can then be re-written as,

$$p(q|\tilde{q}) = \lambda \cdot \prod_{t \in H(q)} p(t|H(\tilde{q}))^{count(q,t)} + (1 - \lambda) \cdot \prod_{t \in T(q)} p(t|T(\tilde{q}))^{count(q,t)} \quad (10)$$

where  $count(q, t)$  is the frequency of  $t$  within  $q$ .

To avoid zero probabilities and estimate more accurate language models, the HEAD and TAIL of questions are smoothed using background collection,

$$p(t|H(\tilde{q})) = \alpha \cdot \hat{p}(t|H(\tilde{q})) + (1 - \alpha) \cdot \hat{p}(t|C) \quad (11)$$

$$p(t|T(\tilde{q})) = \beta \cdot \hat{p}(t|T(\tilde{q})) + (1 - \beta) \cdot \hat{p}(t|C) \quad (12)$$

where  $\hat{p}(t|H(\tilde{q}))$ ,  $\hat{p}(t|T(\tilde{q}))$ , and  $\hat{p}(t|C)$  are the MLE estimators with respect to the HEAD of  $\tilde{q}$ , the TAIL of  $\tilde{q}$ , and the collection  $C$ .

### 3 Experimental Results

We have conducted experiments to verify the effectiveness of our approach to question search. Particularly, we have investigated the use of identifying question topic and question focus for search.

#### 3.1 Dataset and evaluation measures

We made use of the questions obtained from Yahoo! Answers for the evaluation. More specifically, we utilized the *resolved* questions under two of the top-level categories at Yahoo! Answers, namely ‘travel’ and ‘computers & internet’. The questions include 314,616 items from the ‘travel’ category

and 210,785 items from the ‘computers & internet’ category. Each resolved question consists of three fields: ‘title’, ‘description’, and ‘answers’. For search we use only the ‘title’ field. It is assumed that the titles of the questions already provide enough semantic information for understanding users’ information needs.

We developed two test sets, one for the category ‘travel’ denoted as ‘TRL-TST’, and the other for ‘computers & internet’ denoted as ‘CI-TST’. In order to create the test sets, we randomly selected 200 questions for each category.

To obtain the ground-truth of question search, we employed the Vector Space Model (VSM) (Salton et al., 1975) to retrieve the top 20 results and obtained manual judgments. The top 20 results don’t include the queried question itself. Given a returned result by VSM, an assessor is asked to label it with ‘*relevant*’ or ‘*irrelevant*’. If a returned result is considered semantically equivalent (or close) to the queried question, the assessor will label it as ‘*relevant*’; otherwise, the assessor will label it as ‘*irrelevant*’. Two assessors were involved in the manual judgments. Each of them was asked to label 100 questions from ‘TRL-TST’ and 100 from ‘CI-TST’. In the process of manually judging questions, the assessors were presented only the *titles* of the questions (for both the queried questions and the returned questions). Table 2 provides the statistics on the final test set.

	# Queries	# Returned	# Relevant
TRL-TST	200	4,000	256
CI-TST	200	4,000	510

Table 2. Statistics on the Test Data

We utilized two baseline methods for demonstrating the effectiveness of our approach, the VSM and the LMIR (language modeling method for information retrieval) (Ponte and Croft, 1998).

We made use of three measures for evaluating the results of question search methods. They are MAP, R-precision, and MRR.

#### 3.2 Searching questions about ‘travel’

In the experiments, we made use of the questions about ‘travel’ to test the performance of our approach to question search. More specifically, we used the 200 queries in the test set ‘TRL-TST’ to search for ‘relevant’ questions from the 314,616

questions categorized as ‘travel’. Note that only the questions occurring in the test set can be evaluated.

We made use of the taxonomy of questions provided at Yahoo! Answers for the calculation of *specificity of topic terms*. The taxonomy is organized in a tree structure. In the following experiments, we only utilized as the categories of questions the leaf nodes of the taxonomy tree (regarding ‘travel’), which includes 355 categories.

We randomly divided the test queries into five even subsets and conducted 5-fold cross-validation experiments. In each trial, we tuned the parameters  $\lambda$ ,  $\alpha$ , and  $\beta$  in the equation (10)-(12) with four of the five subsets and then applied it to one remaining subset. The experimental results reported below are those averaged over the five trials.

Methods	MAP	R-Precision	MRR
VSM	0.198	0.138	0.228
LMIR	0.203	0.154	0.248
LMIR-CUT	<b>0.236</b>	<b>0.192</b>	<b>0.279</b>

Table 3. Searching Questions about ‘Travel’

In Table 3, our approach denoted by LMIR-CUT is implemented exactly as equation (10). Neither VSM nor LMIR uses the data structure composed of question topic and question focus.

From Table 3, we see that our approach outperforms the baseline approaches VSM and LMIR in terms of all the measures. We conducted a significance test (t-test) on the improvements of our approach over VSM and LMIR. The result indicates that the improvements are statistically significant ( $p$ -value  $< 0.05$ ) in terms of all the evaluation measures.

Figure 3. Balancing between Question Topic and Question Focus

In equation (9), we use the parameter  $\lambda$  to balance the contribution of question topic and the contribution of question focus. Figure 3 illustrates how

influential the value of  $\lambda$  is on the performance of question search in terms of MRR. The result was obtained with the 200 queries directly, instead of 5-fold cross-validation. From Figure 3, we see that our approach performs best when  $\lambda$  is around 0.7. That is, our approach tends to emphasize question topic more than question focus.

We also examined the correctness of question topics and question foci of the 200 queried questions. The question topics and question foci were obtained with the MDL-based tree cut model automatically. In the result, 69 questions have incorrect question topics or question foci. Further analysis shows that the errors came from two categories: (a) 59 questions have only the HEAD parts (that is, none of the topic terms fall within the TAIL part), and (b) 10 have incorrect orders of topic terms because the specificities of topic terms were estimated inaccurately. For questions only having the HEAD parts, our approach (equation (9)) reduces to traditional language modeling approach. Thus, even when the errors of category (a) occur, our approach can still work not worse than the traditional language modeling approach. This also explains why our approach performs best when  $\lambda$  is around 0.7. The error category (a) pushes our model to emphasize more in question topic.

Methods	Results
VSM	<ol style="list-style-type: none"> <li>How cold does it usually get in Charlotte, NC during winters?</li> <li>How long and cold are the winters in Rochester, NY?</li> <li><b>How cold is it in Alaska?</b></li> </ol>
LMIR	<ol style="list-style-type: none"> <li><b>How cold is it in Alaska?</b></li> <li>How cold does it get really in Toronto in the winter?</li> <li>How cold does the Mojave Desert get in the winter?</li> </ol>
LMIR-CUT	<ol style="list-style-type: none"> <li><b>How cold is it in Alaska?</b></li> <li><b>How cold is Alaska in March and outdoor activities?</b></li> <li>How cold does it get in Nova Scotia in the winter?</li> </ol>

Table 4. Search Results for ‘How cold does it get in winters in Alaska?’

Table 4 provides the TOP-3 search results which are given by VSM, LMIR, and LMIR-CUT (our approach) respectively. The questions in bold are labeled as ‘relevant’ in the evaluation set. The queried question seeks for the ‘weather’ information about ‘Alaska’. Both VSM and LMIR rank certain

‘irrelevant’ questions higher than ‘relevant’ questions. The ‘irrelevant’ questions are not about ‘Alaska’ although they are about ‘weather’. The reason is that neither VSM nor PVSM is aware that the query consists of the two aspects ‘weather’ (how cold, winter) and ‘Alaska’. In contrast, our approach assures that both aspects are matched. Note that the HEAD part of the topic chain of the queried question given by our approach is “Alaska” and the TAIL part is “winter → how cold”.

### 3.3 Searching questions about ‘computers & internet’

In the experiments, we made use of the questions about ‘computers & internet’ to test the performance of our proposed approach to question search. More specifically, we used the 200 queries in the test set ‘CI-TST’ to search for ‘relevant’ questions from the 210,785 questions categorized as ‘computers & internet’. For the calculation of *specificity of topic terms*, we utilized as the categories of questions the leaf nodes of the taxonomy tree regarding ‘computers & Internet’, which include 23 categories.

We conducted 5-fold cross-validation for the parameter tuning. The experimental results reported in Table 5 are averaged over the five trials.

Methods	MAP	R-Precision	MRR
VSM	0.236	0.175	0.289
LMIR	0.248	0.191	0.304
LMIR-CUT	<b>0.279</b>	<b>0.230</b>	<b>0.341</b>

Table 5. Searching Questions about ‘Computers & Internet’

Again, we see that our approach outperforms the baseline approaches VSM and LMIR in terms of all the measures. We conducted a significance test (t-test) on the improvements of our approach over VSM and LMIR. The result indicates that the improvements are statistically significant (p-value < 0.05) in terms of all the evaluation measures.

We also conducted the experiment similar to that in Figure 3. Figure 4 provides the result. The trend is consistent with that in Figure 3.

We examined the correctness of (automatically identified) question topics and question foci of the 200 queried questions, too. In the result, 65 questions have incorrect question topics or question foci. Among them, 47 fall in the error category (a) and 18 in the error category (b). The distribution of

errors is also similar to that in Section 3.2, which also justifies the trend presented in Figure 4.

Figure 4. Balancing between Question Topic and Question Focus

## 4 Using Translation Probability

In the setting of question search, besides the topic what we address in the previous sections, another research topic is to fix lexical chasm between questions.

Sometimes, two questions that have the same meaning use very different wording. For example, the questions “where to stay in Hamburg?” and “the best hotel in Hamburg?” have almost the same meaning but are lexically different in question focus (where to stay vs. best hotel). This is the so-called ‘lexical chasm’.

Jeon and Bruce (2007) proposed a mixture model for fixing the lexical chasm between questions. The model is a combination of the language modeling approach (for information retrieval) and translation-based approach (for information retrieval). Our idea of modeling question structure for search can naturally extend to Jeon et al.’s model. More specifically, by using translation probabilities, we can rewrite equation (11) and (12) as follow:

$$p(t|H(\tilde{q})) = \alpha_1 \cdot \hat{p}(t|H(\tilde{q})) + \alpha_2 \cdot \sum_{t' \in H(\tilde{q})} Tr(t|t') \cdot \hat{p}(t'|H(\tilde{q})) + (1 - \alpha_1 - \alpha_2) \cdot \hat{p}(t|C) \quad (13)$$

$$p(t|T(\tilde{q})) = \beta_1 \cdot \hat{p}(t|T(\tilde{q})) + \beta_2 \cdot \sum_{t' \in T(\tilde{q})} Tr(t|t') \cdot \hat{p}(t'|T(\tilde{q})) + (1 - \beta_1 - \beta_2) \cdot \hat{p}(t|C) \quad (14)$$

where  $Tr(t|t')$  denotes the probability that topic term  $t$  is the translation of  $t'$ . In our experiments, to estimate the probability  $Tr(t|t')$ , we used the collections of question titles and question descriptions as the parallel corpus and the IBM model 1 (Brown et al., 1993) as the alignment model.

Usually, users reiterate or paraphrase their questions (already described in question titles) in question descriptions.

We utilized the new model elaborated by equation (13) and (14) for searching questions about ‘travel’ and ‘computers & internet’. The new model is denoted as ‘SMT-CUT’. Table 6 provides the evaluation results. The evaluation was conducted with exactly the same setting as in Section 3. From Table 6, we see that the performance of our approach can be further boosted by using translation probability.

Data	Methods	MAP	R-Precision	MRR
TRL-TST	LMIR-CUT	0.236	0.192	0.279
	SMT-CUT	<b>0.266</b>	<b>0.225</b>	<b>0.308</b>
CI-TST	LMIR-CUT	0.279	0.230	<b>0.341</b>
	SMT-CUT	<b>0.282</b>	<b>0.236</b>	0.337

Table 6. Using Translation Probability

## 5 Related Work

The major focus of previous research efforts on question search is to tackle the lexical chasm problem between questions.

The research of question search is first conducted using FAQ data. FAQ Finder (Burke et al., 1997) heuristically combines statistical similarities and semantic similarities between questions to rank FAQs. Conventional vector space models are used to calculate the statistical similarity and WordNet (Fellbaum, 1998) is used to estimate the semantic similarity. Sneyders (2002) proposed template based FAQ retrieval systems. Lai et al. (2002) proposed an approach to automatically mine FAQs from the Web. Jijkoun and Rijke (2005) used supervised learning methods to extend heuristic extraction of Q/A pairs from FAQ pages, and treated Q/A pair retrieval as a fielded search task.

Harabagiu et al. (2005) used a Question Answer Database (known as QUAB) to support interactive question answering. They compared seven different similarity metrics for selecting related questions from QUAB and found that the concept-based metric performed best.

Recently, the research of question search has been further extended to the community-based Q&A data. For example, Jeon et al. (Jeon et al., 2005a; Jeon et al., 2005b) compared four different retrieval methods, i.e. vector space model, Okapi, language model (LM), and translation-based model, for automatically fixing the lexical chasm between

questions of question search. They found that the translation-based model performed best.

However, all the existing methods treat questions just as plain texts (without considering question structure). In this paper, we proposed to conduct question search by identifying question topic and question focus. To the best of our knowledge, none of the existing studies addressed question search by modeling both question topic and question focus.

Question answering (e.g., Pasca and Harabagiu, 2001; Echihabi and Marcu, 2003; Voorhees, 2004; Metzler and Croft, 2005) relates to question search. Question answering automatically extracts short answers for a relatively limited class of question types from document collections. In contrast to that, question search retrieves answers for an unlimited range of questions by focusing on finding semantically similar questions in an archive.

## 6 Conclusions and Future Work

In this paper, we have proposed an approach to question search which models question topic and question focus in a language modeling framework.

The contribution of this paper can be summarized in 4-fold: (1) A data structure consisting of *question topic* and *question focus* was proposed for summarizing questions; (2) The MDL-based tree cut model was employed to identify question topic and question focus automatically; (3) A new form of language modeling using question topic and question focus was developed for question search; (4) Extensive experiments have been conducted to evaluate the proposed approach using a large collection of real questions obtained from Yahoo! Answers.

Though we only utilize data from community-based question answering service in our experiments, we could also use categorized questions from forum sites and FAQ sites. Thus, as future work, we will try to investigate the use of the proposed approach for other kinds of web services.

## Acknowledgement

We would like to thank Xinying Song, Shasha Li, and Shilin Ding for their efforts on developing the evaluation data. We would also like to thank Stephan H. Stiller for his proof-reading of the paper.

## Abstract

Previous work on statistical language generation has primarily focused on grammaticality and naturalness, scoring generation possibilities according to a language model or user feedback. More recent work has investigated data-driven techniques for controlling linguistic style without overgeneration, by reproducing variation dimensions extracted from corpora. Another line of work has produced handcrafted *rule-based* systems to control specific stylistic dimensions, such as politeness and personality. This paper describes a novel approach that automatically learns to produce recognisable variation along a meaningful stylistic dimension—personality—without the computational cost incurred by overgeneration techniques. We present the first evaluation of a data-driven generation method that projects multiple personality traits *simultaneously* and on a *continuous* scale. We compare our performance to a rule-based generator in the same domain.

## 1 Introduction

Over the last 20 years, statistical language models (SLMs) have been used successfully in many tasks in natural language processing, and the data available for modeling has steadily grown (Lapata and Keller, 2005). Langkilde and Knight (1998) first applied SLMs to statistical natural language generation (SNLG), showing that high quality paraphrases can be generated from an underspecified representation of meaning, by first applying a very underconstrained, rule-based *overgeneration* phase, whose outputs are then ranked by an SLM *scoring* phase. Since then, research in SNLG has explored a range of models for both dialogue and text generation.

One line of work has primarily focused on grammaticality and naturalness, scoring the overgener-

ation phase with a SLM, and evaluating against a gold-standard corpus, using string or tree-match metrics (Langkilde-Geary, 2002; Bangalore and Rambow, 2000; Chambers and Allen, 2004; Belz, 2005; Isard et al., 2006).

Another thread investigates SNLG scoring models trained using higher-level linguistic features to replicate human judgments of utterance quality (Rambow et al., 2001; Nakatsu and White, 2006; Stent and Guo, 2005). The error of these scoring models approaches the gold-standard human ranking with a relatively small training set.

A third SNLG approach eliminates the overgeneration phase (Paiva and Evans, 2005). It applies factor analysis to a corpus exhibiting stylistic variation, and then learns which generation parameters to manipulate to correlate with factor measurements. The generator was shown to reproduce intended factor levels across several factors, thus modelling the stylistic variation as measured in the original corpus.

Our goal is a generation technique that can target multiple stylistic effects *simultaneously* and over a *continuous* scale, controlling stylistic dimensions that are commonly understood and thus *meaningful* to users and application developers. Our intended applications are output utterances for intelligent training or intervention systems, video game characters, or virtual environment avatars. In previous work, we presented PERSONAGE, a psychologically-informed rule-based generator based on the Big Five personality model, and we showed that PERSONAGE can project extreme personality on the extraversion scale, i.e. both introverted and extraverted personality types (Mairesse and Walker, 2007). We used the Big Five model to develop PERSONAGE for several reasons. First, the Big Five has been shown in psychology to ex-

Trait	High	Low
<b>Extraversion</b>	warm, assertive, sociable, excitement seeking, active, spontaneous, optimistic, talkative	shy, quiet, reserved, passive, solitary, moody
<b>Emotional stability</b>	calm, even-tempered, reliable, peaceful, confident	neurotic, anxious, depressed, self-conscious
<b>Agreeableness</b>	trustworthy, considerate, friendly, generous, helpful	unfriendly, selfish, suspicious, uncooperative, malicious
<b>Conscientiousness</b>	competent, disciplined, dutiful, achievement striving	disorganised, impulsive, unreliable, forgetful
<b>Openness to experience</b>	creative, intellectual, curious, cultured, complex	narrow-minded, conservative, ignorant, simple

Table 1: Example adjectives associated with extreme values of the Big Five trait scales.

plain much of the variation in human perceptions of personality differences. Second, we believe that the adjectives used to develop the Big Five model provide an intuitive, *meaningful* definition of linguistic style. Table 1 shows some of the trait adjectives associated with the extremes of each Big Five trait. Third, there are many studies linking personality to linguistic variables (Pennebaker and King, 1999; Mehl et al., 2006, *inter alia*). See (Mairesse and Walker, 2007) for more detail.

In this paper, we further test the utility of basing stylistic variation on the Big Five personality model. The Big Five traits are represented by scalar values that range from 1 to 7, with values normally distributed among humans. While our previous work targeted extreme values of individual traits, here we show that we can target multiple personality traits *simultaneously* and over the *continuous* scales of the Big Five model. Section 2 describes a novel parameter-estimation method that automatically learns to produce recognisable variation for all Big Five traits, without overgeneration, implemented in a new SNLG called PERSONAGE-PE. We show that PERSONAGE-PE generates targets for multiple personality dimensions, using linear and non-linear parameter estimation models to predict generation parameters *directly* from the scalar targets. Section 3.2 shows that humans accurately perceive the intended variation, and Section 3.3 compares PERSONAGE-PE (trained) with PERSONAGE (rule-based; Mairesse and Walker, 2007). We delay a detailed discussion of related work to Section 4, where we summarize and discuss future work.

## 2 Parameter Estimation Models

The data-driven parameter estimation method consists of a development phase and a generation phase (Section 3). The development phase:

1. Uses a base generator to produce multiple utterances by randomly varying its parameters;
2. Collects human judgments rating the personality of each utterance;
3. Trains statistical models to predict the parameters from the personality judgments;

Figure 1: Distribution of average agreeableness ratings from the 2 expert judges for 160 random utterances.

4. Selects the best model for each parameter via cross-validation.

### 2.1 Base Generator

We make minimal assumptions about the input to the generator to favor domain independence. The input is a speech act, a potential content pool that can be used to achieve that speech act, and five scalar personality parameters (1..7), specifying values for the continuous scalar dimensions of each trait in the Big Five model. See Table 1. This requires a base generator that generates multiple outputs expressing the same input content by varying linguistic parameters related to the Big Five traits. We start with the PERSONAGE generator (Mairesse and Walker, 2007), which generates recommendations and comparisons of restaurants. We extend PERSONAGE with new parameters for a total of 67 parameters in PERSONAGE-PE. See Table 2. These parameters are derived from psychological studies identifying linguistic markers of the Big Five traits (Pennebaker and King, 1999; Mehl et al., 2006, *inter alia*). As PERSONAGE’s input parameters are domain-independent, most parameters range continuously between 0 and 1, while pragmatic marker insertion parameters are binary, except for the SUBJECT IMPLICITNESS, STUTTERING and PRONOMI-

Parameters	Description
<b>Content parameters:</b>	
VERBOSITY	Control the number of propositions in the utterance
RESTATEMENTS	Paraphrase an existing proposition, e.g. <i>'Chanpen Thai has great service, it has fantastic waiters'</i>
REPETITIONS	Repeat an existing proposition
CONTENT POLARITY	Control the polarity of the propositions expressed, i.e. referring to negative or positive attributes
REPETITIONS POLARITY	Control the polarity of the restated propositions
CONCESSIONS	Emphasise one attribute over another, e.g. <i>'even if Chanpen Thai has great food, it has bad service'</i>
CONCESSIONS POLARITY	Determine whether positive or negative attributes are emphasised
POLARISATION	Control whether the expressed polarity is neutral or extreme
POSITIVE CONTENT FIRST	Determine whether positive propositions—including the claim—are uttered first
<b>Syntactic template selection parameters:</b>	
SELF-REFERENCES	Control the number of first person pronouns
CLAIM COMPLEXITY	Control the syntactic complexity (syntactic embedding)
CLAIM POLARITY	Control the connotation of the claim, i.e. whether positive or negative affect is expressed
<b>Aggregation operations:</b>	
PERIOD	Leave two propositions in their own sentences, e.g. <i>'Chanpen Thai has great service. It has nice decor.'</i>
RELATIVE CLAUSE	Aggregate propositions with a relative clause, e.g. <i>'Chanpen Thai, which has great service, has nice decor'</i>
WITH CUE WORD	Aggregate propositions using <i>with</i> , e.g. <i>'Chanpen Thai has great service, with nice decor'</i>
CONJUNCTION	Join two propositions using a conjunction, or a comma if more than two propositions
MERGE	Merge the subject and verb of two propositions, e.g. <i>'Chanpen Thai has great service and nice decor'</i>
ALSO CUE WORD	Join two propositions using <i>also</i> , e.g. <i>'Chanpen Thai has great service, also it has nice decor'</i>
CONTRAST - CUE WORD	Contrast two propositions using <i>while, but, however, on the other hand</i> , e.g. <i>'While Chanpen Thai has great service, it has bad decor', 'Chanpen Thai has great service, but it has bad decor'</i>
JUSTIFY - CUE WORD	Justify a proposition using <i>because, since, so</i> , e.g. <i>'Chanpen Thai is the best, because it has great service'</i>
CONCEDE - CUE WORD	Concede a proposition using <i>although, even if, but/though</i> , e.g. <i>'Although Chanpen Thai has great service, it has bad decor', 'Chanpen Thai has great service, but it has bad decor though'</i>
MERGE WITH COMMA	Restate a proposition by repeating only the object, e.g. <i>'Chanpen Thai has great service, nice waiters'</i>
CONJ. WITH ELLIPSIS	Restate a proposition after replacing its object by an ellipsis, e.g. <i>'Chanpen Thai has . . . , it has great service'</i>
<b>Pragmatic markers:</b>	
SUBJECT IMPLICITNESS	Make the restaurant implicit by moving the attribute to the subject, e.g. <i>'the service is great'</i>
NEGATION	Negate a verb by replacing its modifier by its antonym, e.g. <i>'Chanpen Thai doesn't have bad service'</i>
SOFTENER HEDGES	Insert syntactic elements ( <i>sort of, kind of, somewhat, quite, around, rather, I think that, it seems to me that</i> ) to mitigate the strength of a proposition, e.g. <i>'Chanpen Thai has kind of great service'</i> or <i>'It seems to me that Chanpen Thai has rather great service'</i>
EMPHASIZER HEDGES	Insert syntactic elements ( <i>really, basically, actually, just</i> ) to strengthen a proposition, e.g. <i>'Chanpen Thai has really great service'</i> or <i>'Basically, Chanpen Thai just has great service'</i>
ACKNOWLEDGMENTS	Insert an initial back-channel ( <i>yeah, right, ok, I see, oh, well</i> ), e.g. <i>'Well, Chanpen Thai has great service'</i>
FILLED PAUSES	Insert syntactic elements expressing hesitancy ( <i>like, I mean, err, mmhm, you know</i> ), e.g. <i>'I mean, Chanpen Thai has great service, you know'</i> or <i>'Err... Chanpen Thai has, like, great service'</i>
EXCLAMATION	Insert an exclamation mark, e.g. <i>'Chanpen Thai has great service!'</i>
EXPLETIVES	Insert a swear word, e.g. <i>'the service is damn great'</i>
NEAR-EXPLETIVES	Insert a near-swear word, e.g. <i>'the service is darn great'</i>
COMPETENCE MITIGATION	Express the speaker's negative appraisal of the hearer's request, e.g. <i>'everybody knows that . . .'</i>
TAG QUESTION	Insert a tag question, e.g. <i>'the service is great, isn't it?'</i>
STUTTERING	Duplicate the first letters of a restaurant's name, e.g. <i>'Ch-ch-anpen Thai is the best'</i>
CONFIRMATION	Begin the utterance with a confirmation of the restaurant's name, e.g. <i>'did you say Chanpen Thai?'</i>
INITIAL REJECTION	Begin the utterance with a mild rejection, e.g. <i>'I'm not sure'</i>
IN-GROUP MARKER	Refer to the hearer as a member of the same social group, e.g. <i>pal, mate and buddy</i>
PRONOMINALIZATION	Replace occurrences of the restaurant's name by pronouns
<b>Lexical choice parameters:</b>	
LEXICAL FREQUENCY	Control the average frequency of use of each content word, according to BNC frequency counts
WORD LENGTH	Control the average number of letters of each content word
VERB STRENGTH	Control the strength of the selected verbs, e.g. <i>'I would suggest'</i> vs. <i>'I would recommend'</i>

Table 2: The 67 generation parameters whose target values are learned. Aggregation cue words, hedges, acknowledgments and filled pauses are learned individually (as separate parameters), e.g. *kind of* is modeled differently than *somewhat* in the SOFTENER HEDGES category. Parameters are detailed in previous work (Mairesse and Walker, 2007).

NALIZATION parameters.

## 2.2 Random Sample Generation and Expert Judgments

We generate a sample of 160 *random* utterances by varying the parameters in Table 2 with a uniform distribution. This sample is intended to provide enough training material for estimating all 67 parameters for each personality dimension. Following Mairesse

and Walker (2007), two expert judges (not the authors) familiar with the Big Five adjectives (Table 1) evaluate the personality of each utterance using the Ten-Item Personality Inventory (TIPI; Gosling et al., 2003), and also judge the utterance's naturalness. Thus 11 judgments were made for each utterance for a total of 1760 judgments. The TIPI outputs a rating on a scale from 1 (low) to 7 (high) for each Big Five trait. The expert judgments are approximately nor-

mally distributed; Figure 1 shows the distribution for agreeableness.

### 2.3 Statistical Model Training

Training data is created for each generation parameter—i.e. the output variable—to train statistical models predicting the optimal parameter value from the target personality scores. The models are thus based on the simplifying assumption that the generation parameters are independent. Any personality trait whose correlation with a generation decision is below 0.1 is removed from the training data. This has the effect of removing parameters that do not correlate strongly with any trait, which are set to a constant default value at generation time. Since the input parameter values may not be satisfiable depending on the input content, the actual generation decisions made for each utterance are recorded. For example, the CONCESSIONS decision value is the actual number of concessions produced in the utterance. To ensure that the models’ output can control the generator, the generation decision values are normalized to match the input range (0..1) of PERSONAGE-PE. Thus the dataset consists of 160 utterances and the corresponding generation decisions, each associated with 5 personality ratings averaged over both judges.

Parameter estimation models are trained to predict either continuous (e.g. VERBOSITY) or binary (e.g. EXCLAMATION) generation decisions. We compare various learning algorithms using the Weka toolkit (with default values unless specified; Witten and Frank, 2005). Continuous parameters are modeled with a linear regression model (LR), an M5’ model tree (M5), and a model based on support vector machines with a linear kernel (SVM). As regression models can extrapolate beyond the [0, 1] interval, the output parameter values are truncated if needed—at generation time—before being sent to the base generator. Binary parameters are modeled using classifiers that predict whether the parameter is *enabled* or *disabled*. We test a Naive Bayes classifier (NB), a j48 decision tree (J48), a nearest-neighbor classifier using one neighbor (NN), a Java implementation of the RIPPER rule-based learner (JRIP), the AdaBoost boosting algorithm (ADA), and a support vector machines classifier with a linear kernel (SVM).

Figures 2, 3 and 4 show the models learned for the EXCLAMATION (binary), STUTTERING (continuous), and CONTENT POLARITY (continuous) parameters in Table 2. The models predict generation parameters from input personality scores; note that

Condition	Class	Weight
if extraversion > 6.42 then 1 else 0	1	1.81
if extraversion > 4.42 then 1 else 0	1	0.38
if extraversion <= 6.58 then 1 else 0	1	0.22
if extraversion > 4.71 then 1 else 0	1	0.28
if agreeableness > 5.13 then 1 else 0	1	0.42
if extraversion <= 6.58 then 1 else 0	1	0.14
if extraversion > 4.79 then 1 else 0	1	0.19
if extraversion <= 6.58 then 1 else 0	1	0.17

Figure 2: AdaBoost model predicting the EXCLAMATION parameter. Given input trait values, the model outputs the class yielding the largest sum of weights for the rules returning that class. Class 0 = *disabled*, class 1 = *enabled*.

(normalized) Content polarity =
0.054
- 0.102 * (normalized) emotional stability
+ 0.970 * (normalized) agreeableness
- 0.110 * (normalized) conscientiousness
+ 0.013 * (normalized) openness to experience

Figure 3: SVM model with a linear kernel predicting the CONTENT POLARITY parameter.

sometimes the best performing model is non-linear. Given input trait values, the AdaBoost model in Figure 2 outputs the class yielding the largest sum of weights for the rules returning that class. For example, the first rule of the EXCLAMATION model shows that an extraversion score above 6.42 out of 7 would increase the weight of the *enabled* class by 1.81. The fifth rule indicates that a target agreeableness above 5.13 would further increase the weight by .42. The STUTTERING model tree in Figure 4 lets us calculate that a low emotional stability (1.0) together with a neutral conscientiousness and openness to experience (4.0) yield a parameter value of .62 (see LM2), whereas a neutral emotional stability decreases the value down to .17. Figure 4 also shows how personality traits that do not affect the parameter are removed, i.e. emotional stability, conscientiousness and openness to experience are the traits that affect stuttering. The linear model in Figure 3 shows that agreeableness has a strong effect on the CONTENT POLARITY parameter (.97 weight), but emotional stability, conscientiousness and openness to experience also have an effect.

### 2.4 Model Selection

The final step of the development phase identifies the best performing model(s) for each generation parameter via cross-validation. For continuous pa-

Table 4: F-measure of the *enabled* class for classification models of binary parameters. Parameters that do not correlate with any trait are omitted. Results are averaged over a 10-fold cross-validation. JRIP models are not shown as they never perform best.

the most accurately, with the SVM model in Figure 3 producing a correlation of .47 with the true parameter values. Models of the PERIOD aggregation operation also perform well, with a linear regression model yielding a correlation of .36 when realizing a justification, and .27 when contrasting two propositions. CLAIM COMPLEXITY and VERBOSITY are also modeled successfully, with correlations of .33 and .26 using a model tree. The model tree controlling the STUTTERING parameter illustrated in Figure 4 produces a correlation of .23. For binary parameters, Table 4 shows that the Naive Bayes classifier is generally the most accurate, with F-measures of .40 for the IN-GROUP MARKER parameter, and .32 for both the insertion of filled pauses (*err*) and tag questions. The AdaBoost algorithm best predicts the EXCLAMATION parameter, with an F-measure of .38 for the model in Figure 2.

#	Traits	End	Rating	Nat	Output utterance
1.a	Extraversion Agreeableness	high high	4.42 4.94	4.79	Radio Perfecto’s price is 25 dollars but Les Routiers provides adequate food. I imagine they’re alright!
1.b	Emotional stability Conscientiousness	high high	5.35 5.21	5.04	Let’s see, Les Routiers and Radio Perfecto... You would probably appreciate them. Radio Perfecto is in the East Village with kind of acceptable food. Les Routiers is located in Manhattan. Its price is 41 dollars.
2.a	Extraversion Agreeableness	low low	3.65 4.02	3.21	Err... you would probably appreciate Trattoria Rustica, wouldn’t you? It’s in Manhattan, also it’s an italian restaurant. It offers poor ambience, also it’s quite costly.
2.b	Emotional stability Openness to experience	low low	4.13 3.85	4.50	Trattoria Rustica isn’t as bad as the others. Err... even if it’s costly, it offers kind of adequate food, alright? It’s an italian place.

Table 5: Example outputs controlled by the parameter estimation models for a comparison (#1) and a recommendation (#2), with the average judges’ ratings (*Rating*) and naturalness (*Nat*). Ratings are on a scale from 1 to 7, with 1 = very low (e.g. neurotic or introvert) and 7 = very high on the dimension (e.g. emotionally stable or extraverted).

### 3 Evaluation Experiment

The generation phase of our parameter estimation SNLG method consists of the following steps:

1. Use the best performing models to predict parameter values from the desired personality scores;
2. Generate the output utterance using the predicted parameter values.

We then evaluate the output utterances using naive human judges to rate their perceived personality and naturalness.

#### 3.1 Evaluation Method

Given the best performing model for each generation parameter, we generate 5 utterances for each of 5 recommendation and 5 comparison speech acts. Each utterance targets an extreme value for two traits (either 1 or 7 out of 7) and neutral values for the remaining three traits (4 out of 7). The goal is for each utterance to project *multiple* traits on a *continuous* scale. To generate a range of alternatives, a Gaussian noise with a standard deviation of 10% of the full scale is added to each target value.

Subjects were 24 native English speakers (12 male and 12 female graduate students from a range of disciplines from both the U.K. and the U.S.). Subjects evaluate the naturalness and personality of each utterance using the TIPI (Gosling et al., 2003). To limit the experiment’s duration, only the two traits with extreme target values are evaluated for each utterance. Subjects thus answered 5 questions for 50 utterances, two from the TIPI for each extreme trait and one about naturalness (250 judgments in total per subject). Subjects were not told that the utterances were intended to manifest extreme trait values. Table 5 shows several sample outputs and the mean personality ratings from the human judges. For example, utterance 1.a projects a high extraversion through the insertion of an exclamation mark

based on the model in Figure 2, whereas utterance 2.a conveys introversion by beginning with the filled pause *err*. The same utterance also projects a low agreeableness by focusing on negative propositions, through a low CONTENT POLARITY parameter value as per the model in Figure 3. This evaluation addresses a number of open questions discussed below.

- Q1: Is the personality projected by models trained on ratings from a few expert judges recognised by a larger sample of naive judges? (Section 3.2)
- Q2: Can a *combination* of multiple traits within a single utterance be detected by naive judges? (Section 3.2)
- Q3: How does PERSONAGE-PE compare to PERSONAGE, a psychologically-informed rule-based generator for projecting extreme personality? (Section 3.3)
- Q4: Does the parameter estimation SNLG method produce natural utterances? (Section 3.4)

#### 3.2 Parameter Estimation Evaluation

Table 6 shows that extraversion is the dimension modeled most accurately by the parameter estimation models, producing a .45 correlation with the subjects’ ratings ( $p < .01$ ). Emotional stability, agreeableness, and openness to experience ratings also correlate strongly with the target scores, with correlations of .39, .36 and .17 respectively ( $p < .01$ ). Additionally, Table 6 shows that the magnitude of the correlation increases when considering the perception of a hypothetical average subject, i.e. smoothing individual variation by averaging the ratings over all 24 judges, producing a correlation  $r_{avg}$  up to .80 for extraversion. These correlations are unexpectedly high; in corpus analyses, significant correlations as low as .05 to .10 are typically observed between personality and linguistic markers (Pennebaker and King, 1999; Mehl et al., 2006).

Conscientiousness is the only dimension whose ratings do not correlate with the target scores. The

comparison with rule-based results in Section 3.3 suggests that this is not because conscientiousness cannot be exhibited in our domain or manifested in a single utterance, so perhaps this arises from differing perceptions of conscientiousness between the expert and naive judges.

Trait	$r$	$r_{avg}$	$e$
Extraversion	.45 •	.80 •	1.89
Emotional stability	.39 •	.64 •	2.14
Agreeableness	.36 •	.68 •	2.38
Conscientiousness	-.01	-.02	2.79
Openness to experience	.17 •	.41 •	2.51

• statistically significant correlation  
 $p < .05$ , •  $p = .07$  (two-tailed)

Table 6: Pearson’s correlation coefficient  $r$  and mean absolute error  $e$  between the target personality scores and the 480 judges’ ratings (20 ratings per trait for 24 judges);  $r_{avg}$  is the correlation between the personality scores and the average judges’ ratings.

Table 6 shows that the mean absolute error varies between 1.89 and 2.79 on a scale from 1 to 7. Such large errors result from the decision to ask judges to answer just the TIPI questions for the two traits that were the extreme targets (See Section 3.1), because the judges tend to use the whole scale, with approximately normally distributed ratings. This means that although the judges make distinctions leading to high correlations, they do so on a compressed scale. This explains the large correlations despite the magnitude of the absolute error.

Table 7 shows results evaluating whether utterances targeting the extremes of a trait are perceived differently. The ratings differ significantly for all traits but conscientiousness ( $p \leq .001$ ). Thus parameter estimation models can be used in applications that only require discrete binary variation.

Trait	Low	High
Extraversion	3.69	5.06 •
Emotional stability	3.75	4.75 •
Agreeableness	3.42	4.33 •
Conscientiousness	4.16	4.15
Openness to experience	3.71	4.06 •

• statistically significant difference  
 $p \leq .001$  (two-tailed)

Table 7: Average personality ratings for the utterances generated with the low and high target values for each trait on a scale from 1 to 7.

It is important to emphasize that generation parameters were predicted based on 5 target personality values. Thus, the results show that *individual* traits are perceived even when utterances project

other traits as well, confirming that the Big Five theory models independent dimensions and thus provides a useful and meaningful framework for modeling variation in language. Additionally, although we do not directly evaluate the perception of mid-range values of personality target scores, the results suggest that mid-range personality is modeled correctly because the neutral target scores do not affect the perception of extreme traits.

### 3.3 Comparison with Rule-Based Generation

PERSONAGE is a rule-based personality generator based on handcrafted parameter settings derived from psychological studies. Mairesse and Walker (2007) show that this approach generates utterances that are perceptibly different along the extraversion dimension. Table 8 compares the mean ratings of the utterances generated by PERSONAGE-PE with ratings of 20 utterances generated by PERSONAGE for each extreme of each Big Five scale (40 for extraversion, resulting in 240 handcrafted utterances in total). Table 8 shows that the handcrafted parameter settings project a significantly more extreme personality for 6 traits out of 10. However, the learned parameter models for neuroticism, disagreeableness, unconscientiousness and openness to experience do not perform significantly worse than the handcrafted generator. These findings are promising as we discuss further in Section 4.

Method	Rule-based		Learned parameters	
	Low	High	Low	High
Extraversion	2.96	5.98	3.69 ◦	5.05 ◦
Emotional stability	3.29	5.96	3.75	4.75 ◦
Agreeableness	3.41	5.66	3.42	4.33 ◦
Conscientiousness	3.71	5.53	4.16	4.15 ◦
Openness to experience	2.89	4.21	3.71 ◦	4.06

◦, ◦ significant increase or decrease of the variation range over the average rule-based ratings ( $p < .05$ , two-tailed)

Table 8: Pair-wise comparison between the ratings of the utterances generated using PERSONAGE-PE with extreme target values (*Learned Parameters*), and the ratings for utterances generated with Mairesse and Walker’s rule-based PERSONAGE generator, (*Rule-based*). Ratings are averaged over all judges.

### 3.4 Naturalness Evaluation

The naive judges also evaluated the naturalness of the outputs of our trained models. Table 9 shows that the average naturalness is 3.98 out of 7, which is significantly lower ( $p < .05$ ) than the naturalness of handcrafted and randomly generated utterances reported by Mairesse and Walker (2007). It is possible that the differences arise from judgments of utterances targeting multiple traits, or that the naive

judges are more critical.

Trait	Rule-based	Random	Learned
All	4.59	4.38	3.98

Table 9: Average naturalness ratings for utterances generated using (1) PERSONAGE, the rule-based generator, (2) the random utterances (expert judges) and (3) the outputs of PERSONAGE-PE using the parameter estimation models (*Learned*, naive judges). The means differ significantly at the  $p < .05$  level (two-tailed independent sample t-test).

## 4 Conclusion

We present a new method for generating linguistic variation projecting multiple personality traits continuously, by combining and extending previous research in statistical natural language generation (Paiva and Evans, 2005; Rambow et al., 2001; Isard et al., 2006; Mairesse and Walker, 2007). While handcrafted rule-based approaches are limited to variation along a small number of discrete points (Hovy, 1988; Walker et al., 1997; Lester et al., 1997; Power et al., 2003; Cassell and Bickmore, 2003; Piwek, 2003; Mairesse and Walker, 2007; Rehm and André, in press), we learn models that predict parameter values for any arbitrary value on the variation dimension scales. Additionally, our data-driven approach can be applied to any dimension that is meaningful to human judges, and it provides an elegant way to project multiple dimensions simultaneously, by including the relevant dimensions as features of the parameter models’ training data.

Isard et al. (2006) and Mairesse and Walker (2007) also propose a personality generation method, in which a data-driven personality model selects the best utterance from a large candidate set. Isard et al.’s technique has not been evaluated, while Mairesse and Walker’s overgenerate and score approach is inefficient. Paiva and Evans’ technique does not overgenerate (2005), but it requires a search for the optimal generation decisions according to the learned models. Our approach does not require any search or overgeneration, as parameter estimation models predict the generation decisions directly from the target variation dimensions. This technique is therefore beneficial for real-time generation. Moreover the variation dimensions of Paiva and Evans’ data-driven technique are extracted from a corpus: there is thus no guarantee that they can be easily interpreted by humans, and that they generalise to other corpora. Previous work has shown that modeling the relation between personality and

language is far from trivial (Pennebaker and King, 1999; Argamon et al., 2005; Oberlander and Nowson, 2006; Mairesse et al., 2007), suggesting that the control of personality is a harder problem than the control of data-driven variation dimensions.

We present the first human perceptual evaluation of a data-driven stylistic variation method. In terms of our research questions in Section 3.1, we show that models trained on expert judges to project multiple traits in a single utterance generate utterances whose personality is recognized by naive judges. There is only one other similar evaluation of an SNLG (Rambow et al., 2001). Our models perform only slightly worse than a handcrafted rule-based generator in the same domain. These findings are promising as (1) parameter estimation models are able to target any combination of traits over the full range of the Big Five scales; (2) they do not benefit from psychological knowledge, i.e. they are trained on randomly generated utterances.

This work also has several limitations that should be addressed in future work. Even though the parameters of PERSONAGE-PE were suggested by psychological studies (Mairesse and Walker, 2007), some of them are not modeled successfully by our approach, and thus omitted from Tables 3 and 4. This could be due to the relatively small development dataset size (160 utterances to optimize 67 parameters), or to the implementation of some parameters. The strong parameter-independence assumption could also be responsible, but we are not aware of any state of the art implementation for learning multiple dependent variables, and this approach could further aggravate data sparsity issues.

In addition, it is unclear why PERSONAGE performs better for projecting extreme personality and produces more natural utterances, and why PERSONAGE-PE fails to project conscientiousness correctly. It might be possible to improve the parameter estimation models with a larger sample of random utterances at development time, or with additional extreme data generated using the rule-based approach. Such hybrid models are likely to perform better for extreme target scores, as they are trained on more uniformly distributed ratings (e.g. compared to the normal distribution in Figure 1). In addition, we have only shown that personality can be expressed by information presentation speech-acts in the restaurant domain; future work should assess the extent to which the parameters derived from psychological findings are culture, domain, and speech act dependent.

# Correcting Misuse of Verb Forms

John Lee and Stephanie Seneff

Spoken Language Systems

MIT Computer Science and Artificial Intelligence Laboratory

Cambridge, MA 02139, USA

{jsylee,seneff}@csail.mit.edu

## Abstract

This paper proposes a method to correct English verb form errors made by non-native speakers. A basic approach is template matching on parse trees. The proposed method improves on this approach in two ways. To improve recall, irregularities in parse trees caused by verb form errors are taken into account; to improve precision,  $n$ -gram counts are utilized to filter proposed corrections. Evaluation on non-native corpora, representing two genres and mother tongues, shows promising results.

## 1 Introduction

In order to describe the nuances of an action, a verb may be associated with various concepts such as tense, aspect, voice, mood, person and number. In some languages, such as Chinese, the verb itself is not inflected, and these concepts are expressed via other words in the sentence. In highly inflected languages, such as Turkish, many of these concepts are encoded in the inflection of the verb. In between these extremes, English uses a combination of inflections (see Table 1) and “helping words”, or auxiliaries, to form complex verb phrases.

It should come as no surprise, then, that the misuse of verb forms is a common error category for some non-native speakers of English. For example, in the Japanese Learners of English corpus (Izumi et al., 2003), errors related to verbs are among the most frequent categories. Table 2 shows some sentences with these errors.

Form	Example
base (bare)	<i>speak</i>
base (infinitive)	<i>to speak</i>
third person singular	<i>speaks</i>
past	<i>spoke</i>
-ing participle	<i>speaking</i>
-ed participle	<i>spoken</i>

Table 1: Five forms of inflections of English verbs (Quirk et al., 1985), illustrated with the verb “*speak*”. The base form is also used to construct the infinitive with “*to*”. An exception is the verb “*to be*”, which has more forms.

A system that automatically detects and corrects misused verb forms would be both an educational and practical tool for students of English. It may also potentially improve the performance of machine translation and natural language generation systems, especially when the source and target languages employ very different verb systems.

Research on automatic grammar correction has been conducted on a number of different parts-of-speech, such as articles (Knight and Chander, 1994) and prepositions (Chodorow et al., 2007). Errors in verb forms have been covered as part of larger systems such as (Heidorn, 2000), but we believe that their specific research challenges warrant more detailed examination.

We build on the basic approach of template-matching on parse trees in two ways. To improve recall, irregularities in parse trees caused by verb form errors are considered; to improve precision,  $n$ -gram counts are utilized to filter proposed corrections.

We start with a discussion on the scope of our

task in the next section. We then analyze the specific research issues in §3 and survey previous work in §4. A description of our data follows. Finally, we present experimental results and conclude.

## 2 Background

An English verb can be inflected in five forms (see Table 1). Our goal is to correct confusions among these five forms, as well as the infinitive. These confusions can be viewed as symptoms of one of two main underlying categories of errors; roughly speaking, one category is semantic in nature, and the other, syntactic.

### 2.1 Semantic Errors

The first type of error is concerned with inappropriate choices of tense, aspect, voice, or mood. These may be considered errors in semantics. In the sentence below, the verb “live” is expressed in the simple present tense, rather than the perfect progressive:

*He \*lives there since June.* (1)

Either “has been living” or “had been living” may be the valid correction, depending on the context. If there is no temporal expression, correction of tense and aspect would be even more challenging.

Similarly, correcting voice and mood often requires real-world knowledge. Suppose one wants to say “I am prepared for the exam”, but writes “I am preparing for the exam”. Semantic analysis of the context would be required to correct this kind of error, which will not be tackled in this paper<sup>1</sup>.

<sup>1</sup>If the input is “I am \*prepare for the exam”, however, we will attempt to choose between the two possibilities.

Example	Usage
<i>I take a bath and *reading books.</i>	FINITE
<i>I can't *skiing well, but ...</i>	BASE <sub>md</sub>
<i>Why did this *happened?</i>	BASE <sub>do</sub>
<i>But I haven't *decide where to go.</i>	ED <sub>perf</sub>
<i>I don't want *have a baby.</i>	INF <sub>verb</sub>
<i>I have to save my money for *ski.</i>	ING <sub>prep</sub>
<i>My son was very *satisfy with ...</i>	ED <sub>pass</sub>
<i>I am always *talk to my father.</i>	ING <sub>prog</sub>

Table 2: Sentences with verb form errors. The intended usages, shown on the right column, are defined in Table 3.

### 2.2 Syntactic Errors

The second type of error is the misuse of verb forms. Even if the intended tense, aspect, voice and mood are correct, the verb phrase may still be constructed erroneously. This type of error may be further subdivided as follows:

**Subject-Verb Agreement** The verb is not correctly inflected in number and person with respect to the subject. A common error is the confusion between the base form and the third person singular form, e.g.,

*He \*have been living there since June.* (2)

**Auxiliary Agreement** In addition to the modal auxiliaries, other auxiliaries must be used when specifying the perfective or progressive aspect, or the passive voice. Their use results in a complex verb phrase, i.e., one that consists of two or more verb constituents. Mistakes arise when the main verb does not “agree” with the auxiliary. In the sentence below, the present perfect progressive tense (“has been living”) is intended, but the main verb “live” is mistakenly left in the base form:

*He has been \*live there since June.* (3)

In general, the auxiliaries can serve as a hint to the intended verb form, even as the auxiliaries “has been” in the above case suggest that the progressive aspect was intended.

**Complementation** A nonfinite clause can serve as complementation to a verb or to a preposition. In the former case, the verb form in the clause is typically an infinitive or an -ing participle; in the latter, it is usually an -ing participle. Here is an example of a wrong choice of verb form in complementation to a verb:

*He wants \*live there.* (4)

In this sentence, “live”, in its base form, should be modified to its infinitive form as a complementation to the verb “wants”.

This paper focuses on correcting the above three error types: subject-verb agreement, auxiliary agreement, and complementation. Table 3 gives a complete list of verb form usages which will be covered.

Form	Usage	Description	Example
Base Form as Bare Infinitive	BASE <sub>md</sub> BASE <sub>do</sub>	After modals “Do”-support/-periphrasis; emphatic positive	He <b>may</b> call. <b>May</b> he call? He <b>did</b> not call. <b>Did</b> he call? I <b>did</b> call.
Base or 3rd person	FINITE	Simple present or past tense	He calls.
Base Form as to-Infinitive	INF <sub>verb</sub>	Verb complementation	He <b>wants</b> her to call.
-ing participle	ING <sub>prog</sub> ING <sub>verb</sub> ING <sub>prep</sub>	Progressive aspect Verb complementation Prepositional complementation	He <b>was</b> calling. <b>Was</b> he calling? He <b>hated</b> calling. The device is designed <b>for</b> calling
-ed participle	ED <sub>perf</sub> ED <sub>pass</sub>	Perfect aspect Passive voice	He <b>has</b> called. <b>Has</b> he called? He <b>was</b> called. <b>Was</b> he called?

Table 3: Usage of various verb forms. In the examples, the *italized* verbs are the “targets” for correction. In complementations, the main verbs or prepositions are **bolded**; in all other cases, the auxiliaries are **bolded**.

### 3 Research Issues

One strategy for correcting verb form errors is to identify the intended syntactic relationships between the verb in question and its neighbors. For subject-verb agreement, the subject of the verb is obviously crucial (e.g., “*he*” in (2)); the auxiliary is relevant for resolving auxiliary agreement (e.g., “*has been*” in (3)); determining the verb that receives the complementation is necessary for detecting any complementation errors (e.g., “*wants*” in (4)). Once these items are identified, most verb form errors may be corrected in a rather straightforward manner.

The success of this strategy, then, hinges on accurate identification of these items, for example, from parse trees. Ambiguities will need to be resolved, leading to two research issues (§3.2 and §3.3).

#### 3.1 Ambiguities

The three so-called *primary verbs*, “*have*”, “*do*” and “*be*”, can serve as either main or auxiliary verbs. The verb “*be*” can be utilized as a main verb, but also as an auxiliary in the progressive aspect (ING<sub>prog</sub> in Table 3) or the passive voice (ED<sub>pass</sub>). The three examples below illustrate these possibilities:

*This is work not play.* (main verb)  
*My father is working in the lab.* (ING<sub>prog</sub>)  
*A solution is worked out.* (ED<sub>pass</sub>)

ambiguity among these roles is usually straightforward because of the different verb forms (e.g., “*working*” vs. “*worked*”). If the verb forms are incorrect, disambiguation is made more difficult:

*This is work not play.*  
*My father is \*work in the lab.*  
*A solution is \*work out.*

Similar ambiguities are introduced by the other primary verbs<sup>2</sup>. The verb “*have*” can function as an auxiliary in the perfect aspect (ED<sub>perf</sub>) as well as a main verb. The versatile “*do*” can serve as “do”-support or add emphasis (BASE<sub>do</sub>), or simply act as a main verb.

#### 3.2 Automatic Parsing

The ambiguities discussed above may be expected to cause degradation in automatic parsing performance. In other words, sentences containing verb form errors are more likely to yield an “incorrect” parse tree, sometimes with significant differences. For example, the sentence “*My father is \*work in the laboratory*” is parsed (Collins, 1997) as:

(S (NP My father)  
(VP is (NP work))  
(PP in the laboratory))

These different roles clearly affect the forms required for the verbs (if any) that follow. Dis-

<sup>2</sup>The abbreviations ‘s (*is* or *has*) and ‘d (*would* or *had*) compound the ambiguities.

The progressive form “*working*” is substituted with its bare form, which happens to be also a noun. The parser, not unreasonably, identifies “*work*” as a noun. Correcting the *verb* form error in this sentence, then, necessitates considering the *noun* that is apparently a copular complementation.

Anecdotal observations like this suggest that one cannot use parser output naively<sup>3</sup>. We will show that some of the irregularities caused by verb form errors are consistent and can be taken into account.

*One goal of this paper is to recognize irregularities in parse trees caused by verb form errors, in order to increase recall.*

### 3.3 Overgeneralization

One potential consequence of allowing for irregularities in parse tree patterns is overgeneralization. For example, to allow for the “parse error” in §3.2 and to retrieve the word “*work*”, every determiner-less noun would potentially be turned into an *-ing* participle. This would clearly result in many invalid corrections. We propose using *n*-gram counts as a filter to counter this kind of overgeneralization.

*A second goal is to show that n-gram counts can effectively serve as a filter, in order to increase precision.*

## 4 Previous Research

This section discusses previous research on processing verb form errors, and contrasts verb form errors with those of the other parts-of-speech.

### 4.1 Verb Forms

Detection and correction of grammatical errors, including verb forms, have been explored in various applications. Hand-crafted error production rules (or “mal-rules”), augmenting a context-free grammar, are designed for a writing tutor aimed at deaf students (Michaud et al., 2000). Similar strategies with parse trees are pursued in (Bender et al., 2004), and error templates are utilized in (Heidorn, 2000) for a word processor. Carefully hand-crafted rules, when used alone, tend to yield high precision; they

<sup>3</sup>According to a study on parsing ungrammatical sentences (Foster, 2007), subject-verb and determiner-noun agreement errors can lower the F-score of a state-of-the-art probabilistic parser by 1.4%, and context-sensitive spelling errors (not verbs specifically), by 6%.

may, however, be less equipped to detect verb form errors within a perfectly grammatical sentence, such as the example given in §3.2.

An approach combining a hand-crafted context-free grammar and stochastic probabilities is pursued in (Lee and Seneff, 2006), but it is designed for a restricted domain only. A maximum entropy model, using lexical and POS features, is trained in (Izumi et al., 2003) to recognize a variety of errors. It achieves 55% precision and 23% recall overall, on evaluation data that partially overlap with those of the present paper. Unfortunately, results on verb form errors are not reported separately, and comparison with our approach is therefore impossible.

### 4.2 Other Parts-of-speech

Automatic error detection has been performed on other parts-of-speech, e.g., articles (Knight and Chander, 1994) and prepositions (Chodorow et al., 2007). The research issues with these parts-of-speech, however, are quite distinct. Relative to verb forms, errors in these categories do not “disturb” the parse tree as much. The process of feature extraction is thus relatively simple.

## 5 Data

### 5.1 Development Data

To investigate irregularities in parse tree patterns (see §3.2), we utilized the AQUAINT Corpus of English News Text. After parsing the corpus (Collins, 1997), we artificially introduced verb form errors into these sentences, and observed the resulting “disturbances” to the parse trees.

For disambiguation with *n*-grams (see §3.3), we made use of the WEB 1T 5-GRAM corpus. Prepared by Google Inc., it contains English *n*-grams, up to 5-grams, with their observed frequency counts from a large number of web pages.

### 5.2 Evaluation Data

Two corpora were used for evaluation. They were selected to represent two different genres, and two different mother tongues.

**JLE** (Japanese Learners of English corpus) This corpus is based on interviews for the Standard Speaking Test, an English-language proficiency test conducted in Japan (Izumi et al.,

Input	Hypothesized Correction		
	None	Valid	Invalid
w/ errors	<i>false_neg</i>	<i>true_pos</i>	<i>inv_pos</i>
w/o errors	<i>true_neg</i>	<i>false_pos</i>	

Table 4: Possible outcomes of a hypothesized correction.

2003). For 167 of the transcribed interviews, totalling 15,637 sentences<sup>4</sup>, grammatical errors were annotated and their corrections provided. By retaining the verb form errors<sup>5</sup>, but correcting all other error types, we generated a test set in which 477 sentences (3.1%) contain subject-verb agreement errors, and 238 (1.5%) contain auxiliary agreement and complementation errors.

**HKUST** This corpus<sup>6</sup> of short essays was collected from students, all native Chinese speakers, at the Hong Kong University of Science and Technology. It contains a total of 2556 sentences. They tend to be longer and have more complex structures than their counterparts in the JLE. Corrections are not provided; however, part-of-speech tags are given for the original words, and for the intended (but unwritten) corrections. Implications on our evaluation procedure are discussed in §5.4.

### 5.3 Evaluation Metric

For each verb in the input sentence, a change in verb form may be hypothesized. There are five possible outcomes for this hypothesis, as enumerated in Table 4. To penalize “false alarms”, a strict definition is used for false positives — even when the hypothesized correction yields a good sentence, it is still considered a false positive so long as the original sentence is acceptable.

It can sometimes be difficult to determine which words should be considered verbs, as they are not

<sup>4</sup>Obtained by segmenting (Reynar and Ratnaparkhi, 1997) the interviewee turns, and discarding sentences with only one word. The HKUST corpus was processed likewise.

<sup>5</sup>Specifically, those tagged with the “v\_fm1”, “v\_fin” (covering auxiliary agreement and complementation) and “v\_agr” (subject-verb agreement) types; those with semantic errors (see §2.1), i.e. “v\_tns” (tense), are excluded.

<sup>6</sup>Provided by Prof. John Milton, personal communication.

clearly demarcated in our evaluation corpora. We will thus apply the outcomes in Table 4 at the sentence level; that is, the output sentence is considered a true positive only if the original sentence contains errors, and only if valid corrections are offered for all errors.

The following statistics are computed:

**Accuracy** The proportion of sentences which, after being treated by the system, have correct verb forms. That is,  $(true\_neg + true\_pos)$  divided by the total number of sentences.

**Recall** Out of all sentences with verb form errors, the percentage whose errors have been successfully corrected by the system. That is,  $true\_pos$  divided by  $(true\_pos + false\_neg + inv\_pos)$ .

**Detection Precision** This is the first of two types of precision to be reported, and is defined as follows: Out of all sentences for which the system has hypothesized corrections, the percentage that actually contain errors, without regard to the validity of the corrections. That is,  $(true\_pos + inv\_pos)$  divided by  $(true\_pos + inv\_pos + false\_pos)$ .

**Correction Precision** This is the more stringent type of precision. In addition to successfully determining that a correction is needed, the system must offer a valid correction. Formally, it is  $true\_pos$  divided by  $(true\_pos + false\_pos + inv\_pos)$ .

### 5.4 Evaluation Procedure

For the JLE corpus, all figures above will be reported. The HKUST corpus, however, will not be evaluated on subject-verb agreement, since a sizable number of these errors are induced by other changes in the sentence<sup>7</sup>.

Furthermore, the HKUST corpus will require manual evaluation, since the corrections are not annotated. Two native speakers of English were given the edited sentences, as well as the original input. For each pair, they were asked to select one of four statements: one of the two is better, or both are equally correct, or both are equally incorrect. The

<sup>7</sup>e.g., the subject of the verb needs to be changed from singular to plural.

Expected Tree {⟨usage⟩,...}	Tree disturbed by substitution [⟨crr⟩ → ⟨err⟩]
{ING <sub>prog</sub> ,ED <sub>pass</sub> }	<i>A dog is [sleeping→sleep]. I'm [living→live] in XXX city.</i>
<pre> graph TD   VP1[VP] --- be1[be]   VP1 --- VP2[VP]   VP2 --- crr1["crr/{VBG, VBN}"] </pre>	<pre> graph TD   VP3[VP] --- be3[be]   VP3 --- NP3[NP]   NP3 --- err3["err/NN"]   VP4[VP] --- be4[be]   VP4 --- ADJP4[ADJP]   ADJP4 --- err4["err/JJ"] </pre>
{ING <sub>verb</sub> ,INF <sub>verb</sub> }	<i>I like [skiing→ski] very much; She likes to [go→going] around</i>
<pre> graph TD   VP5[VP] --- V5["*/V"]   VP5 --- SG5[SG]   SG5 --- VP6[VP]   VP6 --- crr5["crr/{VBG, TO} ..."] </pre>	<pre> graph TD   VP7[VP] --- V7["*/V"]   VP7 --- NP7[NP]   NP7 --- err7["err/NN"]   VP8[VP] --- V8["*/V"]   VP8 --- PP8[PP]   PP8 --- to8["to/TO"]   PP8 --- SG8[SG]   SG8 --- VP9[VP]   VP9 --- err9["err/VBG"] </pre>
ING <sub>prep</sub>	<i>I lived in France for [studying→study] French language.</i>
<pre> graph TD   PP10[PP] --- IN10["*/IN"]   PP10 --- SG10[SG]   SG10 --- VP11[VP]   VP11 --- crr10["crr/VBG ..."] </pre>	<pre> graph TD   PP12[PP] --- IN12["*/IN"]   PP12 --- NP12[NP]   NP12 --- err12["err/NN"] </pre>

Table 5: Effects of incorrect verb forms on parse trees. The left column shows trees normally expected for the indicated usages (see Table 3). The right column shows the resulting trees when the correct verb form ⟨crr⟩ is replaced by ⟨err⟩. Detailed comments are provided in §6.1.

correction precision is thus the proportion of pairs where the edited sentence is deemed better. Accuracy and recall cannot be computed, since it was impossible to distinguish syntactic errors from semantic ones (see §2).

### 5.5 Baselines

Since the vast majority of verbs are in their correct forms, the *majority baseline* is to propose no correction. Although trivial, it is a surprisingly strong baseline, achieving more than 98% for auxiliary agreement and complementation in JLE, and just shy of 97% for subject-verb agreement.

For auxiliary agreement and complementation, the *verb-only baseline* is also reported. It attempts corrections only when the word in question is actu-

ally tagged as a verb. That is, it ignores the spurious noun- and adjectival phrases in the parse tree discussed in §3.2, and relies only on the output of the part-of-speech tagger.

## 6 Experiments

Corresponding to the issues discussed in §3.2 and §3.3, our experiment consists of two main steps.

### 6.1 Derivation of Tree Patterns

Based on (Quirk et al., 1985), we observed tree patterns for a set of verb form usages, as summarized in Table 3. Using these patterns, we introduced verb form errors into AQUAINT, then re-parsed the corpus (Collins, 1997), and compiled the changes in the “disturbed” trees into a catalog.

<i>N</i> -gram	Example
be {ING <sub>prog</sub> , ED <sub>pass</sub> } *	The dog <i>is sleeping</i> . The door <i>is open</i> .
verb {ING <sub>verb</sub> , INF <sub>verb</sub> } *	I need <i>to do</i> this. I need <i>beef</i> for the curry.
verb <sub>1</sub> *ing and {ING <sub>verb</sub> , INF <sub>verb</sub> }	<i>enjoy</i> reading and <i>going</i> to pachinko <i>go</i> shopping and <i>have</i> dinner
prep {ING <sub>prep</sub> } *	for <i>studying</i> French language a class for <i>sign</i> language
have {ED <sub>perf</sub> } *	I have <i>rented</i> a video I have <i>lunch</i> in Ginza

Table 6: The *n*-grams used for filtering, with examples of sentences which they are intended to differentiate. The hypothesized usages (shown in the curly brackets) as well as the original verb form, are considered. For example, the first sentence is originally “*The dog is \*sleep.*” The three trigrams “*is sleeping .*”, “*is slept .*” and “*is sleep .*” are compared; the first trigram has the highest count, and the correction “*sleeping*” is therefore applied.

A portion of this catalog<sup>8</sup> is shown in Table 5. Comments on {ING<sub>prog</sub>, ED<sub>pass</sub>} can be found in §3.2. Two cases are shown for {ING<sub>verb</sub>, INF<sub>verb</sub>}. In the first case, an *-ing* participle in verb complementation is reduced to its base form, resulting in a noun phrase. In the second, an infinitive is constructed with the *-ing* participle rather than the base form, causing “*to*” to be misconstrued as a preposition. Finally, in ING<sub>prep</sub>, an *-ing* participle in preposition complementation is reduced to its base form, and is subsumed in a noun phrase.

## 6.2 Disambiguation with N-grams

The tree patterns derived from the previous step may be considered as the “necessary” conditions for proposing a change in verb forms. They are not “sufficient”, however, since they tend to be overly general. Indiscriminate application of these patterns on AQUAINT would result in false positives for 46.4% of the sentences.

For those categories with a high rate of false positives (all except BASE<sub>md</sub>, BASE<sub>do</sub> and FINITE), we utilized *n*-grams as filters, allowing a correction only when its *n*-gram count in the WEB 1T 5-GRAM

<sup>8</sup>Due to space constraints, only those trees with significant changes above the leaf level are shown.

Hyp. Usage	False Pos.	Hypothesized Usage	False Pos.
BASE <sub>md</sub>	16.2%	{ING <sub>verb</sub> , INF <sub>verb</sub> }	33.9%
BASE <sub>do</sub>	0.9%	{ING <sub>prog</sub> , ED <sub>pass</sub> }	21.0%
FINITE	12.8%	ING <sub>prep</sub>	13.7%
		ED <sub>perf</sub>	1.4%

Table 7: The distribution of false positives in AQUAINT. The total number of false positives is 994, represents less than 1% of the 100,000 sentences drawn from the corpus.

corpus is greater than that of the original. The filtering step reduced false positives from 46.4% to less than 1%. Table 6 shows the *n*-grams, and Table 7 provides a breakdown of false positives in AQUAINT after *n*-gram filtering.

## 6.3 Results for Subject-Verb Agreement

In JLE, the accuracy of subject-verb agreement error correction is 98.93%. Compared to the majority baseline of 96.95%, the improvement is statistically significant<sup>9</sup>. Recall is 80.92%; detection precision is 83.93%, and correction precision is 81.61%.

Most mistakes are caused by misidentified subjects. Some *wh*-questions prove to be especially difficult, perhaps due to their relative infrequency in newswire texts, on which the parser is trained. One example is the question “*How much extra time does the local train \*takes?*”. The word “*does*” is not recognized as a “do”-support, and so the verb “*take*” was mistakenly turned into a third person form to agree with “*train*”.

## 6.4 Results for Auxiliary Agreement & Complementation

Table 8 summarizes the results for auxiliary agreement and complementation, and Table 2 shows some examples of real sentences corrected by the system. Our proposed method yields 98.94% accuracy. It is a statistically significant improvement over the majority baseline (98.47%), although not significant over the verb-only baseline<sup>10</sup> (98.85%), perhaps a reflection of the small number of test sentences with verb form errors. The Kappa statistic for the man-

<sup>9</sup> $p < 0.005$  according to McNemar’s test.

<sup>10</sup>With  $p = 1 * 10^{-10}$  and  $p = 0.038$ , respectively, according to McNemar’s test

Corpus	Method	Accuracy	Precision (correction)	Precision (detection)	Recall
JLE	verb-only	98.85%	71.43%	84.75%	31.51%
	all	98.94%	68.00%	80.67%	42.86%
HKUST	all	not available	71.71%	not available	

Table 8: Results on the JLE and HKUST corpora for auxiliary agreement and complementation. The majority baseline accuracy is 98.47% for JLE. The verb-only baseline accuracy is 98.85%, as indicated on the second row. “All” denotes the complete proposed method. See §6.4 for detailed comments.

Usage	JLE	HKUST
	Count (Prec.)	Count (Prec.)
BASE <sub>md</sub>	13 (92.3%)	25 (80.0%)
BASE <sub>do</sub>	5 (100%)	0
FINITE	9 (55.6%)	0
ED <sub>perf</sub>	11 (90.9%)	3 (66.7%)
{ING <sub>prog</sub> , ED <sub>pass</sub> }	54 (58.6%)	30 (70.0%)
{ING <sub>verb</sub> , INF <sub>verb</sub> }	45 (60.0%)	16 (59.4%)
ING <sub>prep</sub>	10 (60.0%)	2 (100%)

Table 9: Correction precision of individual correction patterns (see Table 5) on the JLE and HKUST corpus.

ual evaluation of HKUST is 0.76, corresponding to “substantial agreement” between the two evaluators (Landis and Koch, 1977). The correction precisions for the JLE and HKUST corpora are comparable.

Our analysis will focus on {ING<sub>prog</sub>, ED<sub>pass</sub>} and {ING<sub>verb</sub>, INF<sub>verb</sub>}, two categories with relatively numerous correction attempts and low precisions, as shown in Table 9. For {ING<sub>prog</sub>, ED<sub>pass</sub>}, many invalid corrections are due to wrong predictions of voice, which involve semantic choices (see §2.1). For example, the sentence “... the main duty is study well” is edited to “... the main duty is studied well”, a grammatical sentence but semantically unlikely.

For {ING<sub>verb</sub>, INF<sub>verb</sub>}, a substantial portion of the false positives are valid, but unnecessary, corrections. For example, there is no need to turn “I like cooking” into “I like to cook”, as the original is perfectly acceptable. Some kind of confidence measure on the  $n$ -gram counts might be appropriate for reducing such false alarms.

Characteristics of speech transcripts pose some further problems. First, colloquial expressions, such as the word “like”, can be tricky to process. In the

question “Can you like give me the money back”, “like” is misconstrued to be the main verb, and “give” is turned into an infinitive, resulting in “Can you like \*to give me the money back”. Second, there are quite a few incomplete sentences that lack subjects for the verbs. No correction is attempted on them.

Also left uncorrected are misused forms in non-finite clauses that describe a noun. These are typically base forms that should be replaced with *-ing* participles, as in “The girl \*wear a purple skiwear is a student of this ski school”. Efforts to detect this kind of error had resulted in a large number of false alarms.

Recall is further affected by cases where a verb is separated from its auxiliary or main verb by many words, often with conjunctions and other verbs in between. One example is the sentence “I used to climb up the orange trees and \*catching insects”. The word “catching” should be an infinitive complementing “used”, but is placed within a noun phrase together with “trees” and “insects”.

## 7 Conclusion

We have presented a method for correcting verb form errors. We investigated the ways in which verb form errors affect parse trees. When allowed for, these unusual tree patterns can expand correction coverage, but also tend to result in overgeneration of hypothesized corrections.  $N$ -grams have been shown to be an effective filter for this problem.

## 8 Acknowledgments

We thank Prof. John Milton for the HKUST corpus, Tom Lee and Ken Schutte for their assistance with the evaluation, and the anonymous reviewers for their helpful feedback.

## Abstract

In lexicalized grammatical formalisms, it is possible to separate *lexical category assignment* from the combinatory processes that make use of such categories, such as parsing and realization. We adapt techniques from *supertagging* — a relatively recent technique that performs complex lexical tagging before full parsing (Bangalore and Joshi, 1999; Clark, 2002) — for chart realization in OpenCCG, an open-source NLP toolkit for CCG. We call this approach *hypertagging*, as it operates at a level “above” the syntax, tagging semantic representations with syntactic lexical categories. Our results demonstrate that a hypertagger-informed chart realizer can achieve substantial improvements in realization speed (being approximately twice as fast) with superior realization quality.

## 1 Introduction

In lexicalized grammatical formalisms such as Lexicalized Tree Adjoining Grammar (Schabes et al., 1988, LTAG), Combinatory Categorical Grammar (Steedman, 2000, CCG) and Head-Driven Phrase-Structure Grammar (Pollard and Sag, 1994, HPSG), it is possible to separate *lexical category assignment* — the assignment of informative syntactic categories to linguistic objects such as words or lexical predicates — from the combinatory processes that make use of such categories — such as parsing and surface realization. One way of performing lexical assignment is simply to hypothesize all possible lexical categories and then search for the best

combination thereof, as in the CCG parser in (Hockenmaier, 2003) or the chart realizer in (Carroll and Oepen, 2005). A relatively recent technique for lexical category assignment is *supertagging* (Bangalore and Joshi, 1999), a preprocessing step to parsing that assigns likely categories based on word and part-of-speech (POS) contextual information. Supertagging was dubbed “almost parsing” by these authors, because an oracle supertagger left relatively little work for their parser, while speeding up parse times considerably. Supertagging has been more recently extended to a multitagging paradigm in CCG (Clark, 2002; Curran et al., 2006), leading to extremely efficient parsing with state-of-the-art dependency recovery (Clark and Curran, 2007).

We have adapted this multitagging approach to lexical category assignment for realization using the CCG-based natural language toolkit OpenCCG.<sup>1</sup> Instead of basing category assignment on linear word and POS context, however, we predict lexical categories based on contexts within a directed graph structure representing the logical form (LF) of a proposition to be realized. Assigned categories are instantiated in OpenCCG’s chart realizer where, together with a treebank-derived syntactic grammar (Hockenmaier and Steedman, 2007) and a factored language model (Bilmes and Kirchhoff, 2003), they constrain the English word-strings that are chosen to express the LF. We have dubbed this approach *hypertagging*, as it operates at a level “above” the syntax, moving from semantic representations to syntactic categories.

We evaluate this hypertagger in two ways: first,

<sup>1</sup><http://openccg.sourceforge.net>.

we evaluate it as a tagger, where the hypertagger achieves high single-best (93.6%) and multitagging labelling accuracies (95.8–99.4% with category per lexical predication ratios ranging from 1.1 to 3.9).<sup>2</sup> Second, we compare a hypertagger-augmented version of OpenCCG’s chart realizer with the pre-existing chart realizer (White et al., 2007) that simply instantiates the chart with all possible CCG categories (subject to frequency cutoffs) for each input LF predicate. The hypertagger-seeded realizer runs approximately twice as fast as the pre-existing OpenCCG realizer and finds a larger number of complete realizations, resorting less to chart fragment assembly in order to produce an output within a 15 second per-sentence time limit. Moreover, the overall BLEU (Papineni et al., 2002) and METEOR (Lavie and Agarwal, 2007) scores, as well as numbers of exact string matches (as measured against to the original sentences in the CCGbank) are higher for the hypertagger-seeded realizer than for the pre-existing realizer.

This paper is structured as follows: Section 2 provides background on chart realization in OpenCCG using a corpus-derived grammar. Section 3 describes our hypertagging approach and how it is integrated into the realizer. Section 4 describes our results, followed by related work in Section 5 and our conclusions in Section 6.

## 2 Background

### 2.1 Surface Realization with OpenCCG

The OpenCCG surface realizer is based on Steedman’s (2000) version of CCG elaborated with Baldrige and Kruijff’s multi-modal extensions for lexically specified derivation control (Baldrige, 2002; Baldrige and Kruijff, 2003) and hybrid logic dependency semantics (Baldrige and Kruijff, 2002). OpenCCG implements a symbolic-statistical chart realization algorithm (Kay, 1996; Carroll et al., 1999; White, 2006b) combining (1) a theoretically grounded approach to syntax and semantic composition with (2) factored language models (Bilmes and Kirchhoff, 2003) for making choices among the options left open by the grammar.

In OpenCCG, the search for complete realizations

<sup>2</sup>Note that the multitagger is “correct” if the correct tag is anywhere in the multitag set.

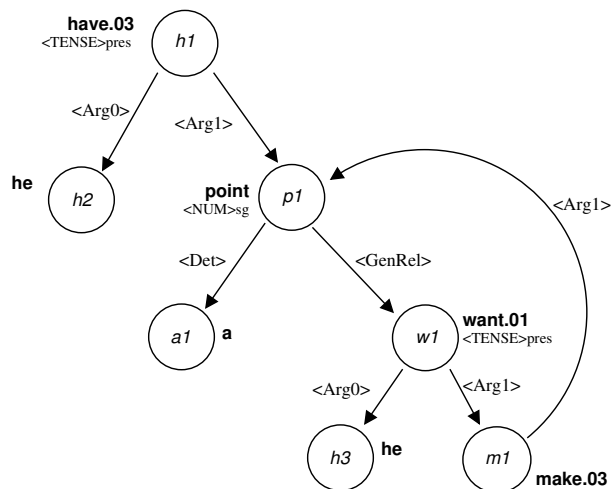

Figure 1: Semantic dependency graph from the CCGbank for *He has a point he wants to make [...]*

makes use of  $n$ -gram language models over words represented as vectors of factors, including surface form, part of speech, supertag and semantic class. The search proceeds in one of two modes, *anytime* or *two-stage* (packing/unpacking). In the anytime mode, a best-first search is performed with a configurable time limit: the scores assigned by the  $n$ -gram model determine the order of the edges on the agenda, and thus have an impact on realization speed. In the two-stage mode, a packed forest of all possible realizations is created in the first stage; in the second stage, the packed representation is unpacked in bottom-up fashion, with scores assigned to the edge for each sign as it is unpacked, much as in (Langkilde, 2000). Edges are grouped into equivalence classes when they have the same syntactic category and cover the same parts of the input logical form. Pruning takes place within equivalence classes of edges. Additionally, to realize a wide range of paraphrases, OpenCCG implements an algorithm for efficiently generating from disjunctive logical forms (White, 2006a).

To illustrate the input to OpenCCG, consider the semantic dependency graph in Figure 1, which is taken from section 00 of a Propbank-enhanced version of the CCGbank (Boxwell and White, 2008). In the graph, each node has a lexical predication (e.g. **make.03**) and a set of semantic features (e.g.  $\langle \text{NUM} \rangle \text{sg}$ ); nodes are connected via dependency relations (e.g.  $\langle \text{ARG0} \rangle$ ). Internally, such

graphs are represented using Hybrid Logic Dependency Semantics (HLDS), a dependency-based approach to representing linguistic meaning developed by Baldridge and Kruijff (2002). In HLDS, hybrid logic (Blackburn, 2000) terms are used to describe dependency graphs. These graphs have been suggested as representations for discourse structure, and have their own underlying semantics (White, 2006b).

To more robustly support broad coverage surface realization, OpenCCG has recently been enhanced to greedily assemble fragments in the event that the realizer fails to find a complete realization. The fragment assembly algorithm begins with the edge for the best partial realization, i.e. the one that covers the most elementary predications in the input logical form, with ties broken according to the n-gram score. (Larger fragments are preferred under the assumption that they are more likely to be grammatical.) Next, the chart and agenda are greedily searched for the best edge whose semantic coverage is disjoint from those selected so far; this process repeats until no further edges can be added to the set of selected fragments. In the final step, these fragments are concatenated, again in a greedy fashion, this time according to the n-gram score of the concatenated edges: starting with the original best edge, the fragment whose concatenation on the left or right side yields the highest score is chosen as the one to concatenate next, until all the fragments have been concatenated into a single output.

## 2.2 Realization from an Enhanced CCGbank

White et al. (2007) describe an ongoing effort to engineer a grammar from the CCGbank (Hockenmaier and Steedman, 2007) — a corpus of CCG derivations derived from the Penn Treebank — suitable for realization with OpenCCG. This process involves converting the corpus to reflect more precise analyses, where feasible, and adding semantic representations to the lexical categories. In the first step, the derivations in the CCGbank are revised to reflect the desired syntactic derivations. Changes to the derivations are necessary to reflect the lexicalized treatment of coordination and punctuation assumed by the multi-modal version of CCG that is implemented in OpenCCG. Further changes are necessary to support semantic dependencies rather than surface syn-

tactic ones; in particular, the features and unification constraints in the categories related to semantically empty function words such complementizers, infinitival-*to*, expletive subjects, and case-marking prepositions are adjusted to reflect their purely syntactic status.

In the second step, a grammar is extracted from the converted CCGbank and augmented with logical forms. Categories and unary type changing rules (corresponding to zero morphemes) are sorted by frequency and extracted if they meet the specified frequency thresholds.

A separate transformation then uses around two dozen generalized templates to add logical forms to the categories, in a fashion reminiscent of (Bos, 2005). The effect of this transformation is illustrated below. Example (1) shows how numbered semantic roles, taken from PropBank (Palmer et al., 2005) when available, are added to the category of an active voice, past tense transitive verb, where **\*pred\*** is a placeholder for the lexical predicate; examples (2) and (3) show how more specific relations are introduced in the category for determiners and the category for the possessive 's, respectively.

- (1)  $s_{1:dcl} \setminus np_2 / np_3 \implies$   
 $s_{1:dcl,x1} \setminus np_{2:x2} / np_{3:x3} : @_{x1}(*pred* \wedge$   
 $\langle TENSE \rangle pres \wedge \langle ARG0 \rangle x2 \wedge \langle ARG1 \rangle x3)$
- (2)  $np_1 / n_1 \implies$   
 $np_{1:x1} / n_{1:x1} : @_{x1}(\langle DET \rangle (d \wedge *pred*))$
- (3)  $np_1 / n_1 \setminus np_2 \implies$   
 $np_{1:x1} / n_{1:x1} \setminus np_{2:x2} : @_{x1}(\langle GENOWN \rangle x2)$

After logical form insertion, the extracted and augmented grammar is loaded and used to parse the sentences in the CCGbank according to the gold-standard derivation. If the derivation can be successfully followed, the parse yields a logical form which is saved along with the corpus sentence in order to later test the realizer. The algorithm for following corpus derivations attempts to continue processing if it encounters a blocked derivation due to sentence-internal punctuation. While punctuation has been partially reanalyzed to use lexical categories, many problem cases remain due to the CCGbank's reliance on punctuation-specific binary rules that are not supported in OpenCCG.

Currently, the algorithm succeeds in creating logical forms for 97.7% of the sentences in the development section (Sect. 00) of the converted CCGbank, and 96.1% of the sentences in the test section (Sect. 23). Of these, 76.6% of the development logical forms are semantic dependency graphs with a single root, while 76.7% of the test logical forms have a single root. The remaining cases, with multiple roots, are missing one or more dependencies required to form a fully connected graph. These missing dependencies usually reflect inadequacies in the current logical form templates.

### 2.3 Factored Language Models

Following White et al. (2007), we use factored trigram models over words, part-of-speech tags and supertags to score partial and complete realizations. The language models were created using the SRILM toolkit (Stolcke, 2002) on the standard training sections (2–21) of the CCGbank, with sentence-initial words (other than proper names) uncapitalized. While these models are considerably smaller than the ones used in (Langkilde-Geary, 2002; Veldal and Oepen, 2005), the training data does have the advantage of being in the same domain and genre (using larger n-gram models remains for future investigation). The models employ interpolated Kneser-Ney smoothing with the default frequency cutoffs. The best performing model interpolates a word trigram model with a trigram model that chains a POS model with a supertag model, where the POS model conditions on the previous two POS tags, and the supertag model conditions on the previous two POS tags as well as the current one.

Note that the use of supertags in the factored language model to score possible realizations is distinct from the prediction of supertags for lexical category assignment: the former takes the words in the local context into account (as in supertagging for parsing), while the latter takes features of the logical form into account. It is this latter process which we call hyper-tagging, and to which we now turn.

## 3 The Approach

### 3.1 Lexical Smoothing and Search Errors

In White et al.’s (2007) initial investigation of scaling up OpenCCG for broad coverage realization,

test set	grammar	complete oracle / best
dev (00)	dev	49.1% / 47.8%
	train	37.5% / 22.6%

Table 1: Percentage of complete realizations using an oracle n-gram model versus the best performing factored language model.

all categories observed more often than a threshold frequency were instantiated for lexical predicates; for unseen words, a simple smoothing strategy based on the part of speech was employed, assigning the most frequent categories for the POS. This approach turned out to suffer from a large number of search errors, where the realizer failed to find a complete realization before timing out even in cases where the grammar supported one. To confirm that search errors had become a significant issue, White et al. compared the percentage of complete realizations (versus fragmentary ones) with their top scoring model against an oracle model that uses a simplified BLEU score based on the target string, which is useful for regression testing as it guides the best-first search to the reference sentence. The comparison involved both a medium-sized (non-blind) grammar derived from the development section and a large grammar derived from the training sections (the latter with slightly higher thresholds). As shown in Table 1, with the large grammar derived from the training sections, many fewer complete realizations are found (before timing out) using the factored language model than are possible, as indicated by the results of using the oracle model. By contrast, the difference is small with the medium-sized grammar derived from the development section. This result is not surprising when one considers that a large number of common words are observed to have many possible categories.

In the next section, we show that a supertagger for CCG realization, or hypertagger, can reduce the problem of search errors by focusing the search space on the most likely lexical categories.

### 3.2 Maximum Entropy Hypertagging

As supertagging for parsing involves studying a given input word and its local context, the concep-

tual equivalent for a lexical predicate in the LF is to study a given node and its local graph structure. Our implementation makes use of three general types of features: lexicalized features, which are simply the names of the parent and child elementary predication nodes, graph structural features, such as the total number of edges emanating from a node, the number of argument and non-argument dependents, and the names of the relations of the dependent nodes to the parent node, and syntactico-semantic attributes of nodes, such as the tense and number. For example, in the HLDS graph shown in Figure 1, the node representing *want* has two dependents, and the relational type of *make* with respect to *want* is ARG1.

Clark (2002) notes in his parsing experiments that the POS tags of the surrounding words are highly informative. As discussed below, a significant gain in hypertagging accuracy resulted from including features sensitive to the POS tags of a node’s parent, the node itself, and all of its arguments and modifiers. Predicting these tags requires the use of a separate POS tagger, which operates in a manner similar to the hypertagger itself, though exploiting a slightly different set of features (e.g., including features corresponding to the four-character prefixes and suffixes of rare logical predication names). Following the (word) supertagging experiments of (Curran et al., 2006) we assigned potentially multiple POS tags to each elementary predication. The POS tags assigned are all those that are some factor  $\beta$  of the highest ranked tag,<sup>3</sup> giving an average of 1.1 POS tags per elementary predication. The values of the corresponding feature functions are the POS tag probabilities according to the POS tagger. At this ambiguity level, the POS tagger is correct  $\approx 92\%$  of the time.

Features for the hypertagger were extracted from semantic dependency graphs extracted from sections 2 through 21 of the CCGbank. In total, 37,168 dependency graphs were derived from the corpus, yielding 468,628 feature parameters.

The resulting contextual features and gold-standard supertag for each predication were then used to train a maximum entropy classifier model.

<sup>3</sup>I.e., all tags  $t$  whose probabilities  $p(t) \geq \beta \cdot p^*$ , where  $p^*$  is the highest ranked tag’s probability.

Maximum entropy models describe a set of probability distributions of the form:

$$p(o | x) = \frac{1}{Z(x)} \cdot \exp\left(\sum_{i=1}^n \lambda_i f_i(o, x)\right)$$

where  $o$  is an outcome,  $x$  is a context, the  $f_i$  are feature functions, the  $\lambda_i$  are the respective weights of the feature functions, and  $Z(x)$  is a normalizing sum over all competing outcomes. More concretely, given an elementary predication labeled *want* (as in Figure 1), a feature function over this node could be:

$$f(o, x) = \begin{cases} 1, & \text{if } o \text{ is } (s[\text{dcl}]\backslash\text{np})/(s[\text{adj}]\backslash\text{np}) \text{ and} \\ & \text{number\_of\_LF\_dependents}(x) = 2 \\ 0, & \text{otherwise.} \end{cases}$$

We used Zhang Le’s maximum entropy toolkit<sup>4</sup> for training the hypertagging model, which uses an implementation of Limited-memory BFGS, an approximate quasi-Newton optimization method from the numerical optimization literature (Liu and Nocedal, 1989). Using L-BFGS allowed us to include continuous feature function values where appropriate (e.g., the probabilities of automatically-assigned POS tags). We trained each hypertagging model to 275 iterations and our POS tagging model to 400 iterations. We used no feature frequency cut-offs, but rather employed Gaussian priors with global variances of 100 and 75, respectively, for the hypertagging and POS tagging models.

### 3.3 Iterative $\beta$ -Best Realization

During realization, the hypertagger serves to probabilistically filter the categories assigned to an elementary predication, as well as to propose categories for rare or unseen predicates. Given a predication, the tagger returns a  $\beta$ -best list of supertags in order of decreasing probability. Increasing the number of categories returned clearly increases the likelihood that the most-correct supertag is among them, but at a corresponding cost in chart size. Accordingly, the hypertagger begins with a highly restrictive value for  $\beta$ , and backs off to progressively less-restrictive values if no complete realization could be found using the set of supertags returned. The search is restarted

<sup>4</sup>[http://homepages.inf.ed.ac.uk/s0450736/maxent\\_toolkit.html](http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html).

Table 2: Hypertagger accuracy on Sections 00 and 23. Results (in percentages) are for per-logical-predication (PR) and per-whole-graph (GRPH) tagging accuracies. Difference between best-only and baselines (b.l.) is significant ( $p < 2 \cdot 10^{-16}$ ) by McNemar’s  $\chi^2$  test.

$\beta$	Tags Pred	Sect00		Sect23	
		PR	GRPH	PR	GRPH
b.l. 1	1	68.7	1.8	68.7	2.3
b.l. 2	2	84.3	9.9	84.4	10.9
1.0	1	93.6	40.4	93.6	38.2
0.16	1.1	95.8	55.7	96.2	56.8
0.05	1.2	96.6	63.8	97.3	66.0
0.0058	1.5	97.9	74.8	98.3	76.9
1.75e-3	1.8	98.4	78.9	98.7	81.8
6.25e-4	2.2	98.7	82.5	99.0	84.3
1.25e-4	3.2	99.0	85.7	99.3	88.5
5.8e-5	3.9	99.1	87.2	99.4	89.9

from scratch with the next  $\beta$  value, though in principle the same chart could be expanded. The iterative,  $\beta$ -best search for a complete realization uses the realizer’s packing mode, which can more quickly determine whether a complete realization is possible. If the halfway point of the overall time limit is reached with no complete realization, the search switches to best-first mode, ultimately assembling fragments if no complete realization can be found during the remaining time.

## 4 Results and Discussion

Several experiments were performed in training and applying the hypertagger. Three different models were created using 1) non-lexicalized features only, 2) all features excluding POS tags, 3) all, 3) all features except syntactico-semantic attributes such as tense and number and 4) all features available. Models trained on these feature subsets were tested against one another on Section 00, and then the best performing model was run on both Section 00 and 23.

### 4.1 Feature Ablation Testing

The the whole feature set was found in feature ablation testing on the development set to outperform all other feature subsets significantly ( $p < 2.2 \cdot 10^{-16}$ ). These results listed in Table 3. As we can see, taking

Table 3: Hypertagger feature ablation testing results on Section 00. The full feature set outperforms all others significantly ( $p < 2.2 \cdot 10^{-16}$ ). Results for per-predication (PR) and per-whole-graph (GRPH) tagging percentage accuracies are listed. (**Key:** **no-POS**=no POS features; **no-attr**=no syntactico-semantic attributes such as tense and number; **non-lex**=non-lexicalized features only (no predication names).

FEATURESET	PR	GRPH
full	93.6	40.37
no-POS	91.3	29.5
no-attr	91.8	31.2
non-lex	91.5	28.7

away any one class of features leads to drop in per-predication tagging accuracy of at least 1.8% and a drop per-whole-graph accuracy of at least 9.2%. As expected from previous work in supertagging (for parsing), POS features resulted in a large improvement in overall accuracy (1.8%). Although the POS tagger by itself is only 92% accurate (as a multi-tagger of 1.1  $\frac{POS}{word}$  average ambiguity) — well below the state-of-the-art for the tagging of words — its predictions are still quite valuable to the hypertagger.

### 4.2 Best Model Hypertagger Accuracy

The results for the full feature set on Sections 00 and 23 are outlined in Table 2. Included in this table are accuracy data for a baseline dummy tagger which simply assigns the most-frequently-seen tag(s) for a given predication and backs off to the overall most frequent tag(s) when confronted with an unseen predication. The development set (00) was used to tune the  $\beta$  parameter to obtain reasonable hypertag ambiguity levels; the model was not otherwise tuned to it. The hypertagger achieves high per-predication and whole-graph accuracies even at small ambiguity levels.

### 4.3 Realizer Performance

Tables 4 and 5 show how the hypertagger improves realization performance on the development and test sections of the CCGbank. As Table 4 indicates, using the hypertagger in an iterative beta-best fashion more than doubles the number of grammatically complete realizations found within the time

Table 5: Realization quality metrics exact match, BLEU and METEOR, on complete realizations only and overall, with and without hypertagger, on Sections 00 and 23.

Section	Hypertagger	Complete		Overall		
		BLEU	METEOR	Exact	BLEU	METEOR
00	with	0.8137	0.9153	15.3%	0.6567	0.8494
	w/o	0.6864	0.8585	11.3%	0.5902	0.8209
23	with	<b>0.8149</b>	0.9162	16.0%	<b>0.6701</b>	0.8557
	w/o	0.6910	0.8606	12.3%	0.6022	0.8273

Table 4: Percentage of grammatically complete realizations, runtimes for complete realizations and overall runtimes, with and without hypertagger, on Sections 00 and 23.

Section	Hypertagger	Percent Complete	Complete Time	Overall Time
00	with	47.4%	1.2s	4.5s
	w/o	22.6%	8.7s	9.5s
23	with	48.5%	<b>1.2s</b>	<b>4.4s</b>
	w/o	23.5%	8.9s	9.6s

limit; on the development set, this improvement eliminates more than the number of known search errors (cf. Table 1). Additionally, by reducing the search space, the hypertagger cuts overall realization times by more than half, and in the cases where complete realizations are found, realization times are reduced by a factor of four, down to 1.2 seconds per sentence on a desktop Linux PC.

Table 5 shows that increasing the number of complete realizations also yields improved BLEU and METEOR scores, as well as more exact matches. In particular, the hypertagger makes possible a more than 6-point improvement in the overall BLEU score on both the development and test sections, and a more than 12-point improvement on the sentences with complete realizations.

As the effort to engineer a grammar suitable for realization from the CCGbank proceeds in parallel to our work on hypertagging, we expect the hypertagger-seeded realizer to continue to improve, since a more complete and precise extracted grammar should enable more complete realizations to be found, and richer semantic representations should

simplify the hypertagging task. Even with the current incomplete set of semantic templates, the hypertagger brings realizer performance roughly up to state-of-the-art levels, as our overall test set BLEU score (0.6701) slightly exceeds that of Cahill and van Genabith (2006), though at a coverage of 96% instead of 98%. We caution, however, that it remains unclear how meaningful it is to directly compare these scores when the realizer inputs vary considerably in their specificity, as Langkilde-Geary’s (2002) experiments dramatically illustrate.

## 5 Related Work

Our approach follows Langkilde-Geary (2002) and Callaway (2003) in aiming to leverage the Penn Treebank to develop a broad-coverage surface realizer for English. However, while these earlier, generation-only approaches made use of converters for transforming the outputs of Treebank parsers to inputs for realization, our approach instead employs a shared bidirectional grammar, so that the input to realization is guaranteed to be the same logical form constructed by the parser. In this regard, our approach is more similar to the ones pursued more recently by Carroll, Oepen and Velldal (2005; 2005; 2006), Nakanishi et al. (2005) and Cahill and van Genabith (2006) with HPSG and LFG grammars.

While we consider our approach to be the first to employ a supertagger for realization, or hypertagger, the approach is clearly reminiscent of the LTAG tree models of Srinivas and Rambow (2000). The main difference between the approaches is that ours consists of a multitagging step followed by the bottom-up construction of a realization chart, while theirs involves the top-down selection of the single most likely supertag for each node that is grammatically

compatible with the parent node, with the probability conditioned only on the child nodes. Note that although their approach does involve a subsequent lattice construction step, it requires making non-standard assumptions about the TAG; in contrast, ours follows the chart realization tradition of working with the same operations of grammatical combination as in parsing, including a well-defined notion of semantic composition. Additionally, as our tagger employs maximum entropy modeling, it is able to take into account a greater variety of contextual features, including those derived from parent nodes.

In comparison to other recent chart realization approaches, Nakanishi et al.'s is similar to ours in that it employs an iterative beam search, dynamically changing the beam size in order to cope with the large search space. However, their log-linear selection models have been adapted from ones used in parsing, and do not condition choices based on features of the input semantics to the same extent. In particular, while they employ a baseline maximum likelihood model that conditions the probability of a lexical entry upon its predicate argument structure (PAS) — that is, the set of elementary predications introduced by the lexical item — this probability does not take into account other elements of the local context, including parents and modifiers, and their lexical predicates. Similarly, Cahill and van Genabith condition the probability of their lexical rules on the set of feature-value pairs linked to the RHS of the rule, but do not take into account any additional context. Since their probabilistic models involve independence assumptions like those in a PCFG, and since they do not employ n-grams for scoring alternative realizations, their approach only keeps the single most likely edge in an equivalence class, rather than packing them into a forest. Carroll, Oepen and Velldal's approach is like Nakanishi et al.'s in that they adapt log-linear parsing models to the realization task; however, they employ manually written grammars on much smaller corpora, and perhaps for this reason they have not faced the need to employ an iterative beam search.

## 6 Conclusion

We have introduced a novel type of supertagger, which we have dubbed a *hypertagger*, that assigns CCG category labels to elementary predications in a structured semantic representation with high accuracy at several levels of tagging ambiguity in a fashion reminiscent of (Bangalore and Rambow, 2000). To our knowledge, we are the first to report tagging results in the semantic-to-syntactic direction. We have also shown that, by integrating this hypertagger with a broad-coverage CCG chart realizer, considerably faster realization times are possible (approximately twice as fast as compared with a realizer that performs simple lexical look-ups) with higher BLEU, METEOR and exact string match scores. Moreover, the hypertagger-augmented realizer finds more than twice the number of complete realizations, and further analysis revealed that the realization quality (as *per* modified BLEU and METEOR) is higher in the cases when the realizer finds a complete realization. This suggests that further improvements to the hypertagger will lead to more complete realizations, hence more high-quality realizations. Finally, further efforts to engineer a grammar suitable for realization from the CCGbank should provide richer feature sets, which, as our feature ablation study suggests, are useful for boosting hypertagging performance, hence for finding better and more complete realizations.

## Abstract

Among syntax-based translation models, the *tree-based* approach, which takes as input a parse tree of the source sentence, is a promising direction being faster and simpler than its string-based counterpart. However, current tree-based systems suffer from a major drawback: they only use the 1-best parse to direct the translation, which potentially introduces translation mistakes due to parsing errors. We propose a *forest-based* approach that translates a packed forest of exponentially many parses, which encodes many more alternatives than standard  $n$ -best lists. Large-scale experiments show an absolute improvement of 1.7 BLEU points over the 1-best baseline. This result is also 0.8 points higher than decoding with 30-best parses, and takes even less time.

## 1 Introduction

Syntax-based machine translation has witnessed promising improvements in recent years. Depending on the type of input, these efforts can be divided into two broad categories: the *string-based* systems whose input is a string to be simultaneously parsed and translated by a synchronous grammar (Wu, 1997; Chiang, 2005; Galley et al., 2006), and the *tree-based* systems whose input is already a parse tree to be directly converted into a target tree or string (Lin, 2004; Ding and Palmer, 2005; Quirk et al., 2005; Liu et al., 2006; Huang et al., 2006). Compared with their string-based counterparts, tree-based systems offer some attractive features: they are much faster in decoding (linear time vs. cubic

time, see (Huang et al., 2006)), do not require a binary-branching grammar as in string-based models (Zhang et al., 2006), and can have separate grammars for parsing and translation, say, a context-free grammar for the former and a tree substitution grammar for the latter (Huang et al., 2006). However, despite these advantages, current tree-based systems suffer from a major drawback: they only use the 1-best parse tree to direct the translation, which potentially introduces translation mistakes due to parsing errors (Quirk and Corston-Oliver, 2006). This situation becomes worse with resource-poor source languages without enough Treebank data to train a high-accuracy parser.

One obvious solution to this problem is to take as input  $k$ -best parses, instead of a single tree. This  $k$ -best list postpones some disambiguation to the decoder, which may recover from parsing errors by getting a better translation from a non 1-best parse. However, a  $k$ -best list, with its limited scope, often has too few variations and too many redundancies; for example, a 50-best list typically encodes a combination of 5 or 6 binary ambiguities (since  $2^5 < 50 < 2^6$ ), and many subtrees are repeated across different parses (Huang, 2008). It is thus inefficient either to decode separately with each of these very similar trees. Longer sentences will also aggravate this situation as the number of parses grows exponentially with the sentence length.

We instead propose a new approach, *forest-based translation* (Section 3), where the decoder translates a *packed forest* of exponentially many parses,<sup>1</sup>

<sup>1</sup>There has been some confusion in the MT literature regarding the term *forest*: the word “forest” in “forest-to-string rules”

Figure 1: An example translation rule ( $r_3$  in Fig. 2).

which compactly encodes many more alternatives than  $k$ -best parses. This scheme can be seen as a compromise between the string-based and tree-based methods, while combining the advantages of both: decoding is still fast, yet does not commit to a single parse. Large-scale experiments (Section 4) show an improvement of 1.7 BLEU points over the 1-best baseline, which is also 0.8 points higher than decoding with 30-best trees, and takes even less time thanks to the sharing of common subtrees.

## 2 Tree-based systems

Current *tree-based* systems perform translation in two separate steps: parsing and decoding. A parser first parses the source language input into a 1-best tree  $T$ , and the decoder then searches for the best *derivation* (a sequence of translation steps)  $d^*$  that converts source tree  $T$  into a target-language string among all possible derivations  $D$ :

$$d^* = \arg \max_{d \in D} P(d|T). \quad (1)$$

We will now proceed with a running example translating from Chinese to English:

- (2) 布什 与 沙龙 举行了 会谈  
*Bùshí yǔ Shānlóng jǔxíng le huìtán*  
 Bush with/and Sharon<sub>1</sub> hold *pass.* talk<sub>2</sub>  
 “Bush held a talk<sub>2</sub> with Sharon<sub>1</sub>”

Figure 2 shows how this process works. The Chinese sentence (a) is first parsed into tree (b), which will be converted into an English string in 5 steps. First, at the root node, we apply rule  $r_1$  preserving top-level word-order between English and Chinese,

$$(r_1) \text{ IP}(x_1:\text{NPB } x_2:\text{VP}) \rightarrow x_1 x_2$$

(Liu et al., 2007) was a misnomer which actually refers to a set of several unrelated subtrees over disjoint spans, and should not be confused with the standard concept of *packed forest*.

Figure 2: An example derivation of tree-to-string translation. Shaded regions denote parts of the tree that is pattern-matched with the rule being applied.

which results in two unfinished subtrees in (c). Then rule  $r_2$  grabs the *Bùshí* subtree and transliterate it

$$(r_2) \text{ NPB}(\text{NR}(\text{Bùshí})) \rightarrow \text{Bush.}$$

Similarly, rule  $r_3$  shown in Figure 1 is applied to the VP subtree, which swaps the two NPBs, yielding the situation in (d). This rule is particularly interesting since it has multiple levels on the source side, which has more expressive power than synchronous context-free grammars where rules are flat.

More formally, a (tree-to-string) **translation rule** (Huang et al., 2006) is a tuple  $\langle t, s, \phi \rangle$ , where  $t$  is the source-side tree, whose internal nodes are labeled by nonterminal symbols in  $N$ , and whose frontier nodes are labeled by source-side terminals in  $\Sigma$  or variables from a set  $\mathcal{X} = \{x_1, x_2, \dots\}$ ;  $s \in (\mathcal{X} \cup \Delta)^*$  is the target-side string where  $\Delta$  is the target language terminal set; and  $\phi$  is a mapping from  $\mathcal{X}$  to nonterminals in  $N$ . Each variable  $x_i \in \mathcal{X}$  occurs *exactly once* in  $t$  and *exactly once* in  $s$ . We denote  $\mathcal{R}$  to be the translation rule set. A similar formalism appears in another form in (Liu et al., 2006). These rules are in the reverse direction of the original string-to-tree transducer rules defined by Galley et al. (2004).

Finally, from step (d) we apply rules  $r_4$  and  $r_5$

( $r_4$ )  $\text{NPB}(\text{NN}(\text{huitán})) \rightarrow \text{a talk}$

( $r_5$ )  $\text{NPB}(\text{NR}(\text{Shālong})) \rightarrow \text{Sharon}$

which perform phrasal translations for the two remaining subtrees, respectively, and get the Chinese translation in (e).

### 3 Forest-based translation

We now extend the tree-based idea from the previous section to the case of forest-based translation. Again, there are two steps, parsing and decoding. In the former, a (modified) parser will parse the input sentence and output a packed forest (Section 3.1) rather than just the 1-best tree. Such a forest is usually huge in size, so we use the *forest pruning algorithm* (Section 3.4) to reduce it to a reasonable size. The pruned parse forest will then be used to direct the translation.

In the decoding step, we first convert the parse forest into a *translation forest* using the translation rule set, by similar techniques of pattern-matching from tree-based decoding (Section 3.2). Then the decoder searches for the best derivation on the translation forest and outputs the target string (Section 3.3).

#### 3.1 Parse Forest

Informally, a packed parse forest, or *forest* in short, is a compact representation of all the derivations (i.e., parse trees) for a given sentence under a context-free grammar (Billot and Lang, 1989). For

example, consider the Chinese sentence in Example (2) above, which has (at least) two readings depending on the part-of-speech of the word  $yǐ$ , which can be either a preposition (P “with”) or a conjunction (CC “and”). The parse tree for the preposition case is shown in Figure 2(b) as the 1-best parse, while for the conjunction case, the two proper nouns (*Bùshí* and *Shālong*) are combined to form a coordinated NP

$$\frac{\text{NPB}_{0,1} \quad \text{CC}_{1,2} \quad \text{NPB}_{2,3}}{\text{NP}_{0,3}} \quad (*)$$

which functions as the subject of the sentence. In this case the Chinese sentence is translated into

(3) “[Bush and Sharon] held a talk”.

Shown in Figure 3(a), these two parse trees can be represented as a single forest by sharing common subtrees such as  $\text{NPB}_{0,1}$  and  $\text{VPB}_{3,6}$ . Such a forest has a structure of a *hypergraph* (Klein and Manning, 2001; Huang and Chiang, 2005), where items like  $\text{NP}_{0,3}$  are called *nodes*, and deductive steps like (\*) correspond to *hyperedges*.

More formally, a **forest** is a pair  $\langle V, E \rangle$ , where  $V$  is the set of **nodes**, and  $E$  the set of **hyperedges**. For a given sentence  $w_{1:l} = w_1 \dots w_l$ , each node  $v \in V$  is in the form of  $X_{i,j}$ , which denotes the recognition of nonterminal  $X$  spanning the substring from positions  $i$  through  $j$  (that is,  $w_{i+1} \dots w_j$ ). Each hyperedge  $e \in E$  is a pair  $\langle \text{tails}(e), \text{head}(e) \rangle$ , where  $\text{head}(e) \in V$  is the *consequent node* in the deductive step, and  $\text{tails}(e) \in V^*$  is the list of *antecedent nodes*. For example, the hyperedge for deduction (\*) is notated:

$$\langle (\text{NPB}_{0,1}, \text{CC}_{1,2}, \text{NPB}_{2,3}), \text{NP}_{0,3} \rangle.$$

There is also a distinguished **root node** TOP in each forest, denoting the goal item in parsing, which is simply  $S_{0,l}$  where  $S$  is the start symbol and  $l$  is the sentence length.

#### 3.2 Translation Forest

Given a parse forest and a translation rule set  $\mathcal{R}$ , we can generate a *translation forest* which has a similar hypergraph structure. Basically, just as the depth-first traversal procedure in tree-based decoding (Figure 2), we visit in top-down order each node  $v$  in the

Figure 3: (a) the parse forest of the example sentence; solid hyperedges denote the 1-best parse in Figure 2(b) while dashed hyperedges denote the alternative parse due to Deduction (\*). (b) the corresponding translation forest after applying the translation rules (lexical rules not shown); the derivation shown in bold solid lines ( $e_1$  and  $e_3$ ) corresponds to the derivation in Figure 2; the one shown in dashed lines ( $e_2$ ,  $e_5$ , and  $e_6$ ) uses the alternative parse and corresponds to the translation in Example (3). (c) the correspondence between translation hyperedges and translation rules.

parse forest, and try to pattern-match each translation rule  $r$  against the local sub-forest under node  $v$ . For example, in Figure 3(a), at node  $VP_{1,6}$ , two rules  $r_3$  and  $r_7$  both matches the local subforest, and will thus generate two *translation hyperedges*  $e_3$  and  $e_4$  (see Figure 3(b-c)).

More formally, we define a function  $match(r, v)$  which attempts to pattern-match rule  $r$  at node  $v$  in the parse forest, and in case of success, returns a list of descendent nodes of  $v$  that are matched to the variables in  $r$ , or returns an empty list if the match fails. Note that this procedure is recursive and may

---

**Pseudocode 1** The conversion algorithm.

---

```
1: Input: parse forest  $H_p$  and rule set  $\mathcal{R}$ 
2: Output: translation forest  $H_t$ 
3: for each node  $v \in V_p$  in top-down order do
4:   for each translation rule  $r \in \mathcal{R}$  do
5:      $vars \leftarrow match(r, v)$   $\triangleright$  variables
6:     if  $vars$  is not empty then
7:        $e \leftarrow \langle vars, v, s(r) \rangle$ 
8:       add translation hyperedge  $e$  to  $H_t$ 
```

---

involve multiple parse hyperedges. For example,

$$match(r_3, VP_{1,6}) = (NPB_{2,3}, NPB_{5,6}),$$

which covers three parse hyperedges, while nodes in gray do not pattern-match any rule (although they are involved in the matching of other nodes, where they match *interior nodes* of the source-side tree fragments in a rule). We can thus construct a translation hyperedge from  $match(r, v)$  to  $v$  for each node  $v$  and rule  $r$ . In addition, we also need to keep track of the *target string*  $s(r)$  specified by rule  $r$ , which includes target-language terminals and variables. For example,  $s(r_3) = \text{“held } x_2 \text{ with } x_1\text{”}$ . The subtranslations of the matched variable nodes will be substituted for the variables in  $s(r)$  to get a complete translation for node  $v$ . So a translation hyperedge  $e$  is a triple  $\langle tails(e), head(e), s \rangle$  where  $s$  is the target string from the rule, for example,

$$e_3 = \langle (NPB_{2,3}, NPB_{5,6}), VP_{1,6}, \text{“held } x_2 \text{ with } x_1\text{”} \rangle.$$

This procedure is summarized in Pseudocode 1.

### 3.3 Decoding Algorithms

The decoder performs two tasks on the translation forest: 1-best search with integrated language model (LM), and  $k$ -best search with LM to be used in minimum error rate training. Both tasks can be done efficiently by forest-based algorithms based on  $k$ -best parsing (Huang and Chiang, 2005).

For 1-best search, we use the *cube pruning* technique (Chiang, 2007; Huang and Chiang, 2007) which approximately intersects the translation forest with the LM. Basically, cube pruning works bottom up in a forest, keeping at most  $k$  +LM items at each node, and uses the best-first expansion idea from the Algorithm 2 of Huang and Chiang (2005) to speed

up the computation. An +LM item of node  $v$  has the form  $(v^{a*b})$ , where  $a$  and  $b$  are the target-language *boundary words*. For example,  $(VP_{1,6}^{\text{held } * \text{Sharon}})$  is an +LM item with its translation starting with “held” and ending with “Sharon”. This scheme can be easily extended to work with a general  $n$ -gram by storing  $n - 1$  words at both ends (Chiang, 2007).

For  $k$ -best search after getting 1-best derivation, we use the lazy Algorithm 3 of Huang and Chiang (2005) that works backwards from the root node, incrementally computing the second, third, through the  $k$ th best alternatives. However, this time we work on a finer-grained forest, called *translation+LM* forest, resulting from the intersection of the translation forest and the LM, with its nodes being the +LM items during cube pruning. Although this new forest is prohibitively large, Algorithm 3 is very efficient with minimal overhead on top of 1-best.

### 3.4 Forest Pruning Algorithm

We use the pruning algorithm of (Jonathan Graehl, p.c.; Huang, 2008) that is very similar to the method based on marginal probability (Charniak and Johnson, 2005), except that it prunes hyperedges as well as nodes. Basically, we use an Inside-Outside algorithm to compute the Viterbi inside cost  $\beta(v)$  and the Viterbi outside cost  $\alpha(v)$  for each node  $v$ , and then compute the **merit**  $\alpha\beta(e)$  for each hyperedge:

$$\alpha\beta(e) = \alpha(head(e)) + \sum_{u_i \in tails(e)} \beta(u_i) \quad (4)$$

Intuitively, this merit is the cost of the best derivation that traverses  $e$ , and the difference  $\delta(e) = \alpha\beta(e) - \beta(\text{TOP})$  can be seen as the distance away from the globally best derivation. We prune away a hyperedge  $e$  if  $\delta(e) > p$  for a threshold  $p$ . Nodes with all incoming hyperedges pruned are also pruned.

## 4 Experiments

We can extend the simple model in Equation 1 to a log-linear one (Liu et al., 2006; Huang et al., 2006):

$$d^* = \arg \max_{d \in D} P(d | T)^{\lambda_0} \cdot e^{\lambda_1 |d|} \cdot P_{\text{lm}}(s)^{\lambda_2} \cdot e^{\lambda_3 |s|} \quad (5)$$

where  $T$  is the 1-best parse,  $e^{\lambda_1 |d|}$  is the penalty term on the number of rules in a derivation,  $P_{\text{lm}}(s)$  is the language model and  $e^{\lambda_3 |s|}$  is the length penalty term

on target translation. The derivation probability conditioned on 1-best tree,  $P(d | T)$ , should now be replaced by  $P(d | H_p)$  where  $H_p$  is the parse forest, which decomposes into the product of probabilities of translation rules  $r \in d$ :

$$P(d | H_p) = \prod_{r \in d} P(r) \quad (6)$$

where each  $P(r)$  is the product of five probabilities:

$$P(r) = P(t | s)^{\lambda_4} \cdot P_{\text{lex}}(t | s)^{\lambda_5} \cdot P(s | t)^{\lambda_6} \cdot P_{\text{lex}}(s | t)^{\lambda_7} \cdot P(t | H_p)^{\lambda_8}. \quad (7)$$

Here  $t$  and  $s$  are the source-side tree and target-side string of rule  $r$ , respectively,  $P(t | s)$  and  $P(s | t)$  are the two translation probabilities, and  $P_{\text{lex}}(\cdot)$  are the lexical probabilities. The only extra term in forest-based decoding is  $P(t | H_p)$  denoting the source side parsing probability of the current translation rule  $r$  in the parse forest, which is the product of probabilities of each parse hyperedge  $e_p$  covered in the pattern-match of  $t$  against  $H_p$  (which can be recorded at conversion time):

$$P(t | H_p) = \prod_{e_p \in H_p, e_p \text{ covered by } t} P(e_p). \quad (8)$$

#### 4.1 Data preparation

Our experiments are on Chinese-to-English translation, and we use the Chinese parser of Xiong et al. (2005) to parse the source side of the bitext. Following Huang (2008), we modify the parser to output a packed forest for each sentence.

Our training corpus consists of 31,011 sentence pairs with 0.8M Chinese words and 0.9M English words. We first word-align them by GIZA++ refined by “diagand” from Koehn et al. (2003), and apply the tree-to-string rule extraction algorithm (Galley et al., 2006; Liu et al., 2006), which resulted in 346K translation rules. Note that our rule extraction is still done on 1-best parses, while decoding is on  $k$ -best parses or packed forests. We also use the SRI Language Modeling Toolkit (Stolcke, 2002) to train a trigram language model with Kneser-Ney smoothing on the English side of the bitext.

We use the 2002 NIST MT Evaluation test set as our development set (878 sentences) and the 2005

Figure 4: Comparison of decoding on forests with decoding on  $k$ -best trees.

NIST MT Evaluation test set as our test set (1082 sentences), with on average 28.28 and 26.31 words per sentence, respectively. We evaluate the translation quality using the *case-sensitive* BLEU-4 metric (Papineni et al., 2002). We use the standard minimum error-rate training (Och, 2003) to tune the feature weights to maximize the system’s BLEU score on the dev set. On dev and test sets, we prune the Chinese parse forests by the forest pruning algorithm in Section 3.4 with a threshold of  $p = 12$ , and then convert them into translation forests using the algorithm in Section 3.2. To increase the coverage of the rule set, we also introduce a *default translation hyperedge* for each parse hyperedge by monotonically translating each tail node, so that we can always at least get a complete translation in the end.

#### 4.2 Results

The BLEU score of the baseline 1-best decoding is 0.2325, which is consistent with the result of 0.2302 in (Liu et al., 2007) on the same training, development and test sets, and with the same rule extraction procedure. The corresponding BLEU score of Pharaoh (Koehn, 2004) is 0.2182 on this dataset.

Figure 4 compares forest decoding with decoding on  $k$ -best trees in terms of speed and quality. Using more than one parse tree apparently improves the BLEU score, but at the cost of much slower decoding, since each of the top- $k$  trees has to be decoded individually although they share many common subtrees. Forest decoding, by contrast, is much faster

Figure 5: Percentage of the  $i$ -th best parse tree being picked in decoding. 32% of the distribution for forest decoding is beyond top-100 and is not shown on this plot.

and produces consistently better BLEU scores. With pruning threshold  $p = 12$ , it achieved a BLEU score of 0.2485, which is an absolute improvement of 1.6% points over the 1-best baseline, and is statistically significant using the *sign-test* of Collins et al. (2005) ( $p < 0.01$ ).

We also investigate the question of how often the  $i$ th-best parse tree is picked to direct the translation ( $i = 1, 2, \dots$ ), in both  $k$ -best and forest decoding schemes. A packed forest can be roughly viewed as a (virtual)  $\infty$ -best list, and we can thus ask how often is a parse beyond top- $k$  used by a forest, which relates to the fundamental limitation of  $k$ -best lists. Figure 5 shows that, the 1-best parse is still preferred 25% of the time among 30-best trees, and 23% of the time by the forest decoder. These ratios decrease dramatically as  $i$  increases, but the forest curve has a much longer tail in large  $i$ . Indeed, 40% of the trees preferred by a forest is beyond top-30, 32% is beyond top-100, and even 20% beyond top-1000. This confirms the fact that we need exponentially large  $k$ -best lists with the explosion of alternatives, whereas a forest can encode these information compactly.

### 4.3 Scaling to large data

We also conduct experiments on a larger dataset, which contains 2.2M training sentence pairs. Besides the trigram language model trained on the English side of these bitext, we also use another trigram model trained on the first 1/3 of the Xinhua portion of Gigaword corpus. The two LMs have dis-

approach \ ruleset	TR	TR+BP
1-best tree	0.2666	0.2939
30-best trees	0.2755	0.3084
forest ( $p = 12$ )	<b>0.2839</b>	<b>0.3149</b>

Table 1: BLEU score results from training on large data.

tinct weights tuned by minimum error rate training. The dev and test sets remain the same as above.

Furthermore, we also make use of bilingual phrases to improve the coverage of the ruleset. Following Liu et al. (2006), we prepare a phrase-table from a phrase-extractor, e.g. Pharaoh, and at decoding time, for each node, we construct on-the-fly flat translation rules from phrases that match the source-side span of the node. These phrases are called *syntactic phrases* which are consistent with syntactic constituents (Chiang, 2005), and have been shown to be helpful in tree-based systems (Galley et al., 2006; Liu et al., 2006).

The final results are shown in Table 1, where TR denotes translation rule only, and TR+BP denotes the inclusion of bilingual phrases. The BLEU score of forest decoder with TR is 0.2839, which is a 1.7% points improvement over the 1-best baseline, and this difference is statistically significant ( $p < 0.01$ ). Using bilingual phrases further improves the BLEU score by 3.1% points, which is 2.1% points higher than the respective 1-best baseline. We suspect this larger improvement is due to the alternative constituents in the forest, which activates many syntactic phrases suppressed by the 1-best parse.

## 5 Conclusion and future work

We have presented a novel forest-based translation approach which uses a packed forest rather than the 1-best parse tree (or  $k$ -best parse trees) to direct the translation. Forest provides a compact data-structure for efficient handling of exponentially many tree structures, and is shown to be a promising direction with state-of-the-art translation results and reasonable decoding speed. This work can thus be viewed as a compromise between string-based and tree-based paradigms, with a good trade-off between speed and accuracy. For future work, we would like to use packed forests not only in decoding, but also for translation rule extraction during training.

## Acknowledgement

Part of this work was done while L. H. was visiting CAS/ICT. The authors were supported by National Natural Science Foundation of China, Contracts 60736014 and 60573188, and 863 State Key Project No. 2006AA010108 (H. M and Q. L.), and by NSF ITR EIA-0205456 (L. H.). We would also like to thank Chris Quirk for inspirations, Yang Liu for help with rule extraction, Mark Johnson for posing the question of virtual  $\infty$ -best list, and the anonymous reviewers for suggestions.

## Abstract

Large-scale discriminative machine translation promises to further the state-of-the-art, but has failed to deliver convincing gains over current heuristic frequency count systems. We argue that a principle reason for this failure is not dealing with multiple, equivalent translations. We present a translation model which models derivations as a latent variable, in both training and decoding, and is fully discriminative and globally optimised. Results show that accounting for multiple derivations does indeed improve performance. Additionally, we show that regularisation is essential for maximum conditional likelihood models in order to avoid degenerate solutions.

## 1 Introduction

Statistical machine translation (SMT) has seen a resurgence in popularity in recent years, with progress being driven by a move to phrase-based and syntax-inspired approaches. Progress within these approaches however has been less dramatic. We believe this is because these frequency count based<sup>1</sup> models cannot easily incorporate non-independent and overlapping features, which are extremely useful in describing the translation process. Discriminative models of translation can include such features without making assumptions of independence or explicitly modelling their interdependence. However, while discriminative models promise much, they have not been shown to deliver significant gains

<sup>1</sup>We class approaches using minimum error rate training (Och, 2003) *frequency count based* as these systems re-scale a handful of generative features estimated from frequency counts and do not support large sets of non-independent features.

over their simpler cousins. We argue that this is due to a number of inherent problems that discriminative models for SMT must address, in particular the problems of spurious ambiguity and degenerate solutions. These occur when there are many ways to translate a source sentence to the same target sentence by applying a sequence of steps (a *derivation*) of either phrase translations or synchronous grammar rules, depending on the type of system. Existing discriminative models require a reference derivation to optimise against, however no parallel corpora annotated for derivations exist. Ideally, a model would account for this ambiguity by marginalising out the derivations, thus predicting the best *translation* rather than the best *derivation*. However, doing so exactly is NP-complete. For this reason, to our knowledge, all discriminative models proposed to date either side-step the problem by choosing simple model and feature structures, such that spurious ambiguity is lessened or removed entirely (Ittycheriah and Roukos, 2007; Watanabe et al., 2007), or else ignore the problem and treat derivations as translations (Liang et al., 2006; Tillmann and Zhang, 2007).

In this paper we directly address the problem of spurious ambiguity in discriminative models. We use a synchronous context free grammar (SCFG) translation system (Chiang, 2007), a model which has yielded state-of-the-art results on many translation tasks. We present two main contributions. First, we develop a log-linear model of translation which is globally trained on a significant number of parallel sentences. This model maximises the conditional likelihood of the data,  $p(\mathbf{e}|\mathbf{f})$ , where  $\mathbf{e}$  and  $\mathbf{f}$  are the English and foreign sentences, respectively. Our estimation method is theoretically sound, avoiding the biases of the heuristic relative frequency estimates

**Figure 1.** Exponential relationship between sentence length and the average number of derivations (on a log scale) for each reference sentence in our training corpus.

(Koehn et al., 2003). Second, within this framework, we model the derivation,  $\mathbf{d}$ , as a latent variable,  $p(\mathbf{e}, \mathbf{d}|\mathbf{f})$ , which is marginalised out in training and decoding. We show empirically that this treatment results in significant improvements over a maximum-derivation model.

The paper is structured as follows. In Section 2 we list the challenges that discriminative SMT must face above and beyond the current systems. We situate our work, and previous work, on discriminative systems in this context. We present our model in Section 3, including our means of training and decoding. Section 4 reports our experimental setup and results, and finally we conclude in Section 5.

## 2 Challenges for Discriminative SMT

Discriminative models allow for the use of expressive features, in the order of thousands or millions, which can reference arbitrary aspects of the source sentence. Given most successful SMT models have a highly lexicalised grammar (or grammar equivalent), these features can be used to smuggle in linguistic information, such as syntax and document context. With this undoubted advantage come four major challenges when compared to standard frequency count SMT models:

1. There is no one reference derivation. Often there are thousands of ways of translating a source sentence into the reference translation. Figure 1 illustrates the exponential relationship

between sentence length and the number of derivations. Training is difficult without a clear target, and predicting only one derivation at test time is fraught with danger.

2. Parallel translation data is often very noisy, with such problems as non-literal translations, poor sentence- and word-alignments. A model which exactly translates the training data will inevitably perform poorly on held-out data. This problem of over-fitting is exacerbated in discriminative models with large, expressive, feature sets. Regularisation is essential for models with more than a handful of features.
3. Learning with a large feature set requires many training examples and typically many iterations of a solver during training. While current models focus solely on efficient decoding, discriminative models must also allow for efficient training.

Past work on discriminative SMT only address some of these problems. To our knowledge no systems directly address Problem 1, instead choosing to ignore the problem by using one or a small handful of reference derivations in an n-best list (Liang et al., 2006; Watanabe et al., 2007), or else making local independence assumptions which side-step the issue (Ittycheriah and Roukos, 2007; Tillmann and Zhang, 2007; Wellington et al., 2006). These systems all include regularisation, thereby addressing Problem 2. An interesting counterpoint is the work of DeNero et al. (2006), who show that their unregularised model finds degenerate solutions. Some of these discriminative systems have been trained on large training sets (Problem 3); these systems are the local models, for which training is much simpler. Both the global models (Liang et al., 2006; Watanabe et al., 2007) use fairly small training sets, and there is no evidence that their techniques will scale to larger data sets.

Our model addresses all three of the above problems within a global model, without resorting to n-best lists or local independence assumptions. Furthermore, our model explicitly accounts for spurious ambiguity without altering the model structure or arbitrarily selecting one derivation. Instead we model the translation distribution with a latent variable for the derivation, which we marginalise out in training and decoding.

**Figure 2.** The dropping of an adjective in this example means that there is no one segmentation that we could choose that would allow a system to learn  $le \rightarrow the$  and  $chapeau \rightarrow hat$ .

$$\begin{aligned}
 \langle S \rangle &\rightarrow \langle S_{\square} X_{\square}, S_{\square} X_{\square} \rangle \\
 \langle S \rangle &\rightarrow \langle X_{\square}, X_{\square} \rangle \\
 \langle X \rangle &\rightarrow \langle ne X_{\square} pas, does not X_{\square} \rangle \\
 \langle X \rangle &\rightarrow \langle va, go \rangle \\
 \langle X \rangle &\rightarrow \langle il, he \rangle
 \end{aligned}$$

**Figure 3.** A simple SCFG, with non-terminal symbols  $S$  and  $X$ , which performs the transduction:  $il ne vas pas \Rightarrow he does not go$

This itself provides robustness to noisy data, in addition to the explicit regularisation from a prior over the model parameters. For example, in many cases there is no one perfect derivation, but rather many imperfect ones which each include some good translation fragments. The model can learn from many of these derivations and thereby learn from all these translation fragments. This situation is illustrated in Figure 2 where the non-translated adjective *red* means neither segmentation is ‘correct’, although both together present positive evidence for the two lexical translations.

We present efficient methods for training and prediction, demonstrating their scaling properties by training on more than a hundred thousand training sentences. Finally, we stress that our main findings are general ones. These results could – and should – be applied to other models, discriminative and generative, phrase- and syntax-based, to further progress the state-of-the-art in machine translation.

### 3 Discriminative Synchronous Transduction

A synchronous context free grammar (SCFG) consists of paired CFG rules with co-indexed non-terminals (Lewis II and Stearns, 1968). By assigning the source and target languages to the respective sides of a SCFG it is possible to describe translation as the process of parsing the source sentence using a CFG, while generating the target translation from

the other (Chiang, 2007). All the models we present use the grammar extraction technique described in Chiang (2007), and are bench-marked against our own implementation of this hierarchical model (Hiero). Figure 3 shows a simple instance of a hierarchical grammar with two non-terminals. Note that our approach is general and could be used with other synchronous grammar transducers (e.g., Galley et al. (2006)).

#### 3.1 A global log-linear model

Our log-linear translation model defines a conditional probability distribution over the target translations of a given source sentence. A particular sequence of SCFG rule applications which produces a translation from a source sentence is referred to as a *derivation*, and each translation may be produced by many different derivations. As the training data only provides source and target sentences, the derivations are modelled as a latent variable.

The conditional probability of a derivation,  $\mathbf{d}$ , for a target translation,  $\mathbf{e}$ , conditioned on the source,  $\mathbf{f}$ , is given by:

$$p_{\Lambda}(\mathbf{d}, \mathbf{e} | \mathbf{f}) = \frac{\exp \sum_k \lambda_k H_k(\mathbf{d}, \mathbf{e}, \mathbf{f})}{Z_{\Lambda}(\mathbf{f})} \quad (1)$$

$$\text{where } H_k(\mathbf{d}, \mathbf{e}, \mathbf{f}) = \sum_{r \in \mathbf{d}} h_k(\mathbf{f}, r) \quad (2)$$

Here  $k$  ranges over the model’s features, and  $\Lambda = \{\lambda_k\}$  are the model parameters (weights for their corresponding features). The feature functions  $H_k$  are predefined real-valued functions over the source and target sentences, and can include overlapping and non-independent features of the data. The features must decompose with the derivation, as shown in (2). The features can reference the entire source sentence coupled with each rule,  $r$ , in a derivation. The distribution is globally normalised by the partition function,  $Z_{\Lambda}(\mathbf{f})$ , which sums out the numerator in (1) for every derivation (and therefore every translation) of  $\mathbf{f}$ :

$$Z_{\Lambda}(\mathbf{f}) = \sum_{\mathbf{e}} \sum_{\mathbf{d} \in \Delta(\mathbf{e}, \mathbf{f})} \exp \sum_k \lambda_k H_k(\mathbf{d}, \mathbf{e}, \mathbf{f})$$

Given (1), the conditional probability of a target translation given the source is the sum over all of its derivations:

$$p_{\Lambda}(\mathbf{e} | \mathbf{f}) = \sum_{\mathbf{d} \in \Delta(\mathbf{e}, \mathbf{f})} p_{\Lambda}(\mathbf{d}, \mathbf{e} | \mathbf{f}) \quad (3)$$

where  $\Delta(\mathbf{e}, \mathbf{f})$  is the set of all derivations of the target sentence  $\mathbf{e}$  from the source  $\mathbf{f}$ .

Most prior work in SMT, both generative and discriminative, has approximated the sum over derivations by choosing a single ‘best’ derivation using a Viterbi or beam search algorithm. In this work we show that it is both tractable and desirable to directly account for derivational ambiguity. Our findings echo those observed for latent variable log-linear models successfully used in monolingual parsing (Clark and Curran, 2007; Petrov et al., 2007). These models marginalise over derivations leading to a dependency structure and splits of non-terminal categories in a PCFG, respectively.

### 3.2 Training

The parameters of our model are estimated from our training sample using a maximum *a posteriori* (MAP) estimator. This maximises the likelihood of the parallel training sentences,  $\mathcal{D} = \{(\mathbf{e}, \mathbf{f})\}$ , penalised using a prior, i.e.,  $\Lambda^{MAP} = \arg \max_{\Lambda} p_{\Lambda}(\mathcal{D})p(\Lambda)$ . We use a zero-mean Gaussian prior with the probability density function  $p_0(\lambda_k) \propto \exp(-\lambda_k^2/2\sigma^2)$ .<sup>2</sup> This results in the following log-likelihood objective and corresponding gradient:

$$\mathcal{L} = \sum_{(\mathbf{e}, \mathbf{f}) \in \mathcal{D}} \log p_{\Lambda}(\mathbf{e}|\mathbf{f}) + \sum_k \log p_0(\lambda_k) \quad (4)$$

$$\frac{\partial \mathcal{L}}{\partial \lambda_k} = E_{p_{\Lambda}(\mathbf{d}|\mathbf{e}, \mathbf{f})}[h_k] - E_{p_{\Lambda}(\mathbf{e}|\mathbf{f})}[h_k] - \frac{\lambda_k}{\sigma^2} \quad (5)$$

In order to train the model, we maximise equation (4) using L-BFGS (Malouf, 2002; Sha and Pereira, 2003). This method has been demonstrated to be effective for (non-convex) log-linear models with latent variables (Clark and Curran, 2004; Petrov et al., 2007). Each L-BFGS iteration requires the objective value and its gradient with respect to the model parameters. These are calculated using inside-outside inference over the feature forest defined by the SCFG parse chart of  $\mathbf{f}$  yielding the partition function,  $Z_{\Lambda}(\mathbf{f})$ , required for the log-likelihood, and the marginals, required for its derivatives.

Efficiently calculating the objective and its gradient requires two separate packed charts, each representing a derivation forest. The first one is the full chart over the space of possible derivations given the

<sup>2</sup>In general, any conjugate prior could be used instead of a simple Gaussian.

source sentence. The inside-outside algorithm over this chart gives the marginal probabilities for each chart cell, from which we can find the feature expectations. The second chart contains the space of derivations which produce the reference translation from the source. The derivations in this chart are a subset of those in the full derivation chart. Again, we use the inside-outside algorithm to find the ‘reference’ feature expectations from this chart. These expectations are analogous to the empirical observation of maximum entropy classifiers.

Given these two charts we can calculate the log-likelihood of the reference translation as the inside-score from the sentence spanning cell of the reference chart, normalised by the inside-score of the spanning cell from the full chart. The gradient is calculated as the difference of the feature expectations of the two charts. Clark and Curran (2004) provides a more complete discussion of parsing with a log-linear model and latent variables.

The full derivation chart is produced using a CYK parser in the same manner as Chiang (2005), and has complexity  $O(|\mathbf{e}|^3)$ . We produce the reference chart by synchronously parsing the source and reference sentences using a variant of CYK algorithm over two dimensions, with a time complexity of  $O(|\mathbf{e}|^3|\mathbf{f}|^3)$ . This is an instance of the ITG alignment algorithm (Wu, 1997). This step requires the reference translation for each training instance to be contained in the model’s hypothesis space. Achieving full coverage implies inducing a grammar which generates all observed source-target pairs, which is difficult in practice. Instead we discard the unreachable portion of the training sample (24% in our experiments). The proportion of discarded sentences is a function of the grammar used. Extraction heuristics other than the method used herein (Chiang, 2007) could allow complete coverage (e.g., Galley et al. (2004)).

### 3.3 Decoding

Accounting for all derivations of a given translation should benefit not only training, but also decoding. Unfortunately marginalising over derivations in decoding is NP-complete. The standard solution is to approximate the maximum probability translation using a single derivation (Koehn et al., 2003).

Here we approximate the sum over derivations directly using a beam search in which we produce a beam of high probability translation sub-strings for each cell in the parse chart. This algorithm is sim-

**Figure 4.** Hypergraph representation of max translation decoding. Each chart cell must store the entire target string generated.

ilar to the methods for decoding with a SCFG intersected with an  $n$ -gram language model, which require language model contexts to be stored in each chart cell. However, while Chiang (2005) stores an abbreviated context composed of the  $n - 1$  target words on the left and right edge of the target substring, here we store the entire target string. Additionally, instead of maximising scores in each beam cell, we sum the inside scores for each derivation that produces a given string for that cell. When the beam search is complete we have a list of translations in the top beam cell spanning the entire source sentence along with their approximated inside derivation scores. Thus we can assign each translation string a probability by normalising its inside score by the sum of the inside scores of all the translations spanning the entire sentence.

Figure 4 illustrates the search process for the simple grammar from Table 2. Each graph node represents a hypothesis translation substring covering a sub-span of the source string. The space of translation sub-strings is exponential in each cell’s span, and our algorithm can only sum over a small fraction of the possible strings. Therefore the resulting probabilities are only estimates. However, as demonstrated in Section 4, this algorithm is considerably more effective than maximum derivation (Viterbi) decoding.

## 4 Evaluation

Our model evaluation was motivated by the following questions: (1) the effect of maximising translations rather than derivations in training and decoding; (2) whether a regularised model performs better than a maximum likelihood model; (3) how the performance of our model compares with a frequency count based hierarchical system; and (4) how translation performance scales with the number of training examples.

We performed all of our experiments on the Europarl V2 French-English parallel corpus.<sup>3</sup> The training data was created by filtering the full corpus for all the French sentences between five and fifteen words in length, resulting in 170K sentence pairs. These limits were chosen as a compromise between experiment turnaround time and leaving a large enough corpus to obtain indicative results. The development and test data was taken from the 2006 NAACL and 2007 ACL workshops on machine translation, also filtered for sentence length.<sup>4</sup> Tuning of the regularisation parameter and MERT training of the benchmark models was performed on *dev2006*, while the test set was the concatenation of *devtest2006*, *test2006* and *test2007*, amounting to 315 development and 1164 test sentences.

Here we focus on evaluating our model’s basic ability to learn a conditional distribution from simple binary features, directly comparable to those currently employed in frequency count models. As such, our base model includes a single binary identity feature per-rule, equivalent to the  $p(e|f)$  parameters defined on each rule in standard models.

As previously noted, our model must be able to derive the reference sentence from the source for it to be included in training. For both our discriminative and benchmark (Hiero) we extracted our grammar on the 170K sentence corpus using the approach described in Chiang (2007), resulting in 7.8 million rules. The discriminative model was then trained on the training partition, however only 130K of the sentences were used as the model could not produce a derivation of the reference for the remaining sentences. There were many grammar rules that the discriminative model did not observe in a reference derivation, and thus could not assign their feature a positive weight. While the benchmark model has a

<sup>3</sup><http://www.statmt.org/europarl/>

Training	Decoding	
	derivation	translation
All Derivations	28.71	31.23
Single Derivation	26.70	27.32
ML ( $\sigma^2 = \infty$ )	25.57	25.97

**Table 1.** A comparison on the impact of accounting for all derivations in training and decoding (development set).

positive count for every rule (7.8M), the discriminative model only observes 1.7M rules in actual reference derivations. Figure 1 illustrates the massive ambiguity present in the training data, with fifteen word sentences averaging over 70M reference derivations.

Performance is evaluated using cased BLEU4 score on the test set. Although there is no direct relationship between BLEU and likelihood, it provides a rough measure for comparing performance.

**Derivational ambiguity** Table 1 shows the impact of accounting for derivational ambiguity in training and decoding.<sup>5</sup> There are two options for training, we could use our latent variable model and optimise the probability of all derivations of the reference translation, or choose a single derivation that yields the reference and optimise its probability alone. The second option raises the difficult question of which one, of the thousands available, we should choose? We use the derivation which contains the most rules. The intuition is that small rules are likely to appear more frequently, and thus generalise better to a test set. In decoding we can search for the maximum probability derivation, which is the standard practice in SMT, or for the maximum probability translation which is what we actually want from our model, i.e. the best translation.

The results clearly indicate the value in optimising translations, rather than derivations. Max-translation decoding for the model trained on single derivations has only a small positive effect, while for the latent variable model the impact is much larger.<sup>6</sup>

For example, our max-derivation model trained on the Europarl data translates *carte sur la table* as *on the table card*. This error in the reordering of *card* (which is an acceptable translation of *carte*) is due to the rule  $\langle X \rangle \rightarrow \langle \text{carte } X_{\square}, X_{\square} \text{ card} \rangle$  being the highest scoring rule for *carte*. This is reasonable, as

<sup>5</sup>When not explicitly stated, both here and in subsequent results, the regularisation parameter was set to one,  $\sigma^2 = 1$ .

<sup>6</sup>We also experimented with using max-translation decoding for standard MER trained translation models, finding that it had a small negative impact on BLEU score.

**Figure 5.** The effect of the beam width (log-scale) on max-translation decoding (development set).

*carte* is a noun, which in the training data, is often observed with a trailing adjective which needs to be reordered when translating into English. In the example there is no adjective, but the simple hierarchical grammar cannot detect this. The max-translation model finds a good translation *card on the table*. This is due to the many rules that enforce monotone ordering around *sur la*,  $\langle X \rangle \rightarrow \langle X_{\square} \text{ sur}, X_{\square} \text{ in} \rangle$   $\langle X \rangle \rightarrow \langle X_{\square} \text{ sur la } X_{\square}, X_{\square} \text{ in the } X_{\square} \rangle$  etc. The scores of these many monotone rules sum to be greater than the reordering rule, thus allowing the model to use the weight of evidence to settle on the correct ordering.

Having established that the search for the best translation is effective, the question remains as to how the beam width over partial translations affects performance. Figure 5 shows the relationship between beam width and development BLEU. Even with a very tight beam of 100, max-translation decoding outperforms maximum-derivation decoding, and performance is increasing even at a width of 10k. In subsequent experiments we use a beam of 5k which provides a good trade-off between performance and speed.

**Regularisation** Table 1 shows that the performance of an unregularised maximum likelihood model lags well behind the regularised max-translation model. From this we can conclude that the maximum likelihood model is overfitting the training set. We suggest that is a result of the degenerate solutions of the conditional maximum likelihood estimate, as described in DeNero et al. (2006). Here we assert that our regularised *maximum a pos-*

Grammar Rules	ML ( $\sigma^2 = \infty$ )	MAP ( $\sigma^2 = 1$ )
$\langle X \rangle \rightarrow \langle \text{carte, map} \rangle$	1.0	0.5
$\langle X \rangle \rightarrow \langle \text{carte, notice} \rangle$	0.0	0.5
$\langle X \rangle \rightarrow \langle \text{sur, on} \rangle$	1.0	1.0
$\langle X \rangle \rightarrow \langle \text{la, the} \rangle$	1.0	1.0
$\langle X \rangle \rightarrow \langle \text{table, table} \rangle$	1.0	0.5
$\langle X \rangle \rightarrow \langle \text{table, chart} \rangle$	0.0	0.5
$\langle X \rangle \rightarrow \langle \text{carte sur, notice on} \rangle$	1.0	0.5
$\langle X \rangle \rightarrow \langle \text{carte sur, map on} \rangle$	0.0	0.5
$\langle X \rangle \rightarrow \langle \text{sur la, on the} \rangle$	1.0	1.0
$\langle X \rangle \rightarrow \langle \text{la table, the table} \rangle$	0.0	0.5
$\langle X \rangle \rightarrow \langle \text{la table, the chart} \rangle$	1.0	0.5
Training data: carte sur la table $\leftrightarrow$ map on the table carte sur la table $\leftrightarrow$ notice on the chart		

**Table 2.** Comparison of the susceptibility to degenerate solutions for a ML and MAP optimised model, using a simple grammar with one parameter per rule and a monotone glue rule:  $\langle X \rangle \rightarrow \langle X_{\boxed{1}} X_{\boxed{2}}, X_{\boxed{1}} X_{\boxed{2}} \rangle$

*teriori* model avoids such solutions.

This is illustrated in Table 2, which shows the conditional probabilities for rules, obtained by locally normalising the rule feature weights for a simple grammar extracted from the ambiguous pair of sentences presented in DeNero et al. (2006). The first column of conditional probabilities corresponds to a maximum likelihood estimate, i.e., without regularisation. As expected, the model finds a degenerate solution in which overlapping rules are exploited in order to minimise the entropy of the rule translation distributions. The second column shows the solution found by our model when regularised by a Gaussian prior with unit variance. Here we see that the model finds the desired solution in which the true ambiguity of the translation rules is preserved. The intuition is that in order to find a degenerate solution, dispreferred rules must be given large negative weights. However the prior penalises large weights, and therefore the best strategy for the regularised model is to evenly distribute probability mass.

**Translation comparison** Having demonstrated that accounting for derivational ambiguity leads to improvements for our discriminative model, we now place the performance of our system in the context of the standard approach to hierarchical translation. To do this we use our own implementation of Hiero (Chiang, 2007), with the same grammar but with the traditional generative feature set trained in a linear model with minimum BLEU training. The feature set includes: a trigram language model (*lm*) trained

System	Test (BLEU)
Discriminative max-derivation	25.78
Hiero ( $p_d, gr, rc, wc$ )	26.48
Discriminative max-translation	27.72
Hiero ( $p_d, p_r, p_d^{lex}, p_r^{lex}, gr, rc, wc$ )	28.14
Hiero ( $p_d, p_r, p_d^{lex}, p_r^{lex}, gr, rc, wc, lm$ )	32.00

**Table 3.** Test set performance compared with a standard Hiero system

on the English side of the unfiltered Europarl corpus; direct and reverse translation scores estimated as relative frequencies ( $p_d, p_r$ ); lexical translation scores ( $p_d^{lex}, p_r^{lex}$ ), a binary flag for the glue rule which allows the model to (dis)favour monotone translation (*gr*); and rule and target word counts (*rc, wc*).

Table 3 shows the results of our system on the test set. Firstly we show the relative scores of our model against Hiero without using reverse translation or lexical features.<sup>7</sup> This allows us to directly study the differences between the two translation models without the added complication of the other features. As well as both modelling the same distribution, when our model is trained with a single parameter per-rule these systems have the same parameter space, differing only in the manner of estimation.

Additionally we show the scores achieved by MERT training the full set of features for Hiero, with and without a language model.<sup>8</sup> We provide these results for reference. To compare our model directly with these systems we would need to incorporate additional features and a language model, work which we have left for a later date.

The relative scores confirm that our model, with its minimalist feature set, achieves comparable performance to the standard feature set without the language model. This is encouraging as our model was trained to optimise likelihood rather than BLEU, yet it is still competitive on that metric. As expected, the language model makes a significant difference to BLEU, however we believe that this effect is orthogonal to the choice of base translation model, thus we would expect a similar gain when integrating a language model into the discriminative system.

An informal comparison of the outputs on the development set, presented in Table 4, suggests that the

<sup>7</sup>Although the most direct comparison for the discriminative model would be with  $p_d$  model alone, omitting the *gr, rc* and *wc* features and MERT training produces poor translations.

<sup>8</sup>Hiero ( $p_d, p_r, p_d^{lex}, p_r^{lex}, gr, rc, wc, lm$ ) represents state-of-the-art performance on this training/testing set.

<b>S:</b> C'est pourquoi nous souhaitons que l'affaire nous soit renvoyée.
<b>R:</b> We therefore want the matter re-referred to ourselves.
<b>D:</b> That is why we want the that matters we to be referred back.
<b>T:</b> That is why we would like the matter to be referred back.
<b>H:</b> That is why we wish that the matter we be referred back.
<b>S:</b> Par contre, la transposition dans les États membres reste trop lente.
<b>R:</b> But implementation by the Member States has still been too slow.
<b>D:</b> However, it is implemented in the Member States is still too slow.
<b>T:</b> However, the implementation measures in Member States remains too slow.
<b>H:</b> In against, transposition in the Member States remains too slow.
<b>S:</b> Aussi, je considère qu'il reste énormément à faire dans ce domaine.
<b>R:</b> I therefore consider that there is an incredible amount still to do in this area.
<b>D:</b> So I think remains a lot to be done in this field.
<b>T:</b> So I think there is still much to be done in this area.
<b>H:</b> Therefore, I think it remains a vast amount to do in this area.

**Table 4.** Example output produced by the max-derivation (D), max-translation (T) decoding algorithms and Hiero( $p_d, p_r, p_d^{lex}, p_r^{lex}, gr, rc, wc$ ) (H) models, relative to the source (S) and reference (R).

translation optimising discriminative model more often produces quite fluent translations, yet not in ways that would lead to an increase in BLEU score.<sup>9</sup> This could be considered a side-effect of optimising likelihood rather than BLEU.

**Scaling** In Figure 6 we plot the scaling characteristics of our models. The systems shown in the graph use the full grammar extracted on the 170k sentence corpus. The number of sentences upon which the iterative training algorithm is used to estimate the parameters is varied from 10k to the maximum 130K for which our model can reproduce the reference translation. As expected, the more data used to train the system, the better the performance. However, as the performance is still increasing significantly when all the parseable sentences are used, it is clear that the system's performance is suffering from the large number (40k) of sentences that are discarded before training.

## 5 Discussion and Further Work

We have shown that explicitly accounting for competing derivations yields translation improvements.

<sup>9</sup>Hiero was MERT trained on this set and has a 2% higher BLEU score compared to the discriminative model.

**Figure 6.** Learning curve showing that the model continues to improve as we increase the number of training sentences (development set)

Our model avoids the estimation biases associated with heuristic frequency count approaches and uses standard regularisation techniques to avoid degenerate maximum likelihood solutions.

Having demonstrated the efficacy of our model with very simple features, the logical next step is to investigate more expressive features. Promising features might include those over source side re-ordering rules (Wang et al., 2007) or source context features (Carpuat and Wu, 2007). Rule frequency features extracted from large training corpora would help the model to overcome the issue of unreachable reference sentences. Such approaches have been shown to be effective in log-linear word-alignment models where only a small supervised corpus is available (Blunsom and Cohn, 2006).

Finally, while in this paper we have focussed on the science of discriminative machine translation, we believe that with suitable engineering this model will advance the state-of-the-art. To do so would require integrating a language model feature into the max-translation decoding algorithm. The use of richer, more linguistic grammars (e.g., Galley et al. (2004)) may also improve the system.

# Efficient Multi-pass Decoding for Synchronous Context Free Grammars

Hao Zhang and Daniel Gildea  
Computer Science Department  
University of Rochester  
Rochester, NY 14627

## Abstract

We take a multi-pass approach to machine translation decoding when using synchronous context-free grammars as the translation model and  $n$ -gram language models: the first pass uses a bigram language model, and the resulting parse forest is used in the second pass to guide search with a trigram language model. The trigram pass closes most of the performance gap between a bigram decoder and a much slower trigram decoder, but takes time that is insignificant in comparison to the bigram pass. An additional fast decoding pass maximizing the expected count of correct translation hypotheses increases the BLEU score significantly.

## 1 Introduction

Statistical machine translation systems based on synchronous grammars have recently shown great promise, but one stumbling block to their widespread adoption is that the decoding, or search, problem during translation is more computationally demanding than in phrase-based systems. This complexity arises from the interaction of the tree-based translation model with an  $n$ -gram language model. Use of longer  $n$ -grams improves translation results, but exacerbates this interaction. In this paper, we present three techniques for attacking this problem in order to obtain fast, high-quality decoders.

First, we present a two-pass decoding algorithm, in which the first pass explores states resulting from an integrated bigram language model, and the second pass expands these states into trigram-based

states. The general bigram-to-trigram technique is common in speech recognition (Murveit et al., 1993), where lattices from a bigram-based decoder are re-scored with a trigram language model. We examine the question of whether, given the reordering inherent in the machine translation problem, lower order  $n$ -grams will provide as valuable a search heuristic as they do for speech recognition.

Second, we explore heuristics for agenda-based search, and present a heuristic for our second pass that combines precomputed language model information with information derived from the first pass. With this heuristic, we achieve the same BLEU scores and model cost as a trigram decoder with essentially the same speed as a bigram decoder.

Third, given the significant speedup in the agenda-based trigram decoding pass, we can rescore the trigram forest to maximize the expected count of correct synchronous constituents of the model, using the product of inside and outside probabilities. Maximizing the expected count of synchronous constituents approximately maximizes BLEU. We find a significant increase in BLEU in the experiments, with minimal additional time.

## 2 Language Model Integrated Decoding for SCFG

We begin by introducing Synchronous Context Free Grammars and their decoding algorithms when an  $n$ -gram language model is integrated into the grammatical search space.

A **synchronous CFG** (SCFG) is a set of context-free rewriting rules for recursively generating string pairs. Each synchronous rule is a pair of CFG rules

with the nonterminals on the right hand side of one CFG rule being one-to-one mapped to the other CFG rule via a permutation  $\pi$ . We adopt the SCFG notation of Satta and Peserico (2005). Superscript *indices* in the right-hand side of grammar rules:

$$X \rightarrow X_1^{(1)} \dots X_n^{(n)}, X_{\pi(1)}^{(\pi(1))} \dots X_{\pi(n)}^{(\pi(n))}$$

indicate that the nonterminals with the same index are linked across the two languages, and will eventually be rewritten by the same rule application. Each  $X_i$  is a variable which can take the value of any non-terminal in the grammar.

In this paper, we focus on binary SCFGs and without loss of generality assume that only the pre-terminal unary rules can generate terminal string pairs. Thus, we are focusing on Inversion Transduction Grammars (Wu, 1997) which are an important subclass of SCFG. Formally, the rules in our grammar include preterminal unary rules:

$$X \rightarrow \mathbf{e/f}$$

for pairing up words or phrases in the two languages and binary production rules with straight or inverted orders that are responsible for building up upper-level synchronous structures. They are straight rules written:

$$X \rightarrow [YZ]$$

and inverted rules written:

$$X \rightarrow \langle YZ \rangle.$$

Most practical non-binary SCFGs can be binarized using the synchronous binarization technique by Zhang et al. (2006). The Hiero-style rules of (Chiang, 2005), which are not strictly binary but binary only on nonterminals:

$$X \rightarrow \text{yu } X^{(1)} \text{ you } X^{(2)}; \text{ have } X^{(2)} \text{ with } X^{(1)}$$

can be handled similarly through either offline binarization or allowing a fixed maximum number of gap words between the right hand side nonterminals in the decoder.

For these reasons, the parsing problems for more realistic synchronous CFGs such as in Chiang (2005) and Galley et al. (2006) are formally equivalent to ITG. Therefore, we believe our focus on ITG

for the search efficiency issue is likely to generalize to other SCFG-based methods.

Without an  $n$ -gram language model, decoding using SCFG is not much different from CFG parsing. At each time a CFG rule is applied on the input string, we apply the synchronized CFG rule for the output language. From a dynamic programming point of view, the DP states are  $X[i, j]$ , where  $X$  ranges over all possible nonterminals and  $i$  and  $j$  range over 0 to the input string length  $|w|$ . Each state stores the best translations obtainable. When we reach the top state  $S[0, |w|]$ , we can get the best translation for the entire sentence. The algorithm is  $O(|w|^3)$ .

However, when we want to integrate an  $n$ -gram language model into the search, our goal is searching for the derivation whose total sum of weights of productions and  $n$ -gram log probabilities is maximized. Now the adjacent span-parameterized states  $X[i, k]$  and  $X[k, j]$  can interact with each other by “peeping into” the leading and trailing  $n - 1$  words on the output side for each state. Different boundary words differentiate the span-parameterized states. Thus, to preserve the dynamic programming property, we need to refine the states by adding the boundary words into the parameterization. The *LM*-integrated states are represented as  $X[i, j, u_{1,\dots,n-1}, v_{1,\dots,n-1}]$ . Since the number of variables involved at each DP step has increased to  $3 + 4(n - 1)$ , the decoding algorithm is asymptotically  $O(|w|^{3+4(n-1)})$ . Although it is possible to use the “hook” trick of Huang et al. (2005) to factorize the DP operations to reduce the complexity to  $O(|w|^{3+3(n-1)})$ , when  $n$  is greater than 2, the complexity is still prohibitive.

### 3 Multi-pass LM-Integrated Decoding

In this section, we describe a multi-pass progressive decoding technique that gradually augments the *LM*-integrated states from lower orders to higher orders. For instance, a bigram-integrated state  $[X, i, j, u, v]$  is said to be a coarse-level state of a trigram-integrated state  $[X, i, j, u, u', v', v]$ , because the latter state refines the previous by specifying more inner words.

Progressive search has been used for HMM’s in speech recognition (Murveit et al., 1993). The gen-

eral idea is to use a simple and fast decoding algorithm to constrain the search space of a following more complex and slower technique. More specifically, a bigram decoding pass is executed forward and backward to figure out the probability of each state. Then the states can be pruned based on their global score using the product of inside and outside probabilities. The advanced decoding algorithm will use the constrained space (a lattice in the case of speech recognition) as a grammatical constraint to help it focus on a smaller search space on which more discriminative features are brought in.

The same idea has been applied to forests for parsing. Charniak and Johnson (2005) use a PCFG to do a pass of inside-outside parsing to reduce the state space of a subsequent lexicalized  $n$ -best parsing algorithm to produce parses that are further re-ranked by a MaxEnt model.

We take the same view as in speech recognition that a trigram integrated model is a finer-grained model than bigram model and in general we can do an  $n - 1$ -gram decoding as a predicative pass for the following  $n$ -gram pass. We need to do inside-outside parsing as coarse-to-fine parsers do. However, we use the outside probability or cost information differently. We do not combine the inside and outside costs of a simpler model to prune the space for a more complex model. Instead, for a given finer-grained state, we combine its true inside cost with the outside cost of its coarse-level counter-part to estimate its worthiness of being explored. The use of the outside cost from a coarser-level as the outside estimate makes our method naturally fall in the framework of A\* parsing.

Klein and Manning (2003) describe an A\* parsing framework for monolingual parsing and admissible outside estimates that are computed using inside/outside parsing algorithm on simplified PCFGs compared to the original PCFG. Zhang and Gildea (2006) describe A\* for ITG and develop admissible heuristics for both alignment and decoding. Both have shown the effectiveness of A\* in situations where the outside estimate approximates the true cost closely such as when the sentences are short. For decoding long sentences, it is difficult to come up with good admissible (or inadmissible) heuristics. If we can afford a bigram decoding pass, the outside cost from a bigram model is conceivably a

very good estimate of the outside cost using a trigram model since a bigram language model and a trigram language model must be strongly correlated. Although we lose the guarantee that the bigram-pass outside estimate is admissible, we expect that it approximates the outside cost very closely, thus very likely to effectively guide the heuristic search.

### 3.1 Inside-outside Coarse Level Decoding

We describe the coarse level decoding pass in this section. The decoding algorithms for the coarse level and the fine level do not necessarily have to be the same. The fine level decoding algorithm is an A\* algorithm. The coarse level decoding algorithm can be CKY or A\* or other alternatives.

Conceptually, the algorithm is finding the shortest hyperpath in the hypergraph in which the nodes are states like  $X[i, j, u_{1, \dots, n-1}, v_{1, \dots, n-1}]$ , and the hyperedges are the applications of the synchronous rules to go from right-hand side states to left-hand side states. The root of the hypergraph is a special node  $S'[0, |w|, \langle s \rangle, \langle /s \rangle]$  which means the entire input sentence has been translated to a string starting with the beginning-of-sentence symbol and ending at the end-of-sentence symbol. If we imagine a starting node that goes to all possible basic translation pairs, i.e., the instances of the terminal translation rules for the input, we are searching the shortest hyperpath from the imaginary bottom node to the root. To help our outside parsing pass, we store the back-pointers at each step of exploration.

The outside parsing pass, however, starts from the root  $S'[|w|, \langle s \rangle, \langle /s \rangle]$  and follows the back-pointers downward to the bottom nodes. The nodes need to be visited in a topological order so that whenever a node is visited, its parents have been visited and its outside cost is over all possible outside parses. The algorithm is described in pseudocode in Algorithm 1. The number of hyperedges to traverse is much fewer than in the inside pass because not every state explored in the bottom up inside pass can finally reach the goal. As for normal outside parsing, the operations are the reverse of inside parsing. We propagate the outside cost of the parent to its children by combining with the inside cost of the other children and the interaction cost, i.e., the language model cost between the focused child and the other children. Since we want to approximate the Viterbi

outside cost, it makes sense to maximize over all possible outside costs for a given node, to be consistent with the maximization of the inside pass. For the nodes that have been explored in the bottom up pass but not in the top-down pass, we set their outside cost to be infinity so that their exploration is preferred only when the viable nodes from the first pass have all been explored in the fine pass.

### 3.2 Heuristics for Fine-grained Decoding

In this section, we summarize the heuristics for finer level decoding.

The motivation for combining the true inside cost of the fine-grained model and the outside estimate given by the coarse-level parsing is to approximate the true global cost of a fine-grained state as closely as possible. We can make the approximation even closer by incorporating local higher-order outside  $n$ -gram information for a state of  $X[i, j, u_{1,\dots,n-1}, v_{1,\dots,n-1}]$  into account. We call this the *best-border* estimate. For example, the best-border estimate for trigram states is:

$$h_{BB}(X, i, j, u_1, u_2, v_1, v_2) = \left[ \max_{s \in S(i, j)} P_{lm}(u_2 | s, u_1) \right] \cdot \left[ \max_{s \in S(i, j)} P_{lm}(s | v_1, v_2) \right]$$

where  $S(i, j)$  is the set of candidate target language words outside the span of  $(i, j)$ .  $h_{BB}$  is the product of the upper bounds for the two on-the-border  $n$ -grams.

This heuristic function was one of the admissible heuristics used by Zhang and Gildea (2006). The benefit of including the best-border estimate is to refine the outside estimate with respect to the inner words which refine the bigram states into the trigram states. If we do not take the inner words into consideration when computing the outside cost, all states that map to the same coarse level state would have the same outside cost. When the simple best-border estimate is combined with the coarse-level outside estimate, it can further boost the search as will be shown in the experiments. To summarize, our recipe

for faster decoding is that using

$$\beta(X[i, j, u_{1,\dots,n-1}, v_{1,\dots,n-1}]) + \alpha(X[i, j, u_1, v_{n-1}]) + h_{BB}(X, i, j, u_{1,\dots,n}, v_{1,\dots,n}) \quad (1)$$

where  $\beta$  is the Viterbi inside cost and  $\alpha$  is the Viterbi outside cost, to globally prioritize the  $n$ -gram integrated states on the agenda for exploration.

### 3.3 Alternative Efficient Decoding Algorithms

The complexity of  $n$ -gram integrated decoding for SCFG has been tackled using other methods.

The hook trick of Huang et al. (2005) factorizes the dynamic programming steps and lowers the asymptotic complexity of the  $n$ -gram integrated decoding, but has not been implemented in large-scale systems where massive pruning is present.

The cube-pruning by Chiang (2007) and the lazy cube-pruning of Huang and Chiang (2007) turn the computation of beam pruning of CYK decoders into a top- $k$  selection problem given two columns of translation hypotheses that need to be combined. The insight for doing the expansion top-down lazily is that there is no need to uniformly explore every cell. The algorithm starts with requesting the first best hypothesis from the root. The request translates into requests for the  $k$ -bests of some of its children and grandchildren and so on, because re-ranking at each node is needed to get the top ones.

Venugopal et al. (2007) also take a two-pass decoding approach, with the first pass leaving the language model boundary words out of the dynamic programming state, such that only one hypothesis is retained for each span and grammar symbol.

## 4 Decoding to Maximize BLEU

The ultimate goal of efficient decoding to find the translation that has a highest evaluation score using the least time possible. Section 3 talks about utilizing the outside cost of a lower-order model to estimate the outside cost of a higher-order model, boosting the search for the higher-order model. By doing so, we hope the intrinsic metric of our model agrees with the extrinsic metric of evaluation so that fast search for the model is equivalent to efficient decoding. But the mismatch between the two is evident, as we will see in the experiments. In this section,

         $\alpha(X[i, j, u, v]) + \beta(Y[i, k, v', v]) + rule(X \rightarrow \langle YZ \rangle) + bigram(u', v') \}$ 
    end if
  end for
end for
```

---

we deal with the mismatch by introducing another decoding pass that maximizes the expected count of synchronous constituents in the tree corresponding to the translation returned. BLEU is based on  $n$ -gram precision, and since each synchronous constituent in the tree adds a new 4-gram to the translation at the point where its children are concatenated, the additional pass approximately maximizes BLEU.

Kumar and Byrne (2004) proposed the framework of Minimum Bayesian Risk (MBR) decoding that minimizes the expected loss given a loss function. Their MBR decoding is a reranking pass over an  $n$ -best list of translations returned by the decoder. Our algorithm is another dynamic programming decoding pass on the trigram forest, and is similar to the parsing algorithm for maximizing expected labelled recall presented by Goodman (1996).

#### 4.1 Maximizing the expected count of correct synchronous constituents

We introduce an algorithm that maximizes the expected count of correct synchronous constituents. Given a synchronous constituent specified by the state  $[X, i, j, u, u', v', v]$ , its probability of being correct in the model is

$$\begin{aligned} EC([X, i, j, u, u', v', v]) \\ = \alpha([X, i, j, u, u', v', v]) \cdot \beta([X, i, j, u, u', v', v]), \end{aligned}$$

where  $\alpha$  is the outside probability and  $\beta$  is the inside probability. We approximate  $\beta$  and  $\alpha$  using the Viterbi probabilities. Since decoding from bottom up in the trigram pass already gives us the inside Viterbi scores, we only have to visit the nodes in the reverse order once we reach the root to compute the Viterbi outside scores. The outside-pass Algorithm 1 for bigram decoding can be generalized to the trigram case. We want to maximize over all translations (synchronous trees)  $T$  in the forest after the trigram decoding pass according to

$$\max_T \sum_{[X, i, j, u, u', v', v] \in T} EC([X, i, j, u, u', v', v]).$$

The expression can be factorized and computed using dynamic programming on the forest.

## 5 Experiments

We did our decoding experiments on the LDC 2002 MT evaluation data set for translation of Chinese newswire sentences into English. The evaluation data set has 10 human translation references for each sentence. There are a total of 371 Chinese sentences of no more than 20 words in the data set. These sentences are the test set for our different versions of language-model-integrated ITG decoders. We evaluate the translation results by comparing them against the reference translations using the BLEU metric.

The word-to-word translation probabilities are from the translation model of IBM Model 4 trained on a 160-million-word English-Chinese parallel corpus using GIZA++. The phrase-to-phrase translation probabilities are trained on 833K parallel sentences. 758K of this was data made available by ISI, and another 75K was FBIS data. The language model is trained on a 30-million-word English corpus. The rule probabilities for ITG are trained using EM on a corpus of 18,773 sentence pairs with a total of 276,113 Chinese words and 315,415 English words.

### 5.1 Bigram-pass Outside Cost as Trigram-pass Outside Estimate

We first fix the beam for the bigram pass, and change the outside heuristics for the trigram pass to show the difference before and after using the first-pass outside cost estimate and the border estimate. We choose the beam size for the CYK bigram pass to be 10 on the log scale. The first row of Table 1 shows the number of explored hyperedges for the bigram pass and its BLEU score. In the rows below, we compare the additional numbers of hyperedges that need to be explored in the trigram pass using different outside heuristics. It takes too long to finish using uniform outside estimate; we have to use a tight beam to control the agenda-based exploration. Using the bigram outside cost estimate makes a huge difference. Furthermore, using Equation 1, adding the additional heuristics on the best trigrams that can appear on the borders of the current hypothesis, on average we only need to explore 2700 additional hyperedges per sentence to boost the BLEU score from 21.77 to 23.46. The boost is so significant that overall the dominant part of search time is no longer the second pass but the first bigram pass (inside pass actually) which provides a constrained space and outside heuristics for the second pass.

### 5.2 Two-pass decoding versus One-pass decoding

By varying the beam size for the first pass, we can plot graphs of model scores versus search time and BLEU scores versus search time as shown in Figure 1. We use a very large beam for the second pass due to the reason that the outside estimate for the second pass is discriminative enough to guide the

<i>Decoding Method</i>	Avg. Hyperedges	BLEU
Bigram Pass	167K	21.77
Trigram Pass		
UNI	–	–
BO	+ 629.7K=796.7K	23.56
<i>BO+BB</i>	+2.7K =169.7K	23.46
Trigram One-pass, with Beam	6401K	23.47

Table 1: Speed and BLEU scores for two-pass decoding. UNI stands for the uniform (zero) outside estimate. BO stands for the bigram outside cost estimate. BB stands for the best border estimate, which is added to BO.

<i>Decoder</i>	Time	BLEU	Model Score
One-pass agenda	4317s	22.25	-208.849
One-pass CYK	3793s	22.89	-207.309
<i>Multi-pass, CYK first</i>			
<i>agenda second pass</i>	3689s	23.56	-205.344
<b>MEC third pass</b>	<b>3749s</b>	<b>24.07</b>	<b>-203.878</b>
Lazy-cube-pruning	3746s	22.16	-208.575

Table 2: Summary of different trigram decoding strategies, using about the same time (10 seconds per sentence).

search. We sum up the total number of seconds for both passes to compare with the baseline systems. On average, less than 5% of time is spent in the second pass.

In Figure 1, we have four competing decoders. *bitri\_cyk* is our two-pass decoder, using CYK as the first pass decoding algorithm and using agenda-based decoding in the second pass which is guided by the first pass. *agenda* is our trigram-integrated agenda-based decoder. The other two systems are also one-pass. *cyk* is our trigram-integrated CYK decoder. *lazy\_kbest* is our top-down k-best-style decoder.<sup>1</sup>

Figure 1(left) compares the search efficiencies of the four systems. *bitri\_cyk* at the top ranks first. *cyk* follows it. The curves of *lazy\_kbest* and *agenda* cross

<sup>1</sup>In our implementation of the lazy-cube-pruning based ITG decoder, we vary the re-ranking buffer size and the top-*k* list size which are the two controlling parameters for the search space. But we did not use any *LM* estimate to achieve early stopping as suggested by Huang and Chiang (2007). Also, we did not have a translation-model-only pruning pass. So the results shown in this paper for the lazy cube pruning method is not of its best performance.

and are both below the curves of *bitri\_cyk* and *cyk*. This figure indicates the advantage of the two-pass decoding strategy in producing translations with a high model score in less time.

However, model scores do not directly translate into BLEU scores. In Figure 1(right), *bitri\_cyk* is better than *CYK* only in a certain time window when the beam is neither too small nor too large. But the window is actually where we are interested – it ranges from 5 seconds per sentence to 20 seconds per sentence. Table 2 summarizes the performance of the four decoders when the decoding speed is at 10 seconds per sentence.

### 5.3 Does the hook trick help?

We have many choices in implementing the bigram decoding pass. We can do either *CYK* or agenda-based decoding. We can also use the dynamic programming hook trick. We are particularly interested in the effect of the hook trick in a large-scale system with aggressive pruning.

Figure 2 compares the four possible combinations of the decoding choices for the first pass: *bitri\_cyk*, *bitri\_agenda*, *bitri\_cyk\_hook* and *bitri\_agenda\_hook*. *bitri\_cyk* which simply uses *CYK* as the first pass decoding algorithm is the best in terms of performance and time trade-off. The hook-based decoders do not show an advantage in our experiments. Only *bitri\_agenda\_hook* gets slightly better than *bitri\_agenda* when the beam size increases. So, it is very likely the overhead of building hooks offsets its benefit when we massively prune the hypotheses.

### 5.4 Maximizing BLEU

The *bitri\_cyk* decoder spends little time in the agenda-based trigram pass, quickly reaching the goal item starting from the bottom of the chart. In order to maximize BLEU score using the algorithm described in Section 4, we need a sizable trigram forest as a starting point. Therefore, we keep popping off more items from the agenda after the goal is reached. Simply by exploring more (200 times the log beam) after-goal items, we can optimize the Viterbi synchronous parse significantly, shown in Figure 3(left) in terms of model score versus search time.

However, the mismatch between model score and BLEU score persists. So, we try our algorithm

of maximizing expected count of synchronous constituents on the trigram forest. We find significant improvement in BLEU, as shown in Figure 3 (right) by the curve of *bitri\_cyk\_epass\_me\_cons*. *bitri\_cyk\_epass\_me\_cons* beats both *bitri\_cyk* and *cyk* in terms of BLEU versus time if using more than 1.5 seconds on average to decode each sentence. At each time point, the difference in BLEU between *bitri\_cyk\_epass\_me\_cons* and the highest of *bitri\_cyk* and *cyk* is around .5 points consistently as we vary the beam size for the first pass. We achieve the record-high BLEU score 24.34 using on average 21 seconds per sentence, compared to the next-highest score of 23.92 achieved by *cyk* using on average 78 seconds per sentence.

## 6 Conclusion

We present a multi-pass method to speed up  $n$ -gram integrated decoding for SCFG. We use an inside/outside parsing algorithm to get the Viterbi outside cost of bigram integrated states which is used as an outside estimate for trigram integrated states. The coarse-level outside cost plus the simple estimate for border trigrams speeds up the trigram decoding pass hundreds of times compared to using no outside estimate.

Maximizing the probability of the synchronous derivation is not equivalent to maximizing BLEU. We use a rescoring decoding pass that maximizes the expected count of synchronous constituents. This technique, together with the progressive search at previous stages, gives a decoder that produces the highest BLEU score we have obtained on the data in a very reasonable amount of time.

As future work, new metrics for the final pass may be able to better approximate BLEU. As the bigram decoding pass currently takes the bulk of the decoding time, better heuristics for this phase may speed up the system further.

## Abstract

We propose the use of regular tree grammars (RTGs) as a formalism for the underspecified processing of scope ambiguities. By applying standard results on RTGs, we obtain a novel algorithm for eliminating equivalent readings and the first efficient algorithm for computing the best reading of a scope ambiguity. We also show how to derive RTGs from more traditional underspecified descriptions.

## 1 Introduction

Underspecification (Reyle, 1993; Copestake et al., 2005; Bos, 1996; Egg et al., 2001) has become the standard approach to dealing with scope ambiguity in large-scale hand-written grammars (see e.g. Copestake and Flickinger (2000)). The key idea behind underspecification is that the parser avoids computing all scope readings. Instead, it computes a single compact *underspecified description* for each parse. One can then strengthen the underspecified description to efficiently eliminate subsets of readings that were not intended in the given context (Koller and Niehren, 2000; Koller and Thater, 2006); so when the individual readings are eventually computed, the number of remaining readings is much smaller and much closer to the actual perceived ambiguity of the sentence.

In the past few years, a “standard model” of scope underspecification has emerged: A range of formalisms from Underspecified DRT (Reyle, 1993) to dominance graphs (Althaus et al., 2003) have offered mechanisms to specify the “semantic material” of which the semantic representations are built up, plus dominance or outscoping relations between these building blocks. This has been a very successful approach, but recent algorithms for eliminating subsets of readings have pushed the expres-

sive power of these formalisms to their limits; for instance, Koller and Thater (2006) speculate that further improvements over their (incomplete) redundancy elimination algorithm require a more expressive formalism than dominance graphs. On the theoretical side, Ebert (2005) has shown that none of the major underspecification formalisms are *expressively complete*, i.e. supports the description of an arbitrary subset of readings. Furthermore, the somewhat implicit nature of dominance-based descriptions makes it difficult to systematically associate readings with probabilities or costs and then compute a best reading.

In this paper, we address both of these shortcomings by proposing *regular tree grammars (RTGs)* as a novel underspecification formalism. Regular tree grammars (Comon et al., 2007) are a standard approach for specifying sets of trees in theoretical computer science, and are closely related to regular tree transducers as used e.g. in recent work on statistical MT (Knight and Graehl, 2005) and grammar formalisms (Shieber, 2006). We show that the “dominance charts” proposed by Koller and Thater (2005b) can be naturally seen as regular tree grammars; using their algorithm, classical underspecified descriptions (dominance graphs) can be translated into RTGs that describe the same sets of readings. However, RTGs are trivially expressively complete because every finite tree language is also regular. We exploit this increase in expressive power in presenting a novel redundancy elimination algorithm that is simpler and more powerful than the one by Koller and Thater (2006); in our algorithm, redundancy elimination amounts to intersection of regular tree languages. Furthermore, we show how to define a PCFG-style cost model on RTGs and compute best readings of deterministic RTGs efficiently, and illustrate this model on a machine learning based model

of scope preferences (Higgins and Sadock, 2003). To our knowledge, this is the first efficient algorithm for computing best readings of a scope ambiguity in the literature.

The paper is structured as follows. In Section 2, we will first sketch the existing standard approach to underspecification. We will then define regular tree grammars and show how to see them as an underspecification formalism in Section 3. We will present the new redundancy elimination algorithm, based on language intersection, in Section 4, and show how to equip RTGs with weights and compute best readings in Section 5. We conclude in Section 6.

## 2 Underspecification

The key idea behind scope underspecification is to describe all readings of an ambiguous expression with a single, compact underspecified representation (USR). This simplifies semantics construction, and current algorithms (Koller and Thater, 2005a) support the efficient enumeration of readings from an USR when it is necessary. Furthermore, it is possible to perform certain semantic processing tasks such as eliminating redundant readings (see Section 4) directly on the level of underspecified representations without explicitly enumerating individual readings.

Under the “standard model” of scope underspecification, readings are considered as formulas or trees. USRs specify the “semantic material” common to all readings, plus dominance or outscopes relations between these building blocks. In this paper, we consider dominance graphs (Egg et al., 2001; Althaus et al., 2003) as one representative of this class. An example dominance graph is shown on the left of Fig. 1. It represents the five readings of the sentence “a representative of a company saw every sample.” The (directed, labelled) graph consists of seven subtrees, or *fragments*, plus *dominance edges* relating nodes of these fragments. Each reading is encoded as one *configuration* of the dominance graph, which can be obtained by “plugging” the tree fragments into each other, in a way that respects the dominance edges: The source node of each dominance edge must dominate (i.e., be an ancestor of) the target node in each configuration. The trees in Fig. 1a–e are the five configurations of the example graph.

An important class of dominance graphs are *hy-*

*pernormally connected* dominance graphs, or *dominance nets* (Niehren and Thater, 2003). The precise definition of dominance nets is not important here, but note that virtually all underspecified descriptions that are produced by current grammars are nets (Flickinger et al., 2005). For the rest of the paper, we restrict ourselves to dominance graphs that are hypernormally connected.

## 3 Regular tree grammars

We will now recall the definition of regular tree grammars and show how they can be used as an underspecification formalism.

### 3.1 Definition

Let  $\Sigma$  be an alphabet, or signature, of tree constructors  $\{f, g, a, \dots\}$ , each of which is equipped with an arity  $\text{ar}(f) \geq 0$ . A *finite constructor tree*  $t$  is a finite tree in which each node is labelled with a symbol of  $\Sigma$ , and the number of children of the node is exactly the arity of this symbol. For instance, the configurations in Fig. 1a–e are finite constructor trees over the signature  $\{a_x|2, a_y|2, \text{comp}_z|0, \dots\}$ . Finite constructor trees can be seen as ground terms over  $\Sigma$  that respect the arities. We write  $T(\Sigma)$  for the finite constructor trees over  $\Sigma$ .

A *regular tree grammar* (RTG) is a 4-tuple  $G = (S, N, \Sigma, R)$  consisting of a *nonterminal alphabet*  $N$ , a *terminal alphabet*  $\Sigma$ , a *start symbol*  $S \in N$ , and a finite set of *production rules*  $R$  of the form  $A \rightarrow \beta$ , where  $A \in N$  and  $\beta \in T(\Sigma \cup N)$ ; the nonterminals count as zero-place constructors. Two finite constructor trees  $t, t' \in T(\Sigma \cup N)$  stand in the *derivation relation*,  $t \rightarrow_G t'$ , if  $t'$  can be built from  $t$  by replacing an occurrence of some nonterminal  $A$  by the tree on the right-hand side of some production for  $A$ . The *language generated by*  $G$ ,  $L(G)$ , is the set  $\{t \in T(\Sigma) \mid S \rightarrow_G^* t\}$ , i.e. all terms of terminal symbols that can be derived from the start symbol by a sequence of rule applications. Note that  $L(G)$  is a possibly infinite language of finite trees. As usual, we write  $A \rightarrow t_1 \mid \dots \mid t_n$  as shorthand for the  $n$  production rules  $A \rightarrow t_i$  ( $1 \leq i \leq n$ ). See Comon et al. (2007) for more details.

The languages that can be accepted by regular tree grammars are called *regular tree languages* (RTLs), and regular tree grammars are equivalent to *regular*

Figure 1: A dominance graph (left) and its five configurations.

*tree automata*, which are defined essentially like the well-known regular string automata, except that they assign states to the nodes in a tree rather than the positions in a string. Tree automata are related to tree transducers as used e.g. in statistical machine translation (Knight and Graehl, 2005) exactly like finite-state string automata are related to finite-state string transducers, i.e. they use identical mechanisms to accept rather than transduce languages. Many theoretical results carry over from regular string languages to regular tree languages; for instance, membership of a tree in a RTL can be decided in linear time, RTLs are closed under intersection, union, and complement, and so forth.

### 3.2 Regular tree grammars in underspecification

We can now use regular tree grammars in underspecification by representing the semantic representations as trees and taking an RTG  $G$  as an underspecified description of the trees in  $L(G)$ . For example, the five configurations in Fig. 1 can be represented as the tree language accepted by the following grammar with start symbol  $S$ .

$$\begin{aligned}
S &\rightarrow a_x(A_1, A_2) \mid a_z(B_1, A_3) \mid every_y(B_3, A_4) \\
A_1 &\rightarrow a_z(B_1, B_2) \\
A_2 &\rightarrow every_y(B_3, B_4) \\
A_3 &\rightarrow a_x(B_2, A_2) \mid every_y(B_3, A_5) \\
A_4 &\rightarrow a_x(A_1, B_4) \mid a_z(B_1, A_5) \\
A_5 &\rightarrow a_x(B_2, B_4) \\
B_1 &\rightarrow comp_z \quad B_2 \rightarrow repr-of_{x,z} \\
B_3 &\rightarrow sample_y \quad B_4 \rightarrow see_{x,y}
\end{aligned}$$

More generally, every finite set of trees can be written as the tree language accepted by a non-recursive regular tree grammar such as this. This grammar can be much smaller than the set of trees, because nonterminal symbols (which stand for sets of possibly many subtrees) can be used on the right-hand sides of multiple rules. Thus an RTG is a compact representation of a set of trees in the same way that a parse chart is a compact representation of the

set of parse trees of a context-free string grammar. Note that each tree can be enumerated from the RTG in linear time.

### 3.3 From dominance graphs to tree grammars

Furthermore, regular tree grammars can be systematically computed from more traditional underspecified descriptions. Koller and Thater (2005b) demonstrate how to compute a *dominance chart* from a dominance graph  $D$  by tabulating how a subgraph can be decomposed into smaller subgraphs by removing what they call a “free fragment”. If  $D$  is hypernormally connected, this chart can be read as a regular tree grammar whose nonterminal symbols are subgraphs of the dominance graph, and whose terminal symbols are names of fragments. For the example graph in Fig. 1, it looks as follows.

$$\begin{aligned}
\{1, 2, 3, 4, 5, 6, 7\} &\rightarrow 1(\{2, 4, 5\}, \{3, 6, 7\}) \\
\{1, 2, 3, 4, 5, 6, 7\} &\rightarrow 2(\{4\}, \{1, 3, 5, 6, 7\}) \\
\{1, 2, 3, 4, 5, 6, 7\} &\rightarrow 3(\{6\}, \{1, 2, 4, 5, 7\}) \\
\{1, 3, 5, 6, 7\} &\rightarrow 1(\{5\}, \{3, 6, 7\}) \mid 3(\{6\}, \{1, 5, 7\}) \\
\{1, 2, 4, 5, 7\} &\rightarrow 1(\{2, 4, 5\}, \{7\}) \mid 2(\{4\}, \{1, 5, 7\}) \\
\{1, 5, 7\} &\rightarrow 1(\{5\}, \{7\}) \\
\{2, 4, 5\} &\rightarrow 2(\{4\}, \{5\}) \quad \{4\} \rightarrow 4 \quad \{6\} \rightarrow 6 \\
\{3, 6, 7\} &\rightarrow 3(\{6\}, \{7\}) \quad \{5\} \rightarrow 5 \quad \{7\} \rightarrow 7
\end{aligned}$$

This grammar accepts, again, five different trees, whose labels are the node names of the dominance graph, for instance  $1(2(4, 5), 3(6, 7))$ . If  $f: \Sigma \rightarrow \Sigma'$  is a *relabelling function* from one terminal alphabet to another, we can write  $f(G)$  for the grammar  $(S, N, \Sigma', R')$ , where  $R' = \{A \rightarrow f(a)(B_1, \dots, B_n) \mid A \rightarrow a(B_1, \dots, B_n) \in R\}$ . Now if we choose  $f$  to be the labelling function of  $D$  (which maps node names to node labels) and  $G$  is the chart of  $D$ , then  $L(f(G))$  will be the set of configurations of  $D$ . The grammar in Section 3.2 is simply  $f(G)$  for the chart above (up to consistent renaming of nonterminals).

In the worst case, the dominance chart of a dominance graph with  $n$  fragments has  $O(2^n)$  production rules (Koller and Thater, 2005b), i.e. charts may be exponential in size; but note that this is still an

Figure 2: Chart sizes in the Rondane corpus.

improvement over the  $n!$  configurations that these worst-case examples have. In practice, RTGs that are computed by converting the USR computed by a grammar remain compact: Fig. 2 compares the average number of configurations and the average number of RTG production rules for USRs of increasing sizes in the Rondane treebank (see Sect. 4.3); the bars represent the number of sentences for USRs of a certain size. Even for the most ambiguous sentence, which has about  $4.5 \times 10^{12}$  scope readings, the dominance chart has only about 75 000 rules, and it takes only 15 seconds on a modern consumer PC (Intel Core 2 Duo at 2 GHz) to compute the grammar from the graph. Computing the charts for all 999 MRS-nets in the treebank takes about 45 seconds.

## 4 Expressive completeness and redundancy elimination

Because every finite tree language is regular, RTGs constitute an *expressively complete* underspecification formalism in the sense of Ebert (2005): They can represent arbitrary subsets of the original set of readings. Ebert shows that the classical dominance-based underspecification formalisms, such as MRS, Hole Semantics, and dominance graphs, are all expressively incomplete, which Koller and Thater (2006) speculate might be a practical problem for algorithms that strengthen USRs to remove unwanted readings. We will now show how both the expressive completeness and the availability of standard constructions for RTGs can be exploited to get an improved redundancy elimination algorithm.

### 4.1 Redundancy elimination

Redundancy elimination (Vestre, 1991; Chaves, 2003; Koller and Thater, 2006) is the problem of deriving from an USR  $U$  another USR  $U'$ , such that the readings of  $U'$  are a proper subset of the read-

ings of  $U$ , but every reading in  $U$  is semantically equivalent to some reading in  $U'$ . For instance, the following sentence from the Rondane treebank is analyzed as having six quantifiers and 480 readings by the ERG grammar; these readings fall into just two semantic equivalence classes, characterized by the relative scope of “the lee of” and “a small hillside”. A redundancy elimination would therefore ideally reduce the underspecified description to one that has only two readings (one for each class).

- (1) We quickly put up the tents in the lee of a small hillside and cook for the first time in the open. (Rondane 892)

Koller and Thater (2006) define semantic equivalence in terms of a rewrite system that specifies under what conditions two quantifiers may exchange their positions without changing the meaning of the semantic representation. For example, if we assume the following rewrite system (with just a single rule), the five configurations in Fig. 1a-e fall into three equivalence classes – indicated by the dotted boxes around the names a-e – because two pairs of readings can be rewritten into each other.

- (2)  $a_x(a_z(P, Q), R) \rightarrow a_z(P, a_x(Q, R))$

Based on this definition, Koller and Thater (2006) present an algorithm (henceforth, KT06) that deletes rules from a dominance chart and thus removes subsets of readings from the USR. The KT06 algorithm is fast and quite effective in practice. However, it essentially predicts for each production rule of a dominance chart whether each configuration that can be built with this rule is equivalent to a configuration that can be built with some other production for the same subgraph, and is therefore rather complex.

### 4.2 Redundancy elimination as language intersection

We now define a new algorithm for redundancy elimination. It is based on the intersection of regular tree languages, and will be much simpler and more powerful than KT06.

Let  $G = (S, N, \Sigma, R)$  be an RTG with a linear order on the terminals  $\Sigma$ ; for ease of presentation, we assume  $\Sigma \subseteq \mathbb{N}$ . Furthermore, let  $f : \Sigma \rightarrow \Sigma'$  be a relabelling function into the signature  $\Sigma'$  of the rewrite

system. For example,  $G$  could be the dominance chart of some dominance graph  $D$ , and  $f$  could be the labelling function of  $D$ .

We can then define a tree language  $L_F$  as follows:  $L_F$  contains all trees over  $\Sigma$  that do not contain a subtree of the form  $q_1(x_1, \dots, x_{i-1}, q_2(\dots), x_{i+1}, \dots, x_k)$  where  $q_1 > q_2$  and the rewrite system contains a rule that has  $f(q_1)(X_1, \dots, X_{i-1}, f(q_2)(\dots), X_{i+1}, \dots, X_k)$  on the left or right hand side.  $L_F$  is a regular tree language, and can be accepted by a regular tree grammar  $G_F$  with  $O(n)$  nonterminals and  $O(n^2)$  rules, where  $n = |\Sigma'|$ . A filter grammar for Fig. 1 looks as follows:

$$\begin{array}{l} S \rightarrow 1(S, S) \mid 2(S, Q_1) \mid 3(S, S) \mid 4 \mid \dots \mid 7 \\ Q_1 \rightarrow 2(S, Q_1) \mid 3(S, S) \mid 4 \mid \dots \mid 7 \end{array}$$

This grammar accepts all trees over  $\Sigma$  except ones in which a node with label 2 is the parent of a node with label 1, because such trees correspond to configurations in which a node with label  $a_z$  is the parent of a node with label  $a_x$ ,  $a_z$  and  $a_x$  are permutable, and  $2 > 1$ . In particular, it will accept the configurations (b), (c), and (e) in Fig. 1, but not (a) or (d).

Since regular tree languages are closed under intersection, we can compute a grammar  $G'$  such that  $L(G') = L(G) \cap L_F$ . This grammar has  $O(nk)$  nonterminals and  $O(n^2k)$  productions, where  $k$  is the number of production rules in  $G$ , and can be computed in time  $O(n^2k)$ . The relabelled grammar  $f(G')$  accepts all trees in which adjacent occurrences of permutable quantifiers are in a canonical order (sorted from lowest to highest node name). For example, the grammar  $G'$  for the example looks as follows; note that the nonterminal alphabet of  $G'$  is the product of the nonterminal alphabets of  $G$  and  $G_F$ .

$$\begin{array}{ll} \{1, 2, 3, 4, 5, 6, 7\}_S & \rightarrow 1(\{2, 4, 5\}_S, \{3, 6, 7\}_S) \\ \{1, 2, 3, 4, 5, 6, 7\}_S & \rightarrow 2(\{4\}_S, \{1, 3, 5, 6, 7\}_{Q_1}) \\ \{1, 2, 3, 4, 5, 6, 7\}_S & \rightarrow 3(\{6\}_S, \{1, 2, 4, 5, 7\}_S) \\ \{1, 3, 5, 6, 7\}_{Q_1} & \rightarrow 3(\{6\}_S, \{1, 5, 7\}_S) \\ \{1, 2, 4, 5, 7\}_S & \rightarrow 1(\{2, 4, 5\}_S, \{7\}_S) \\ \{1, 2, 4, 5, 7\}_S & \rightarrow 2(\{4\}_S, \{1, 5, 7\}_{Q_1}) \\ \{2, 4, 5\}_S & \rightarrow 2(\{4\}_S, \{5\}_{Q_1}) & \{4\}_S & \rightarrow 4 \\ \{3, 6, 7\}_S & \rightarrow 3(\{6\}_S, \{7\}_S) & \{5\}_S & \rightarrow 5 \\ \{1, 5, 7\}_S & \rightarrow 1(\{5\}_S, \{7\}_S) & \{5\}_{Q_1} & \rightarrow 5 \\ \{6\}_S & \rightarrow 6 & \{7\}_S & \rightarrow 7 \end{array}$$

Significantly, the grammar contains no productions for  $\{1, 3, 5, 6, 7\}_{Q_1}$  with terminal symbol 1, and no production for  $\{1, 5, 7\}_{Q_1}$ . This reduces the tree language accepted by  $f(G')$  to just the configurations (b), (c), and (e) in Fig. 1, i.e. exactly one

representative of every equivalence class. Notice that there are two different nonterminals,  $\{5\}_{Q_1}$  and  $\{5\}_S$ , corresponding to the subgraph  $\{5\}$ , so the intersected RTG is not a dominance chart any more. As we will see below, this increased expressivity increases the power of the redundancy elimination algorithm.

### 4.3 Evaluation

The algorithm presented here is not only more transparent than KT06, but also more powerful; for example, it will reduce the graph in Fig. 4 of Koller and Thater (2006) completely, whereas KT06 won't.

To measure the extent to which the new algorithm improves upon KT06, we compare both algorithms on the USRs in the Rondane treebank (version of January 2006). The Rondane treebank is a ‘‘Redwoods style’’ treebank (Oepen et al., 2002) containing MRS-based underspecified representations for sentences from the tourism domain, and is distributed together with the English Resource Grammar (ERG) (Copestake and Flickinger, 2000).

The treebank contains 999 MRS-nets, which we translate automatically into dominance graphs and further into RTGs; the median number of scope readings per sentence is 56. For our experiment, we consider all 950 MRS-nets with less than 650 000 configurations. We use a slightly weaker version of the rewrite system that Koller and Thater (2006) used in their evaluation.

It turns out that the median number of equivalence classes, computed by pairwise comparison of all configurations, is 8. The median number of configurations that remain after running our algorithm is also 8. By contrast, the median number after running KT06 is 11. For a more fine-grained comparison, Fig. 3 shows the percentage of USRs for which the two algorithms achieve complete reduction, i.e. retain only one reading per equivalence class. In the diagram, we have grouped USRs according to the natural logarithm of their numbers of configurations, and report the percentage of USRs in this group on which the algorithms were complete. The new algorithm dramatically outperforms KT06: In total, it reduces 96% of all USRs completely, whereas KT06 was complete only for 40%. This increase in completeness is partially due to the new algorithm's ability to use non-chart RTGs: For 28% of the sentences,

Figure 3: Percentage of USRs in Rondane for which the algorithms achieve complete reduction.

it computes RTGs that are not dominance charts. KT06 was only able to reduce 5 of these 263 graphs completely.

The algorithm needs 25 seconds to run for the entire corpus (old algorithm: 17 seconds), and it would take 50 (38) more seconds to run on the 49 large USRs that we exclude from the experiment. By contrast, it takes about 7 hours to compute the equivalence classes by pairwise comparison, and it would take an estimated several billion years to compute the equivalence classes of the excluded USRs. In short, the redundancy elimination algorithm presented here achieves nearly complete reduction at a tiny fraction of the runtime, and makes a useful task that was completely infeasible before possible.

#### 4.4 Compactness

Finally, let us briefly consider the ramifications of expressive completeness on efficiency. Ebert (2005) proves that no expressively complete underspecification formalism can be *compact*, i.e. in the worst case, the USR of a set of readings become exponentially large in the number of scope-bearing operators. In the case of RTGs, this worst case is achieved by grammars of the form  $S \rightarrow t_1 \mid \dots \mid t_n$ , where  $t_1, \dots, t_n$  are the trees we want to describe. This grammar is as big as the number of readings, i.e. worst-case exponential in the number  $n$  of scope-bearing operators, and essentially amounts to a meta-level disjunction over the readings.

Ebert takes the incompatibility between compactness and expressive completeness as a fundamental problem for underspecification. We don't see things quite as bleakly. Expressions of natural language itself are (extremely underspecified) descriptions of sets of semantic representations, and so Ebert's argument applies to NL expressions as well. This

means that describing a given set of readings may require an exponentially long discourse. Ebert's definition of compactness may be too harsh: An USR, although exponential-size in the number of quantifiers, may still be polynomial-size in the length of the discourse in the worst case.

Nevertheless, the tradeoff between compactness and expressive power is important for the design of underspecification formalisms, and RTGs offer a unique answer. They are expressively complete; but as we have seen in Fig. 2, the RTGs that are derived by semantic construction are compact, and even intersecting them with filter grammars for redundancy elimination only blows up their sizes by a factor of  $O(n^2)$ . As we add more and more information to an RTG to reduce the set of readings, ultimately to those readings that were meant in the actual context of the utterance, the grammar will become less and less compact; but this trend is counterbalanced by the overall reduction in the number of readings. For the USRs in Rondane, the intersected RTGs are, on average, 6% smaller than the original charts. Only 30% are larger than the charts, by a maximal factor of 3.66. Therefore we believe that the theoretical non-compactness should not be a major problem in a well-designed practical system.

## 5 Computing best configurations

A second advantage of using RTGs as an underspecification formalism is that we can apply existing algorithms for computing the best derivations of *weighted* regular tree grammars to compute best (that is, cheapest or most probable) configurations. This gives us the first efficient algorithm for computing the preferred reading of a scope ambiguity.

We define weighted dominance graphs and weighted tree grammars, show how to translate the former into the latter and discuss an example.

### 5.1 Weighted dominance graphs

A *weighted* dominance graph  $D = (V, E_T \uplus E_D \uplus W_D \uplus W_I)$  is a dominance graph with two new types of edges – *soft dominance edges*,  $W_D$ , and *soft disjointness edges*,  $W_I$  –, each of which is equipped with a numeric weight. Soft dominance and disjointness edges provide a mechanism for assigning weights to configurations; a soft dominance edge ex-

Figure 4: The graph of Fig. 1 with soft constraints

presses a preference that two nodes dominate each other in a configuration, whereas a soft disjointness edge expresses a preference that two nodes are *disjoint*, i.e. neither dominates the other.

We take the *hard backbone* of  $D$  to be the ordinary dominance graph  $B(D) = (V, E_T \uplus E_D)$  obtained by removing all soft edges. The set of *configurations* of a weighted graph  $D$  is the set of configurations of its hard backbone. For each configuration  $t$  of  $D$ , we define the *weight*  $c(t)$  to be the product of the weights of all soft dominance and disjointness edges that are satisfied in  $t$ . We can then ask for configurations of maximal weight.

Weighted dominance graphs can be used to encode the standard models of scope preferences (Pafel, 1997; Higgins and Sadock, 2003). For example, Higgins and Sadock (2003) present a machine learning approach for determining pairwise preferences as to whether a quantifier  $Q_1$  dominates another quantifier  $Q_2$ ,  $Q_2$  dominates  $Q_1$ , or neither (i.e. they are disjoint). We can represent these numbers as the weights of soft dominance and disjointness edges. An example (with artificial weights) is shown in Fig. 4; we draw the soft dominance edges as curved dotted arrows and the soft disjointness edges as angled double-headed arrows. Each soft edge is annotated with its weight. The hard backbone of this dominance graph is our example graph from Fig. 1, so it has the same five configurations. The weighted graph assigns a weight of 8 to configuration (a), a weight of 1 to (d), and a weight of 9 to (e); this is also the configuration of maximum weight.

## 5.2 Weighted tree grammars

In order to compute the maximal-weight configuration of a weighted dominance graph, we will first translate it into a *weighted regular tree grammar*. A weighted regular tree grammar (wRTG) (Graehl and Knight, 2004) is a 5-tuple  $G = (S, N, \Sigma, R, c)$  such

that  $G' = (S, N, \Sigma, R)$  is a regular tree grammar and  $c : R \rightarrow \mathbb{R}$  is a function that assigns each production rule a weight.  $G$  accepts the same language of trees as  $G'$ . It assigns each derivation a cost equal to the product of the costs of the production rules used in this derivation, and it assigns each tree in the language a cost equal to the sum of the costs of its derivations. Thus wRTGs define weights in a way that is extremely similar to PCFGs, except that we don't require any weights to sum to one.

Given a weighted, hypernormally connected dominance graph  $D$ , we can extend the chart of  $B(D)$  to a wRTG by assigning rule weights as follows: The weight of a rule  $D_0 \rightarrow i(D_1, \dots, D_n)$  is the product over the weights of all soft dominance and disjointness edges that are established by this rule. We say that a rule establishes a soft dominance edge from  $u$  to  $v$  if  $u = i$  and  $v$  is in one of the subgraphs  $D_1, \dots, D_n$ ; we say that it establishes a soft disjointness edge between  $u$  and  $v$  if  $u$  and  $v$  are in different subgraphs  $D_j$  and  $D_k$  ( $j \neq k$ ). It can be shown that the weight this grammar assigns to each derivation is equal to the weight that the original dominance graph assigns to the corresponding configuration.

If we apply this construction to the example graph in Fig. 4, we obtain the following wRTG:

$$\begin{array}{ll}
 \{1, \dots, 7\} \rightarrow a_x(\{2, 4, 5\}, \{3, 6, 7\}) & [9] \\
 \{1, \dots, 7\} \rightarrow a_z(\{4\}, \{1, 3, 5, 6, 7\}) & [1] \\
 \{1, \dots, 7\} \rightarrow every_y(\{6\}, \{1, 2, 4, 5, 7\}) & [8] \\
 \{2, 4, 5\} \rightarrow a_z(\{4\}, \{5\}) & [1] \\
 \{3, 6, 7\} \rightarrow every_y(\{6\}, \{7\}) & [1] \\
 \{1, 3, 5, 6, 7\} \rightarrow a_x(\{5\}, \{3, 6, 7\}) & [1] \\
 \{1, 3, 5, 6, 7\} \rightarrow every_y(\{6\}, \{1, 5, 7\}) & [8] \\
 \{1, 2, 4, 5, 7\} \rightarrow a_x(\{2, 4, 5\}, \{7\}) & [1] \\
 \{1, 2, 4, 5, 7\} \rightarrow a_z(\{4\}, \{1, 5, 7\}) & [1] \\
 \{1, 5, 7\} \rightarrow a_x(\{5\}, \{7\}) & [1] \\
 \{4\} \rightarrow comp_z & [1] \quad \{5\} \rightarrow repr-of_{x,z} & [1] \\
 \{6\} \rightarrow sample_y & [1] \quad \{7\} \rightarrow see_{x,y} & [1]
 \end{array}$$

For example, picking “ $a_z$ ” as the root of a configuration (Fig. 1 (c), (d)) of the entire graph has a weight of 1, because this rule establishes no soft edges. On the other hand, choosing “ $a_x$ ” as the root has a weight of 9, because this establishes the soft disjointness edge (and in fact, leads to the derivation of the maximum-weight configuration in Fig. 1 (e)).

## 5.3 Computing the best configuration

The problem of computing the best configuration of a weighted dominance graph – or equivalently, the

best derivation of a weighted tree grammar – can now be solved by standard algorithms for wRTGs. For example, Knight and Graehl (2005) present an algorithm to extract the best derivation of a wRTG in time  $O(t + n \log n)$  where  $n$  is the number of nonterminals and  $t$  is the number of rules. In practice, we can extract the best reading of the most ambiguous sentence in the Rondane treebank ( $4.5 \times 10^{12}$  readings, 75 000 grammar rules) with random soft edges in about a second.

However, notice that this is not the same problem as computing the best *tree* in the language accepted by a wRTG, as trees may have multiple derivations. The problem of computing the best tree is NP-complete (Sima'an, 1996). However, if the weighted regular tree automaton corresponding to the wRTG is deterministic, every tree has only one derivation, and thus computing best trees becomes easy again. The tree automata for dominance charts are always deterministic, and the automata for RTGs as in Section 3.2 (whose terminals correspond to the graph's node labels) are also typically deterministic if the variable names are part of the quantifier node labels. Furthermore, there are algorithms for determinizing weighted tree automata (Borchardt and Vogler, 2003; May and Knight, 2006), which could be applied as preprocessing steps for wRTGs.

## 6 Conclusion

In this paper, we have shown how regular tree grammars can be used as a formalism for scope underspecification, and have exploited the power of this view in a novel, simpler, and more complete algorithm for redundancy elimination and the first efficient algorithm for computing the best reading of a scope ambiguity. In both cases, we have adapted standard algorithms for RTGs, which illustrates the usefulness of using such a well-understood formalism. In the worst case, the RTG for a scope ambiguity is exponential in the number of scope bearers in the sentence; this is a necessary consequence of their expressive completeness. However, those RTGs that are computed by semantic construction and redundancy elimination remain compact.

Rather than showing how to do semantic construction for RTGs, we have presented an algorithm that computes RTGs from more standard underspecifica-

tion formalisms. We see RTGs as an “underspecification assembly language” – they support efficient and useful algorithms, but direct semantic construction may be inconvenient, and RTGs will rather be obtained by “compiling” higher-level underspecified representations such as dominance graphs or MRS.

This perspective also allows us to establish a connection to approaches to semantic construction which use chart-based packing methods rather than dominance-based underspecification to manage scope ambiguities. For instance, both Combinatory Categorical Grammars (Steedman, 2000) and synchronous grammars (Nesson and Shieber, 2006) represent syntactic and semantic ambiguity as part of the same parse chart. These parse charts can be seen as regular tree grammars that accept the language of parse trees, and conceivably an RTG that describes only the semantic and not the syntactic ambiguity could be automatically extracted. We could thus reconcile these completely separate approaches to semantic construction within the same formal framework, and RTG-based algorithms (e.g., for redundancy elimination) would apply equally to dominance-based and chart-based approaches. Indeed, for one particular grammar formalism it has even been shown that the parse chart contains an isomorphic image of a dominance chart (Koller and Rambow, 2007).

Finally, we have only scratched the surface of what can be done with the computation of best configurations in Section 5. The algorithms generalize easily to weights that are taken from an arbitrary ordered semiring (Golan, 1999; Borchardt and Vogler, 2003) and to computing minimal-weight rather than maximal-weight configurations. It is also useful in applications beyond semantic construction, e.g. in discourse parsing (Regneri et al., 2008).

**Acknowledgments.** We have benefited greatly from fruitful discussions on weighted tree grammars with Kevin Knight and Jonathan Graehl, and on discourse underspecification with Markus Egg. We also thank Christian Ebert, Marco Kuhlmann, Alex Lascarides, and the reviewers for their comments on the paper. Finally, we are deeply grateful to our former colleague Joachim Niehren, who was a great fan of tree automata before we even knew what they are.

## Abstract

There are many possible different semantic relationships between nominals. Classification of such relationships is an important and difficult task (for example, the well known noun compound classification task is a special case of this problem). We propose a novel *pattern clusters* method for nominal relationship (NR) classification. Pattern clusters are discovered in a large corpus independently of any particular training set, in an unsupervised manner. Each of the extracted clusters corresponds to some unspecified semantic relationship. The pattern clusters are then used to construct features for training and classification of specific inter-nominal relationships. Our NR classification evaluation strictly follows the ACL SemEval-07 Task 4 datasets and protocol, obtaining an f-score of 70.6, as opposed to 64.8 of the best previous work that did not use the manually provided WordNet sense disambiguation tags.

## 1 Introduction

Automatic extraction and classification of semantic relationships is a major field of activity, of both practical and theoretical interest. A prominent type of semantic relationships is that holding between nominals<sup>1</sup>. For example, in noun compounds many different semantic relationships are encoded by the same simple form (Girju et al., 2005): ‘dog food’ denotes food consumed by dogs, while ‘summer morn-

<sup>1</sup>Our use of the term ‘nominal’ follows (Girju et al., 2007), and includes simple nouns, noun compounds and multiword expressions serving as nouns.

ing’ denotes a morning that happens in the summer. These two relationships are completely different semantically but are similar syntactically, and distinguishing between them could be essential for NLP applications such as question answering and machine translation.

Relation classification usually relies on a training set in the form of tagged data. To improve results, some systems utilize additional manually constructed semantic resources such as WordNet (WN) (Beamer et al., 2007). However, in many domains and languages such resources are not available. Furthermore, usage of such resources frequently requires disambiguation and connection of the data to the resource (word sense disambiguation in the case of WordNet). Manual disambiguation is unfeasible in many practical tasks, and an automatic one may introduce errors and greatly degrade performance. It thus makes sense to try to minimize the usage of such resources, and utilize only corpus contexts in which the relevant words appear.

A leading method for utilizing context information for classification and extraction of relationships is that of patterns (Hearst, 1992; Pantel and Pannacchiotti, 2006). The standard classification process is to find in an auxiliary corpus a set of patterns in which a given training word pair co-appears, and use pattern-word pair co-appearance statistics as features for machine learning algorithms.

In this paper we introduce a novel approach, based on utilizing pattern clusters that are prepared separately and independently of the training set. We do not utilize any manually constructed resource or any manual tagging of training data beyond the cor-

rect classification, thus making our method applicable to fully automated tasks and less domain and language dependent. Moreover, our pattern clustering algorithm is fully unsupervised.

Our method is based on the observation that while each lexical pattern can be highly ambiguous, several patterns in conjunction can reliably define and represent a lexical relationship. Accordingly, we construct pattern clusters from a large generic corpus, each such cluster potentially representing some important generic relationship. This step is done without accessing any training data, anticipating that most meaningful relationships, including those in a given classification problem, will be represented by some of the discovered clusters. We then use the training set to label some of the clusters, and the labeled clusters to assign classes to tested items. One of the advantages of our method is that it can be used not only for classification, but also for further analysis and retrieval of the observed relationships<sup>2</sup>.

The semantic relationships between the components of noun compounds and between nominals in general are not easy to categorize rigorously. Several different relationship hierarchies have been proposed (Nastase and Szpakowicz, 2003; Moldovan et al., 2004). Some classes, like Container-Contained, Time-Event and Product-Producer, appear in several classification schemes, while classes like Tool-Object are more vaguely defined and are subdivided differently. Recently, SemEval-07 Task 4 (Girju et al., 2007) proposed a benchmark dataset that includes a subset of 7 widely accepted nominal relationship (NR) classes, allowing consistent evaluation of different NR classification algorithms. In the SemEval event, 14 research teams evaluated their algorithms using this benchmark. Some of the teams have used the manually annotated WN labels provided with the dataset, and some have not.

We evaluated our algorithm on SemEval-07 Task 4 data, showing superior results over participating algorithms that did not utilize WordNet disambiguation tags. We also show how pattern clusters can be used for a completely unsupervised classification of

---

<sup>2</sup>In (Davidov and Rappoport, 2008) we focus on the pattern cluster resource type itself, presenting an evaluation of its intrinsic quality based on SAT tests. In the present paper we focus on showing how the resource can be used to improve a known NLP task.

the test set. Since in this case no training data is used, this allows the automated discovery of a potentially unbiased classification scheme.

Section 2 discusses related work, Section 3 outlines the pattern clustering algorithm, Section 4 details three classification methods, and Sections 5 and 6 describe the evaluation protocol and results.

## 2 Related Work

Numerous methods have been devised for classification of semantic relationships, among which those holding between nominals constitute a prominent category. Major differences between these methods include available resources, degree of preprocessing, features used, classification algorithm and the nature of training/test data.

### 2.1 Available Resources

Many relation classification algorithms utilize WordNet. Among the 15 systems presented by the 14 SemEval teams, some utilized the manually provided WordNet tags for the dataset pairs (e.g., (Beamer et al., 2007)). In all cases, usage of WN tags improves the results significantly. Some other systems that avoided using the labels used WN as a supporting resource for their algorithms (Costello, 2007; Nakov and Hearst, 2007; Kim and Baldwin, 2007). Only three avoided WN altogether (Hendrickx et al., 2007; Bedmar et al., 2007; Aramaki et al., 2006).

Other resources used for relationship discovery include Wikipedia (Strube and Ponzetto, 2006), thesauri or synonym sets (Turney, 2005) and domain-specific semantic hierarchies like MeSH (Rosario and Hearst, 2001).

While usage of these resources is beneficial in many cases, high quality word sense annotation is not easily available. Besides, lexical resources are not available for many languages, and their coverage is limited even for English when applied to some restricted domains. In this paper we do not use any manually annotated resources apart from the classification training set.

### 2.2 Degree of Preprocessing

Many relationship classification methods utilize some language-dependent preprocessing, like deep or shallow parsing, part of speech tagging and

named entity annotation (Pantel et al., 2004). While the obtained features were shown to improve classification performance, they tend to be language dependent and error-prone when working on unusual text domains and are also highly computationally intensive when processing large corpora. To make our approach as language independent and efficient as possible, we avoided using any such preprocessing techniques.

### 2.3 Classification Features

A wide variety of features are used by different algorithms, ranging from simple bag-of-words frequencies to WordNet-based features (Moldovan et al., 2004). Several studies utilize syntactic features. Many other works manually develop a set of heuristic features devised with some specific relationship in mind, like a WordNet-based meronymy feature (Bedmar et al., 2007) or size-of feature (Aramaki et al., 2006). However, the most prominent feature type is based on lexico-syntactic patterns in which the related words co-appear.

Since (Hearst, 1992), numerous works have used patterns for discovery and identification of instances of semantic relationships (e.g., (Girju et al., 2006; Snow et al., 2006; Banko et al., 2007)). Rosenfeld and Feldman (2007) discover relationship instances by clustering entities appearing in similar contexts. Strategies were developed for discovery of multiple patterns for some specified lexical relationship (Pantel and Pennacchiotti, 2006) and for unsupervised pattern ranking (Turney, 2006). Davidov et al. (2007) use pattern clusters to define general relationships, but these are specific to a given concept. No study so far has proposed a method to define, discover and represent general relationships present in an arbitrary corpus.

In (Davidov and Rappoport, 2008) we present an approach to extract pattern clusters from an untagged corpus. Each such cluster represents some unspecified lexical relationship. In this paper, we use these pattern clusters as the (only) source of machine learning features for a nominal relationship classification problem. Unlike the majority of current studies, we avoid using any other features that require some language-specific information or are devised for specific relationship types.

### 2.4 Classification Algorithm

Various learning algorithms have been used for relation classification. Common choices include variations of SVM (Girju et al., 2004; Nastase et al., 2006), decision trees and memory-based learners. Freely available tools like Weka (Witten and Frank, 1999) allow easy experimentation with common learning algorithms (Hendrickx et al., 2007). In this paper we did not focus on a single ML algorithm, letting algorithm selection be automatically based on cross-validation results on the training set, as in (Hendrickx et al., 2007) but using more algorithms and allowing a more flexible parameter choice.

### 2.5 Training Data

As stated above, several categorization schemes for nominals have been proposed. Nastase and Szpakowicz (2003) proposed a two-level hierarchy with 5 (30) classes at the top (bottom) levels<sup>3</sup>. This hierarchy and a corresponding dataset were used in (Turney, 2005; Turney, 2006) and (Nastase et al., 2006) for evaluation of their algorithms. Moldovan et al. (2004) proposed a different scheme with 35 classes. The most recent dataset has been developed for SemEval 07 Task 4 (Girju et al., 2007). This manually annotated dataset includes a representative rather than exhaustive list of 7 important nominal relationships. We have used this dataset, strictly following the evaluation protocol. This made it possible to meaningfully compare our method to state-of-the-art methods for relation classification.

## 3 Pattern Clustering Algorithm

Our pattern clustering algorithm is designed for the unsupervised definition and discovery of generic semantic relationships. The algorithm first discovers and clusters patterns in which a single ('hook') word participates, and then merges the resulting clusters to form the final structure. In (Davidov and Rappoport, 2008) we describe the algorithm at length, discuss its behavior and parameters in detail, and evaluate its intrinsic quality. To assist readers of the present paper, in this section we provide an overview. Examples of some resulting pattern clusters are given in Section 6. We refer to a pattern

<sup>3</sup>Actually, there were 50 relationships at the bottom level, but valid nominal instances were found only for 30.

contained in our clusters (a pattern type) as a ‘pattern’ and to an occurrence of a pattern in the corpus (a pattern token) as a ‘pattern instance’.

The algorithm does not rely on any data from the classification training set, hence we do not need to repeat its execution for different classification problems. To calibrate its parameters, we ran it a few times with varied parameters settings, producing several different configurations of pattern clusters with different degrees of noise, coverage and granularity. We then chose the best configuration for our task automatically without re-running pattern clustering for each specific problem (see Section 5.3).

### 3.1 Hook Words and Hook Corpora

As a first step, we randomly sample a set of hook words, which will be used in order to discover relationships that generally occur in the corpus. To avoid selection of ambiguous words or typos, we do not select words with frequency higher than a parameter  $F_C$  and lower than a threshold  $F_B$ . We also limit the total number  $N$  of hook words. For each hook word, we now create a *hook corpus*, the set of the contexts in which the word appears. Each context is a window containing  $W$  words or punctuation characters before and after the hook word.

### 3.2 Pattern Specification

To specify patterns, following (Davidov and Rapoport, 2006) we classify words into high-frequency words (HFWs) and content words (CWs). A word whose frequency is more (less) than  $F_H$  ( $F_C$ ) is considered to be a HFW (CW). Our patterns have the general form

**[Prefix]**  $CW_1$  **[Infix]**  $CW_2$  **[Postfix]**

where Prefix, Infix and Postfix contain only HFWs. We require Prefix and Postfix to be a single HFW, while Infix can contain any number of HFWs (limiting pattern length by window size). This form may include patterns like ‘*such X as Y and*’. At this stage, the pattern slots can contain only single words; however, when using the final pattern clusters for nominal relationship classification, slots can contain multiword nominals.

### 3.3 Discovery of Target Words

For each of the hook corpora, we now extract all pattern instances where one CW slot contains the

hook word and the other CW slot contains some other (‘target’) word. To avoid the selection of common words as target words, and to avoid targets appearing in pattern instances that are relatively fixed multiword expressions, we sort all target words in a given hook corpus by pointwise mutual information between hook and target, and drop patterns obtained from pattern instances containing the lowest and highest  $L$  percent of target words.

### 3.4 Pattern Clustering

We now have for each hook corpus a set of patterns, together with the target words used for their extraction, and we want to cluster pattern types. First, we group in clusters all patterns extracted using the same target word. Second, we merge clusters that share more than  $S$  percent of their patterns. Some patterns can appear in more than a single cluster. Finally, we merge pattern clusters from different hook corpora, to avoid clusters specific to a single hook word. During merging, we define and utilize *core patterns* and *unconfirmed patterns*, which are weighed differently during cluster labeling (see Section 4.2). We merge clusters from different hook corpora using the following algorithm:

1. Remove all patterns originating from a single hook corpus only.
2. Mark all patterns of all present clusters as unconfirmed.
3. While there exists some cluster  $C_1$  from corpus  $D_X$  containing only unconfirmed patterns:
  - (a) Select a cluster with a minimal number of patterns.
  - (b) For each corpus  $D$  different from  $D_X$ :
    - i. Scan  $D$  for clusters  $C_2$  that share at least  $S$  percent of their patterns, and all of their core patterns, with  $C_1$ .
    - ii. Add all patterns of  $C_2$  to  $C_1$ , setting all shared patterns as core and all others as unconfirmed.
    - iii. Remove cluster  $C_2$ .
  - (c) If all of  $C_1$ ’s patterns remain unconfirmed remove  $C_1$ .
4. If several clusters have the same set of core patterns merge them according to rules (i,ii).

At the end of this stage, we have a set of pattern clusters where for each cluster there are two subsets, core patterns and unconfirmed patterns.

## 4 Relationship Classification

Up to this stage we did not access the training set in any way and we did not use the fact that the target relations are those holding between nominals. Hence, only a small part of the acquired pattern clusters may be relevant for a given NR classification task, while other clusters can represent completely different relationships (e.g., between verbs). We now use the acquired clusters to learn a model for the given labeled training set and to use this model for classification of the test set. First we describe how we deal with data sparseness. Then we propose a HITS measure used for cluster labeling, and finally we present three different classification methods that utilize pattern clusters.

### 4.1 Enrichment of Provided Data

Our classification algorithm is based on contexts of given nominal pairs. Co-appearance of nominal pairs can be very rare (in fact, some word pairs in the Task 4 set co-appear only once in Yahoo web search). Hence we need more contexts where the given nominals or nominals similar to them co-appear. This step does not require the training labels (the correct classifications), so we do it for both training and test pairs. We do it in two stages: extracting similar nominals, and obtaining more contexts.

#### 4.1.1 Extracting more words

For each nominal pair  $(w_1, w_2)$  in a given sentence  $S$ , we use a method similar to (Davidov and Rappoport, 2006) to extract words that have a shared meaning with  $w_1$  or  $w_2$ . We discover such words by scanning our corpora and querying the web for symmetric patterns (obtained automatically from the corpus as in (Davidov and Rappoport, 2006)) that contain  $w_1$  or  $w_2$ . To avoid getting instances of  $w_{1,2}$  with a different meaning, we also require that the second word will appear in the same text paragraph or the same web page. For example, if we are given a pair  $\langle \text{loans}, \text{students} \rangle$  and we see a sentence ‘... *loans and scholarships for students and professionals ...*’, we use the symmetric pattern ‘X and Y’ to add the word *scholarships* to the group of *loans* and to add the word *professionals* to the group of *students*. We do not take words from the sentence ‘*In European soccer there are transfers and*

*loans...*’ since its context does not contain the word *students*. In cases where there are only several or zero instances where the two nominals co-appear, we dismiss the latter rule and scan for each nominal separately. Note that ‘loans’ can also be a verb, so usage of a part-of-speech tagger might reduce noise.

If the number of instances for a desired nominal is very low, our algorithm trims the first words in these nominal and repeats the search (e.g.,  $\langle \text{simulation study}, \text{voluminous results} \rangle$  becomes  $\langle \text{study}, \text{results} \rangle$ ). This step is the only one specific to English, using the nature of English noun compounds. Our desire in this case is to keep the head words.

#### 4.1.2 Extracting more contexts using the new words

To find more instances where nominals similar to  $w_1$  and  $w_2$  co-appear in HFW patterns, we construct web queries using combinations of each nominal’s group and extract patterns from the search result snapshots (the two line summary provided by search engines for each search result).

### 4.2 The HITS Measure

To use clusters for classification we define a HITS measure similar to that of (Davidov et al., 2007), reflecting the affinity of a given nominal pair to a given cluster. We use the pattern clusters from Section 3 and the additional data collected during the enrichment phase to estimate a HITS value for each cluster and each pair in the training and test sets. For a given nominal pair  $(w_1, w_2)$  and cluster  $C$  with  $n$  core patterns  $P_{core}$  and  $m$  unconfirmed patterns  $P_{unconf}$ ,

$$\begin{aligned} \text{HITS}(C, (w_1, w_2)) &= \\ &|\{p; (w_1, w_2) \text{ appears in } p \in P_{core}\}| / n + \\ &\alpha \times |\{p; (w_1, w_2) \text{ appears in } p \in P_{unconf}\}| / m. \end{aligned}$$

In this formula, ‘appears in’ means that the nominal pair appears in instances of this pattern extracted from the original corpus or retrieved from the web at the previous stage. Thus if some pair appears in most of the patterns of some cluster it receives a high HITS value for this cluster.  $\alpha$  (0..1) is a parameter that lets us modify the relative weight of core and unconfirmed patterns.

### 4.3 Classification Using Pattern Clusters

We present three ways to use pattern clusters for relationship classification.

#### 4.3.1 Classification by cluster labeling

One way to train a classifier in our case is to attach a single relationship label to each cluster during the training phase, and to assign each unlabeled pair to some labeled cluster during the test phase. We use the following normalized HITS measure to label the involved pattern clusters. Denote by  $k_i$  the number of training pairs in class  $i$  in training set  $T$ . Then

$$Label(C) = \underset{p \in T, Label(p)=i}{argmax_i} \sum hits(C, p) / k_i$$

Clusters where the above sum is zero remain unlabeled. In the test phase we assign to each test pair  $p$  the label of the labeled cluster  $C$  that received the highest  $HITS(C, p)$  value. If there are several clusters with a highest HITS value, then the algorithm selects a ‘clarifying’ set of patterns – patterns that are different in these best clusters. Then it constructs clarifying web queries that contain the test nominal pair inside the clarifying patterns. The effect is to increment the HITS value of the cluster containing a clarifying pattern if an appropriate pattern instance (including the target nominals) was found on the web. We start with the most frequent clarifying pattern and perform additional queries until no clarifying patterns are left or until some labeled cluster obtains a highest HITS value. If no patterns are left but there are still several winning clusters, we assign to the pair the label of the cluster with the largest number of pattern instances in the corpus.

One advantage of this method is that we get as a by-product a set of labeled pattern clusters. Examination of this set can help to distinguish and analyze (by means of patterns) which different relationships actually exist for each class in the training set. Furthermore, labeled pattern clusters can be used for web queries to obtain additional examples of the same relationship.

#### 4.3.2 Classification by cluster HITS values as features

In this method we treat the HITS measure for a cluster as a feature for a machine learning classification

algorithm. To do this, we construct feature vectors from each training pair, where each feature is the HITS measure corresponding to a single pattern cluster. We prepare test vectors similarly. Once we have feature vectors, we can use a variety of classifiers (we used those in Weka) to construct a model and to evaluate it on the test set.

#### 4.3.3 Unsupervised clustering

If we are not given any training set, it is still possible to separate between different relationship types by grouping the feature vectors of Section 4.3.2 into clusters. This can be done by applying k-means or another clustering algorithm to the feature vectors described above. This makes the whole approach completely unsupervised. However, it does not provide any inherent labeling, making an evaluation difficult.

## 5 Experimental Setup

The main problem in a fair evaluation of NR classification is that there is no widely accepted list of possible relationships between nominals. In our evaluation we have selected the setup and data from SemEval-07 Task 4 (Girju et al., 2007). Selecting this type of dataset allowed us to compare to 6 submitted state-of-art systems that evaluated on exactly the same data and to 9 other systems that utilize additional information (WN labels). We have applied our three different classification methods on the given data set.

### 5.1 SemEval-07 Task 4 Overview

Task 4 (Girju et al., 2007) involves classification of relationships between simple nominals other than named entities. Seven distinct relationships were chosen: Cause-Effect, Instrument-Agency, Product-Producer, Origin-Entity, Theme-Tool, Part-Whole, and Content-Container. For each relationship, the provided dataset consists of 140 training and 70 test examples. Examples were binary tagged as belonging/not belonging to the tested relationship. The vast majority of negative examples were near-misses, acquired from the web using the same lexico-syntactic patterns as the positives. Examples appear as sentences with the nominal pair tagged. Nouns in this pair were manually labeled with their corresponding WordNet 3 labels and the web queries used to

obtain the sentences. The 15 submitted systems were assigned into 4 categories according to whether they use the WordNet and Query tags (some systems were assigned to more than a single category, since they reported experiments in several settings). In our evaluation we do not utilize WordNet or Query tags, hence we compare ourselves with the corresponding group (A), containing 6 systems.

## 5.2 Corpus and Web Access

Our algorithm uses two corpora. We estimate frequencies and perform primary search on a local web corpus containing about 68GB untagged plain text. This corpus was extracted from the web starting from open directory links, comprising English web pages with varied topics and styles (Gabrilovich and Markovitch, 2005). To enrich the set of given word pairs and patterns as described in Section 4.1 and to perform clarifying queries, we utilize the Yahoo API for web queries. For each query, if the desired words/patterns were found in a page link’s snapshot, we do not use the link, otherwise we download the page from the retrieved link and then extract the required data. If only several links were found for a given word pair we perform local crawling to depth 3 in an attempt to discover more instances.

## 5.3 Parameters and Learning Algorithm

Our algorithm utilizes several parameters. Instead of calibrating them manually, we only provided a desired range for each, and the final parameter values were obtained during selection of the best-performing setup using 10-fold cross-validation on the training set. For each parameter we have estimated its desired range using the (Nastase and Szpakowicz, 2003) set as a development set. Note that this set uses an entirely different relationship classification scheme. We ran the pattern clustering phase on 128 different sets of parameters, obtaining 128 different clustering schemes with varied granularity, noise and coverage.

The parameter ranges obtained are:  $F_C$  (meta-pattern content word frequency and upper bound for hook word selection): 100 – 5000 words per million (wpm);  $F_H$  (meta-pattern HFW): 10 – 100 wpm;  $F_B$  (low word count for hook word filtering): 1 – 50 wpm;  $N$  (number of hook words): 100 – 1000;  $W$  (window size): 5 or window = sentence;  $L$  (tar-

get word mutual information filter):  $1/3 - 1/5$ ;  $S$  (cluster overlap filter for cluster merging):  $2/3$ ;  $\alpha$  (core vs. unconfirmed weight for HITS estimation):  $0.1 - 0.01$ ;  $S$  (commonality for cluster merging):  $2/3$ . As designed, each parameter indeed influences a certain effect. Naturally, the parameters are not mutually independent. Selecting the best configuration in the cross-validation phase makes the algorithm flexible and less dependent on hard-coded parameter values.

Selection of learning algorithm and its algorithm-specific parameters were done as follows. For each of the 7 classification tasks (one per relationship type), for each of the 128 pattern clustering schemes, we prepared a list of most of the compatible algorithms available in Weka, and we automatically selected the model (a parameter set and an algorithm) which gave the best 10-fold cross-validation results. The winning algorithms were LWL (Atkeson et al., 1997), SMO (Platt, 1999), and K\* (Cleary and Trigg, 1995) (there were 7 tasks, and different algorithms could be selected for each task). We then used the obtained model to classify the testing set. This allowed us to avoid fixing parameters that are best for a specific dataset but not for others. Since each dataset has only 140 examples, the computation time of each learning algorithm is negligible.

## 6 Results

The pattern clustering phase results in 90 to 3000 distinct pattern clusters, depending on the parameter setup. Manual sampling of these clusters indeed reveals that many clusters contain patterns specific to some apparent lexical relationship. For example, we have discovered such clusters as: {‘buy  $Y$  accessory for  $X$ ’, ‘shipping  $Y$  for  $X$ ’, ‘ $Y$  is available for  $X$ ’, ‘ $Y$  are available for  $X$ ’, ‘ $Y$  are available for  $X$  systems’, ‘ $Y$  for  $X$ ’} and {‘best  $X$  for  $Y$ ’, ‘ $X$  types for  $Y$ ’, ‘ $Y$  with  $X$ ’, ‘ $X$  is required for  $Y$ ’, ‘ $X$  as required for  $Y$ ’, ‘ $X$  for  $Y$ ’}. Note that some patterns (‘ $Y$  for  $X$ ’) can appear in many clusters.

We applied the three classification methods described in Section 4.3 to Task 4 data. For supervised classification we strictly followed the SemEval datasets and rules. For unsupervised classification we did not use any training data. Using the k-means algorithm, we obtained two nearly equal unlabeled

Method	P	R	F	Acc
Unsupervised clustering (4.3.3)	64.5	61.3	62.0	64.5
Cluster Labeling (4.3.1)	65.1	69.0	67.2	68.5
HITS Features (4.3.2)	<b>69.1</b>	<b>70.6</b>	<b>70.6</b>	<b>70.1</b>
Best Task 4 (no WordNet)	66.1	66.7	64.8	66.0
Best Task 4 (with WordNet)	79.7	69.8	72.4	76.3

Table 1: Our SemEval-07 Task 4 results.

Relation Type	F	Acc	C
Cause-Effect	69.7	71.4	2
Instrument-Agency	76.5	74.2	1
Product-Producer	76.4	83.8	1
Origin-Entity	65.4	62.6	4
Theme-Tool	59.4	58.7	6
Part-Whole	74.3	70.9	1
Content-Container	72.6	69.2	2

Table 2: By-relation Task 4 HITS-based results. **C** is the number of clusters with positive labels.

clusters containing test samples. For evaluation we assigned a negative/positive label to these two clusters according to the best alignment with true labels.

Table 1 shows our results, along with the best Task 4 result not using WordNet labels (Costello, 2007). For reference, the best results overall (Beamer et al., 2007) are also shown. The table shows precision (P) recall (R), F-score (F), and Accuracy (Acc) (percentage of correctly classified examples).

We can see that while our algorithm is not as good as the best method that utilizes WordNet tags, results are superior to all participants who did not use these tags. We can also see that the unsupervised method results are above the random baseline (50%). In fact, our results (f-score 62.0, accuracy 64.5) are better than the averaged results (58.0, 61.1) of the group that did not utilize WN tags.

Table 2 shows the HITS-based classification results (F-score and Accuracy) and the number of positively labeled clusters (C) for each relation. As observed by participants of Task 4, we can see that different sets vary greatly in difficulty. However, we also obtain a nice insight as to why this happens – relations like Theme-Tool seem very ambiguous and are mapped to several clusters, while relations like Product-Producer seem to be well-defined by the obtained pattern clusters.

The SemEval dataset does not explicitly mark items whose correct classification requires analysis of the context of the whole sentence in which they appear. Since our algorithm does not utilize test sen-

tence contextual information, we do not expect it to show exceptional performance on such items. This is a good topic for future research.

Since the SemEval dataset is of a very specific nature, we have also applied our classification framework to the (Nastase and Szpakowicz, 2003) dataset, which contains 600 pairs labeled with 5 main relationship types. We have used the exact evaluation procedure described in (Turney, 2006), achieving a class f-score average of 60.1, as opposed to 54.6 in (Turney, 2005) and 51.2 in (Nastase et al., 2006). This shows that our method produces superior results for rather differing datasets.

## 7 Conclusion

Relationship classification is known to improve many practical tasks, e.g., textual entailment (Tatu and Moldovan, 2005). We have presented a novel framework for relationship classification, based on pattern clusters prepared as a standalone resource independently of the training set.

Our method outperforms current state-of-the-art algorithms that do not utilize WordNet tags on Task 4 of SemEval-07. In practical situations, it would not be feasible to provide a large amount of such sense disambiguation tags manually. Our method also shows competitive performance compared to the majority of task participants that do utilize WN tags. Our method can produce labeled pattern clusters, which can be potentially useful for automatic discovery of additional instances for a given relationship. We intend to pursue this promising direction in future work.

## Abstract

This paper proposes a framework for representing the meaning of phrases and sentences in vector space. Central to our approach is vector composition which we operationalize in terms of additive and multiplicative functions. Under this framework, we introduce a wide range of composition models which we evaluate empirically on a sentence similarity task. Experimental results demonstrate that the multiplicative models are superior to the additive alternatives when compared against human judgments.

## 1 Introduction

Vector-based models of word meaning (Lund and Burgess, 1996; Landauer and Dumais, 1997) have become increasingly popular in natural language processing (NLP) and cognitive science. The appeal of these models lies in their ability to represent meaning simply by using distributional information under the assumption that words occurring within similar contexts are semantically similar (Harris, 1968).

A variety of NLP tasks have made good use of vector-based models. Examples include automatic thesaurus extraction (Grefenstette, 1994), word sense discrimination (Schütze, 1998) and disambiguation (McCarthy et al., 2004), collocation extraction (Schone and Jurafsky, 2001), text segmentation (Choi et al., 2001), and notably information retrieval (Salton et al., 1975). In cognitive science vector-based models have been successful in simulating semantic priming (Lund and Burgess, 1996; Landauer and Dumais, 1997) and text comprehension (Landauer and Dumais, 1997; Foltz et al.,

1998). Moreover, the vector similarities within such semantic spaces have been shown to substantially correlate with human similarity judgments (McDonald, 2000) and word association norms (Denhire and Lemaire, 2004).

Despite their widespread use, vector-based models are typically directed at representing words in isolation and methods for constructing representations for phrases or sentences have received little attention in the literature. In fact, the commonest method for combining the vectors is to average them. Vector averaging is unfortunately insensitive to word order, and more generally syntactic structure, giving the same representation to any constructions that happen to share the same vocabulary. This is illustrated in the example below taken from Landauer et al. (1997). Sentences (1-a) and (1-b) contain exactly the same set of words but their meaning is entirely different.

- (1) a. It was not the sales manager who hit the bottle that day, but the office worker with the serious drinking problem.
- b. That day the office manager, who was drinking, hit the problem sales worker with a bottle, but it was not serious.

While vector addition has been effective in some applications such as essay grading (Landauer and Dumais, 1997) and coherence assessment (Foltz et al., 1998), there is ample empirical evidence that syntactic relations across and within sentences are crucial for sentence and discourse processing (Neville et al., 1991; West and Stanovich, 1986) and modulate cognitive behavior in sentence priming (Till et al., 1988) and inference tasks (Heit and

Rubinstein, 1994).

Computational models of semantics which use symbolic logic representations (Montague, 1974) can account naturally for the meaning of phrases or sentences. Central in these models is the notion of compositionality — the meaning of complex expressions is determined by the meanings of their constituent expressions and the rules used to combine them. Here, semantic analysis is guided by syntactic structure, and therefore sentences (1-a) and (1-b) receive distinct representations. The downside of this approach is that differences in meaning are qualitative rather than quantitative, and degrees of similarity cannot be expressed easily.

In this paper we examine models of semantic composition that are empirically grounded and can represent similarity relations. We present a general framework for vector-based composition which allows us to consider different classes of models. Specifically, we present both additive and multiplicative models of vector combination and assess their performance on a sentence similarity rating experiment. Our results show that the multiplicative models are superior and correlate significantly with behavioral data.

## 2 Related Work

The problem of vector composition has received some attention in the connectionist literature, particularly in response to criticisms of the ability of connectionist representations to handle complex structures (Fodor and Pylyshyn, 1988). While neural networks can readily represent single distinct objects, in the case of multiple objects there are fundamental difficulties in keeping track of which features are bound to which objects. For the hierarchical structure of natural language this binding problem becomes particularly acute. For example, simplistic approaches to handling sentences such as *John loves Mary* and *Mary loves John* typically fail to make valid representations in one of two ways. Either there is a failure to distinguish between these two structures, because the network fails to keep track of the fact that *John* is subject in one and object in the other, or there is a failure to recognize that both structures involve the same participants, because *John* as a subject has a distinct representation from *John* as an object. In contrast, symbolic representations can naturally handle the binding of constituents to their roles, in a systematic manner that

avoids both these problems.

Smolensky (1990) proposed the use of tensor products as a means of binding one vector to another. The tensor product  $\mathbf{u} \otimes \mathbf{v}$  is a matrix whose components are all the possible products  $u_i v_j$  of the components of vectors  $\mathbf{u}$  and  $\mathbf{v}$ . A major difficulty with tensor products is their dimensionality which is higher than the dimensionality of the original vectors (precisely, the tensor product has dimensionality  $m \times n$ ). To overcome this problem, other techniques have been proposed in which the binding of two vectors results in a vector which has the same dimensionality as its components. Holographic reduced representations (Plate, 1991) are one implementation of this idea where the tensor product is projected back onto the space of its components.

The projection is defined in terms of *circular convolution* a mathematical function that compresses the tensor product of two vectors. The compression is achieved by summing along the transdiagonal elements of the tensor product. Noisy versions of the original vectors can be recovered by means of *circular correlation* which is the approximate inverse of circular convolution. The success of circular correlation crucially depends on the components of the  $n$ -dimensional vectors  $\mathbf{u}$  and  $\mathbf{v}$  being randomly distributed with mean 0 and variance  $\frac{1}{n}$ . This poses problems for modeling linguistic data which is typically represented by vectors with non-random structure.

Vector addition is by far the most common method for representing the meaning of linguistic sequences. For example, assuming that individual words are represented by vectors, we can compute the meaning of a sentence by taking their mean (Foltz et al., 1998; Landauer and Dumais, 1997). Vector addition does not increase the dimensionality of the resulting vector. However, since it is order independent, it cannot capture meaning differences that are modulated by differences in syntactic structure. Kintsch (2001) proposes a variation on the vector addition theme in an attempt to model how the meaning of a predicate (e.g., *run*) varies depending on the arguments it operates upon (e.g. *the horse ran* vs. *the color ran*). The idea is to add not only the vectors representing the predicate and its argument but also the neighbors associated with both of them. The neighbors, Kintsch argues, can ‘strengthen features of the predicate that are appropriate for the argument of the predication’.

	animal	stable	village	gallop	jokey
horse	0	6	2	10	4
run	1	8	4	4	0

Figure 1: A hypothetical semantic space for *horse* and *run*

Unfortunately, comparisons across vector composition models have been few and far between in the literature. The merits of different approaches are illustrated with a few hand picked examples and parameter values and large scale evaluations are uniformly absent (see Frank et al. (2007) for a criticism of Kintsch’s (2001) evaluation standards). Our work proposes a framework for vector composition which allows the derivation of different types of models and licenses two fundamental composition operations, multiplication and addition (and their combination). Under this framework, we introduce novel composition models which we compare empirically against previous work using a rigorous evaluation methodology.

### 3 Composition Models

We formulate semantic composition as a function of two vectors,  $\mathbf{u}$  and  $\mathbf{v}$ . We assume that individual words are represented by vectors acquired from a corpus following any of the parametrisations that have been suggested in the literature.<sup>1</sup> We briefly note here that a word’s vector typically represents its co-occurrence with neighboring words. The construction of the semantic space depends on the definition of linguistic context (e.g., neighbouring words can be documents or collocations), the number of components used (e.g., the  $k$  most frequent words in a corpus), and their values (e.g., as raw co-occurrence frequencies or ratios of probabilities). A hypothetical semantic space is illustrated in Figure 1. Here, the space has only five dimensions, and the matrix cells denote the co-occurrence of the target words (*horse* and *run*) with the context words *animal*, *stable*, and so on.

Let  $\mathbf{p}$  denote the composition of two vectors  $\mathbf{u}$  and  $\mathbf{v}$ , representing a pair of constituents which stand in some syntactic relation  $R$ . Let  $K$  stand for any additional knowledge or information which is needed to construct the semantics of their composi-

<sup>1</sup>A detailed treatment of existing semantic space models is outside the scope of the present paper. We refer the interested reader to Padó and Lapata (2007) for a comprehensive overview.

tion. We define a general class of models for this process of composition as:

$$\mathbf{p} = f(\mathbf{u}, \mathbf{v}, R, K) \quad (1)$$

The expression above allows us to derive models for which  $\mathbf{p}$  is constructed in a distinct space from  $\mathbf{u}$  and  $\mathbf{v}$ , as is the case for tensor products. It also allows us to derive models in which composition makes use of background knowledge  $K$  and models in which composition has a dependence, via the argument  $R$ , on syntax.

To derive specific models from this general framework requires the identification of appropriate constraints to narrow the space of functions being considered. One particularly useful constraint is to hold  $R$  fixed by focusing on a single well defined linguistic structure, for example the verb-subject relation. Another simplification concerns  $K$  which can be ignored so as to explore what can be achieved in the absence of additional knowledge. This reduces the class of models to:

$$\mathbf{p} = f(\mathbf{u}, \mathbf{v}) \quad (2)$$

However, this still leaves the particular form of the function  $f$  unspecified. Now, if we assume that  $\mathbf{p}$  lies in the same space as  $\mathbf{u}$  and  $\mathbf{v}$ , avoiding the issues of dimensionality associated with tensor products, and that  $f$  is a linear function, for simplicity, of the cartesian product of  $\mathbf{u}$  and  $\mathbf{v}$ , then we generate a class of *additive* models:

$$\mathbf{p} = \mathbf{A}\mathbf{u} + \mathbf{B}\mathbf{v} \quad (3)$$

where  $\mathbf{A}$  and  $\mathbf{B}$  are matrices which determine the contributions made by  $\mathbf{u}$  and  $\mathbf{v}$  to the product  $\mathbf{p}$ . In contrast, if we assume that  $f$  is a linear function of the tensor product of  $\mathbf{u}$  and  $\mathbf{v}$ , then we obtain *multiplicative* models:

$$\mathbf{p} = \mathbf{C}\mathbf{u}\mathbf{v} \quad (4)$$

where  $\mathbf{C}$  is a tensor of rank 3, which projects the tensor product of  $\mathbf{u}$  and  $\mathbf{v}$  onto the space of  $\mathbf{p}$ .

Further constraints can be introduced to reduce the free parameters in these models. So, if we assume that only the  $i$ th components of  $\mathbf{u}$  and  $\mathbf{v}$  contribute to the  $i$ th component of  $\mathbf{p}$ , that these components are not dependent on  $i$ , and that the function is symmetric with regard to the interchange of  $\mathbf{u}$

and  $\mathbf{v}$ , we obtain a simpler instantiation of an additive model:

$$p_i = u_i + v_i \quad (5)$$

Analogously, under the same assumptions, we obtain the following simpler multiplicative model:

$$p_i = u_i \cdot v_i \quad (6)$$

For example, according to (5), the addition of the two vectors representing *horse* and *run* in Figure 1 would yield  $\mathbf{horse} + \mathbf{run} = [1 \ 14 \ 6 \ 14 \ 4]$ . Whereas their product, as given by (6), is  $\mathbf{horse} \cdot \mathbf{run} = [0 \ 48 \ 8 \ 40 \ 0]$ .

Although the composition model in (5) is commonly used in the literature, from a linguistic perspective, the model in (6) is more appealing. Simply adding the vectors  $\mathbf{u}$  and  $\mathbf{v}$  lumps their contents together rather than allowing the content of one vector to pick out the relevant content of the other. Instead, it could be argued that the contribution of the  $i$ th component of  $\mathbf{u}$  should be scaled according to its relevance to  $\mathbf{v}$ , and vice versa. In effect, this is what model (6) achieves.

As a result of the assumption of symmetry, both these models are ‘bag of words’ models and word order insensitive. Relaxing the assumption of symmetry in the case of the simple additive model produces a model which weighs the contribution of the two components differently:

$$p_i = \alpha u_i + \beta v_i \quad (7)$$

This allows additive models to become more syntax aware, since semantically important constituents can participate more actively in the composition. As an example if we set  $\alpha$  to 0.4 and  $\beta$  to 0.6, then  $\mathbf{horse} = [0 \ 2.4 \ 0.8 \ 4 \ 1.6]$  and  $\mathbf{run} = [0.6 \ 4.8 \ 2.4 \ 2.4 \ 0]$ , and their sum  $\mathbf{horse} + \mathbf{run} = [0.6 \ 5.6 \ 3.2 \ 6.4 \ 1.6]$ .

An extreme form of this differential in the contribution of constituents is where one of the vectors, say  $\mathbf{u}$ , contributes nothing at all to the combination:

$$p_i = v_j \quad (8)$$

Admittedly the model in (8) is impoverished and rather simplistic, however it can serve as a simple baseline against which to compare more sophisticated models.

The models considered so far assume that components do not ‘interfere’ with each other, i.e., that

only the  $i$ th components of  $\mathbf{u}$  and  $\mathbf{v}$  contribute to the  $i$ th component of  $\mathbf{p}$ . Another class of models can be derived by relaxing this constraint. To give a concrete example, circular convolution is an instance of the general multiplicative model which breaks this constraint by allowing  $u_j$  to contribute to  $p_i$ :

$$p_i = \sum_j u_j \cdot v_{i-j} \quad (9)$$

It is also possible to re-introduce the dependence on  $K$  into the model of vector composition. For additive models, a natural way to achieve this is to include further vectors into the summation. These vectors are not arbitrary and ideally they must exhibit some relation to the words of the construction under consideration. When modeling predicate-argument structures, Kintsch (2001) proposes including one or more distributional neighbors,  $\mathbf{n}$ , of the predicate:

$$\mathbf{p} = \mathbf{u} + \mathbf{v} + \sum \mathbf{n} \quad (10)$$

Note that considerable latitude is allowed in selecting the appropriate neighbors. Kintsch (2001) considers only the  $m$  most similar neighbors to the predicate, from which he subsequently selects  $k$ , those most similar to its argument. So, if in the composition of *horse* with *run*, the chosen neighbor is *ride*,  $\mathbf{ride} = [2 \ 15 \ 7 \ 9 \ 1]$ , then this produces the representation  $\mathbf{horse} + \mathbf{run} + \mathbf{ride} = [3 \ 29 \ 13 \ 23 \ 5]$ . In contrast to the simple additive model, this extended model is sensitive to syntactic structure, since  $\mathbf{n}$  is chosen from among the neighbors of the predicate, distinguishing it from the argument.

Although we have presented multiplicative and additive models separately, there is nothing inherent in our formulation that disallows their combination. The proposal is not merely notational. One potential drawback of multiplicative models is the effect of components with value zero. Since the product of zero with any number is itself zero, the presence of zeroes in either of the vectors leads to information being essentially thrown away. Combining the multiplicative model with an additive model, which does not suffer from this problem, could mitigate this problem:

$$p_i = \alpha u_i + \beta v_i + \gamma u_i v_i \quad (11)$$

where  $\alpha$ ,  $\beta$ , and  $\gamma$  are weighting constants.

## 4 Evaluation Set-up

We evaluated the models presented in Section 3 on a sentence similarity task initially proposed by Kintsch (2001). In his study, Kintsch builds a model of how a verb's meaning is modified in the context of its subject. He argues that the subjects of *ran* in *The color ran* and *The horse ran* select different senses of *ran*. This change in the verb's sense is equated to a shift in its position in semantic space. To quantify this shift, Kintsch proposes measuring similarity relative to other verbs acting as landmarks, for example *gallop* and *dissolve*. The idea here is that an appropriate composition model when applied to *horse* and *ran* will yield a vector closer to the landmark *gallop* than *dissolve*. Conversely, when *color* is combined with *ran*, the resulting vector will be closer to *dissolve* than *gallop*.

Focusing on a single compositional structure, namely intransitive verbs and their subjects, is a good point of departure for studying vector combination. Any adequate model of composition must be able to represent argument-verb meaning. Moreover by using a minimal structure we factor out inessential degrees of freedom and are able to assess the merits of different models on an equal footing. Unfortunately, Kintsch (2001) demonstrates how his own composition algorithm works intuitively on a few hand selected examples but does not provide a comprehensive test set. In order to establish an independent measure of sentence similarity, we assembled a set of experimental materials and elicited similarity ratings from human subjects. In the following we describe our data collection procedure and give details on how our composition models were constructed and evaluated.

**Materials and Design** Our materials consisted of sentences with an intransitive verb and its subject. We first compiled a list of intransitive verbs from CELEX<sup>2</sup>. All occurrences of these verbs with a subject noun were next extracted from a RASP parsed (Briscoe and Carroll, 2002) version of the British National Corpus (BNC). Verbs and nouns that were attested less than fifty times in the BNC were removed as they would result in unreliable vectors. Each reference subject-verb tuple (e.g., *horse ran*) was paired with two landmarks, each a synonym of the verb. The landmarks were chosen so as to represent distinct verb senses, one compatible

with the reference (e.g., *horse galloped*) and one incompatible (e.g., *horse dissolved*). Landmarks were taken from WordNet (Fellbaum, 1998). Specifically, they belonged to different synsets and were maximally dissimilar as measured by the Jiang and Conrath (1997) measure.<sup>3</sup>

Our initial set of candidate materials consisted of 20 verbs, each paired with 10 nouns, and 2 landmarks (400 pairs of sentences in total). These were further pretested to allow the selection of a subset of items showing clear variations in sense as we wanted to have a balanced set of similar and dissimilar sentences. In the pretest, subjects saw a reference sentence containing a subject-verb tuple and its landmarks and were asked to choose which landmark was most similar to the reference or neither. Our items were converted into simple sentences (all in past tense) by adding articles where appropriate. The stimuli were administered to four separate groups; each group saw one set of 100 sentences. The pretest was completed by 53 participants.

For each reference verb, the subjects' responses were entered into a contingency table, whose rows corresponded to nouns and columns to each possible answer (i.e., one of the two landmarks). Each cell recorded the number of times our subjects selected the landmark as compatible with the noun or not. We used Fisher's exact test to determine which verbs and nouns showed the greatest variation in landmark preference and items with *p*-values greater than 0.001 were discarded. This yielded a reduced set of experimental items (120 in total) consisting of 15 reference verbs, each with 4 nouns, and 2 landmarks.

**Procedure and Subjects** Participants first saw a set of instructions that explained the sentence similarity task and provided several examples. Then the experimental items were presented; each contained two sentences, one with the reference verb and one with its landmark. Examples of our items are given in Table 1. Here, *burn* is a high similarity landmark (High) for the reference *The fire glowed*, whereas *beam* is a low similarity landmark (Low). The opposite is the case for the reference *The face*

<sup>3</sup>We assessed a wide range of semantic similarity measures using the WordNet similarity package (Pedersen et al., 2004). Most of them yielded similar results. We selected Jiang and Conrath's measure since it has been shown to perform consistently well across several cognitive and NLP tasks (Budanitsky and Hirst, 2001).

<sup>2</sup><http://www.ru.nl/celex/>

Noun	Reference	High	Low
The fire	glowed	burned	beamed
The face	glowed	beamed	burned
The child	strayed	roamed	digressed
The discussion	strayed	digressed	roamed
The sales	slumped	declined	slouched
The shoulders	slumped	slouched	declined

Table 1: Example Stimuli with High and Low similarity landmarks

*glowed*. Sentence pairs were presented serially in random order. Participants were asked to rate how similar the two sentences were on a scale of one to seven. The study was conducted remotely over the Internet using Webexp<sup>4</sup>, a software package designed for conducting psycholinguistic studies over the web. 49 unpaid volunteers completed the experiment, all native speakers of English.

**Analysis of Similarity Ratings** The reliability of the collected judgments is important for our evaluation experiments; we therefore performed several tests to validate the quality of the ratings. First, we examined whether participants gave high ratings to high similarity sentence pairs and low ratings to low similarity ones. Figure 2 presents a box-and-whisker plot of the distribution of the ratings. As we can see sentences with high similarity landmarks are perceived as more similar to the reference sentence. A Wilcoxon rank sum test confirmed that the difference is statistically significant ( $p < 0.01$ ). We also measured how well humans agree in their ratings. We employed leave-one-out resampling (Weiss and Kulikowski, 1991), by correlating the data obtained from each participant with the ratings obtained from all other participants. We used Spearman’s  $\rho$ , a non parametric correlation coefficient, to avoid making any assumptions about the distribution of the similarity ratings. The average inter-subject agreement<sup>5</sup> was  $\rho = 0.40$ . We believe that this level of agreement is satisfactory given that naive subjects are asked to provide judgments on fine-grained semantic distinctions (see Table 1). More evidence that this is not an easy task comes from Figure 2 where we observe some overlap in the ratings for High and Low similarity items.

<sup>4</sup><http://www.webexp.info/>

<sup>5</sup>Note that Spearman’s rho tends to yield lower coefficients compared to parametric alternatives such as Pearson’s  $r$ .

Figure 2: Distribution of elicited ratings for High and Low similarity items

**Model Parameters** Irrespectively of their form, all composition models discussed here are based on a semantic space for representing the meanings of individual words. The semantic space we used in our experiments was built on a lemmatised version of the BNC. Following previous work (Bullinaria and Levy, 2007), we optimized its parameters on a word-based semantic similarity task. The task involves examining the degree of linear relationship between the human judgments for two individual words and vector-based similarity values. We experimented with a variety of dimensions (ranging from 50 to 500,000), vector component definitions (e.g., pointwise mutual information or log likelihood ratio) and similarity measures (e.g., cosine or confusion probability). We used WordSim353, a benchmark dataset (Finkelstein et al., 2002), consisting of relatedness judgments (on a scale of 0 to 10) for 353 word pairs.

We obtained best results with a model using a context window of five words on either side of the target word, the cosine measure, and 2,000 vector components. The latter were the most common context words (excluding a stop list of function words). These components were set to the ratio of the probability of the context word given the target word to the probability of the context word overall. This configuration gave high correlations with the WordSim353 similarity judgments using the cosine measure. In addition, Bullinaria and Levy (2007) found that these parameters perform well on a number of other tasks such as the synonymy task from the *Test of English as a Foreign Language* (TOEFL).

Our composition models have no additional pa-

rameters beyond the semantic space just described, with three exceptions. First, the additive model in (7) weighs differentially the contribution of the two constituents. In our case, these are the subject noun and the intransitive verb. To this end, we optimized the weights on a small held-out set. Specifically, we considered eleven models, varying in their weightings, in steps of 10%, from 100% noun through 50% of both verb and noun to 100% verb. For the best performing model the weight for the verb was 80% and for the noun 20%. Secondly, we optimized the weightings in the combined model (11) with a similar grid search over its three parameters. This yielded a weighted sum consisting of 95% verb, 0% noun and 5% of their multiplicative combination. Finally, Kintsch’s (2001) additive model has two extra parameters. The  $m$  neighbors most similar to the predicate, and the  $k$  of  $m$  neighbors closest to its argument. In our experiments we selected parameters that Kintsch reports as optimal. Specifically,  $m$  was set to 20 and  $k$  to 1.

**Evaluation Methodology** We evaluated the proposed composition models in two ways. First, we used the models to estimate the cosine similarity between the reference sentence and its landmarks. We expect better models to yield a pattern of similarity scores like those observed in the human ratings (see Figure 2). A more scrupulous evaluation requires directly correlating all the individual participants’ similarity judgments with those of the models.<sup>6</sup> We used Spearman’s  $\rho$  for our correlation analyses. Again, better models should correlate better with the experimental data. We assume that the inter-subject agreement can serve as an upper bound for comparing the fit of our models against the human judgments.

## 5 Results

Our experiments assessed the performance of seven composition models. These included three additive models, i.e., simple addition (equation (5), Add), weighted addition (equation (7), WeightAdd), and Kintsch’s (2001) model (equation (10), Kintsch), a multiplicative model (equation (6), Multiply), and also a model which combines multiplication with

<sup>6</sup>We avoided correlating the model predictions with averaged participant judgments as this is inappropriate given the ordinal nature of the scale of these judgments and also leads to a dependence between the number of participants and the magnitude of the correlation coefficient.

Model	High	Low	$\rho$
NonComp	0.27	0.26	0.08**
Add	0.59	0.59	0.04*
WeightAdd	0.35	0.34	0.09**
Kintsch	0.47	0.45	0.09**
Multiply	0.42	0.28	0.17**
Combined	0.38	0.28	0.19**
UpperBound	4.94	3.25	0.40**

Table 2: Model means for High and Low similarity items and correlation coefficients with human judgments (\*:  $p < 0.05$ , \*\*:  $p < 0.01$ )

addition (equation (11), Combined). As a baseline we simply estimated the similarity between the reference verb and its landmarks without taking the subject noun into account (equation (8), NonComp). Table 2 shows the average model ratings for High and Low similarity items. For comparison, we also show the human ratings for these items (UpperBound). Here, we are interested in relative differences, since the two types of ratings correspond to different scales. Model similarities have been estimated using cosine which ranges from 0 to 1, whereas our subjects rated the sentences on a scale from 1 to 7.

The simple additive model fails to distinguish between High and Low Similarity items. We observe a similar pattern for the non compositional baseline model, the weighted additive model and Kintsch (2001). The multiplicative and combined models yield means closer to the human ratings. The difference between High and Low similarity values estimated by these models are statistically significant ( $p < 0.01$  using the Wilcoxon rank sum test). Figure 3 shows the distribution of estimated similarities under the multiplicative model.

The results of our correlation analysis are also given in Table 2. As can be seen, all models are significantly correlated with the human ratings. In order to establish which ones fit our data better, we examined whether the correlation coefficients achieved differ significantly using a  $t$ -test (Cohen and Cohen, 1983). The lowest correlation ( $\rho = 0.04$ ) is observed for the simple additive model which is not significantly different from the non-compositional baseline model. The weighted additive model ( $\rho = 0.09$ ) is not significantly different from the baseline either or Kintsch (2001) ( $\rho = 0.09$ ). Given that the basis

Figure 3: Distribution of predicted similarities for the vector multiplication model on High and Low similarity items

of Kintsch’s model is the summation of the verb, a neighbor close to the verb and the noun, it is not surprising that it produces results similar to a summation which weights the verb more heavily than the noun. The multiplicative model yields a better fit with the experimental data,  $\rho = 0.17$ . The combined model is best overall with  $\rho = 0.19$ . However, the difference between the two models is not statistically significant. Also note that in contrast to the combined model, the multiplicative model does not have any free parameters and hence does not require optimization for this particular task.

## 6 Discussion

In this paper we presented a general framework for vector-based semantic composition. We formulated composition as a function of two vectors and introduced several models based on addition and multiplication. Despite the popularity of additive models, our experimental results showed the superiority of models utilizing multiplicative combinations, at least for the sentence similarity task attempted here. We conjecture that the additive models are not sensitive to the fine-grained meaning distinctions involved in our materials. Previous applications of vector addition to document indexing (Deerwester et al., 1990) or essay grading (Landauer et al., 1997) were more concerned with modeling the gist of a document rather than the meaning of its sentences. Importantly, additive models capture composition by considering *all* vector components representing the meaning of the verb and its subject,

whereas multiplicative models consider a subset, namely non-zero components. The resulting vector is sparser but expresses more succinctly the meaning of the predicate-argument structure, and thus allows semantic similarity to be modelled more accurately.

Further research is needed to gain a deeper understanding of vector composition, both in terms of modeling a wider range of structures (e.g., adjective-noun, noun-noun) and also in terms of exploring the space of models more fully. We anticipate that more substantial correlations can be achieved by implementing more sophisticated models from within the framework outlined here. In particular, the general class of multiplicative models (see equation (4)) appears to be a fruitful area to explore. Future directions include constraining the number of free parameters in linguistically plausible ways and scaling to larger datasets.

The applications of the framework discussed here are many and varied both for cognitive science and NLP. We intend to assess the potential of our composition models on context sensitive semantic priming (Till et al., 1988) and inductive inference (Heit and Rubinstein, 1994). NLP tasks that could benefit from composition models include paraphrase identification and context-dependent language modeling (Coccaro and Jurafsky, 1998).

# Exploiting Feature Hierarchy for Transfer Learning in Named Entity Recognition

Andrew Arnold, Ramesh Nallapati and William W. Cohen

Machine Learning Department, Carnegie Mellon University, Pittsburgh, PA, USA  
{aarnold, nmramesh, wcohen}@cs.cmu.edu

## Abstract

We present a novel hierarchical prior structure for supervised transfer learning in named entity recognition, motivated by the common structure of feature spaces for this task across natural language data sets. The problem of transfer learning, where information gained in one learning task is used to improve performance in another related task, is an important new area of research. In the subproblem of domain adaptation, a model trained over a source domain is generalized to perform well on a related target domain, where the two domains' data are distributed similarly, but not identically. We introduce the concept of groups of closely-related domains, called *genres*, and show how inter-genre adaptation is related to domain adaptation. We also examine multi-task learning, where two domains may be related, but where the concept to be learned in each case is distinct. We show that our prior conveys useful information across domains, genres and tasks, while remaining robust to spurious signals not related to the target domain and concept. We further show that our model generalizes a class of similar hierarchical priors, smoothed to varying degrees, and lay the groundwork for future exploration in this area.

## 1 Introduction

### 1.1 Problem definition

Consider the task of *named entity recognition* (NER). Specifically, you are given a corpus of news articles in which all tokens have been labeled as either belonging to personal name mentions or not. The standard supervised machine learning problem is to learn a classifier over this training data that will successfully label unseen test data drawn from the same distribution as the training data, where “same distribution” could mean anything from having the train and test articles written by the same author to

having them written in the same language. Having successfully trained a named entity classifier on this news data, now consider the problem of learning to classify tokens as names in e-mail data. An intuitive solution might be to simply retrain the classifier, *de novo*, on the e-mail data. Practically, however, large, labeled datasets are often expensive to build and this solution would not scale across a large number of different datasets.

Clearly the problems of identifying names in news articles and e-mails are closely related, and learning to do well on one should help your performance on the other. At the same time, however, there are serious differences between the two problems that need to be addressed. For instance, capitalization, which will certainly be a useful feature in the news problem, may prove less informative in the e-mail data since the rules of capitalization are followed less strictly in that domain.

These are the problems we address in this paper. In particular, we develop a novel prior for named entity recognition that exploits the hierarchical feature space often found in natural language domains (§1.2) and allows for the transfer of information from labeled datasets in other domains (§1.3). §2 introduces the *maximum entropy* (maxent) and *conditional random field* (CRF) learning techniques employed, along with specifications for the design and training of our hierarchical prior. Finally, in §3 we present an empirical investigation of our prior's performance against a number of baselines, demonstrating both its effectiveness and robustness.

### 1.2 Hierarchical feature trees

In many NER problems, features are often constructed as a series of transformations of the input training data, performed in sequence. Thus, if our task is to identify tokens as either being (*O*)*outside* or (*I*)*inside* person names, and we are given the labeled

sample training sentence:

*O O O O O I*  
 Give the book to Professor Caldwell  
 (1)

one such useful feature might be: *Is the token one slot to the left of the current token Professor?* We can represent this symbolically as *L.I.Professor* where we describe the whole space of useful features of this form as:  $\{direction = (L)eft, (C)urrent, (R)ight\} \cdot \{distance = 1, 2, 3, \dots\} \cdot \{value = Professor, book, \dots\}$ . We can conceptualize this structure as a tree, where each slot in the symbolic name of a feature is a branch and each period between slots represents another level, going from root to leaf as read left to right. Thus a subsection of the entire feature tree for the token *Caldwell* could be drawn as in Figure 1 (zoomed in on the section of the tree where the *L.I.Professor* feature resides).

Figure 1: Graphical representation of a hierarchical feature tree for token *Caldwell* in example Sentence 1.

Representing feature spaces with this kind of tree, besides often coinciding with the explicit language used by common natural language toolkits (Cohen, 2004), has the added benefit of allowing a model to easily back-off, or smooth, to decreasing levels of specificity. For example, the leaf level of the feature tree for our sample Sentence 1 tells us that the word *Professor* is important, with respect to labeling person names, when located one slot to the left of the current word being classified. This may be useful in the context of an academic corpus, but might be less useful in a medical domain where the word *Professor* occurs less often. Instead, we might want to learn the related feature *L.I.Dr*. In fact, it might be useful to generalize across multiple domains the fact that the word immediately preceding the current word is often important with respect

---

Table 1: A few examples of the feature hierarchy

to the named entity status of the current word. This is easily accomplished by backing up one level from a leaf in the tree structure to its parent, to represent a class of features such as *L.I.\**. It has been shown empirically that, while the significance of *particular* features might vary between domains and tasks, certain generalized *classes* of features retain their importance across domains (Minkov et al., 2005). By backing-off in this way, we can use the feature hierarchy as a prior for transferring beliefs about the significance of entire *classes* of features across domains and tasks. Some examples illustrating this idea are shown in table 1.

### 1.3 Transfer learning

When only the type of data being examined is allowed to vary (from news articles to e-mails, for example), the problem is called *domain adaptation* (Daumé III and Marcu, 2006). When the task being learned varies (say, from identifying person names to identifying protein names), the problem is called *multi-task learning* (Caruana, 1997). Both of these are considered specific types of the overarching *transfer learning* problem, and both seem to require a way of altering the classifier learned on the first problem (called the *source domain*, or *source task*) to fit the specifics of the second problem (called the *target domain*, or *target task*).

More formally, given an example  $x$  and a class label  $y$ , the standard statistical classification task is to assign a probability,  $p(y|x)$ , to  $x$  of belonging to class  $y$ . In the binary classification case the labels are  $Y \in \{0, 1\}$ . In the case we examine, each example  $x_i$  is represented as a vector of binary features  $(f_1(x_i), \dots, f_F(x_i))$  where  $F$  is the number of features. The data consists of two disjoint subsets: the training set  $(X_{train}, Y_{train}) = \{(x_1, y_1) \dots (x_N, y_N)\}$ , available to the model for its training and the test set  $X_{test} = (x_1, \dots, x_M)$ , upon which we want to use our trained classifier to make predictions.

In the paradigm of *inductive learning*,  $(X_{train}, Y_{train})$  are known, while both  $X_{test}$  and  $Y_{test}$  are completely hidden during training time. In this cases  $X_{test}$  and  $X_{train}$  are both assumed to have been drawn from the same distribution,  $\mathcal{D}$ . In the setting of *transfer learning*, however, we would like to apply our trained classifier to examples drawn from a distribution different from the one upon which it was trained. We therefore assume there are two different distributions,  $\mathcal{D}^{source}$  and  $\mathcal{D}^{target}$ , from which data may be drawn. Given this notation we can then precisely state the transfer learning problem as trying to assign labels  $Y_{test}^{target}$  to test data  $X_{test}^{target}$  drawn from  $\mathcal{D}^{target}$ , given training data  $(X_{train}^{source}, Y_{train}^{source})$  drawn from  $\mathcal{D}^{source}$ .

In this paper we focus on two subproblems of transfer learning:

- *domain adaptation*, where we assume  $Y$  (the set of possible labels) is the same for both  $\mathcal{D}^{source}$  and  $\mathcal{D}^{target}$ , while  $\mathcal{D}^{source}$  and  $\mathcal{D}^{target}$  themselves are allowed to vary between domains.
- *multi-task learning* (Ando and Zhang, 2005; Caruana, 1997; Sutton and McCallum, 2005; Zhang et al., 2005) in which the task (and label set) is allowed to vary from source to target.

Domain adaptation can be further distinguished by the degree of relatedness between the source and target domains. For example, in this work we group data collected in the same medium (e.g., all annotated e-mails or all annotated news articles) as belonging to the same *genre*. Although the specific boundary between domain and genre for a particular set of data is often subjective, it is nevertheless a useful distinction to draw.

One common way of addressing the transfer learning problem is to use a *prior* which, in conjunction with a probabilistic model, allows one to specify *a priori* beliefs about a distribution, thus biasing the results a learning algorithm would have produced had it only been allowed to see the training data (Raina et al., 2006). In the example from §1.1, our belief that capitalization is less strict in e-mails than in news articles could be encoded in a prior that biased the importance of the capitalization feature to be lower for e-mails than news articles. In the next section we address the problem of how to come up with a suitable prior for transfer learning across named entity recognition problems.

## 2 Models considered

### 2.1 Basic Conditional Random Fields

In this work, we will base our work on Conditional Random Fields (CRF's) (Lafferty et al., 2001), which are now one of the most preferred sequential models for many natural language processing tasks.

The parametric form of the CRF for a sentence of length  $n$  is given as follows:

$$p_{\Lambda}(\mathbf{Y} = \mathbf{y}|\mathbf{x}) = \frac{1}{Z(\mathbf{x})} \exp\left(\sum_{i=1}^n \sum_{j=1}^F f_j(\mathbf{x}, y_i) \lambda_j\right) \quad (2)$$

where  $Z(\mathbf{x})$  is the normalization term. CRF learns a model consisting of a set of weights  $\Lambda = \{\lambda_1 \dots \lambda_F\}$  over the features so as to maximize the conditional likelihood of the training data,  $p(Y_{train}|X_{train})$ , given the model  $p_{\Lambda}$ .

### 2.2 CRF with Gaussian priors

To avoid overfitting the training data, these  $\lambda$ 's are often further constrained by the use of a Gaussian prior (Chen and Rosenfeld, 1999) with diagonal covariance,  $\mathcal{N}(\mu, \sigma^2)$ , which tries to maximize:

$$\operatorname{argmax}_{\Lambda} \sum_{k=1}^N \left( \log p_{\Lambda}(\mathbf{y}_k|\mathbf{x}_k) \right) - \beta \sum_j^F \frac{(\lambda_j - \mu_j)^2}{2\sigma_j^2}$$

where  $\beta > 0$  is a parameter controlling the amount of regularization, and  $N$  is the number of sentences in the training set.

### 2.3 Source trained priors

One recently proposed method (Chelba and Acero, 2004) for transfer learning in Maximum Entropy models<sup>1</sup> involves modifying the  $\mu$ 's of this Gaussian prior. First a model of the source domain,  $\Lambda^{source}$ , is learned by training on  $\{X_{train}^{source}, Y_{train}^{source}\}$ . Then a model of the target domain is trained over a limited set of labeled target data  $\{X_{train}^{target}, Y_{train}^{target}\}$ , but instead of regularizing this  $\Lambda^{target}$  to be near zero (i.e. setting  $\mu = 0$ ),  $\Lambda^{target}$  is instead regularized towards the previously learned source values  $\Lambda^{source}$  (by setting  $\mu = \Lambda^{source}$ , while  $\sigma^2$  remains 1) and thus minimizing  $(\Lambda^{target} - \Lambda^{source})^2$ .

<sup>1</sup>Maximum Entropy models are special cases of CRFs that use the I.I.D. assumption. The method under discussion can also be extended to CRF directly.

Note that, since this model requires  $Y_{train}^{target}$  in order to learn  $\Lambda^{target}$ , it, in effect, requires two distinct labeled training datasets: one on which to *train* the prior, and another on which to learn the model’s final weights (which we call *tuning*), using the previously trained prior for regularization. If we are unable to find a match between features in the training and tuning datasets (for instance, if a word appears in the tuning corpus but not the training), we back-off to a standard  $\mathcal{N}(0, 1)$  prior for that feature.

Figure 2: Graphical representation of the hierarchical transfer model.

## 2.4 New model: Hierarchical prior model

In this section, we will present a new model that learns simultaneously from multiple domains, by taking advantage of our feature hierarchy.

We will assume that there are  $D$  domains in which we are learning simultaneously. Let there be  $M_d$  training data in each domain  $d$ . For our experiments with non-identically distributed, independent data, we use conditional random fields (cf. §2.1). However, this model can be extended to any discriminative probabilistic model such as the MaxEnt model. Let  $\Lambda^{(d)} = (\lambda_1^{(d)}, \dots, \lambda_{F_d}^{(d)})$  be the parameters of the discriminative model in the domain  $d$  where  $F_d$  represents the number of features in the domain  $d$ .

Further, we will also assume that the features of different domains share a common hierarchy represented by a tree  $\mathcal{T}$ , whose leaf nodes are the features themselves (cf. Figure 1). The model parameters  $\Lambda^{(d)}$ , then, form the parameters of the leaves of this hierarchy. Each non-leaf node  $n \in \text{non-leaf}(\mathcal{T})$  of

the tree is also associated with a hyper-parameter  $z_n$ . Note that since the hierarchy is a tree, each node  $n$  has only one parent, represented by  $\text{pa}(n)$ . Similarly, we represent the set of children nodes of a node  $n$  as  $\text{ch}(n)$ .

The entire graphical model for an example consisting of three domains is shown in Figure 2. The conditional likelihood of the entire training data  $(\mathbf{y}, \mathbf{x}) = \{(\mathbf{y}_1^{(d)}, \mathbf{x}_1^{(d)}), \dots, (\mathbf{y}_{M_d}^{(d)}, \mathbf{x}_{M_d}^{(d)})\}_{d=1}^D$  is given by:

$$\begin{aligned}
 P(\mathbf{y}|\mathbf{x}, \mathbf{w}, \mathbf{z}) &= \left\{ \prod_{d=1}^D \prod_{k=1}^{M_d} P(\mathbf{y}_k^{(d)}|\mathbf{x}_k^{(d)}, \Lambda^{(d)}) \right\} \\
 &\times \left\{ \prod_{d=1}^D \prod_{f=1}^{F_d} \mathcal{N}(\lambda_f^{(d)}|z_{\text{pa}(f^{(d)})}, 1) \right\} \\
 &\times \left\{ \prod_{n \in \mathcal{T}_{\text{nonleaf}}} \mathcal{N}(z_n|z_{\text{pa}(n)}, 1) \right\} \quad (3)
 \end{aligned}$$

where the terms in the first line of eq. (3) represent the likelihood of data in each domain given their corresponding model parameters, the second line represents the likelihood of each model parameter in each domain given the hyper-parameter of its parent in the tree hierarchy of features and the last term goes over the entire tree  $\mathcal{T}$  except the leaf nodes. Note that in the last term, the hyper-parameters are shared across the domains, so there is no product over  $d$ .

We perform a MAP estimation for each model parameter as well as the hyper-parameters. Accordingly, the estimates are given as follows:

$$\begin{aligned}
 \lambda_f^{(d)} &= \sum_{i=1}^{M_d} \frac{\partial}{\partial \lambda_f^{(d)}} \left( \log P(\mathbf{y}_i^d|\mathbf{x}_i^{(d)}, \Lambda^{(d)}) \right) \\
 &+ z_{\text{pa}(f^{(d)})} \\
 z_n &= \frac{z_{\text{pa}(n)} + \sum_{i \in \text{ch}(n)} (\lambda|z)_i}{1 + |\text{ch}(n)|} \quad (4)
 \end{aligned}$$

where we used the notation  $(\lambda|z)_i$  because node  $i$ , the child node of  $n$ , could be a parameter node or a hyper-parameter node depending on the position of the node  $n$  in the hierarchy. Essentially, in this model, the weights of the leaf nodes (model parameters) depend on the log-likelihood as well as the prior weight of its parent. Additionally, the weight

of each hyper-parameter node in the tree is computed as the average of all its children nodes and its parent, resulting in a *smoothing* effect, both up and down the tree.

## 2.5 An approximate Hierarchical prior model

The Hierarchical prior model is a theoretically well founded model for transfer learning through feature heirarchy. However, our preliminary experiments indicated that its performance on real-life data sets is not as good as expected. Although a more thorough investigation needs to be carried out, our analysis indicates that the main reason for this phenomenon is over-smoothing. In other words, by letting the information propagate from the leaf nodes in the hierarchy all the way to the root node, the model loses its ability to discriminate between its features.

As a solution to this problem, we propose an approximate version of this model that weds ideas from the exact heirarchical prior model and the Chelba model.

As with the Chelba prior method in §2.3, this approximate hierarchical method also requires two distinct data sets, one for training the prior and another for tuning the final weights. Unlike Chelba, we smooth the weights of the priors using the feature-tree hierarchy presented in §1.1, like the hierarchical prior model.

For smoothing of each feature weight, we chose to back-off in the tree as little as possible until we had a large enough sample of prior data (measured as  $M$ , the number of subtrees below the current node) on which to form a reliable estimate of the mean and variance of each feature or class of features. For example, if the tuning data set is as in Sentence 1, but the prior contains no instances of the word *Professor*, then we would back-off and compute the prior mean and variance on the next higher level in the tree. Thus the prior for *L.I.Professor* would be  $\mathcal{N}(\text{mean}(L.I.*), \text{variance}(L.I.*))$ , where  $\text{mean}()$  and  $\text{variance}()$  of *L.I.\** are the sample mean and variance of all the features in the prior dataset that match the pattern *L.I.\** – or, put another way, all the siblings of *L.I.Professor* in the feature tree. If fewer than  $M$  such siblings exist, we continue backing-off, up the tree, until an ancestor with sufficient descendants is found. A detailed description of the approximate hierarchical algorithm is shown in table 2.

---

**Input:**  $\mathcal{D}^{source} = (X_{train}^{source}, Y_{train}^{source})$   
 $\mathcal{D}^{target} = (X_{train}^{target}, Y_{train}^{target})$ ;  
 Feature sets  $\mathcal{F}^{source}, \mathcal{F}^{target}$ ;  
 Feature Hierarchies  $\mathcal{H}^{source}, \mathcal{H}^{target}$   
 Minimum membership size  $M$

---

Train CRF using  $\mathcal{D}^{source}$  to obtain feature weights  $\Lambda^{source}$

For each feature  $f \in \mathcal{F}^{target}$

  Initialize: node  $n = f$

  While ( $n \notin \mathcal{H}^{source}$

  or  $|\text{Leaves}(\mathcal{H}^{source}(n))| \leq M$ )

  and  $n \neq \text{root}(\mathcal{H}^{target})$

$n \leftarrow \text{Pa}(\mathcal{H}^{target}(n))$

  Compute  $\mu_f$  and  $\sigma_f$  using the sample

$\{\lambda_i^{source} \mid i \in \text{Leaves}(\mathcal{H}^{source}(n))\}$

Train Gaussian prior CRF using  $\mathcal{D}^{target}$  as data and  $\{\mu_f\}$  and  $\{\sigma_f\}$  as Gaussian prior parameters.

**Output:** Parameters of the new CRF  $\Lambda^{target}$ .

---

Table 2: Algorithm for approximate hierarchical prior:  $\text{Pa}(\mathcal{H}^{source}(n))$  is the parent of node  $n$  in feature hierarchy  $\mathcal{H}^{source}$ ;  $|\text{Leaves}(\mathcal{H}^{source}(n))|$  indicates the number of leaf nodes (basic features) under a node  $n$  in the hierarchy  $\mathcal{H}^{source}$ .

It is important to note that this smoothed tree is an approximation of the exact model presented in §2.4 and thus an important parameter of this method in practice is the degree to which one chooses to smooth up or down the tree. One of the benefits of this model is that the semantics of the hierarchy (how to define a feature, a parent, how and when to back-off and up the tree, etc.) can be specified by the user, in reference to the specific datasets and tasks under consideration. For our experiments, the semantics of the tree are as presented in §1.1.

The Chelba method can be thought of as a hierarchical prior in which no smoothing is performed on the tree at all. Only the leaf nodes of the prior’s feature tree are considered, and, if no match can be found between the tuning and prior’s training datasets’ features, a  $\mathcal{N}(0, 1)$  prior is used instead. However, in the new approximate hierarchical model, even if a certain feature in the tuning dataset does not have an analog in the training dataset, we can always back-off until an appropriate match is found, even to the level of the root.

Henceforth, we will use only the approximate hierarchical model in our experiments and discussion.

Table 3: Summary of data used in experiments

Corpus	Genre	Task
UTexas	Bio	Protein
Yapex	Bio	Protein
MUC6	News	Person
MUC7	News	Person
CSPACE	E-mail	Person

### 3 Investigation

#### 3.1 Data, domains and tasks

For our experiments, we have chosen five different corpora (summarized in Table 3). Although each corpus can be considered its own *domain* (due to variations in annotation standards, specific task, date of collection, etc), they can also be roughly grouped into three different *genres*. These are: *abstracts from biological journals* [UT (Bunescu et al., 2004), Yapex (Franzén et al., 2002)]; *news articles* [MUC6 (Fisher et al., 1995), MUC7 (Borthwick et al., 1998)]; and *personal e-mails* [CSPACE (Kraut et al., 2004)]. Each corpus, depending on its *genre*, is labeled with one of two name-finding *tasks*:

- protein names in biological abstracts
- person names in news articles and e-mails

We chose this array of corpora so that we could evaluate our hierarchical prior’s ability to generalize across and incorporate information from a variety of domains, genres and tasks.

In each case, each item (abstract, article or e-mail) was tokenized and each token was hand-labeled as either being part of a name (protein or person) or not, respectively. We used a standard natural language toolkit (Cohen, 2004) to compute tens of thousands of binary features on each of these tokens, encoding such information as capitalization patterns and contextual information from surrounding words. This toolkit produces features of the type described in §1.2 and thus was amenable to our hierarchical prior model. In particular, we chose to use the simplest default, out-of-the-box feature generator and purposefully did not use specifically engineered features, dictionaries, or other techniques commonly employed to boost performance on such tasks. The goal of our experiments was to see to what degree named entity recognition problems naturally conformed to hierarchical methods, and not just to achieve the highest performance possible.

Intra-genre transfer performance evaluated on MUC6

Figure 3: Adding a relevant HIER prior helps compared to the GAUSS baseline ((c) > (a)), while simply CAT’ing or using CHELBA can hurt ((d) ≈ (b) < (a), except with very little data), and never beats HIER ((c) > (b) ≈ (d)).

#### 3.2 Experiments & results

We evaluated the performance of various transfer learning methods on the data and tasks described in §3.1. Specifically, we compared our approximate hierarchical prior model (HIER), implemented as a CRF, against three baselines:

- GAUSS: CRF model tuned on a single domain’s data, using a standard  $\mathcal{N}(0, 1)$  prior
- CAT: CRF model tuned on a concatenation of multiple domains’ data, using a  $\mathcal{N}(0, 1)$  prior
- CHELBA: CRF model tuned on one domain’s data, using a prior trained on a different, related domain’s data (cf. §2.3)

We use token-level *F1* as our main evaluation measure, combining precision and recall into one metric.

##### 3.2.1 Intra-genre, same-task transfer learning

Figure 3 shows the results of an experiment in learning to recognize person names in MUC6 news articles. In this experiment we examined the effect of adding extra data from a different, but related domain from the same genre, namely, MUC7. Line *a* shows the *F1* performance of a CRF model tuned only on the target MUC6 domain (GAUSS) across a range of tuning data sizes. Line *b* shows the same experiment, but this time the CRF model has been tuned on a dataset comprised of a simple concatenation of the training MUC6 data from (*a*), along with a different training set from MUC7 (CAT). We can see that adding extra data in this way, though

Inter-genre transfer performance evaluated on MUC6

Figure 4: Transfer aware priors CHELBA and HIER effectively filter irrelevant data. Adding more irrelevant data to the priors doesn't hurt ((e)  $\approx$  (g)  $\approx$  (h)), while simply CAT'ing it, in this case, is disastrous ((f)  $\ll$  (e)).

the data is closely related both in domain and task, has actually hurt the performance of our recognizer for training sizes of moderate to large size. This is most likely because, although the MUC6 and MUC7 datasets are closely related, they are still drawn from different distributions and thus cannot be intermingled indiscriminately. Line *c* shows the same combination of MUC6 and MUC7, only this time the datasets have been combined using the HIER prior. In this case, the performance actually does improve, both with respect to the single-dataset trained baseline (*a*) and the naively trained double-dataset (*b*). Finally, line *d* shows the results of the CHELBA prior. Curiously, though the domains are closely related, it does more poorly than even the non-transfer GAUSS. One possible explanation is that, although much of the vocabulary is shared across domains, the interpretation of the features of these words may differ. Since CHELBA doesn't model the hierarchy among features like HIER, it is unable to smooth away these discrepancies. In contrast, we see that our HIER prior is able to successfully combine the relevant parts of data across domains while filtering the irrelevant, and possibly detrimental, ones. This experiment was repeated for other sets of intra-genre tasks, and the results are summarized in §3.2.3.

### 3.2.2 Inter-genre, multi-task transfer learning

In Figure 4 we see that the properties of the hierarchical prior hold even when transferring across

tasks. Here again we are trying to learn to recognize person names in MUC6 e-mails, but this time, instead of adding only other datasets similarly labeled with person names, we are additionally adding biological corpora (UT & YAPEX), labeled not with person names but with protein names instead, along with the CSPACE e-mail and MUC7 news article corpora. The robustness of our prior prevents a model trained on all five domains (*g*) from degrading away from the intra-genre, same-task baseline (*e*), unlike the model trained on concatenated data (*f*). CHELBA (*h*) performs similarly well in this case, perhaps because the domains are so different that almost none of the features match between prior and tuning data, and thus CHELBA backs-off to a standard  $\mathcal{N}(0, 1)$  prior.

This robustness in the face of less similarly related data is very important since these types of transfer methods are most useful when one possesses only very little target domain data. In this situation, it is often difficult to accurately estimate performance and so one would like assurance that any transfer method being applied will not have negative effects.

### 3.2.3 Comparison of HIER prior to baselines

Each scatter plot in Figure 5 shows the relative performance of a baseline method against HIER. Each point represents the results of two experiments: the y-coordinate is the F1 score of the baseline method (shown on the y-axis), while the x-coordinate represents the score of the HIER method in the same experiment. Thus, points lying below the  $y = x$  line represent experiments for which HIER received a higher F1 value than did the baseline. While all three plots show HIER outperforming each of the three baselines, not surprisingly, the non-transfer GAUSS method suffers the worst, followed by the naive concatenation (CAT) baseline. Both methods fail to make any explicit distinction between the source and target domains and thus suffer when the domains differ even slightly from each other. Although the differences are more subtle, the right-most plot of Figure 5 suggests HIER is likewise able to outperform the non-hierarchical CHELBA prior in certain transfer scenarios. CHELBA is able to avoid suffering as much as the other baselines when faced with large difference between domains, but is still unable to capture

Figure 5: Comparative performance of baseline methods (GAUSS, CAT, CHELBA) vs. HIER prior, as trained on nine prior datasets (both pure and concatenated) of various sample sizes, evaluated on MUC6 and CSPACE datasets. Points below the  $y = x$  line indicate HIER outperforming baselines.

as many dependencies between domains as HIER.

#### 4 Conclusions, related & future work

In this work we have introduced hierarchical feature tree priors for use in transfer learning on named entity extraction tasks. We have provided evidence that motivates these models on intuitive, theoretical and empirical grounds, and have gone on to demonstrate their effectiveness in relation to other, competitive transfer methods. Specifically, we have shown that hierarchical priors allow the user enough flexibility to customize their semantics to a specific problem, while providing enough structure to resist unintended negative effects when used inappropriately. Thus hierarchical priors seem a natural, effective and robust choice for transferring learning across NER datasets and tasks.

Some of the first formulations of the transfer learning problem were presented over 10 years ago (Thrun, 1996; Baxter, 1997). Other techniques have tried to quantify the generalizability of certain features across domains (Daumé III and Marcu, 2006; Jiang and Zhai, 2006), or tried to exploit the common structure of related problems (Ben-David et al., 2007; Schölkopf et al., 2005). Most of this prior work deals with supervised transfer learning, and thus requires labeled source domain data, though there are examples of unsupervised (Arnold

et al., 2007), semi-supervised (Grandvalet and Bengio, 2005; Blitzer et al., 2006), and transductive approaches (Taskar et al., 2003).

Recent work using so-called meta-level priors to transfer information across tasks (Lee et al., 2007), while related, does not take into explicit account the hierarchical structure of these meta-level features often found in NLP tasks. Daumé allows an extra degree of freedom among the features of his domains, implicitly creating a two-level feature hierarchy with one branch for *general* features, and another for *domain specific* ones, but does not extend his hierarchy further (Daumé III, 2007)). Similarly, work on hierarchical penalization (Szafranski et al., 2007) in two-level trees tries to produce models that rely only on a relatively small number of groups of variable, as structured by the tree, as opposed to transferring knowledge between branches themselves.

Our future work is focused on designing an algorithm to optimally choose a smoothing regime for the learned feature trees so as to better exploit the similarities between domains while neutralizing their differences. Along these lines, we are working on methods to reduce the amount of labeled target domain data needed to tune the prior-based models, looking forward to semi-supervised and unsupervised transfer methods.

Ralph Grishman

## Abstract

We apply the hypothesis of “One Sense Per Discourse” (Yarowsky, 1995) to information extraction (IE), and extend the scope of “discourse” from one single document to a cluster of topically-related documents. We employ a similar approach to propagate consistent event arguments across sentences and documents. Combining global evidence from related documents with local decisions, we design a simple scheme to conduct cross-document inference for improving the ACE event extraction task<sup>1</sup>. Without using any additional labeled data this new approach obtained 7.6% higher F-Measure in trigger labeling and 6% higher F-Measure in argument labeling over a state-of-the-art IE system which extracts events independently for each sentence.

## 1 Introduction

Identifying events of a particular type within individual documents – ‘classical’ information extraction – remains a difficult task. Recognizing the different forms in which an event may be expressed, distinguishing events of different types, and finding the arguments of an event are all challenging tasks.

Fortunately, many of these events will be reported multiple times, in different forms, both within the same document and within *topically-related* documents (i.e. a collection of documents sharing participants in potential events). We can

take advantage of these alternate descriptions to improve event extraction in the original document, by favoring consistency of interpretation across sentences and documents. Several recent studies involving specific event types have stressed the benefits of going beyond traditional single-document extraction; in particular, Yangarber (2006) has emphasized this potential in his work on medical information extraction. In this paper we demonstrate that appreciable improvements are possible over the variety of event types in the ACE (Automatic Content Extraction) evaluation through the use of cross-sentence and cross-document evidence.

As we shall describe below, we can make use of consistency at several levels: consistency of word sense across different instances of the same word in related documents, and consistency of arguments and roles across different mentions of the same or related events. Such methods allow us to build dynamic background knowledge as required to interpret a document and can compensate for the limited annotated training data which can be provided for each event type.

## 2 Task and Baseline System

### 2.1 ACE Event Extraction Task

The event extraction task we are addressing is that of the Automatic Content Extraction (ACE) evaluations<sup>2</sup>. ACE defines the following terminology:

---

<sup>1</sup> <http://www.nist.gov/speech/tests/ace/>

---

<sup>2</sup> In this paper we don’t consider event mention coreference resolution and so don’t distinguish event mentions and events.

**entity**: an object or a set of objects in one of the semantic categories of interest

**mention**: a reference to an entity (typically, a noun phrase)

**event trigger**: the main word which most clearly expresses an event occurrence

**event arguments**: the mentions that are involved in an event (participants)

**event mention**: a phrase or sentence within which an event is described, including trigger and arguments

The 2005 ACE evaluation had 8 types of events, with 33 subtypes; for the purpose of this paper, we will treat these simply as 33 distinct event types. For example, for a sentence:

*Barry Diller on Wednesday quit as chief of Vivendi Universal Entertainment.*

the event extractor should detect a “Personnel\_End-Position” event mention, with the trigger word, the position, the person who quit the position, the organization, and the time during which the event happened:

	Trigger	<i>Quit</i>
Arguments	Role = Person	<i>Barry Diller</i>
	Role = Organization	<i>Vivendi Universal Entertainment</i>
	Role = Position	<i>Chief</i>
	Role = Time-within	<i>Wednesday</i>

Table 1. Event Extraction Example

We define the following standards to determine the *correctness* of an event mention:

- *A trigger is correctly labeled* if its event type and offsets match a reference trigger.
- *An argument is correctly identified* if its event type and offsets match any of the reference argument mentions.
- *An argument is correctly identified and classified* if its event type, offsets, and role match any of the reference argument mentions.

## 2.2 A Baseline Within-Sentence Event Tagger

We use a state-of-the-art English IE system as our baseline (Grishman et al., 2005). This system extracts events independently for each sentence. Its training and test procedures are as follows.

The system combines pattern matching with statistical models. For every event mention in the ACE training corpus, patterns are constructed based on the sequences of constituent heads separating the trigger and arguments. In addition, a set of Maximum Entropy based classifiers are trained:

- **Trigger Labeling**: to distinguish event mentions from non-event-mentions, to classify event mentions by type;
- **Argument Classifier**: to distinguish arguments from non-arguments;
- **Role Classifier**: to classify arguments by argument role.
- **Reportable-Event Classifier**: Given a trigger, an event type, and a set of arguments, to determine whether there is a reportable event mention.

In the test procedure, each document is scanned for instances of triggers from the training corpus. When an instance is found, the system tries to match the environment of the trigger against the set of patterns associated with that trigger. This pattern-matching process, if successful, will assign some of the mentions in the sentence as arguments of a potential event mention. The argument classifier is applied to the remaining mentions in the sentence; for any argument passing that classifier, the role classifier is used to assign a role to it. Finally, once all arguments have been assigned, the reportable-event classifier is applied to the potential event mention; if the result is successful, this event mention is reported.

## 3 Motivations

In this section we shall present our motivations based on error analysis for the baseline event tagger.

### 3.1 One Trigger Sense Per Cluster

Across a heterogeneous document corpus, a particular verb can sometimes be trigger and sometimes not, and can represent different event types. However, for a collection of topically-related documents, the distribution may be much more convergent. We investigate this hypothesis by automatically obtaining 25 related documents for each test text. The statistics of some trigger examples are presented in table 2.

Candidate Triggers		Event Type	Perc./Freq. as trigger in ACE training corpora	Perc./Freq. as trigger in test document	Perc./Freq. as trigger in test + related documents
Correct Event Triggers	<i>advance</i>	Movement_Transport	31% of 16	50% of 2	88.9% of 27
	<i>fire</i>	Personnel_End-Position	7% of 81	100% of 2	100% of 10
	<i>fire</i>	Conflict_Attack	54% of 81	100% of 3	100% of 19
	<i>replace</i>	Personnel_End-Position	5% of 20	100% of 1	83.3% of 6
	<i>form</i>	Business_Start-Org	12% of 8	100% of 2	100% of 23
	<i>talk</i>	Contact_Meet	59% of 74	100% of 4	100% of 26
Incorrect Event Triggers	<i>hurt</i>	Life_Injure	24% of 33	0% of 2	0% of 7
	<i>execution</i>	Life_Die	12% of 8	0% of 4	4% of 24

Table 2. Examples: Percentage of a Word as Event Trigger in Different Data Collections

As we can see from the table, the likelihood of a candidate word being an event trigger in the test document is closer to its distribution in the collection of related documents than the uniform training corpora. So if we can determine the sense (event type) of a word in the related documents, this will allow us to infer its sense in the test document. In this way related documents can help recover event mentions missed by within-sentence extraction.

For example, in a document about “the advance into Baghdad”:

**Example 1:**

**[Test Sentence]**

*Most US army commanders believe it is critical to pause the breakneck **advance** towards Baghdad to secure the supply lines and make sure weapons are operable and troops resupplied....*

**[Sentences from Related Documents]**

*British and US forces report gains in the **advance** on Baghdad and take control of Umm Qasr, despite a fierce sandstorm which slows another flank.*

...

The baseline event tagger is not able to detect “advance” as a “Movement\_Transport” event trigger because there is no pattern “advance towards [Place]” in the ACE training corpora (“advance” by itself is too ambiguous). The training data, however, does include the pattern “advance on [Place]”, which allows the instance of “advance” in the related documents to be successfully identified with high confidence by pattern matching as an event. This provides us much stronger “feedback” confidence in tagging ‘advance’ in the test sentence as a correct trigger.

On the other hand, if a word is not tagged as an event trigger in most related documents, then it’s less likely to be correct in the test sentence despite its high local confidence. For example, in a document about “assessment of Russian president Putin”:

**Example 2:**

**[Test Sentence]**

*But few at the Kremlin forum suggested that Putin’s own standing among voters will be **hurt** by Russia’s apparent diplomacy failures.*

**[Sentences from Related Documents]**

*Putin boosted ties with the United States by throwing his support behind its war on terrorism after the Sept. 11 attacks, but the Iraq war has **hurt** the relationship.*

...

The word “hurt” in the test sentence is mistakenly identified as a “Life\_Injure” trigger with high local confidence (because the within-sentence extractor misanalyzes “voters” as the object of “hurt” and so matches the pattern “[Person] be hurt”). Based on the fact that many other instances of “hurt” are not “Life\_Injure” triggers in the related documents, we can successfully remove this wrong event mention in the test document.

### 3.2 One Argument Role Per Cluster

Inspired by the observation about trigger distribution, we propose a similar hypothesis – one argument role per cluster for event arguments. In other words, each entity plays the same argument role, or no role, for events with the same type in a collection of related documents. For example,

### Example 3:

#### [Test Sentence]

*Vivendi* earlier this week confirmed months of press speculation that it planned to **shed** its entertainment assets by the end of the year.

#### [Sentences from Related Documents]

*Vivendi* has been trying to **sell** assets to pay off huge debt, estimated at the end of last month at more than \$13 billion.

Under the reported plans, Blackstone Group would **buy** *Vivendi*'s theme park division, including Universal Studios Hollywood, Universal Orlando in Florida...

...

The above test sentence doesn't include an explicit trigger word to indicate "Vivendi" as a "seller" of a "Transaction\_Transfer-Ownership" event mention, but "Vivendi" is correctly identified as "seller" in many other related sentences (by matching patterns "[Seller] sell" and "buy [Seller]'s"). So we can incorporate such additional information to enhance the confidence of "Vivendi" as a "seller" in the test sentence.

On the other hand, we can remove spurious arguments with low cross-document frequency and confidence. In the following example,

### Example 4:

#### [Test Sentence]

*The Davao Medical Center*, a regional government hospital, recorded 19 deaths with 50 wounded.

"the Davao Medical Center" is mistakenly tagged as "Place" for a "Life\_Die" event mention. But the same annotation for this mention doesn't appear again in the related documents, so we can determine it's a spurious argument.

## 4 System Approach Overview

Based on the above motivations we propose to incorporate global evidence from a cluster of related documents to refine local decisions. This section gives more details about the baseline within-sentence event tagger, and the information retrieval system we use to obtain related documents. In the next section we shall focus on describing the inference procedure.

### 4.1 System Pipeline

Figure 1 depicts the general procedure of our approach.  $EMSet$  represents a set of event mentions which is gradually updated.

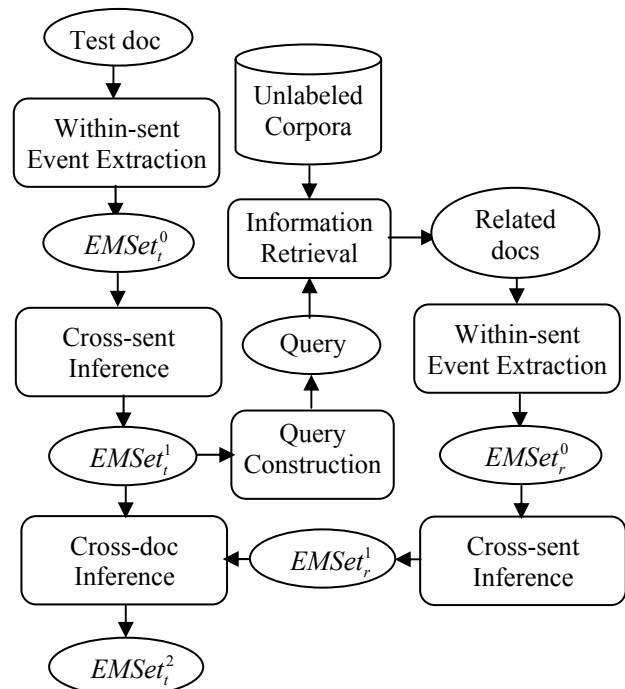

Figure 1. Cross-doc Inference for Event Extraction

### 4.2 Within-Sentence Event Extraction

For each event mention in a test document  $t$ , the baseline Maximum Entropy based classifiers produce three types of confidence values:

- $LConf(trigger, etype)$ : The probability of a string  $trigger$  indicating an event mention with type  $etype$ ; if the event mention is produced by pattern matching then assign confidence 1.
- $LConf(arg, etype)$ : The probability that a mention  $arg$  is an argument of some particular event type  $etype$ .
- $LConf(arg, etype, role)$ : If  $arg$  is an argument with event type  $etype$ , the probability of  $arg$  having some particular  $role$ .

We apply within-sentence event extraction to get an initial set of event mentions  $EMSet_t^0$ , and conduct cross-sentence inference (details will be presented in section 5) to get an updated set of event mentions  $EMSet_t^1$ .

### 4.3 Information Retrieval

We then use the INDRI retrieval system (Strohman et al., 2005) to obtain the top N (N=25 in this pa-

per<sup>3</sup>) related documents. We construct an INDRI query from the triggers and arguments, each weighted by local confidence and frequency in the test document. For each argument we also add other names coreferential with or bearing some ACE relation to the argument.

For each related document  $r$  returned by INDRI, we repeat the within-sentence event extraction and cross-sentence inference procedure, and get an expanded event mention set  $EMSet_{t+r}^1$ . Then we apply cross-document inference to  $EMSet_{t+r}^1$  and get the final event mention output  $EMSet_t^2$ .

## 5 Global Inference

The central idea of inference is to obtain document-wide and cluster-wide statistics about the frequency with which triggers and arguments are associated with particular types of events, and then use this information to correct event and argument identification and classification.

For a set of event mentions we tabulate the following document-wide and cluster-wide confidence-weighted frequencies:

- for each trigger string, the frequency with which it appears as the trigger of an event of a particular type;
- for each event argument string and the names coreferential with or related to the argument, the frequency of the event type;
- for each event argument string and the names coreferential with or related to the argument, the frequency of the event type and role.

Besides these frequencies, we also define the following *margin* metric to compute the confidence of the best (most frequent) event type or role:

$$\text{Margin} = \frac{(\text{WeightedFrequency}(\text{most frequent value}) - \text{WeightedFrequency}(\text{second most freq value}))}{\text{WeightedFrequency}(\text{second most freq value})}$$

A large margin indicates greater confidence in the most frequent value. We summarize the frequency and confidence metrics in Table 3.

Based on these confidence metrics, we designed the inference rules in Table 4. These rules are applied in the order (1) to (9) based on the principle of improving ‘local’ information before global

propagation. Although the rules may seem complex, they basically serve two functions:

- to remove triggers and arguments with low (local or cluster-wide) confidence;
- to adjust trigger and argument identification and classification to achieve (document-wide or cluster-wide) consistency.

## 6 Experimental Results and Analysis

In this section we present the results of applying this inference method to improve ACE event extraction.

### 6.1 Data

We used 10 newswire texts from ACE 2005 training corpora (from March to May of 2003) as our development set, and then conduct blind test on a separate set of 40 ACE 2005 newswire texts. For each test text we retrieved 25 related texts from English TDT5 corpus which in total consists of 278,108 texts (from April to September of 2003).

### 6.2 Confidence Metric Thresholding

We select the thresholds ( $\delta_k$  with  $k=1\sim 13$ ) for various confidence metrics by optimizing the F-measure score of each rule on the development set, as shown in Figure 2 and 3 as follows.

Each curve in Figure 2 and 3 shows the effect on precision and recall of varying the threshold for an individual rule.

Figure 2. Trigger Labeling Performance with Confidence Thresholding on Dev Set

<sup>3</sup> We tested different  $N \in [10, 75]$  on dev set; and  $N=25$  achieved best gains.

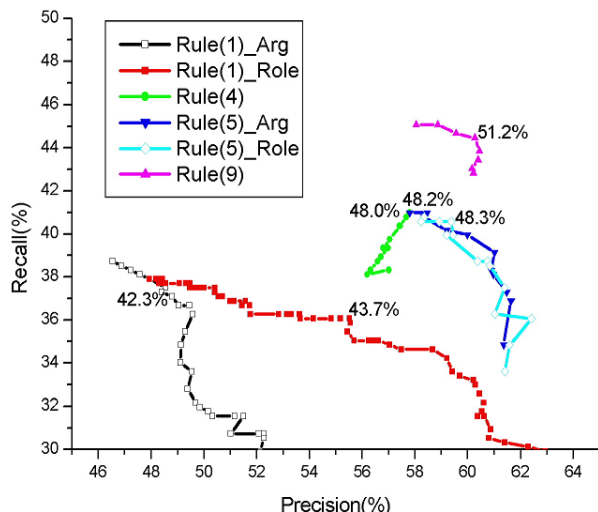

Figure 3. Argument Labeling Performance with Confidence Thresholding on Dev Set

The labeled point on each curve shows the best F-measure that can be obtained on the development set by adjusting the threshold for that rule. The gain obtained by applying successive rules can be seen in the progression of successive points towards higher recall and, for argument labeling, precision<sup>4</sup>.

### 6.3 Overall Performance

Table 5 shows the overall Precision (P), Recall (R) and F-Measure (F) scores for the blind test set. In addition, we also measured the performance of two human annotators who prepared the ACE 2005 training data on 28 newswire texts (a subset of the blind test set). The final key was produced by review and adjudication of the two annotations.

Both cross-sentence and cross-document inferences provided significant improvement over the baseline with local confidence thresholds controlled.

We conducted the Wilcoxon Matched-Pairs Signed-Ranks Test on a document basis. The results show that the improvement using cross-sentence inference is significant at a 99.9% confidence level for both trigger and argument labeling; adding cross-document inference is significant at a 99.9% confidence level for trigger labeling and 93.4% confidence level for argument labeling.

<sup>4</sup> We didn't show the classification adjusting rules (2), (6) and (8) here because of their relatively small impact on dev set.

### 6.4 Discussion

From table 5 we can see that for trigger labeling our approach dramatically enhanced recall (22.9% improvement) with some loss (7.4%) in precision. This precision loss was much larger than that for the development set (0.3%). This indicates that the trigger propagation thresholds optimized on the development set were too low for the blind test set and thus more spurious triggers got propagated. The improved trigger labeling is better than one human annotator and only 4.7% worse than another.

For argument labeling we can see that cross-sentence inference improved both identification (3.7% higher F-Measure) and classification (6.1% higher accuracy); and cross-document inference mainly provided further gains (1.9%) in classification. This shows that identification consistency may be achieved within a narrower context while the classification task favors more global background knowledge in order to solve some difficult cases. This matches the situation of human annotation as well: we may decide whether a mention is involved in some particular event or not by reading and analyzing the target sentence itself; but in order to decide the argument's role we may need to frequently refer to wider discourse in order to infer and confirm our decision. In fact sometimes it requires us to check more similar web pages or even wikipedia databases. This was exactly the intuition of our approach. We should also note that human annotators label arguments based on perfect entity mentions, but our system used the output from the IE system. So the gap was also partially due to worse entity detection.

Error analysis on the inference procedure shows that the propagation rules (3), (4), (7) and (9) produced a few extra false alarms. For trigger labeling, most of these errors appear for support verbs such as "take" and "get" which can only represent an event mention together with other verbs or nouns. Some other errors happen on nouns and adjectives. These are difficult tasks even for human annotators. As shown in table 5 the inter-annotator agreement on trigger identification is only about 40%. Besides some obvious overlooked cases (it's probably difficult for a human to remember 33 different event types during annotation), most difficulties were caused by judging generic verbs, nouns and adjectives.

Performance System/Human	Trigger Identification +Classification			Argument Identification			Argument Classification Accuracy	Argument Identification +Classification		
	P	R	F	P	R	F		P	R	F
Within-Sentence IE with Rule (1) (Baseline)	67.6	53.5	59.7	47.8	38.3	42.5	86.0	41.2	32.9	36.6
Cross-sentence Inference	64.3	59.4	61.8	54.6	38.5	45.1	90.2	49.2	34.7	40.7
Cross-sentence+ Cross-doc Inference	<b>60.2</b>	<b>76.4</b>	<b>67.3</b>	<b>55.7</b>	<b>39.5</b>	<b>46.2</b>	<b>92.1</b>	<b>51.3</b>	<b>36.4</b>	<b>42.6</b>
Human Annotator1	59.2	59.4	59.3	60.0	69.4	64.4	85.8	51.6	59.5	55.3
Human Annotator2	69.2	75.0	72.0	62.7	85.4	72.3	86.3	54.1	73.7	62.4
Inter-Annotator Agreement	41.9	38.8	40.3	55.2	46.7	50.6	91.7	50.6	42.9	46.4

Table 5. Overall Performance on Blind Test Set (%)

In fact, compared to a statistical tagger trained on the corpus after expert adjudication, a human annotator tends to make more mistakes in trigger classification. For example it’s hard to decide whether “named” represents a “Personnel\_Nominate” or “Personnel\_Start-Position” event mention; “hacked to death” represents a “Life\_Die” or “Conflict\_Attack” event mention without following more specific annotation guidelines.

## 7 Related Work

The trigger labeling task described in this paper is in part a task of word sense disambiguation (WSD), so we have used the idea of sense consistency introduced in (Yarowsky, 1995), extending it to operate across related documents.

Almost all the current event extraction systems focus on processing single documents and, except for coreference resolution, operate a sentence at a time (Grishman et al., 2005; Ahn, 2006; Hardy et al., 2006).

We share the view of using global inference to improve event extraction with some recent research. Yangarber et al. (Yangarber and Jokipii, 2005; Yangarber, 2006; Yangarber et al., 2007) applied cross-document inference to correct local extraction results for disease name, location and start/end time. Mann (2007) encoded specific inference rules to improve extraction of CEO (name, start year, end year) in the MUC management succession task. In addition, Patwardhan and Riloff (2007) also demonstrated that selectively applying event patterns to relevant regions can improve MUC event extraction. We expand the idea to more general event types and use informa-

tion retrieval techniques to obtain wider background knowledge from related documents.

## 8 Conclusion and Future Work

One of the initial goals for IE was to create a database of relations and events from the entire input corpus, and allow further logical reasoning on the database. The artificial constraint that extraction should be done independently for each document was introduced in part to simplify the task and its evaluation. In this paper we propose a new approach to break down the document boundaries for event extraction. We gather together event extraction results from a set of related documents, and then apply inference and constraints to enhance IE performance.

In the short term, the approach provides a platform for many byproducts. For example, we can naturally get an event-driven summary for the collection of related documents; the sentences including high-confidence events can be used as additional training data to bootstrap the event tagger; from related events in different timeframes we can derive entailment rules; the refined consistent events can serve better for other NLP tasks such as template based question-answering. The aggregation approach described here can be easily extended to improve relation detection and coreference resolution (two argument mentions referring to the same role of related events are likely to corefer). Ultimately we would like to extend the system to perform essential, although probably lightweight, event prediction.

$XSent-Trigger-Freq(trigger, etype)$	The weighted frequency of string $trigger$ appearing as the trigger of an event of type $etype$ across all sentences within a document
$XDoc-Trigger-Freq(trigger, etype)$	The weighted frequency of string $trigger$ appearing as the trigger of an event of type $etype$ across all documents in a cluster
$XDoc-Trigger-BestFreq(trigger)$	Maximum over all $etypes$ of $XDoc-Trigger-Freq(trigger, etype)$
$XDoc-Arg-Freq(arg, etype)$	The weighted frequency of $arg$ appearing as an argument of an event of type $etype$ across all documents in a cluster
$XDoc-Role-Freq(arg, etype, role)$	The weighted frequency of $arg$ appearing as an argument of an event of type $etype$ with role $role$ across all documents in a cluster
$XDoc-Role-BestFreq(arg)$	Maximum over all $etypes$ and roles of $XDoc-Role-Freq(arg, etype, role)$
$XSent-Trigger-Margin(trigger)$	The margin value of $trigger$ in $XSent-Trigger-Freq$
$XDoc-Trigger-Margin(trigger)$	The margin value of $trigger$ in $XDoc-Trigger-Freq$
$XDoc-Role-Margin(arg)$	The margin value of $arg$ in $XDoc-Role-Freq$

Table 3. Global Frequency and Confidence Metrics

<b>Rule (1): Remove Triggers and Arguments with Low Local Confidence</b>
If $LConf(trigger, etype) < \delta_1$ , then delete the whole event mention $EM$ ; If $LConf(arg, etype) < \delta_2$ or $LConf(arg, etype, role) < \delta_3$ , then delete $arg$ .
<b>Rule (2): Adjust Trigger Classification to Achieve Document-wide Consistency</b>
If $XSent-Trigger-Margin(trigger) > \delta_4$ , then propagate the most frequent $etype$ to all event mentions with $trigger$ in the document; and correct roles for corresponding arguments.
<b>Rule (3): Adjust Trigger Identification to Achieve Document-wide Consistency</b>
If $LConf(trigger, etype) > \delta_5$ , then propagate $etype$ to all unlabeled strings $trigger$ in the document.
<b>Rule (4): Adjust Argument Identification to Achieve Document-wide Consistency</b>
If $LConf(arg, etype) > \delta_6$ , then in the document, for each sentence containing an event mention $EM$ with $etype$ , add any unlabeled mention in that sentence with the same head as $arg$ as an argument of $EM$ with $role$ .
<b>Rule (5): Remove Triggers and Arguments with Low Cluster-wide Confidence</b>
If $XDoc-Trigger-Freq(trigger, etype) < \delta_7$ , then delete $EM$ ; If $XDoc-Arg-Freq(arg, etype) < \delta_8$ or $XDoc-Role-Freq(arg, etype, role) < \delta_9$ , then delete $arg$ .
<b>Rule (6): Adjust Trigger Classification to Achieve Cluster-wide Consistency</b>
If $XDoc-Trigger-Margin(trigger) > \delta_{10}$ , then propagate most frequent $etype$ to all event mentions with $trigger$ in the cluster; and correct roles for corresponding arguments.
<b>Rule (7): Adjust Trigger Identification to Achieve Cluster-wide Consistency</b>
If $XDoc-Trigger-BestFreq(trigger) > \delta_{11}$ , then propagate $etype$ to all unlabeled strings $trigger$ in the cluster, override the results of Rule (3) if conflict.
<b>Rule (8): Adjust Argument Classification to Achieve Cluster-wide Consistency</b>
If $XDoc-Role-Margin(arg) > \delta_{12}$ , then propagate the most frequent $etype$ and $role$ to all arguments with the same head as $arg$ in the entire cluster.
<b>Rule (9): Adjust Argument Identification to Achieve Cluster-wide Consistency</b>
If $XDoc-Role-BestFreq(arg) > \delta_{13}$ , then in the cluster, for each sentence containing an event mention $EM$ with $etype$ , add any unlabeled mention in that sentence with the same head as $arg$ as an argument of $EM$ with $role$ .

# Learning Document-Level Semantic Properties from Free-text Annotations

S.R.K. Branavan Harr Chen Jacob Eisenstein Regina Barzilay

## Abstract

This paper demonstrates a new method for leveraging free-text annotations to infer semantic properties of documents. Free-text annotations are becoming increasingly abundant, due to the recent dramatic growth in semi-structured, user-generated online content. An example of such content is product reviews, which are often annotated by their authors with pros/cons keyphrases such as “a real bargain” or “good value.” To exploit such noisy annotations, we simultaneously find a hidden paraphrase structure of the keyphrases, a model of the document texts, and the underlying semantic properties that link the two. This allows us to predict properties of unannotated documents. Our approach is implemented as a hierarchical Bayesian model with joint inference, which increases the robustness of the keyphrase clustering and encourages the document model to correlate with semantically meaningful properties. We perform several evaluations of our model, and find that it substantially outperforms alternative approaches.

## 1 Introduction

A central problem in language understanding is transforming raw text into structured representations. Learning-based approaches have dramatically increased the scope and robustness of this type of automatic language processing, but they are typically dependent on large expert-annotated datasets, which are costly to produce. In this paper, we show how novice-generated free-text annotations available online can be leveraged to automatically infer document-level semantic properties.

With the rapid increase of online content created by end users, noisy free-text annotations have

pros/cons: <i>great nutritional value</i> ... combines it all: an amazing product, quick and friendly service, cleanliness, great nutrition ...
pros/cons: <i>a bit pricey, healthy</i> ... is an awesome place to go if you are health conscious. They have some really great low calorie dishes and they publish the calories and fat grams per serving.

Figure 1: Excerpts from online restaurant reviews with pros/cons phrase lists. Both reviews discuss healthiness, but use different keyphrases.

become widely available (Vickery and Wunsch-Vincent, 2007; Sterling, 2005). For example, consider reviews of consumer products and services. Often, such reviews are annotated with *keyphrase* lists of pros and cons. We would like to use these keyphrase lists as training labels, so that the properties of unannotated reviews can be predicted. Having such a system would facilitate structured access and summarization of this data. However, novice-generated keyphrase annotations are incomplete descriptions of their corresponding review texts. Furthermore, they lack consistency: the same underlying property may be expressed in many ways, e.g., “healthy” and “great nutritional value” (see Figure 1). To take advantage of such noisy labels, a system must both uncover their hidden clustering into *properties*, and learn to predict these properties from review text.

This paper presents a model that addresses both problems simultaneously. We assume that both the document text and the selection of keyphrases are governed by the underlying hidden properties of the document. Each property indexes a language model, thus allowing documents that incorporate the same

property to share similar features. In addition, each keyphrase is associated with a property; keyphrases that are associated with the same property should have similar distributional and surface features.

We link these two ideas in a joint hierarchical Bayesian model. Keyphrases are clustered based on their distributional and lexical properties, and a hidden topic model is applied to the document text. Crucially, the keyphrase clusters and document topics are linked, and inference is performed jointly. This increases the robustness of the keyphrase clustering, and ensures that the inferred hidden topics are indicative of salient semantic properties.

Our model is broadly applicable to many scenarios where documents are annotated in a noisy manner. In this work, we apply our method to a collection of reviews in two categories: restaurants and cell phones. The training data consists of review text and the associated pros/cons lists. We then evaluate the ability of our model to predict review properties when the pros/cons list is hidden. Across a variety of evaluation scenarios, our algorithm consistently outperforms alternative strategies by a wide margin.

## 2 Related Work

**Review Analysis** Our approach relates to previous work on property extraction from reviews (Popescu et al., 2005; Hu and Liu, 2004; Kim and Hovy, 2006). These methods extract lists of phrases, which are analogous to the keyphrases we use as input to our algorithm. However, our approach is distinguished in two ways: first, we are able to predict keyphrases beyond those that appear verbatim in the text. Second, our approach learns the relationships between keyphrases, allowing us to draw direct comparisons between reviews.

**Bayesian Topic Modeling** One aspect of our model views properties as distributions over words in the document. This approach is inspired by methods in the topic modeling literature, such as Latent Dirichlet Allocation (LDA) (Blei et al., 2003), where topics are treated as hidden variables that govern the distribution of words in a text. Our algorithm extends this notion by biasing the induced hidden topics toward a clustering of known keyphrases. Tying these two information sources together enhances the robustness of the hidden topics, thereby increasing

the chance that the induced structure corresponds to semantically meaningful properties.

Recent work has examined coupling topic models with explicit supervision (Blei and McAuliffe, 2007; Titov and McDonald, 2008). However, such approaches assume that the documents are labeled within a predefined annotation structure, *e.g.*, the properties of food, ambiance, and service for restaurants. In contrast, we address free-text annotations created by end users, without known semantic properties. Rather than requiring a predefined annotation structure, our model infers one from the data.

## 3 Problem Formulation

We formulate our problem as follows. We assume a dataset composed of documents with associated keyphrases. Each document may be marked with multiple keyphrases that express unseen semantic properties. Across the entire collection, several keyphrases may express the same property. The keyphrases are also incomplete — review texts often express properties that are not mentioned in their keyphrases. At training time, our model has access to both text and keyphrases; at test time, the goal is to predict the properties supported by a previously unseen document. We can then use this property list to generate an appropriate set of keyphrases.

## 4 Model Description

Our approach leverages both keyphrase clustering and distributional analysis of the text in a joint, hierarchical Bayesian model. Keyphrases are drawn from a set of clusters; words in the documents are drawn from language models indexed by a set of topics, where the topics correspond to the keyphrase clusters. Crucially, we bias the assignment of hidden topics in the text to be similar to the topics represented by the keyphrases of the document, but we permit some words to be drawn from other topics not represented by the keyphrases. This flexibility in the coupling allows the model to learn effectively in the presence of incomplete keyphrase annotations, while still encouraging the keyphrase clustering to cohere with the topics supported by the text.

We train the model on documents annotated with keyphrases. During training, we learn a hidden topic model from the text; each topic is also asso-

- $\psi$  – keyphrase cluster model
- $x$  – keyphrase cluster assignment
- $s$  – keyphrase similarity values
- $h$  – document keyphrases
- $\eta$  – document keyphrase topics
- $\lambda$  – probability of selecting  $\eta$  instead of  $\phi$
- $c$  – selects between  $\eta$  and  $\phi$  for word topics
- $\phi$  – document topic model
- $z$  – word topic assignment
- $\theta$  – language models of each topic
- $w$  – document words

$$\begin{aligned} \psi &\sim \text{Dirichlet}(\psi_0) \\ x_\ell &\sim \text{Multinomial}(\psi) \\ s_{\ell, \ell'} &\sim \begin{cases} \text{Beta}(\alpha_{=}) & \text{if } x_\ell = x_{\ell'} \\ \text{Beta}(\alpha_{\neq}) & \text{otherwise} \end{cases} \\ \eta_d &= [\eta_{d,1} \dots \eta_{d,K}]^T \\ &\text{where} \\ \eta_{d,k} &\propto \begin{cases} 1 & \text{if } x_\ell = k \text{ for any } \ell \in h_d \\ 0 & \text{otherwise} \end{cases} \\ \lambda &\sim \text{Beta}(\lambda_0) \\ c_{d,n} &\sim \text{Bernoulli}(\lambda) \\ \phi_d &\sim \text{Dirichlet}(\phi_0) \\ z_{d,n} &\sim \begin{cases} \text{Multinomial}(\eta_d) & \text{if } c_{d,n} = 1 \\ \text{Multinomial}(\phi_d) & \text{otherwise} \end{cases} \\ \theta_k &\sim \text{Dirichlet}(\theta_0) \\ w_{d,n} &\sim \text{Multinomial}(\theta_{z_{d,n}}) \end{aligned}$$

Figure 2: The plate diagram for our model. Shaded circles denote observed variables, and squares denote hyperparameters. The dotted arrows indicate that  $\eta$  is constructed deterministically from  $x$  and  $h$ .

ciated with a cluster of keyphrases. At test time, we are presented with documents that do not contain keyphrase annotations. The hidden topic model of the review text is used to determine the properties that a document as a whole supports. For each property, we compute the proportion of the document’s words assigned to it. Properties with proportions above a set threshold (tuned on a development set) are predicted as being supported.

#### 4.1 Keyphrase Clustering

One of our goals is to cluster the keyphrases, such that each cluster corresponds to a well-defined property. We represent each distinct keyphrase as a vector of similarity scores computed over the set of observed keyphrases; these scores are represented by  $s$  in Figure 2, the plate diagram of our model.<sup>1</sup> Modeling the similarity matrix rather than the sur-

<sup>1</sup>We assume that similarity scores are conditionally independent given the keyphrase clustering, though the scores are in fact related. Such simplifying assumptions have been previously used with success in NLP (e.g., Toutanova and Johnson, 2007), though a more theoretically sound treatment of the similarity matrix is an area for future research.

face forms allows arbitrary comparisons between keyphrases, e.g., permitting the use of both lexical and distributional information. The lexical comparison is based on the cosine similarity between the keyphrase words. The distributional similarity is quantified in terms of the co-occurrence of keyphrases across review texts. Our model is inherently capable of using any arbitrary source of similarity information; for a discussion of similarity metrics, see Lin (1998).

#### 4.2 Document-level Distributional Analysis

Our analysis of the document text is based on probabilistic topic models such as LDA (Blei et al., 2003). In the LDA framework, each word is generated from a language model that is indexed by the word’s topic assignment. Thus, rather than identifying a single topic for a document, LDA identifies a distribution over topics.

Our word model operates similarly, identifying a topic for each word, written as  $z$  in Figure 2. To tie these topics to the keyphrases, we deterministically construct a document-specific topic distribu-

tion from the clusters represented by the document’s keyphrases — this is  $\eta$  in the figure.  $\eta$  assigns equal probability to all topics that are represented in the keyphrases, and a small smoothing probability to other topics.

As noted above, properties may be expressed in the text even when no related keyphrase appears. For this reason, we also construct a document-specific topic distribution  $\phi$ . The auxiliary variable  $c$  indicates whether a given word’s topic is drawn from the set of keyphrase clusters, or from this topic distribution.

### 4.3 Generative Process

In this section, we describe the underlying generative process more formally.

First we consider the set of all keyphrases observed across the entire corpus, of which there are  $L$ . We draw a multinomial distribution  $\psi$  over the  $K$  keyphrase clusters from a symmetric Dirichlet prior  $\psi_0$ . Then for the  $\ell^{\text{th}}$  keyphrase, a cluster assignment  $x_\ell$  is drawn from the multinomial  $\psi$ . Finally, the similarity matrix  $\mathbf{s} \in [0, 1]^{L \times L}$  is constructed. Each entry  $s_{\ell, \ell'}$  is drawn independently, depending on the cluster assignments  $x_\ell$  and  $x_{\ell'}$ . Specifically,  $s_{\ell, \ell'}$  is drawn from a Beta distribution with parameters  $\alpha_ =$  if  $x_\ell = x_{\ell'}$  and  $\alpha_{\neq}$  otherwise. The parameters  $\alpha_ =$  linearly bias  $s_{\ell, \ell'}$  towards one (Beta( $\alpha_ =$ )  $\equiv$  Beta(2, 1)), and the parameters  $\alpha_{\neq}$  linearly bias  $s_{\ell, \ell'}$  towards zero (Beta( $\alpha_{\neq}$ )  $\equiv$  Beta(1, 2)).

Next, the words in each of the  $D$  documents are generated. Document  $d$  has  $N_d$  words;  $z_{d,n}$  is the topic for word  $w_{d,n}$ . These latent topics are drawn either from the set of clusters represented by the document’s keyphrases, or from the document’s topic model  $\phi_d$ . We deterministically construct a document-specific keyphrase topic model  $\eta_d$ , based on the keyphrase cluster assignments  $\mathbf{x}$  and the observed keyphrases  $h_d$ . The multinomial  $\eta_d$  assigns equal probability to each topic that is represented by a phrase in  $h_d$ , and a small probability to other topics.

As noted earlier, a document’s text may support properties that are not mentioned in its observed keyphrases. For that reason, we draw a document topic multinomial  $\phi_d$  from a symmetric Dirichlet prior  $\phi_0$ . The binary auxiliary variable  $c_{d,n}$  determines whether the word’s topic is drawn from the

keyphrase model  $\eta_d$  or the document topic model  $\phi_d$ .  $c_{d,n}$  is drawn from a weighted coin flip, with probability  $\lambda$ ;  $\lambda$  is drawn from a Beta distribution with prior  $\lambda_0$ . We have  $z_{d,n} \sim \eta_d$  if  $c_{d,n} = 1$ , and  $z_{d,n} \sim \phi_d$  otherwise. Finally, the word  $w_{d,n}$  is drawn from the multinomial  $\theta_{z_{d,n}}$ , where  $z_{d,n}$  indexes a topic-specific language model. Each of the  $K$  language models  $\theta_k$  is drawn from a symmetric Dirichlet prior  $\theta_0$ .

## 5 Posterior Sampling

Ultimately, we need to compute the model’s posterior distribution given the training data. Doing so analytically is intractable due to the complexity of the model, but sampling-based techniques can be used to estimate the posterior. We employ Gibbs sampling, previously used in NLP by Finkel et al. (2005) and Goldwater et al. (2006), among others. This technique repeatedly samples from the conditional distributions of each hidden variable, eventually converging on a Markov chain whose stationary distribution is the posterior distribution of the hidden variables in the model (Gelman et al., 2004). We now present sampling equations for each of the hidden variables in Figure 2.

The prior over keyphrase clusters  $\psi$  is sampled based on hyperprior  $\psi_0$  and keyphrase cluster assignments  $\mathbf{x}$ . We write  $p(\psi | \dots)$  to mean the probability conditioned on all the other variables.

$$\begin{aligned} p(\psi | \dots) &\propto p(\psi | \psi_0) p(\mathbf{x} | \psi), \\ &= p(\psi | \psi_0) \prod_{\ell} p(x_\ell | \psi) \\ &= \text{Dir}(\psi; \psi_0) \prod_{\ell} \text{Mul}(x_\ell; \psi) \\ &= \text{Dir}(\psi; \psi'), \end{aligned}$$

where  $\psi'_i = \psi_0 + \text{count}(x_\ell = i)$ . This update rule is due to the conjugacy of the multinomial to the Dirichlet distribution. The first line follows from Bayes’ rule, and the second line from the conditional independence of each keyphrase assignment  $x_\ell$  from the others, given  $\psi$ .

$\phi_d$  and  $\theta_k$  are resampled in a similar manner:

$$\begin{aligned} p(\phi_d | \dots) &\propto \text{Dir}(\phi_d; \phi'_d), \\ p(\theta_k | \dots) &\propto \text{Dir}(\theta_k; \theta'_k), \end{aligned}$$

$$\begin{aligned}
p(x_\ell | \dots) &\propto p(x_\ell | \psi) p(\mathbf{s} | x_\ell, \mathbf{x}_{-\ell}, \alpha) p(\mathbf{z} | \eta, \psi, \mathbf{c}) \\
&\propto p(x_\ell | \psi) \left[ \prod_{\ell' \neq \ell} p(s_{\ell, \ell'} | x_\ell, x_{\ell'}, \alpha) \right] \left[ \prod_d \prod_{c_{d,n}=1}^D p(z_{d,n} | \eta_d) \right] \\
&= \text{Mul}(x_\ell; \psi) \left[ \prod_{\ell' \neq \ell} \text{Beta}(s_{\ell, \ell'}; \alpha_{x_\ell, x_{\ell'}}) \right] \left[ \prod_d \prod_{c_{d,n}=1}^D \text{Mul}(z_{d,n}; \eta_d) \right]
\end{aligned}$$

Figure 3: The resampling equation for the keyphrase cluster assignments.

where  $\phi'_{d,i} = \phi_0 + \text{count}(z_{d,n} = i \wedge c_{d,n} = 0)$  and  $\theta'_{k,i} = \theta_0 + \sum_d \text{count}(w_{d,n} = i \wedge z_{d,n} = k)$ . In building the counts for  $\phi'_{d,i}$ , we consider only cases in which  $c_{d,n} = 0$ , indicating that the topic  $z_{d,n}$  is indeed drawn from the document topic model  $\phi_d$ . Similarly, when building the counts for  $\theta'_{k,i}$ , we consider only cases in which the word  $w_{d,n}$  is drawn from topic  $k$ .

To resample  $\lambda$ , we employ the conjugacy of the Beta prior to the Bernoulli observation likelihoods, adding counts of  $c$  to the prior  $\lambda_0$ .

$$p(\lambda | \dots) \propto \text{Beta}(\lambda; \lambda'),$$

$$\text{where } \lambda' = \lambda_0 + \left[ \begin{array}{c} \sum_d \text{count}(c_{d,n} = 1) \\ \sum_d \text{count}(c_{d,n} = 0) \end{array} \right].$$

The keyphrase cluster assignments are represented by  $\mathbf{x}$ , whose sampling distribution depends on  $\psi$ ,  $\mathbf{s}$ , and  $\mathbf{z}$ , via  $\eta$ . The equation is shown in Figure 3. The first term is the prior on  $x_\ell$ . The second term encodes the dependence of the similarity matrix  $\mathbf{s}$  on the cluster assignments; with slight abuse of notation, we write  $\alpha_{x_\ell, x_{\ell'}}$  to denote  $\alpha_{=}$  if  $x_\ell = x_{\ell'}$ , and  $\alpha_{\neq}$  otherwise. The third term is the dependence of the word topics  $z_{d,n}$  on the topic distribution  $\eta_d$ . We compute the final result of Figure 3 for each possible setting of  $x_\ell$ , and then sample from the normalized multinomial.

The word topics  $\mathbf{z}$  are sampled according to keyphrase topic distribution  $\eta_d$ , document topic distribution  $\phi_d$ , words  $\mathbf{w}$ , and auxiliary variables  $\mathbf{c}$ :

$$\begin{aligned}
p(z_{d,n} | \dots) &\propto p(z_{d,n} | \phi_d, \eta_d, c_{d,n}) p(w_{d,n} | z_{d,n}, \theta) \\
&= \begin{cases} \text{Mul}(z_{d,n}; \eta_d) \text{Mul}(w_{d,n}; \theta_{z_{d,n}}) & \text{if } c_{d,n} = 1, \\ \text{Mul}(z_{d,n}; \phi_d) \text{Mul}(w_{d,n}; \theta_{z_{d,n}}) & \text{otherwise.} \end{cases}
\end{aligned}$$

As with  $x_\ell$ , each  $z_{d,n}$  is sampled by computing the conditional likelihood of each possible setting within a constant of proportionality, and then sampling from the normalized multinomial.

Finally, we sample each auxiliary variable  $c_{d,n}$ , which indicates whether the hidden topic  $z_{d,n}$  is drawn from  $\eta_d$  or  $\phi_d$ . The conditional probability for  $c_{d,n}$  depends on its prior  $\lambda$  and the hidden topic assignments  $z_{d,n}$ :

$$\begin{aligned}
p(c_{d,n} | \dots) &\propto p(c_{d,n} | \lambda) p(z_{d,n} | \eta_d, \phi_d, c_{d,n}) \\
&= \begin{cases} \text{Bern}(c_{d,n}; \lambda) \text{Mul}(z_{d,n}; \eta_d) & \text{if } c_{d,n} = 1, \\ \text{Bern}(c_{d,n}; \lambda) \text{Mul}(z_{d,n}; \phi_d) & \text{otherwise.} \end{cases}
\end{aligned}$$

We compute the likelihood of  $c_{d,n} = 0$  and  $c_{d,n} = 1$  within a constant of proportionality, and then sample from the normalized Bernoulli distribution.

## 6 Experimental Setup

**Data Sets** We evaluate our system on reviews from two categories, restaurants and cell phones. These reviews were downloaded from the popular Epinions<sup>2</sup> website. Users of this website evaluate products by providing both a textual description of their opinion, as well as concise lists of keyphrases (pros and cons) summarizing the review. The statistics of this dataset are provided in Table 1. For each of the categories, we randomly selected 50%, 15%, and 35% of the documents as training, development, and test sets, respectively.

Manual analysis of this data reveals that authors often omit properties mentioned in the text from the list of keyphrases. To obtain a complete gold

<sup>2</sup><http://www.epinions.com/>

	Restaurants	Cell Phones
# of reviews	3883	1112
Avg. review length	916.9	1056.9
Avg. keyphrases / review	3.42	4.91

Table 1: Statistics of the reviews dataset by category.

standard, we hand-annotated a subset of the reviews from the restaurant category. The annotation effort focused on eight commonly mentioned properties, such as those underlying the keyphrases “pleasant atmosphere” and “attentive staff.” Two raters annotated 160 reviews, 30 of which were annotated by both. Cohen’s kappa, a measure of interrater agreement ranging from zero to one, was 0.78 for this subset, indicating high agreement (Cohen, 1960).

Each review was annotated with 2.56 properties on average. Each manually-annotated property corresponded to an average of 19.1 keyphrases in the restaurant data, and 6.7 keyphrases in the cell phone data. This supports our intuition that a single semantic property may be expressed using a variety of different keyphrases.

**Training** Our model needs to be provided with the number of clusters  $K$ . We set  $K$  large enough for the model to learn effectively on the development set. For the restaurant data — where the gold standard identified eight semantic properties — we set  $K$  to 20, allowing the model to account for keyphrases not included in the eight most common properties. For the cell phones category, we set  $K$  to 30.

To improve the model’s convergence rate, we perform two initialization steps for the Gibbs sampler. First, sampling is done only on the keyphrase clustering component of the model, ignoring document text. Second, we fix this clustering and sample the remaining model parameters. These two steps are run for 5,000 iterations each. The full joint model is then sampled for 100,000 iterations. Inspection of the parameter estimates confirms model convergence. On a 2GHz dual-core desktop machine, a multi-threaded C++ implementation of model training takes about two hours for each dataset.

**Inference** The final point estimate used for testing is an average (for continuous variables) or a mode (for discrete variables) over the last 1,000 Gibbs sampling iterations. Averaging is a heuristic that is applicable in our case because our sam-

ple histograms are unimodal and exhibit low skew. The model usually works equally well using single-sample estimates, but is more prone to estimation noise.

As previously mentioned, we convert word topic assignments to document properties by examining the proportion of words supporting each property. A threshold for this proportion is set for each property via the development set.

**Evaluation** Our first evaluation examines the accuracy of our model and the baselines by comparing their output against the keyphrases provided by the review authors. More specifically, the model first predicts the properties supported by a given review. We then test whether the original authors’ keyphrases are contained in the clusters associated with these properties.

As noted above, the authors’ keyphrases are often incomplete. To perform a noise-free comparison, we based our second evaluation on the manually constructed gold standard for the restaurant category. We took the most commonly observed keyphrase from each of the eight annotated properties, and tested whether they are supported by the model based on the document text.

In both types of evaluation, we measure the model’s performance using precision, recall, and F-score. These are computed in the standard manner, based on the model’s keyphrase predictions compared against the corresponding references. The sign test was used for statistical significance testing (De Groot and Schervish, 2001).

**Baselines** To the best of our knowledge, this task not been previously addressed in the literature. We therefore consider five baselines that allow us to explore the properties of this task and our model.

*Random:* Each keyphrase is supported by a document with probability of one half. This baseline’s results are computed (in expectation) rather than actually run. This method is expected to have a recall of 0.5, because in expectation it will select half of the correct keyphrases. Its precision is the proportion of supported keyphrases in the test set.

*Phrase in text:* A keyphrase is supported by a document if it appears verbatim in the text. Because of this narrow requirement, precision should be high whereas recall will be low.

	Restaurants gold standard annotation			Restaurants free-text annotation			Cell Phones free-text annotation		
	Recall	Prec.	F-score	Recall	Prec.	F-score	Recall	Prec.	F-score
Random	0.500	0.300	* 0.375	0.500	0.500	* 0.500	0.500	0.489	* 0.494
Phrase in text	0.048	0.500	* 0.087	0.078	0.909	* 0.144	0.171	0.529	* 0.259
Cluster in text	0.223	0.534	0.314	0.517	0.640	* 0.572	0.829	0.547	0.659
Phrase classifier	0.028	0.636	* 0.053	0.068	0.963	* 0.126	0.029	0.600	* 0.055
Cluster classifier	0.113	0.622	◇ 0.192	0.255	0.907	* 0.398	0.210	0.759	0.328
Our model	0.625	0.416	<b>0.500</b>	0.901	0.652	<b>0.757</b>	0.886	0.585	<b>0.705</b>
Our model + gold clusters	0.582	0.398	0.472	0.795	0.627	* 0.701	0.886	0.520	◇ 0.655

Table 2: Comparison of the property predictions made by our model and the baselines in the two categories as evaluated against the gold and free-text annotations. Results for our model using the fixed, manually-created gold clusterings are also shown. The methods against which our model has significantly better results on the sign test are indicated with a \* for  $p \leq 0.05$ , and  $\diamond$  for  $p \leq 0.1$ .

*Cluster in text:* A keyphrase is supported by a document if it or any of its paraphrases appears in the text. Paraphrasing is based on our model’s clustering of the keyphrases. The use of paraphrasing information enhances recall at the potential cost of precision, depending on the quality of the clustering.

*Phrase classifier:* Discriminative classifiers are trained for each keyphrase. Positive examples are documents that are labeled with the keyphrase; all other documents are negative examples. A keyphrase is supported by a document if that keyphrase’s classifier returns positive.

*Cluster classifier:* Discriminative classifiers are trained for each cluster of keyphrases, using our model’s clustering. Positive examples are documents that are labeled with any keyphrase from the cluster; all other documents are negative examples. All keyphrases of a cluster are supported by a document if that cluster’s classifier returns positive.

*Phrase classifier* and *cluster classifier* employ maximum entropy classifiers, trained on the same features as our model, *i.e.*, word counts. The former is high-precision/low-recall, because for any particular keyphrase, its synonymous keyphrases would be considered negative examples. The latter broadens the positive examples, which should improve recall. We used Zhang Le’s MaxEnt toolkit<sup>3</sup> to build these classifiers.

<sup>3</sup>[http://homepages.inf.ed.ac.uk/s0450736/maxent\\_toolkit.html](http://homepages.inf.ed.ac.uk/s0450736/maxent_toolkit.html)

## 7 Results

**Comparative performance** Table 2 presents the results of the evaluation scenarios described above. Our model outperforms every baseline by a wide margin in all evaluations.

The absolute performance of the automatic methods indicates the difficulty of the task. For instance, evaluation against gold standard annotations shows that the random baseline outperforms all of the other baselines. We observe similar disappointing results for the non-random baselines against the free-text annotations. The precision and recall characteristics of the baselines match our previously described expectations.

The poor performance of the discriminative models seems surprising at first. However, these results can be explained by the degree of noise in the training data, specifically, the aforementioned sparsity of free-text annotations. As previously described, our technique allows document text topics to stochastically derive from either the keyphrases or a background distribution — this allows our model to learn effectively from incomplete annotations. In fact, when we force all text topics to derive from keyphrase clusters in our model, its performance degrades to the level of the classifiers or worse, with an F-score of 0.390 in the restaurant category and 0.171 in the cell phone category.

**Impact of paraphrasing** As previously observed in entailment research (Dagan et al., 2006), paraphrasing information contributes greatly to improved performance on semantic inference. This is

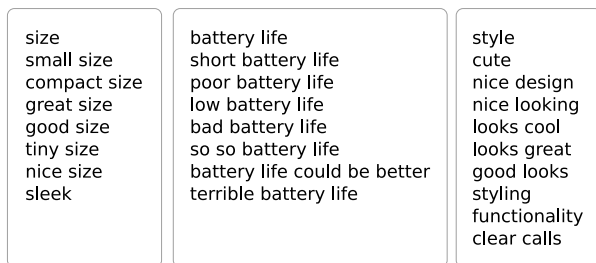

Figure 4: Sample keyphrase clusters that our model infers in the cell phone category.

confirmed by the dramatic difference in results between the *cluster in text* and *phrase in text* baselines. Therefore it is important to quantify the quality of automatically computed paraphrases, such as those illustrated in Figure 4.

	Restaurants	Cell Phones
Keyphrase similarity only	0.931	0.759
Joint training	<b>0.966</b>	<b>0.876</b>

Table 3: Rand Index scores of our model’s clusters, using only keyphrase similarity vs. using keyphrases and text jointly. Comparison of cluster quality is against the gold standard.

One way to assess clustering quality is to compare it against a “gold standard” clustering, as constructed in Section 6. For this purpose, we use the *Rand Index* (Rand, 1971), a measure of cluster similarity. This measure varies from zero to one; higher scores are better. Table 3 shows the Rand Indices for our model’s clustering, as well as the clustering obtained by using only keyphrase similarity. These scores confirm that joint inference produces better clusters than using only keyphrases.

Another way of assessing cluster quality is to consider the impact of using the gold standard clustering instead of our model’s clustering. As shown in the last two lines of Table 2, using the gold clustering yields results worse than using the model clustering. This indicates that for the purposes of our task, the model clustering is of sufficient quality.

## 8 Conclusions and Future Work

In this paper, we have shown how free-text annotations provided by novice users can be leveraged as a training set for document-level semantic inference. The resulting hierarchical Bayesian model

overcomes the lack of consistency in such annotations by inducing a hidden structure of semantic properties, which correspond both to clusters of keyphrases and hidden topic models in the text. Our system successfully extracts semantic properties of unannotated restaurant and cell phone reviews, empirically validating our approach.

Our present model makes strong assumptions about the independence of similarity scores. We believe this could be avoided by modeling the generation of the entire similarity matrix jointly. We have also assumed that the properties themselves are unstructured, but they are in fact related in interesting ways. For example, it would be desirable to model antonyms explicitly, *e.g.*, no restaurant review should be simultaneously labeled as having good and bad food. The correlated topic model (Blei and Lafferty, 2006) is one way to account for relationships between hidden topics; more structured representations, such as hierarchies, may also be considered.

Finally, the core idea of using free-text as a source of training labels has wide applicability, and has the potential to enable sophisticated content search and analysis. For example, online blog entries are often tagged with short keyphrases. Our technique could be used to standardize these tags, and assign keyphrases to untagged blogs. The notion of free-text annotations is also very broad — we are currently exploring the applicability of this model to Wikipedia articles, using section titles as keyphrases, to build standard article schemas.

Y.Feng-4@sms.ed.ac.uk, mlap@inf.ed.ac.uk

## Abstract

The availability of databases of images labeled with keywords is necessary for developing and evaluating image annotation models. Dataset collection is however a costly and time consuming task. In this paper we exploit the vast resource of images available on the web. We create a database of pictures that are naturally embedded into news articles and propose to use their captions as a proxy for annotation keywords. Experimental results show that an image annotation model can be developed on this dataset alone without the overhead of manual annotation. We also demonstrate that the news article associated with the picture can be used to boost image annotation performance.

## 1 Introduction

As the number of image collections is rapidly growing, so does the need to browse and search them. Recent years have witnessed significant progress in developing methods for image retrieval<sup>1</sup>, many of which are query-based. Given a database of images, each annotated with keywords, the query is used to retrieve relevant pictures under the assumption that the annotations can essentially capture their semantics.

One stumbling block to the widespread use of query-based image retrieval systems is obtaining the keywords for the images. Since manual annotation is expensive, time-consuming and practically infeasible for large databases, there has been great in-

<sup>1</sup>The approaches are too numerous to list; we refer the interested reader to Datta et al. (2005) for an overview.

terest in automating the image annotation process (see references). More formally, given an image  $I$  with visual features  $V_i = \{v_1, v_2, \dots, v_N\}$  and a set of keywords  $W = \{w_1, w_2, \dots, w_M\}$ , the task consists in finding *automatically* the keyword subset  $W_I \subset W$ , which can appropriately describe the image  $I$ . Indeed, several approaches have been proposed to solve this problem under a variety of learning paradigms. These range from supervised classification (Vailaya et al., 2001; Smeulders et al., 2000) to instantiations of the noisy-channel model (Duygulu et al., 2002), to clustering (Barnard et al., 2002), and methods inspired by information retrieval (Lavrenko et al., 2003; Feng et al., 2004).

Obviously in order to develop accurate image annotation models, some manually labeled data is required. Previous approaches have been developed and tested almost exclusively on the Corel database. The latter contains 600 CD-ROMs, each containing about 100 images representing the same topic or concept, e.g., people, landscape, male. Each topic is associated with keywords and these are assumed to also describe the images under this topic. As an example consider the pictures in Figure 1 which are classified under the topic *male* and have the description keywords *man, male, people, cloth, and face*.

Current image annotation methods work well when large amounts of labeled images are available but can run into severe difficulties when the number of images and keywords for a given topic is relatively small. Unfortunately, databases like Corel are few and far between and somewhat idealized. Corel contains clusters of many closely related images which in turn share keyword descriptions, thus allowing models to learn image-keyword associations

Figure 1: Images from the Corel database, exemplifying the concept *male* with keyword descriptions *man*, *male*, *people*, *cloth*, and *face*.

reliably (Tang and Lewis, 2007). It is unlikely that models trained on this database will perform well out-of-domain on other image collections which are more noisy and do not share these characteristics. Furthermore, in order to develop robust image annotation models, it is crucial to have large and diverse datasets both for training and evaluation.

In this work, we aim to relieve the data acquisition bottleneck associated with automatic image annotation by taking advantage of resources where images and their annotations co-occur naturally. News articles associated with images and their captions spring readily to mind (e.g., BBC News, Yahoo News). So, rather than laboriously annotating images with their keywords, we simply treat captions as labels. These annotations are admittedly noisy and far from ideal. Captions can be denotative (describing the objects the image depicts) but also connotative (describing sociological, political, or economic attitudes reflected in the image). Importantly, our images are not standalone, they come with news articles whose content is shared with the image. So, by processing the accompanying document, we can effectively learn about the image and reduce the effect of noise due to the approximate nature of the caption labels. To give a simple example, if two words appear both in the caption and the document, it is more likely that the annotation is genuine.

In what follows, we present a new database consisting of articles, images, and their captions which we collected from an on-line news source. We then propose an image annotation model which can learn from our noisy annotations and the auxiliary documents. Specifically, we extend and modify Lavrenko’s (2003) continuous relevance model

to suit our task. Our experimental results show that this model can successfully scale to our database, without making use of explicit human annotations in any way. We also show that the auxiliary document contains important information for generating more accurate image descriptions.

## 2 Related Work

Automatic image annotation is a popular task in computer vision. The earliest approaches are closely related to image classification (Vailaya et al., 2001; Smeulders et al., 2000), where pictures are assigned a set of simple descriptions such as indoor, outdoor, landscape, people, animal. A binary classifier is trained for each concept, sometimes in a “one vs all” setting. The focus here is mostly on image processing and good feature selection (e.g., colour, texture, contours) rather than the annotation task itself.

Recently, much progress has been made on the image annotation task thanks to three factors. The availability of the Corel database, the use of unsupervised methods and new insights from the related fields of natural language processing and information retrieval. The co-occurrence model (Mori et al., 1999) collects co-occurrence counts between words and image features and uses them to predict annotations for new images. Duygulu et al. (2002) improve on this model by treating image regions and keywords as a bi-text and using the EM algorithm to construct an image region-word dictionary.

Another way of capturing co-occurrence information is to introduce latent variables linking image features with words. Standard latent semantic analysis (LSA) and its probabilistic variant (PLSA) have been applied to this task (Hofmann, 1998). Barnard et al. (2002) propose a hierarchical latent model in order to account for the fact that some words are more general than others. More sophisticated graphical models (Blei and Jordan, 2003) have also been employed including Gaussian Mixture Models (GMM) and Latent Dirichlet Allocation (LDA).

Finally, relevance models originally developed for information retrieval, have been successfully applied to image annotation (Lavrenko et al., 2003; Feng et al., 2004). A key idea behind these models is to find the images most similar to the test image and then use their shared keywords for annotation.

Our approach differs from previous work in two

important respects. Firstly, our ultimate goal is to develop an image annotation model that can cope with real-world images and noisy data sets. To this end we are faced with the challenge of building an appropriate database for testing and training purposes. Our solution is to leverage the vast resource of images available on the web but also the fact that many of these images are implicitly annotated. For example, news articles often contain images whose captions can be thought of as annotations. Secondly, we allow our image annotation model access to knowledge sources other than the image and its keywords. This is relatively straightforward in our case; an image and its accompanying document have shared content, and we can use the latter to glean information about the former. But we hope to illustrate the more general point that auxiliary linguistic information can indeed bring performance improvements on the image annotation task.

### 3 BBC News Database

Our database consists of news images which are abundant. Many on-line news providers supply pictures with news articles, some even classify news into broad topic categories (e.g., business, world, sports, entertainment). Importantly, news images often display several objects and complex scenes and are usually associated with captions describing their contents. The captions are image specific and use a rich vocabulary. This is in marked contrast to the Corel database whose images contain one or two salient objects and a limited vocabulary (typically around 300 words).

We downloaded 3,361 news articles from the BBC News website.<sup>2</sup> Each article was accompanied with an image and its caption. We thus created a database of image-caption-document tuples. The documents cover a wide range of topics including national and international politics, advanced technology, sports, education, etc. An example of an entry in our database is illustrated in Figure 2. Here, the image caption is *Marcin and Florent face intense competition from outside Europe* and the accompanying article discusses EU subsidies to farmers. The images are usually 203 pixels wide and 152 pixels high. The average caption length is 5.35 tokens, and the average document length 133.85 tokens. Our

<sup>2</sup><http://news.bbc.co.uk/>

Figure 2: A sample from our BBC News database. Each entry contains an image, a caption for the image, and the accompanying document with its title.

captions have a vocabulary of 2,167 words and our documents 6,253. The vocabulary shared between captions and documents is 2,056 words.

### 4 Extending the Continuous Relevance Annotation Model

Our work is an extension of the continuous relevance annotation model put forward in Lavrenko et al. (2003). Unlike other unsupervised approaches where a set of latent variables is introduced, each defining a joint distribution on the space of keywords and image features, the relevance model captures the joint probability of images and annotated words *directly*, without requiring an intermediate clustering stage. This model is a good point of departure for our task for several reasons, both theoretical and empirical. Firstly, expectations are computed over every single point in the training set and

therefore parameters can be estimated without EM. Indeed, Lavrenko et al. achieve competitive performance with latent variable models. Secondly, the generation of feature vectors is modeled directly, so there is no need for quantization. Thirdly, as we show below the model can be easily extended to incorporate information outside the image and its keywords.

In the following we first lay out the assumptions underlying our model. We next describe the continuous relevance model in more detail and present our extensions and modifications.

**Assumptions** Since we are using a non-standard database, namely images embedded in documents, it is important to clarify what we mean by image annotation, and how the precise nature of our data impacts the task. We thus make the following assumptions:

1. The caption describes the content of the image directly or indirectly. Unlike traditional image annotation where keywords describe salient objects, captions supply more detailed information, not only about objects, and their attributes, but also events. In Figure 2 the caption mentions Marcin and Florent the two individuals shown in the picture but also the fact that they face competition from outside Europe.
2. Since our images are implicitly rather than explicitly labeled, we do not assume that we can annotate *all* objects present in the image. Instead, we hope to be able to model event-related information such as “what happened”, “who did it”, “when” and “where”. Our annotation task is therefore more semantic in nature than traditionally assumed.
3. The accompanying document describes the content of the image. This is trivially true for news documents where the images conventionally depict events, objects or people mentioned in the article.

To validate these assumptions, we performed the following experiment on our BBC News dataset. We randomly selected 240 image-caption pairs and manually assessed whether the caption content words (i.e., nouns, verbs, and adjectives) could describe the image. We found out that the captions express the picture’s content 90% of the time. Furthermore, approximately 88% of the nouns in sub-

ject or object position directly denote salient picture objects. We thus conclude that the captions contain useful information about the picture and can be used for annotation purposes.

**Model Description** The continuous relevance image annotation model (Lavrenko et al., 2003) generatively learns the joint probability distribution  $P(V, W)$  of words  $W$  and image regions  $V$ . The key assumption here is that the process of generating images is conditionally independent from the process of generating words. Each annotated image in the training set is treated as a latent variable. Then for an unknown image  $I$ , we estimate:

$$P(V_I, W_I) = \sum_{s \in D} P(V_I|s)P(W_I|s)P(s), \quad (1)$$

where  $D$  is the number of images in the training database,  $V_I$  are visual features of the image regions representing  $I$ ,  $W_I$  are the keywords of  $I$ ,  $s$  is a latent variable (i.e., an image-annotation pair), and  $P(s)$  the prior probability of  $s$ . The latter is drawn from a uniform distribution:

$$P(s) = \frac{1}{N_D} \quad (2)$$

where  $N_D$  is number of the latent variables in the training database  $D$ .

When estimating  $P(V_I|s)$ , the probability of image regions and words, Lavrenko et al. (2003) reasonably assume a generative Gaussian kernel distribution for the image regions:

$$P(V_I|s) = \prod_{r=1}^{N_{V_I}} P_g(v_r|s) \quad (3)$$

$$= \prod_{r=1}^{N_{V_I}} \frac{1}{n_{s_v}} \sum_{i=1}^{n_{s_v}} \frac{\exp\{(v_r - v_i)^T \Sigma^{-1} (v_r - v_i)\}}{\sqrt{2^k \pi^k |\Sigma|}}$$

where  $N_{V_I}$  is the number of regions in image  $I$ ,  $v_r$  the feature vector for region  $r$  in image  $I$ ,  $n_{s_v}$  the number of regions in the image of latent variable  $s$ ,  $v_i$  the feature vector for region  $i$  in  $s$ ’s image,  $k$  the dimension of the image feature vectors and  $\Sigma$  the feature covariance matrix. According to equation (3), a Gaussian kernel is fit to every feature vector  $v_i$  corresponding to region  $i$  in the image of the latent variable  $s$ . Each kernel here is determined by the feature covariance matrix  $\Sigma$ , and for simplicity,  $\Sigma$  is assumed to be a diagonal matrix:  $\Sigma = \beta I$ , where  $I$  is the identity matrix; and  $\beta$  is a scalar modulating the bandwidth of

the kernel whose value is optimized on the development set.

Lavrenko et al. (2003) estimate the word probabilities  $P(W|s)$  using a multinomial distribution. This is a reasonable assumption in the Corel dataset, where the annotations have similar lengths and the words reflect the salience of objects in the image (the multinomial model tends to favor words that appear multiple times in the annotation). However, in our dataset the annotations have varying lengths, and do not necessarily reflect object salience. We are more interested in modeling the *presence* or *absence* of words in the annotation and thus use the multiple-Bernoulli distribution to generate words (Feng et al., 2004). And rather than relying solely on annotations in the training database, we can also take the accompanying document into account using a weighted combination.

The probability of sampling a set of words  $W$  given a latent variable  $s$  from the underlying multiple Bernoulli distribution that has generated the training set  $D$  is:

$$P(W|s) = \prod_{w \in W} P(w|s) \prod_{w \notin W} (1 - P(w|s)) \quad (4)$$

where  $P(w|s)$  denotes the probability of the  $w$ 'th component of the multiple Bernoulli distribution. Now, in estimating  $P(w|s)$  we can include the document as:

$$P_{est}(w|s) = \alpha P_{est}(w|s_a) + (1 - \alpha) P_{est}(w|s_d) \quad (5)$$

where  $\alpha$  is a smoothing parameter tuned on the development set,  $s_a$  is the annotation for the latent variable  $s$  and  $s_d$  its corresponding document.

Equation (5) smooths the influence of the annotation words and allows to offset the negative effect of the noise inherent in our dataset. Since our images are implicitly annotated, there is no guarantee that the annotations are all appropriate. By taking into account  $P_{est}(w|s_d)$ , it is possible to annotate an image with a word that appears in the document but is not included in the caption.

We use a Bayesian framework for estimating  $P_{est}(w|s_a)$ . Specifically, we assume a beta prior (conjugate to the Bernoulli distribution) for each word:

$$P_{est}(w|s_a) = \frac{\mu b_{w,s_a} + N_w}{\mu + D} \quad (6)$$

where  $\mu$  is a smoothing parameter estimated on the development set,  $b_{w,s_a}$  is a Boolean variable denoting whether  $w$  appears in the annotation  $s_a$ , and  $N_w$  is the number of latent variables that contain  $w$  in their annotations.

We estimate  $P_{est}(w|s_d)$  using maximum likelihood estimation (Ponte and Croft, 1998):

$$P_{est}(w|s_d) = \frac{num_{w,s_d}}{num_{s_d}} \quad (7)$$

where  $num_{w,s_d}$  denotes the frequency of  $w$  in the accompanying document of latent variable  $s$  and  $num_{s_d}$  the number of all tokens in the document. Note that we purposely leave  $P_{est}$  unsmoothed, since it is used as a means of balancing the weight of word frequencies in annotations. So, if a word does not appear in the document, the possibility of selecting it will not be greater than  $\alpha$  (see Equation (5)).

Unfortunately, including the document in the estimation of  $P_{est}(w|s)$  increases the vocabulary which in turn increases computation time. Given a test image-document pair, we must evaluate  $P(w|V_I)$  for every  $w$  in our vocabulary which is the union of the caption and document words. We reduce the search space, by scoring each document word with its  $tf * idf$  weight (Salton and McGill, 1983) and adding the  $n$ -best candidates to our caption vocabulary. This way the vocabulary is not fixed in advance for all images but changes dynamically depending on the document at hand.

**Re-ranking the Annotation Hypotheses** It is easy to see that the output of our model is a ranked word list. Typically, the  $k$ -best words are taken to be the automatic annotations for a test image  $I$  (Duygulu et al., 2002; Lavrenko et al., 2003; Jeon and Manmatha, 2004) where  $k$  is a small number and the same for all images.

So far we have taken account of the auxiliary document rather naively, by considering its vocabulary in the estimation of  $P(W|s)$ . Crucially, documents are written with one or more topics in mind. The image (and its annotations) are likely to represent these topics, so ideally our model should prefer words that are strong topic indicators. A simple way to implement this idea is by re-ranking our  $k$ -best list according to a topic model estimated from the entire document collection.

Specifically, we use Latent Dirichlet Allocation (LDA) as our topic model (Blei et al., 2003). LDA

represents documents as a mixture of topics and has been previously used to perform document classification (Blei et al., 2003) and ad-hoc information retrieval (Wei and Croft, 2006) with good results. Given a collection of documents and a set of latent variables (i.e., the number of topics), the LDA model estimates the probability of topics per document and the probability of words per topic. The topic mixture is drawn from a conjugate Dirichlet prior that remains the same for all documents.

For our re-ranking task, we use the LDA model to infer the  $m$ -best topics in the accompanying document. We then select from the output of our model those words that are most likely according to these topics. To give a concrete example, let us assume that for a given image our model has produced five annotations,  $w_1, w_2, w_3, w_4$ , and  $w_5$ . However, according to the LDA model neither  $w_2$  nor  $w_5$  are likely topic indicators. We therefore remove  $w_2$  and  $w_5$  and substitute them with words further down the ranked list that are topical (e.g.,  $w_6$  and  $w_7$ ). An advantage of using LDA is that at test time we can perform inference without retraining the topic model.

## 5 Experimental Setup

In this section we discuss our experimental design for assessing the performance of the model presented above. We give details on our training procedure and parameter estimation, describe our features, and present the baseline methods used for comparison with our approach.

**Data** Our model was trained and tested on the database introduced in Section 3. We used 2,881 image-caption-document tuples for training, 240 tuples for development and 240 for testing. The documents and captions were part-of-speech tagged and lemmatized with Tree Tagger (Schmid, 1994). Words other than nouns, verbs, and adjectives were discarded. Words that were attested less than five times in the training set were also removed to avoid unreliable estimation. In total, our vocabulary consisted of 8,309 words.

**Model Parameters** Images are typically segmented into regions prior to training. We impose a fixed-size rectangular grid on each image rather than attempting segmentation using a general purpose algorithm such as normalized cuts (Shi and Malik,

Color
average of RGB components, standard deviation
average of LUV components, standard deviation
average of LAB components, standard deviation
Texture
output of DCT transformation

2000). Using a grid avoids unnecessary errors from image segmentation algorithms, reduces computation time, and simplifies parameter estimation (Feng et al., 2004). Taking the small size and low resolution of the BBC News images into account, we average divide each image into  $6 \times 5$  rectangles and extract features for each region. We use 46 features based on color, texture, and shape. They are summarized in Table 2.

The model presented in Section 4 has a few parameters that must be selected empirically on the development set. These include the vocabulary size, which is dependent on the  $n$  words with the highest  $tf * idf$  scores in each document, and the number of topics for the LDA-based re-ranker. We obtained best performance with  $n$  set to 100 (no cutoff was applied in cases where the vocabulary was less than 100). We trained an LDA model with 20 topics on our document collection using David Blei’s implementation.<sup>3</sup> We used this model to re-rank the output of our annotation model according to the three most likely topics in each document.

**Baselines** We compared our model against three baselines. The first baseline is based on  $tf * idf$  (Salton and McGill, 1983). We rank the document’s content words (i.e., nouns, verbs, and adjectives) according to their  $tf * idf$  weight and select the top  $k$  to be the final annotations. Our second baseline simply annotates the image with the document’s title. Again we only use content words (the average title length in the training set was 4.0 words). Our third baseline is Lavrenko et al.’s (2003) continuous relevance model. It is trained solely on image-caption

pairs, uses a vocabulary of 2,167 words and the same features as our extended model.

**Evaluation** Our evaluation follows the experimental methodology proposed in Duygulu et al. (2002). We are given an un-annotated image  $I$  and are asked to automatically produce suitable annotations for  $I$ . Given a set of image regions  $V_I$ , we use equation (1) to derive the conditional distribution  $P(w|V_I)$ . We consider the  $k$ -best words as the annotations for  $I$ . We present results using the top 10, 15, and 20 annotation words. We assess our model’s performance using precision/recall and F1. In our task, precision is the percentage of correctly annotated words over all annotations that the system suggested. Recall, is the percentage of correctly annotated words over the number of genuine annotations in the test data. F1 is the harmonic mean of precision and recall. These measures are averaged over the set of test words.

## 6 Results

Our experiments were driven by three questions: (1) Is it possible to create an annotation model from noisy data that has not been explicitly hand labeled for this task? (2) What is the contribution of the auxiliary document? As mentioned earlier, considering the document increases the model’s computational complexity, which can be justified as long as we demonstrate a substantial increase in performance. (3) What is the contribution of the image? Here, we are trying to assess if the image features matter. For instance, we could simply generate annotation words by processing the document alone.

Our results are summarized in Table 1. We compare the annotation performance of the model proposed in this paper (ExtModel) with Lavrenko et al.’s (2003) original continuous relevance model (Lavrenko03) and two other simpler models which

do not take the image into account (*tf \* idf* and DocTitle). First, note that the original relevance model performs best when the annotation output is restricted to 10 words with an F1 of 11.81% (recall is 9.05 and precision 16.01). F1 is marginally worse with 15 output words and decreases by 2% with 20. This model does not take any document-based information into account, it is trained solely on image-caption pairs. On the Corel test set the same model obtains a precision of 19.0% and a recall of 16.0% with a vocabulary of 260 words. Although these results are not strictly comparable with ours due to the different nature of the training data (in addition, we output 10 annotation words, whereas Lavrenko et al. (2003) output 5), they give some indication of the decrease in performance incurred when using a more challenging dataset. Unlike Corel, our images have greater variety, non-overlapping content and employ a larger vocabulary (2,167 vs. 260 words).

When the document is taken into account (see ExtModel in Table 1), F1 improves by 8.01% (recall is 14.72% and precision 27.95%). Increasing the size of the output annotations to 15 or 20 yields better recall, at the expense of precision. Eliminating the LDA reranker from the extended model decreases F1 by 0.62%. Incidentally, LDA can be also used to rerank the output of Lavrenko et al.’s (2003) model. LDA also increases the performance of this model by 0.41%.

Finally, considering the document alone, without the image yields inferior performance. This is true for the *tf \* idf* model and the model based on the document titles.<sup>4</sup> Interestingly, the latter yields precision similar to Lavrenko et al. (2003). This is probably due to the fact that the document’s title is in a sense similar to a caption. It often contains words that describe the document’s gist and expectedly

<sup>4</sup>Reranking the output of these models with LDA slightly decreases performance (approximately by 0.2%).

Figure 3: Examples of annotations generated by our model (ExtModel), the continuous relevance model (Lavrenko03), and the two baselines based on *tf \* idf* and the document title (DocTitle). Words in bold face indicate exact matches, underlined words are semantically compatible. The original captions are in the last row.

some of these words will be also appropriate for the image. In fact, in our dataset, the title words are a subset of those found in the captions.

Examples of the annotations generated by our model are shown in Figure 3. We also include the annotations produced by Lavrenko et. al's (2003) model and the two baselines. As we can see our model annotates the image with words that are not always included in the caption. Some of these are synonyms of the caption words (e.g., *child* and *intelligent* in left image of Figure 3), whereas others express additional information (e.g., *mother*, *woman*). Also note that complex scene images remain challenging (see the center image in Figure 3). Such images are better analyzed at a higher resolution and probably require more training examples.

## 7 Conclusions and Future Work

In this paper, we describe a new approach for the collection of image annotation datasets. Specifically, we leverage the vast resource of images available on the Internet while exploiting the fact that many of them are labeled with captions. Our experiments show that it is possible to learn an image annotation model from caption-picture pairs even if these are not explicitly annotated in any way. We also show that the annotation model benefits substantially from

additional information, beyond the caption or image. In our case this information is provided by the news documents associated with the pictures. But more generally our results indicate that further linguistic knowledge is needed to improve performance on the image annotation task. For instance, resources like WordNet (Fellbaum, 1998) can be used to expand the annotations by exploiting information about is-a relationships.

The uses of the database discussed in this article are many and varied. An interesting future direction concerns the application of the proposed model in a semi-supervised setting where the annotation output is iteratively refined with some manual intervention. Another possibility would be to use the document to increase the annotation keywords by identifying synonyms or even sentences that are similar to the image caption. Also note that our analysis of the accompanying document was rather shallow, limited to part of speech tagging. It is reasonable to assume that results would improve with more sophisticated preprocessing (i.e., named entity recognition, parsing, word sense disambiguation). Finally, we also believe that the model proposed here can be usefully employed in an information retrieval setting, where the goal is to find the image most relevant for a given query or document.

szarvas@inf.u-szeged.hu

## Abstract

Since facts or statements in a hedge or negated context typically appear as false positives, the proper handling of these language phenomena is of great importance in biomedical text mining. In this paper we demonstrate the importance of hedge classification experimentally in two real life scenarios, namely the ICD-9-CM coding of radiology reports and gene name Entity Extraction from scientific texts. We analysed the major differences of speculative language in these tasks and developed a maxent-based solution for both the free text and scientific text processing tasks. Based on our results, we draw conclusions on the possible ways of tackling speculative language in biomedical texts.

## 1 Introduction

The highly accurate identification of several regularly occurring language phenomena like the speculative use of language, negation and past tense (temporal resolution) is a prerequisite for the efficient processing of biomedical texts. In various natural language processing tasks, relevant statements appearing in a speculative context are treated as false positives. Hedge detection seeks to perform a kind of semantic filtering of texts, that is it tries to separate factual statements from speculative/uncertain ones.

### 1.1 Hedging in biomedical NLP

To demonstrate the detrimental effects of speculative language on biomedical NLP tasks, we will consider two inherently different sample tasks, namely

the ICD-9-CM coding of radiology records and gene information extraction from biomedical scientific texts. The general features of texts used in these tasks differ significantly from each other, but both tasks require the exclusion of uncertain (or speculative) items from processing.

#### 1.1.1 Gene Name and interaction extraction from scientific texts

The test set of the hedge classification dataset<sup>1</sup> (Medlock and Briscoe, 2007) has also been annotated for gene names<sup>2</sup>.

Examples of speculative assertions:

*Thus, the D-mib wing phenotype may result from defective N inductive signaling at the D-V boundary. A similar role of Croquemort has not yet been tested, but seems likely since the crq mutant used in this study (crqKG01679) is lethal in pupae.*

After an automatic parallelisation of the 2 annotations (sentence matching) we found that a significant part of the gene names mentioned (638 occurrences out of a total of 1968) appears in a speculative sentence. This means that approximately 1 in every 3 genes should be excluded from the interaction detection process. These results suggest that a major portion of system false positives could be due to hedging if hedge detection had been neglected by a gene interaction extraction system.

#### 1.1.2 ICD-9-CM coding of radiology records

Automating the assignment of ICD-9-CM codes for radiology records was the subject of a shared task

<sup>1</sup><http://www.cl.cam.ac.uk/~bwm23/>

<sup>2</sup><http://www.cl.cam.ac.uk/~nk304/>

challenge organised in Spring 2007. The detailed description of the task, and the challenge itself can be found in (Pestian et al., 2007) and online<sup>3</sup>. ICD-9-CM codes that are assigned to each report after the patient’s clinical treatment are used for the reimbursement process by insurance companies. There are official guidelines for coding radiology reports (Moisio, 2006). These guidelines strictly state that an uncertain diagnosis should never be coded, hence identifying reports with a diagnosis in a speculative context is an inevitable step in the development of automated ICD-9-CM coding systems. The following examples illustrate a typical non-speculative context where a given code should be added, and a speculative context where the same code should never be assigned to the report:

**non-speculative:** *Subsegmental **atelectasis** in the left lower lobe, otherwise normal exam.*

**speculative:** *Findings suggesting viral or reactive airway disease with right lower lobe **atelectasis** or pneumonia.* In an ICD-9 coding system developed for the challenge, the inclusion of a hedge classifier module (a simple keyword-based lookup method with 38 keywords) improved the overall system performance from 79.7% to 89.3%.

## 1.2 Related work

Although a fair amount of literature on hedging in scientific texts has been produced since the 1990s (e.g. (Hyland, 1994)), speculative language from a Natural Language Processing perspective has only been studied in the past few years. This phenomenon, together with others used to express forms of authorial opinion, is often classified under the notion of subjectivity (Wiebe et al., 2004), (Shanahan et al., 2005). Previous studies (Light et al., 2004) showed that the detection of hedging can be solved effectively by looking for specific keywords which imply that the content of a sentence is speculative and constructing simple expert rules that describe the circumstances of where and how a keyword should appear. Another possibility is to treat the problem as a classification task and train a statistical model to discriminate speculative and non-speculative assertions. This approach requires the availability of labeled instances to train the models

on. Riloff et al. (Riloff et al., 2003) applied bootstrapping to recognise subjective noun keywords and classify sentences as subjective or objective in newswire texts. Medlock and Briscoe (Medlock and Briscoe, 2007) proposed a weakly supervised setting for hedge classification in scientific texts where the aim is to minimise human supervision needed to obtain an adequate amount of training data.

Here we follow (Medlock and Briscoe, 2007) and treat the identification of speculative language as the classification of sentences for either speculative or non-speculative assertions, and extend their methodology in several ways. Thus given labeled sets  $S_{spec}$  and  $S_{nspec}$  the task is to train a model that, for each sentence  $s$ , is capable of deciding whether a previously unseen  $s$  is speculative or not.

The contributions of this paper are the following:

- The construction of a complex feature selection procedure which successfully reduces the number of keyword candidates without excluding helpful keywords.
- We demonstrate that with a very limited amount of expert supervision in finalising the feature representation, it is possible to build accurate hedge classifiers from (semi-) automatically collected training data.
- The extension of the feature representation used by previous works with bigrams and trigrams and an evaluation of the benefit of using longer keywords in hedge classification.
- We annotated a small test corpora of biomedical scientific papers from a different source to demonstrate that hedge keywords are highly task-specific and thus constructing models that generalise well from one task to another is not feasible without a noticeable loss in accuracy.

## 2 Methods

### 2.1 Feature space representation

Hedge classification can essentially be handled by acquiring task specific keywords that trigger speculative assertions more or less independently of each other. As regards the nature of this task, a vector space model (VSM) is a straightforward and suitable representation for statistical learning. As VSM

<sup>3</sup><http://www.computationalmedicine.org/challenge/index.php>

is inadequate for capturing the (possibly relevant) relations between subsequent tokens, we decided to extend the representation with bi- and trigrams of words. We chose not to add any weighting of features (by frequency or importance) and for the Maximum Entropy Model classifier we included binary data about whether single features occurred in the given context or not.

## 2.2 Probabilistic training data acquisition

To build our classifier models, we used the dataset gathered and made available by (Medlock and Briscoe, 2007). They commenced with the seed set  $S_{spec}$  gathered automatically (all sentences containing *suggest* or *likely* – two very good speculative keywords), and  $S_{nspec}$  that consisted of randomly selected sentences from which the most probable speculative instances were filtered out by a pattern matching and manual supervision procedure. With these seed sets they then performed the following iterative method to enlarge the initial training sets, adding examples to both classes from an unlabelled pool of sentences called  $U$ :

1. Generate seed training data:  $S_{spec}$  and  $S_{nspec}$
2. Initialise:  $T_{spec} \leftarrow S_{spec}$  and  $T_{nspec} \leftarrow S_{nspec}$
3. Iterate:
  - Train classifier using  $T_{spec}$  and  $T_{nspec}$
  - Order  $U$  by  $P(spec)$  values assigned by the classifier
  - $T_{spec} \leftarrow$  most probable batch
  - $T_{nspec} \leftarrow$  least probable batch

What makes this iterative method efficient is that, as we said earlier, hedging is expressed via keywords in natural language texts; and often several keywords are present in a single sentence. The seed set  $S_{spec}$  contained either *suggest* or *likely*, and due to the fact that other keywords cooccur with these two in many sentences, they appeared in  $S_{spec}$  with reasonable frequency. For example,  $P(spec|may) = 0.9985$  on the seed sets created by (Medlock and Briscoe, 2007). The iterative extension of the training sets for each class further boosted this effect, and skewed the distribution of speculative indicators as sentences containing them

were likely to be added to the extended training set for the speculative class, and unlikely to fall into the non-speculative set.

We should add here that the very same feature has an inevitable, but very important side effect that is detrimental to the classification accuracy of models trained on a dataset which has been obtained this way. This side effect is that other words (often common words or stopwords) that tend to cooccur with hedge cues will also be subject to the same iterative distortion of their distribution in speculative and non-speculative uses. Perhaps the best example of this is the word *it*. Being a stopword in our case, and having no relevance at all to speculative assertions, it has a class conditional probability of  $P(spec|it) = 74.67\%$  on the seed sets. This is due to the use of phrases like *it suggests that*, *it is likely*, and so on. After the iterative extension of training sets, the class-conditional probability of *it* dramatically increased, to  $P(spec|it) = 94.32\%$ . This is a consequence of the frequent co-occurrence of *it* with meaningful hedge cues and the probabilistic model used and happens with many other irrelevant terms (not just stopwords). The automatic elimination of these irrelevant candidates is one of our main goals (to limit the number of candidates for manual consideration and thus to reduce the human effort required to select meaningful hedge cues).

This shows that, in addition to the desired effect of introducing further speculative keywords and biasing their distribution towards the speculative class, this iterative process also introduces significant noise into the dataset. This observation led us to the conclusion that in order to build efficient classifiers based on this kind of dataset, we should filter out noise. In the next part we will present our feature selection procedure (evaluated in the Results section) which is capable of underranking irrelevant keywords in the majority of cases.

## 2.3 Feature (or keyword) selection

To handle the inherent noise in the training dataset that originates from its weakly supervised construction, we applied the following feature selection procedure. The main idea behind it is that it is unlikely that more than two keywords are present in the text, which are useful for deciding whether an instance is speculative. Here we performed the following steps:

1. We ranked the features  $x$  by frequency and their class conditional probability  $P(spec|x)$ . We then selected those features that had  $P(spec|x) > 0.94$  (this threshold was chosen arbitrarily) and appeared in the training dataset with reasonable frequency (frequency above  $10^{-5}$ ). This set constituted the 2407 candidates which we used in the second analysis phase.
2. For trigrams, bigrams and unigrams – processed separately – we calculated a new class-conditional probability for each feature  $x$ , discarding those observations of  $x$  in speculative instances where  $x$  was not among the two highest ranked candidate. Negative credit was given for all occurrences in non-speculative contexts. We discarded any feature that became unreliable (i.e. any whose frequency dropped below the threshold or the strict class-conditional probability dropped below 0.94). We did this separately for the uni-, bi- and trigrams to avoid filtering out longer phrases because more frequent, shorter candidates took the credit for all their occurrences. In this step we filtered out 85% of all the keyword candidates and kept 362 uni-, bi-, and trigrams altogether.
3. In the next step we re-evaluated all 362 candidates together and filtered out all phrases that had a shorter and thus more frequent substring of themselves among the features, with a similar class-conditional probability on the speculative class (worse by 2% at most). Here we discarded a further 30% of the candidates and kept 253 uni-, bi-, and trigrams altogether.

This efficient way of reranking and selecting potentially relevant features (we managed to discard 89.5% of all the initial candidates automatically) made it easier for us to manually validate the remaining keywords. This allowed us to incorporate supervision into the learning model in the feature representation stage, but keep the weakly supervised modelling (with only 5 minutes of expert supervision required).

## 2.4 Maximum Entropy Classifier

Maximum Entropy Models (Berger et al., 1996) seek to maximise the conditional probability of classes, given certain observations (features). This is performed by weighting features to maximise the likelihood of data and, for each instance, decisions are made based on features present at that point, thus maxent classification is quite suitable for our purposes. As feature weights are mutually estimated, the maxent classifier is capable of taking feature dependence into account. This is useful in cases like the feature  $it$  being dependent on others when observed in a speculative context. By downweighting such features, maxent is capable of modelling to a certain extent the special characteristics which arise from the automatic or weakly supervised training data acquisition procedure. We used the OpenNLP maxent package, which is freely available<sup>4</sup>.

## 3 Results

In this section we will present our results for hedge classification as a standalone task. In experiments we made use of the hedge classification dataset of scientific texts provided by (Medlock and Briscoe, 2007) and used a labeled dataset generated automatically based on false positive predictions of an ICD-9-CM coding system.

### 3.1 Results for hedge classification in biomedical texts

As regards the degree of human intervention needed, our classification and feature selection model falls within the category of weakly supervised machine learning. In the following sections we will evaluate our above-mentioned contributions one by one, describing their effects on feature space size (efficiency in feature and noise filtering) and classification accuracy. In order to compare our results with Medlock and Briscoe’s results (Medlock and Briscoe, 2007), we will always give the  $BEP(spec)$  that they used – the break-even-point of precision and recall<sup>5</sup>. We will also present  $F_{\beta=1}(spec)$  values

<sup>4</sup><http://maxent.sourceforge.net/>

<sup>5</sup>It is the point on the precision-recall curve of  $spec$  class where  $P = R$ . If an exact  $P = R$  cannot be realised due to the equal ranking of many instances, we use the point closest to  $P = R$  and set  $BEP(spec) = (P + R)/2$ . BEP is an

which show how good the models are at recognising speculative assertions.

### 3.1.1 The effects of automatic feature selection

The method we proposed seems especially effective in the sense that we successfully reduced the number of keyword candidates from an initial 2407 words having  $P(spec|x) > 0.94$  to 253, which is a reduction of almost 90%. During the process, very few useful keywords were eliminated and this indicated that our feature selection procedure was capable of distinguishing useful keywords from noise (i.e. keywords having a very high speculative class-conditional probability due to the skewed characteristics of the automatically gathered training dataset). The 2407-keyword model achieved a  $BEP(spec)$  of 76.05% and  $F_{\beta=1}(spec)$  of 73.61%, while the model after feature selection performed better, achieving a  $BEP(spec)$  score of 78.68% and  $F_{\beta=1}(spec)$  score of 78.09%. Simplifying the model to predict a *spec* label each time a keyword was present (by discarding those 29 features that were too weak to predict *spec* alone) slightly increased both the  $BEP(spec)$  and  $F_{\beta=1}(spec)$  values to 78.95% and 78.25%. This shows that the Maximum Entropy Model in this situation could not learn any meaningful hypothesis from the co-occurrence of individually weak keywords.

### 3.1.2 Improvements by manual feature selection

After a dimension reduction via a strict reranking of features, the resulting number of keyword candidates allowed us to sort the retained phrases manually and discard clearly irrelevant ones. We judged a phrase irrelevant if we could consider no situation in which the phrase could be used to express hedging. Here 63 out of the 253 keywords retained by the automatic selection were found to be **potentially** relevant in hedge classification. All these features were sufficient for predicting the *spec* class alone, thus we again found that the learnt model reduced to a single keyword-based decision.<sup>6</sup> These 63 key-

interesting metric as it demonstrates how well we can trade-off precision for recall.

<sup>6</sup>We kept the test set blind during the selection of relevant keywords. This meant that some of them eventually proved to be irrelevant, or even lowered the classification accuracy. Examples of such keywords were *will*, *these data* and *hypothesis*.

words yielded a classifier with a  $BEP(spec)$  score of 82.02% and  $F_{\beta=1}(spec)$  of 80.88%.

### 3.1.3 Results obtained adding external dictionaries

In our final model we added the keywords used in (Light et al., 2004) and those gathered for our ICD-9-CM hedge detection module. Here we decided not to check whether these keywords made sense in scientific texts or not, but instead left this task to the maximum entropy classifier, and added only those keywords that were found reliable enough to predict *spec* label alone by the maxent model trained on the training dataset. These experiments confirmed that hedge cues are indeed task specific – several cues that were reliable in radiology reports proved to be of no use for scientific texts. We managed to increase the number of our features from 63 to 71 using these two external dictionaries.

These additional keywords helped us to increase the overall coverage of the model. Our final hedge classifier yielded a  $BEP(spec)$  score of 85.29% and  $F_{\beta=1}(spec)$  score of 85.08% (89.53% Precision, 81.05% Recall) for the speculative class. This meant an overall classification accuracy of 92.97%.

Using this system as a pre-processing module for a hypothetical gene interaction extraction system, we found that our classifier successfully excluded gene names mentioned in a speculative sentence (it removed 81.66% of all speculative mentions) and this filtering was performed with a respectable precision of 93.71% ( $F_{\beta=1}(spec) = 87.27%$ ).

Articles	4
Sentences	1087
Spec sentences	190
Nspec sentences	897

Table 1: Characteristics of the BMC hedge dataset.

### 3.1.4 Evaluation on scientific texts from a different source

Following the annotation standards of Medlock and Briscoe (Medlock and Briscoe, 2007), we manually annotated 4 full articles downloaded from the

We assumed that these might suggest a speculative assertion.

BMC Bioinformatics website to evaluate our final model on documents from an external source. The chief characteristics of this dataset (which is available at<sup>7</sup>) is shown in Table 1. Surprisingly, the model learnt on FlyBase articles seemed to generalise to these texts only to a limited extent. Our hedge classifier model yielded a  $BEP(spec) = 75.88\%$  and  $F_{\beta=1}(spec) = 74.93\%$  (mainly due to a drop in precision), which is unexpectedly low compared to the previous results.

Analysis of errors revealed that some keywords which proved to be very reliable hedge cues in FlyBase articles were also used in non-speculative contexts in the BMC articles. Over 50% (24 out of 47) of our false positive predictions were due to the different use of 2 keywords, *possible* and *likely*. These keywords were many times used in a mathematical context (referring to probabilities) and thus expressed no speculative meaning, while such uses were not represented in the FlyBase articles (otherwise bigram or trigram features could have captured these non-speculative uses).

### 3.1.5 The effect of using 2-3 word-long phrases as hedge cues

Our experiments demonstrated that it is indeed a good idea to include longer phrases in the vector space model representation of sentences. One third of the features used by our advanced model were either bigrams or trigrams. About half of these were the kind of phrases that had no unigram components of themselves in the feature set, so these could be regarded as meaningful standalone features. Examples of such speculative markers in the fruit fly dataset were: *results support, these observations, indicate that, not clear, does not appear, ...* The majority of these phrases were found to be reliable enough for our maximum entropy model to predict a speculative class based on that single feature.

Our model using just unigram features achieved a  $BEP(spec)$  score of 78.68% and  $F_{\beta=1}(spec)$  score of 80.23%, which means that using bigram and trigram hedge cues here significantly improved the performance (the difference in  $BEP(spec)$  and  $F_{\beta=1}(spec)$  scores were 5.23% and 4.97%, respectively).

<sup>7</sup><http://www.inf.u-szeged.hu/~szarvas/homepage/hedge.html>

## 3.2 Results for hedge classification in radiology reports

In this section we present results using the above-mentioned methods for the automatic detection of speculative assertions in radiology reports. Here we generated training data by an automated procedure. Since hedge cues cause systems to predict false positive labels, our idea here was to train Maximum Entropy Models for the false positive classifications of our ICD-9-CM coding system using the vector space representation of radiology reports. That is, we classified every sentence that contained a medical term (disease or symptom name) and caused the automated ICD-9 coder<sup>8</sup> to predict a false positive code was treated as a speculative sentence and all the rest were treated as non-speculative sentences.

Here a significant part of the false positive predictions of an ICD-9-CM coding system that did not handle hedging originated from speculative assertions, which led us to expect that we would have the most hedge cues among the top ranked keywords which implied false positive labels.

Taking the above points into account, we used the training set of the publicly available ICD-9-CM dataset to build our model and then evaluated each single token by this model to measure their predictivity for a false positive code. Not surprisingly, some of the best hedge cues appeared among the highest ranked features, while some did not (they did not occur frequently enough in the training data to be captured by statistical methods).

For this task, we set the initial  $P(spec|x)$  threshold for filtering to 0.7 since the dataset was generated by a different process and we expected hedge cues to have lower class-conditional probabilities without the effect of the probabilistic data acquisition method that had been applied for scientific texts. Using all 167 terms as keywords that had  $P(spec|x) > 0.7$  resulted in a hedge classifier with an  $F_{\beta=1}(spec)$  score of 64.04%

After the feature selection process 54 keywords were retained. This 54-keyword maxent classifier got an  $F_{\beta=1}(spec)$  score of 79.73%. Plugging this model (without manual filtering) into the ICD-9 coding system as a hedge module, the ICD-9 coder

<sup>8</sup>Here the ICD-9 coding system did not handle the hedging task.

yielded an F measure of 88.64%, which is much better than one without a hedge module (79.7%).

Our experiments revealed that in radiology reports, which mainly concentrate on listing the identified diseases and symptoms (facts) and the physician’s impressions (speculative parts), detecting hedge instances can be performed accurately using unigram features. All bi- and trigrams retained by our feature selection process had unigram equivalents that were eliminated due to the noise present in the automatically generated training data.

We manually examined all keywords that had a  $P(spec) > 0.5$  given as a standalone instance for our maxent model, and constructed a dictionary of hedge cues from the promising candidates. Here we judged 34 out of 54 candidates to be potentially useful for hedging. Using these 34 keywords we got an  $F_{\beta=1}(spec)$  performance of 81.96% due to the improved precision score.

Extending the dictionary with the keywords we gathered from the fruit fly dataset increased the  $F_{\beta=1}(spec)$  score to 82.07% with only one out-domain keyword accepted by the maxent classifier.

	Biomedical papers		Medical reports
	$BEP(spec)$	$F_{\beta=1}(spec)$	$F_{\beta=1}(spec)$
Baseline 1	60.00	–	48.99
Baseline 2	76.30	–	–

Feature selection	78.68	78.09	79.73
Manual feat. sel.	82.02	80.88	81.96
Outer dictionary	85.29	85.08	82.07

Table 2: Summary of results.

## 4 Conclusions

The overall results of our study are summarised in a concise way in Table 2. We list  $BEP(spec)$  and  $F_{\beta=1}(spec)$  values for the scientific text dataset, and  $F_{\beta=1}(spec)$  for the clinical free text dataset. Baseline 1 denotes the substring matching system of Light et al. (Light et al., 2004) and Baseline 2 denotes the system of Medlock and Briscoe (Medlock and Briscoe, 2007). For clinical free texts, Baseline 1 is an out-domain model since the keywords were

collected for scientific texts by (Light et al., 2004). The third row corresponds to a model using all keywords  $P(spec|x)$  above the threshold and the fourth row a model after automatic noise filtering, while the fifth row shows the performance after the manual filtering of automatically selected keywords. The last row shows the benefit gained by adding reliable keywords from an external hedge keyword dictionary.

Our results presented above confirm our hypothesis that speculative language plays an important role in the biomedical domain, and it should be handled in various NLP applications. We experimentally compared the general features of this task in texts from two different domains, namely medical free texts (radiology reports), and scientific articles on the fruit fly from FlyBase.

The radiology reports had mainly unambiguous single-term hedge cues. On the other hand, it proved to be useful to consider bi- and trigrams as hedge cues in scientific texts. This, and the fact that many hedge cues were found to be ambiguous (they appeared in both speculative and non-speculative assertions) can be attributed to the literary style of the articles. Next, as the learnt maximum entropy models show, the hedge classification task reduces to a lookup for single keywords or phrases and to the evaluation of the text based on the most relevant cue alone. Removing those features that were insufficient to classify an instance as a hedge individually did not produce any difference in the  $F_{\beta=1}(spec)$  scores. This latter fact justified a view of ours, namely that during the construction of a statistical hedge detection module for a given application the main issue is to find the task-specific keywords.

Our findings based on the two datasets employed show that automatic or weakly supervised data acquisition, combined with automatic and manual feature selection to eliminate the skewed nature of the data obtained, is a good way of building hedge classifier modules with an acceptable performance.

The analysis of errors indicate that more complex features like dependency structure and clausal phrase information could only help in allocating the scope of hedge cues detected in a sentence, not the detection of any itself. Our finding that token unigram features are capable of solving the task accurately agrees with the the results of previous works on hedge classification ((Light et al., 2004), (Med-

lock and Briscoe, 2007)), and we argue that 2-3 word-long phrases also play an important role as hedge cues and as non-speculative uses of an otherwise speculative keyword as well (i.e. to resolve an ambiguity). In contrast to the findings of Wiebe et al. ((Wiebe et al., 2004)), who addressed the broader task of subjectivity learning and found that the density of other potentially subjective cues in the context benefits classification accuracy, we observed that the co-occurrence of speculative cues in a sentence does not help in classifying a term as speculative or not. Realising that our learnt models never predicted speculative labels based on the presence of two or more individually weak cues and discarding such terms that were not reliable enough to predict a speculative label (using that term alone as a single feature) slightly improved performance, we came to the conclusion that even though speculative keywords tend to cooccur, and two keywords are present in many sentences; hedge cues have a speculative meaning (or not) on their own without the other term having much impact on this.

The main issue thus lies in the selection of keywords, for which we proposed a procedure that is capable of reducing the number of candidates to an acceptable level for human evaluation – even in data collected automatically and thus having some undesirable properties.

The worse results on biomedical scientific papers from a different source also corroborates our finding that hedge cues can be highly ambiguous. In our experiments two keywords that are practically never used in a non-speculative context in the FlyBase articles we used for training were responsible for 50% of false positives in BMC texts since they were used in a different meaning. In our case, the keywords *possible* and *likely* are apparently always used as speculative terms in the FlyBase articles used, while the articles from BMC Bioinformatics frequently used such cliché phrases as *all possible combinations* or *less likely / more likely ...* (referring to probabilities shown in the figures). This shows that the portability of hedge classifiers is limited, and cannot really be done without the examination of the specific features of target texts or a more heterogeneous corpus is required for training. The construction of hedge classifiers for each separate target application in a weakly supervised way seems

feasible though. Collecting bi- and trigrams which cover non-speculative usages of otherwise common hedge cues is a promising solution for addressing the false positives in hedge classifiers and for improving the portability of hedge modules.

#### 4.1 Resolving the scope of hedge keywords

In this paper we focused on the recognition of hedge cues in texts. Another important issue would be to determine the scope of hedge cues in order to locate uncertain sentence parts. This can be solved effectively using a parser adapted for biomedical papers. We manually evaluated the parse trees generated by (Miyao and Tsujii, 2005) and came to the conclusion that for each keyword it is possible to define the scope of the keyword using subtrees linked to the keyword in the predicate-argument syntactic structure or by the immediate subsequent phrase (e.g. prepositional phrase). Naturally, parse errors result in (slightly) mislocated scopes but we had the general impression that state-of-the-art parsers could be used efficiently for this issue. On the other hand, this approach requires a human expert to define the scope for each keyword separately using the predicate-argument relations, or to determine keywords that act similarly and their scope can be located with the same rules. Another possibility is simply to define the scope to be each token up to the end of the sentence (and optionally to the previous punctuation mark). The latter solution has been implemented by us and works accurately for clinical free texts. This simple algorithm is similar to NegEx (Chapman et al., 2001) as we use a list of phrases and their context, but we look for punctuation marks to determine the scopes of keywords instead of applying a fixed window size.

## Abstract

This study presents a novel approach to the problem of system portability across different domains: a sentiment annotation system that integrates a corpus-based classifier trained on a small set of annotated in-domain data and a lexicon-based system trained on WordNet. The paper explores the challenges of system portability across domains and text genres (movie reviews, news, blogs, and product reviews), highlights the factors affecting system performance on out-of-domain and small-set in-domain data, and presents a new system consisting of the ensemble of two classifiers with precision-based vote weighting, that provides significant gains in accuracy and recall over the corpus-based classifier and the lexicon-based system taken individually.

## 1 Introduction

One of the emerging directions in NLP is the development of machine learning methods that perform well not only on the domain on which they were trained, but also on other domains, for which training data is not available or is not sufficient to ensure adequate machine learning. Many applications require reliable processing of heterogeneous corpora, such as the World Wide Web, where the diversity of genres and domains present in the Internet limits the feasibility of in-domain training. In this paper, sentiment annotation is defined as the assignment of positive, negative or neutral sentiment values to texts, sentences, and other linguistic units. Recent experiments assessing system portability across different domains, conducted by Aue

and Gamon (2005), demonstrated that sentiment annotation classifiers trained in one domain do not perform well on other domains. A number of methods has been proposed in order to overcome this system portability limitation by using out-of-domain data, unlabelled in-domain corpora or a combination of in-domain and out-of-domain examples (Aue and Gamon, 2005; Bai et al., 2005; Drezde et al., 2007; Tan et al., 2007).

In this paper, we present a novel approach to the problem of system portability across different domains by developing a sentiment annotation system that integrates a corpus-based classifier with a lexicon-based system trained on WordNet. By adopting this approach, we sought to develop a system that relies on both general and domain-specific knowledge, as humans do when analyzing a text. The information contained in lexicographical sources, such as WordNet, reflects a lay person's general knowledge about the world, while domain-specific knowledge can be acquired through classifier training on a small set of in-domain data.

The first part of this paper reviews the extant literature on domain adaptation in sentiment analysis and highlights promising directions for research. The second part establishes a baseline for system evaluation by drawing comparisons of system performance across four different domains/genres - movie reviews, news, blogs, and product reviews. The final, third part of the paper presents our system, composed of an ensemble of two classifiers - one trained on WordNet glosses and synsets and the other trained on a small in-domain training set.

## 2 Domain Adaptation in Sentiment Research

Most text-level sentiment classifiers use standard machine learning techniques to learn and select features from labeled corpora. Such approaches work well in situations where large labeled corpora are available for training and validation (e.g., movie reviews), but they do not perform well when training data is scarce or when it comes from a different domain (Aue and Gamon, 2005; Read, 2005), topic (Read, 2005) or time period (Read, 2005). There are two alternatives to supervised machine learning that can be used to get around this problem: on the one hand, general lists of sentiment clues/features can be acquired from domain-independent sources such as dictionaries or the Internet, on the other hand, unsupervised and weakly-supervised approaches can be used to take advantage of a small number of annotated in-domain examples and/or of unlabelled in-domain data.

The first approach, using general word lists automatically acquired from the Internet or from dictionaries, outperforms corpus-based classifiers when such classifiers use out-of-domain training data or when the training corpus is not sufficiently large to accumulate the necessary feature frequency information. But such general word lists were shown to perform worse than statistical models built on sufficiently large in-domain training sets of movie reviews (Pang et al., 2002). On other domains, such as product reviews, the performance of systems that use general word lists is comparable to the performance of supervised machine learning approaches (Gamon and Aue, 2005).

The recognition of major performance deficiencies of supervised machine learning methods with insufficient or out-of-domain training brought about an increased interest in unsupervised and weakly-supervised approaches to feature learning. For instance, Aue and Gamon (2005) proposed training on a small number of labeled examples and large quantities of unlabelled in-domain data. This system performed well even when compared to systems trained on a large set of in-domain examples: on feedback messages from a web survey on knowledge bases, Aue and Gamon report 73.86% accuracy using unlabelled data compared to 77.34% for

in-domain and 72.39% for the best out-of-domain training on a large training set.

Drezde et al. (2007) applied structural correspondence learning (Drezde et al., 2007) to the task of domain adaptation for sentiment classification of product reviews. They showed that, depending on the domain, a small number (e.g., 50) of labeled examples allows to adapt the model learned on another corpus to a new domain. However, they note that the success of such adaptation and the number of necessary in-domain examples depends on the similarity between the original domain and the new one. Similarly, Tan et al. (2007) suggested to combine out-of-domain labeled examples with unlabelled ones from the target domain in order to solve the domain-transfer problem. They applied an out-of-domain-trained SVM classifier to label examples from the target domain and then retrained the classifier using these new examples. In order to maximize the utility of the examples from the target domain, these examples were selected using Similarity Ranking and Relative Similarity Ranking algorithms (Tan et al., 2007). Depending on the similarity between domains, this method brought up to 15% gain compared to the baseline SVM.

Overall, the development of semi-supervised approaches to sentiment tagging is a promising direction of the research in this area but so far, based on reported results, the performance of such methods is inferior to the supervised approaches with in-domain training and to the methods that use general word lists. It also strongly depends on the similarity between the domains as has been shown by (Drezde et al., 2007; Tan et al., 2007).

## 3 Factors Affecting System Performance

The comparison of system performance across different domains involves a number of factors that can significantly affect system performance – from training set size to level of analysis (sentence or entire document), document domain/genre and many other factors. In this section we present a series of experiments conducted to assess the effects of different external factors (i.e., factors unrelated to the merits of the system itself) on system performance in order to establish the baseline for performance comparisons across different domains/genres.

### 3.1 Level of Analysis

Research on sentiment annotation is usually conducted at the text (Aue and Gamon, 2005; Pang et al., 2002; Pang and Lee, 2004; Riloff et al., 2006; Turney, 2002; Turney and Littman, 2003) or at the sentence levels (Gamon and Aue, 2005; Hu and Liu, 2004; Kim and Hovy, 2005; Riloff et al., 2006). It should be noted that each of these levels presents different challenges for sentiment annotation. For example, it has been observed that texts often contain multiple opinions on different topics (Turney, 2002; Wiebe et al., 2001), which makes assignment of the overall sentiment to the whole document problematic. On the other hand, each individual sentence contains a limited number of sentiment clues, which often negatively affects the accuracy and recall if that single sentiment clue encountered in the sentence was not learned by the system.

Since the comparison of sentiment annotation system performance on texts and on sentences has not been attempted to date, we also sought to close this gap in the literature by conducting the first set of our comparative experiments on data sets of 2,002 movie review texts and 10,662 movie review snippets (5331 with positive and 5331 with negative sentiment) provided by Bo Pang (<http://www.cs.cornell.edu/People/pabo/movie-review-data/>).

### 3.2 Domain Effects

The second set of our experiments explores system performance on different domains at sentence level. For this we used four different data sets of sentences annotated with sentiment tags:

- A set of movie review snippets (further: movie) from (Pang and Lee, 2005). This dataset of 10,662 snippets was collected automatically from [www.rottentomatoes.com](http://www.rottentomatoes.com) website. All sentences in reviews marked “rotten” were considered negative and snippets from “fresh” reviews were deemed positive. In order to make the results obtained on this dataset comparable to other domains, a randomly selected subset of 1066 snippets was used in the experiments.
- A balanced corpus of 800 manually annotated sentences extracted from 83 newspaper texts

(further, news). The full set of sentences was annotated by one judge. 200 sentences from this corpus (100 positive and 100 negative) were also randomly selected from the corpus for an inter-annotator agreement study and were manually annotated by two independent annotators. The pairwise agreement between annotators was calculated as the percent of same tags divided by the number of sentences with this tag in the gold standard. The pair-wise agreement between the three annotators ranged from 92.5 to 95.9% ( $\kappa=0.74$  and 0.75 respectively) on positive vs. negative tags.

- A set of sentences taken from personal weblogs (further, blogs) posted on LiveJournal (<http://www.livejournal.com>) and on <http://www.cyberjournalist.com>. This corpus is composed of 800 sentences (400 sentences with positive and 400 sentences with negative sentiment). In order to establish the inter-annotator agreement, two independent judges were asked to annotate 200 sentences from this corpus. The agreement between the two annotators on positive vs. negative tags reached 99% ( $\kappa=0.97$ ).
- A set of 1200 product review (PR) sentences extracted from the annotated corpus made available by Bing Liu (Hu and Liu, 2004) (<http://www.cs.uic.edu/liub/FBS/FBS.html>).

The data set sizes are summarized in Table 1.

	Movies	News	Blogs	PR
Text level	2002 texts	n/a	n/a	n/a
Sentence level	10662 snippets	800 sent.	800 sent.	1200 sent.

Table 1: Datasets

### 3.3 Establishing a Baseline for a Corpus-based System (CBS)

Supervised statistical methods have been very successful in sentiment tagging of texts: on movie review texts they reach accuracies of 85-90% (Aue and Gamon, 2005; Pang and Lee, 2004). These methods perform particularly well when a large volume of labeled data from the same domain as the

test set is available for training (Aue and Gamon, 2005). For this reason, most of the research on sentiment tagging using statistical classifiers was limited to product and movie reviews, where review authors usually indicate their sentiment in a form of a standardized score that accompanies the texts of their reviews.

The lack of sufficient data for training appears to be the main reason for the virtual absence of experiments with statistical classifiers in sentiment tagging at the sentence level. To our knowledge, the only work that describes the application of statistical classifiers (SVM) to sentence-level sentiment classification is (Gamon and Aue, 2005)<sup>1</sup>. The average performance of the system on ternary classification (positive, negative, and neutral) was between 0.50 and 0.52 for both average precision and recall. The results reported by (Riloff et al., 2006) for binary classification of sentences in a related domain of *subjectivity* tagging (i.e., the separation of sentiment-laden from neutral sentences) suggest that statistical classifiers can perform well on this task: the authors have reached 74.9% accuracy on the MPQA corpus (Riloff et al., 2006).

In order to explore the performance of different approaches in sentiment annotation at the text and sentence levels, we used a basic Naïve Bayes classifier. It has been shown that both Naïve Bayes and SVMs perform with similar accuracy on different sentiment tagging tasks (Pang and Lee, 2004). These observations were confirmed with our own experiments with SVMs and Naïve Bayes (Table 3). We used the Weka package (<http://www.cs.waikato.ac.nz/ml/weka/>) with default settings.

In the sections that follow, we describe a set of comparative experiments with SVMs and Naïve Bayes classifiers (1) on texts and sentences and (2) on four different domains (movie reviews, news, blogs, and product reviews). System runs with unigrams, bigrams, and trigrams as features and with different training set sizes are presented.

<sup>1</sup>Recently, a similar task has been addressed by the Affective Text Task at SemEval-1 where even shorter units – headlines – were classified into positive, negative and neutral categories using a variety of techniques (Strapparava and Mihalcea, 2007).

## 4 Experiments

### 4.1 System Performance on Texts vs. Sentences

The experiments comparing in-domain trained system performance on texts vs. sentences were conducted on 2,002 movie review texts and on 10,662 movie review snippets. The results with 10-fold cross-validation are reported in Table 2<sup>2</sup>.

	Trained on Texts		Trained on Sent.	
	Tested on Texts	Tested on Sent.	Tested on Texts	Tested on Sent.
1gram	<b>81.1</b>	69.0	66.8	<b>77.4</b>
2gram	<b>83.7</b>	68.6	71.2	<b>73.9</b>
3gram	<b>82.5</b>	64.1	70.0	<b>65.4</b>

Table 2: Accuracy of Naïve Bayes on movie reviews.

Consistent with findings in the literature (Cui et al., 2006; Dave et al., 2003; Gamon and Aue, 2005), on the large corpus of movie review texts, the in-domain-trained system based solely on unigrams had lower accuracy than the similar system trained on bigrams. But the trigrams fared slightly worse than bigrams. On sentences, however, we have observed an inverse pattern: unigrams performed better than bigrams and trigrams. These results highlight a special property of sentence-level annotation: *greater sensitivity to sparseness* of the model: On texts, classifier error on one particular sentiment marker is often compensated by a number of correctly identified other sentiment clues. Since sentences usually contain a much smaller number of sentiment clues than texts, sentence-level annotation more readily yields errors when a single sentiment clue is incorrectly identified or missed by the system. Due to lower frequency of higher-order n-grams (as opposed to unigrams), higher-order n-gram language models are more sparse, which increases the probability of missing a particular sentiment marker in a sentence (Table 3<sup>3</sup>). Very large

<sup>2</sup>All results are statistically significant at  $\alpha = 0.01$  with two exceptions: the difference between trigrams and bigrams for the system trained and tested on texts is statistically significant at  $\alpha=0.1$  and for the system trained on sentences and tested on texts is not statistically significant at  $\alpha = 0.01$ .

<sup>3</sup>The results for movie reviews are lower than those reported in Table 2 since the dataset is 10 times smaller, which results in less accurate classification. The statistical significance of the

training sets are required to overcome this higher n-gram sparseness in sentence-level annotation.

Dataset	Movie	News	Blogs	PRs
Dataset size	1066	800	800	1200
unigrams				
SVM	68.5	61.5	63.85	76.9
NB	60.2	59.5	60.5	74.25
nb features	5410	4544	3615	2832
bigrams				
SVM	59.9	63.2	61.5	75.9
NB	57.0	58.4	59.5	67.8
nb features	16286	14633	15182	12951
trigrams				
SVM	54.3	55.4	52.7	64.4
NB	53.3	57.0	56.0	69.7
nb features	20837	18738	19847	19132

Table 3: Accuracy of unigram, bigram and trigram models across domains.

## 4.2 System Performance on Different Domains

In the second set of experiments we sought to compare system results on sentences using in-domain and out-of-domain training. Table 4 shows that in-domain training, as expected, consistently yields superior accuracy than out-of-domain training across all four datasets: movie reviews (Movies), news, blogs, and product reviews (PRs). The numbers for in-domain trained runs are highlighted in bold.

Training Data	Test Data			
	Movies	News	Blogs	PRs
Movies	<b>68.5</b>	55.2	53.2	60.7
News	55.0	<b>61.5</b>	56.25	57.4
Blogs	53.7	49.9	<b>63.85</b>	58.8
PRs	55.8	55.9	56.25	<b>76.9</b>

Table 4: Accuracy of SVM with unigram model

results depends on the genre and size of the n-gram: on product reviews, all results are statistically significant at  $\alpha = 0.025$  level; on movie reviews, the difference between Naïve Bayes and SVM is statistically significant at  $\alpha = 0.01$  but the significance diminishes as the size of the n-gram increases; on news, only bi-grams produce a statistically significant ( $\alpha = 0.01$ ) difference between the two machine learning methods, while on blogs the difference between SVMs and Naïve Bayes is most pronounced when unigrams are used ( $\alpha = 0.025$ ).

It is interesting to note that *on sentences*, regardless of the domain used in system training and regardless of the domain used in system testing, unigrams tend to perform better than higher-order n-grams. This observation suggests that, given the constraints on the size of the available training sets, unigram-based systems may be better suited for sentence-level sentiment annotation.

## 5 Lexicon-Based Approach

The search for a base-learner that can produce greatest synergies with a classifier trained on small-set in-domain data has turned our attention to lexicon-based systems. Since the benefits from combining classifiers that always make similar decisions is minimal, the two (or more) base-learners should complement each other (Alpaydin, 2004). Since a system based on a fairly different learning approach is more likely to produce a different decision under a given set of circumstances, the diversity of approaches integrated in the ensemble of classifiers was expected to have a beneficial effect on the overall system performance.

A lexicon-based approach capitalizes on the fact that dictionaries, such as WordNet (Fellbaum, 1998), contain a comprehensive and domain-independent set of sentiment clues that exist in general English. A system trained on such general data, therefore, should be less sensitive to domain changes. This robustness, however is expected to come at some cost, since some domain-specific sentiment clues may not be covered in the dictionary. Our hypothesis was, therefore, that a lexicon-based system will perform worse than an in-domain trained classifier but possibly better than a classifier trained on out-of domain data.

One of the limitations of general lexicons and dictionaries, such as WordNet (Fellbaum, 1998), as training sets for sentiment tagging systems is that they contain only definitions of individual words and, hence, only unigrams could be effectively learned from dictionary entries. Since the structure of WordNet glosses is fairly different from that of other types of corpora, we developed a system that used the list of human-annotated adjectives from (Hatzivassiloglou and McKeown, 1997) as a seed list and then learned additional unigrams

from WordNet synsets and glosses with up to 88% accuracy, when evaluated against General Inquirer (Stone et al., 1966) (GI) on the intersection of our automatically acquired list with GI. In order to expand the list coverage for our experiments at the text and sentence levels, we then augmented the list by adding to it all the words annotated with “Positiv” or “Negativ” tags in GI, that were not picked up by the system. The resulting list of features contained 11,000 unigrams with the degree of membership in the category of positive or negative sentiment assigned to each of them.

In order to assign the membership score to each word, we did 58 system runs on unique non-intersecting seed lists drawn from manually annotated list of positive and negative adjectives from (Hatzivassiloglou and McKeown, 1997). The 58 runs were then collapsed into a single set of 7,813 unique words. For each word we computed a score by subtracting the total number of runs assigning this word a negative sentiment from the total of the runs that consider it positive. The resulting measure, termed Net Overlap Score (NOS), reflected the number of ties linking a given word with other sentiment-laden words in WordNet, and hence, could be used as a measure of the words’ centrality in the fuzzy category of sentiment. The NOSs were then normalized into the interval from -1 to +1 using a sigmoid fuzzy membership function (Zadeh, 1975)<sup>4</sup>. Only words with fuzzy membership degree not equal to zero were retained in the list. The resulting list contained 10,809 sentiment-bearing words of different parts of speech. The sentiment determination at the sentence and text level was then done by summing up the scores of all identified positive unigrams (NOS>0) and all negative unigrams (NOS<0) (Andreevskaia and Bergler, 2006).

### 5.1 Establishing a Baseline for the Lexicon-Based System (LBS)

The baseline performance of the Lexicon-Based System (LBS) described above is presented in Table 5, along with the performance results of the in-domain- and out-of-domain-trained SVM classifier.

Table 5 confirms the predicted pattern: the LBS performs with lower accuracy than *in-domain-*

	Movies	News	Blogs	PRs
LBS	57.5	62.3	63.3	59.3
SVM in-dom.	68.5	61.5	63.85	76.9
SVM out-of-dom.	55.8	55.9	56.25	60.7

Table 5: System accuracy on best runs on sentences

trained corpus-based classifiers, and with similar or better accuracy than the corpus-based classifiers trained on *out-of-domain* data. Thus, the lexicon-based approach is characterized by a bounded but stable performance when the system is ported across domains. These performance characteristics of corpus-based and lexicon-based approaches prompt further investigation into the possibility to combine the portability of dictionary-trained systems with the accuracy of in-domain trained systems.

## 6 Integrating the Corpus-based and Dictionary-based Approaches

The strategy of integration of two or more systems in a single ensemble of classifiers has been actively used on different tasks within NLP. In sentiment tagging and related areas, Aue and Gamon (2005) demonstrated that combining classifiers can be a valuable tool in domain adaptation for sentiment analysis. In the ensemble of classifiers, they used a combination of nine SVM-based classifiers deployed to learn unigrams, bigrams, and trigrams on three different domains, while the fourth domain was used as an evaluation set. Using then an SVM meta-classifier trained on a small number of target domain examples to combine the nine base classifiers, they obtained a statistically significant improvement on out-of-domain texts from book reviews, knowledge-base feedback, and product support services survey data. No improvement occurred on movie reviews.

Pang and Lee (2004) applied two different classifiers to perform sentiment annotation in two sequential steps: the first classifier separated subjective (sentiment-laden) texts from objective (neutral) ones and then they used the second classifier to classify the subjective texts into positive and negative. Das and Chen (2004) used five classifiers to determine market sentiment on Yahoo! postings. Simple majority vote was applied to make decisions within

<sup>4</sup>With coefficients:  $\alpha=1, \gamma=15$ .

the ensemble of classifiers and achieved accuracy of 62% on ternary in-domain classification.

In this study we describe a system that attempts to combine the portability of a dictionary-trained system (LBS) with the accuracy of an in-domain trained corpus-based system (CBS). The selection of these two classifiers for this system, thus, was theory-based. The section that follows describes the classifier integration and presents the performance results of the system consisting of an ensemble CBS and LBS classifier and a precision-based vote weighting procedure.

### 6.1 The Classifier Integration Procedure and System Evaluation

The comparative analysis of the corpus-based and lexicon-based systems described above revealed that the errors produced by CBS and LBS were to a great extent complementary (i.e., where one classifier makes an error, the other tends to give the correct answer). This provided further justification to the integration of corpus-based and lexicon-based approaches in a single system.

Table 6 below illustrates the complementarity of the performance CBS and LBS classifiers on the positive and negative categories. In this experiment, the corpus-based classifier was trained on 400 annotated product review sentences<sup>5</sup>. The two systems were then evaluated on a test set of another 400 product review sentences. The results reported in Table 6 are statistically significant at  $\alpha = 0.01$ .

	CBS	LBS
Precision positives	<b>89.3%</b>	69.3%
Precision negatives	55.5%	<b>81.5%</b>
Pos/Neg Precision	58.0%	72.1%

Table 6: Base-learners' precision and recall on product reviews on test data.

Table 6 shows that the corpus-based system has a very good precision on those sentences that it classifies as positive but makes a lot of errors on those sentences that it deems negative. At the same time, the lexicon-based system has low precision on positives

<sup>5</sup>The small training set explains relatively low overall performance of the CBS system.

and high precision on negatives<sup>6</sup>. Such complementary distribution of errors produced by the two systems was observed on different data sets from different domains, which suggests that the observed distribution pattern reflects the properties of each of the classifiers, rather than the specifics of the domain/genre.

In order to take advantage of the observed complementarity of the two systems, the following procedure was used. First, a small set of in-domain data was used to train the CBS system. Then both CBS and LBS systems were run separately on the same training set, and for each classifier, the precision measures were calculated separately for those sentences that the classifier considered positive and those it considered negative. The chance-level performance (50%) was then subtracted from the precision figures to ensure that the final weights reflect by how much the classifier's precision exceeds the chance level. The resulting chance-adjusted precision numbers of the two classifiers were then normalized, so that the weights of CBS and LBS classifiers sum up to 100% on positive and to 100% on negative sentences. These weights were then used to adjust the contribution of each classifier to the decision of the ensemble system. The choice of the weight applied to the classifier decision, thus, varied depending on whether the classifier scored a given sentence as positive or as negative. The resulting system was then tested on a separate test set of sentences<sup>7</sup>. The small-set training and evaluation experiments with the system were performed on different domains using 3-fold validation.

The experiments conducted with the Ensemble system were designed to explore system performance under conditions of limited availability of annotated data for classifier training. For this reason, the numbers reported for the corpus-based classifier do not reflect the full potential of machine learning approaches when sufficient in-domain training data is available. Table 7 presents the results of these experiments by domain/genre. The results

<sup>6</sup>These results are consistent with an observation in (Kennedy and Inkpen, 2006), where a lexicon-based system performed with a better precision on negative than on positive texts.

<sup>7</sup>The size of the test set varied in different experiments due to the availability of annotated data for a particular domain.

are statistically significant at  $\alpha = 0.01$ , except the runs on movie reviews where the difference between the LBS and Ensemble classifiers was significant at  $\alpha = 0.05$ .

	LBS	CBS	Ensemble
News	Acc 67.8	53.2	<b>73.3</b>
	F 0.82	0.71	<b>0.85</b>
Movies	Acc 54.5	53.5	<b>62.1</b>
	F 0.73	0.72	<b>0.77</b>
Blogs	Acc 61.2	51.1	<b>70.9</b>
	F 0.78	0.69	<b>0.83</b>
PRs	Acc 59.5	58.9	<b>78.0</b>
	F 0.77	0.75	<b>0.88</b>
Average	Acc 60.7	54.2	71.1
	F 0.77	0.72	0.83

Table 7: Performance of the ensemble classifier

Table 7 shows that the combination of two classifiers into an ensemble using the weighting technique described above leads to consistent improvement in system performance across all domains/genres. In the ensemble system, the average gain in accuracy across the four domains was 16.9% relative to CBS and 10.3% relative to LBS. Moreover, the gain in accuracy and precision was not offset by decreases in recall: the net gain in recall was 7.4% relative to CBS and 13.5% vs. LBS. The ensemble system on average reached 99.1% recall. The F-measure has increased from 0.77 and 0.72 for LBS and CBS classifiers respectively to 0.83 for the whole ensemble system.

## 7 Discussion

The development of domain-independent sentiment determination systems poses a substantial challenge for researchers in NLP and artificial intelligence. The results presented in this study suggest that the integration of two fairly different classifier learning approaches in a single ensemble of classifiers can yield substantial gains in system performance on all measures. The most substantial gains occurred in recall, accuracy, and F-measure.

This study permits to highlight a set of factors that enable substantial performance gains with the ensemble of classifiers approach. Such gains are most likely when (1) the errors made by the clas-

sifiers are complementary, i.e., where one classifier makes an error, the other tends to give the correct answer, (2) the classifier errors are not fully random and occur more often in a certain segment (or category) of classifier results, and (3) there is a way for a system to identify that low-precision segment and reduce the weights of that classifier’s results on that segment accordingly. The two classifiers used in this study – corpus-based and lexicon-based – provided an interesting illustration of potential performance gains associated with these three conditions. The use of precision of classifier results on the positives and negatives proved to be an effective technique for classifier vote weighting within the ensemble.

## 8 Conclusion

This study contributes to the research on sentiment tagging, domain adaptation, and the development of ensembles of classifiers (1) by proposing a novel approach for sentiment determination at sentence level and delineating the conditions under which greatest synergies among combined classifiers can be achieved, (2) by describing a precision-based technique for assigning differential weights to classifier results on different categories identified by the classifier (i.e., categories of positive vs. negative sentences), and (3) by proposing a new method for sentiment annotation in situations where the annotated in-domain data is scarce and insufficient to ensure adequate performance of the corpus-based classifier, which still remains the preferred choice when large volumes of annotated data are available for system training.

Among the most promising directions for future research in the direction laid out in this paper is the deployment of more advanced classifiers and feature selection techniques that can further enhance the performance of the ensemble of classifiers. The precision-based vote weighting technique may prove to be effective also in situations, where more than two classifiers are integrated into a single system. We expect that these more advanced ensemble-of-classifiers systems would inherit the benefits of multiple complementary approaches to sentiment annotation and will be able to achieve better and more stable accuracy on in-domain, as well as on out-of-domain data.

# A Generic Sentence Trimmer with CRFs

**Tadashi Nomoto**

National Institute of Japanese Literature

Tokyo, 190-0014, Japan  
nomoto@acm.org

## Abstract

The paper presents a novel sentence trimmer in Japanese, which combines a non-statistical yet generic tree generation model and Conditional Random Fields (CRFs), to address improving the grammaticality of compression while retaining its relevance. Experiments found that the present approach outperforms in grammaticality and in relevance a dependency-centric approach (Oguro et al., 2000; Morooka et al., 2004; Yamagata et al., 2006; Fukutomi et al., 2007) – the only line of work in prior literature (on Japanese compression) we are aware of that allows replication and permits a direct comparison.

## 1 Introduction

For better or worse, much of prior work on sentence compression (Riezler et al., 2003; McDonald, 2006; Turner and Charniak, 2005) turned to a single corpus developed by Knight and Marcu (2002) (K&M, henceforth) for evaluating their approaches.

The K&M corpus is a moderately sized corpus consisting of 1,087 pairs of sentence and compression, which account for about 2% of a Ziff-Davis collection from which it was derived. Despite its limited scale, prior work in sentence compression relied heavily on this particular corpus for establishing results (Turner and Charniak, 2005; McDonald, 2006; Clarke and Lapata, 2006; Galley and McKeown, 2007). It was not until recently that researchers started to turn attention to an alternative approach which does not require supervised data (Turner and Charniak, 2005).

Our approach is broadly in line with prior work (Jing, 2000; Dorr et al., 2003; Riezler et al., 2003; Clarke and Lapata, 2006), in that we make use of some form of syntactic knowledge to constrain compressions we generate. What sets this work apart from them, however, is a novel use we make of Conditional Random Fields (CRFs) to select among possible compressions (Lafferty et al., 2001; Sutton and McCallum, 2006). An obvious benefit of using CRFs for sentence compression is that the model provides a general (and principled) probabilistic framework which permits information from various sources to be integrated towards compressing sentence, a property K&M do not share.

Nonetheless, there is some cost that comes with the straightforward use of CRFs as a discriminative classifier in sentence compression; its outputs are often ungrammatical and it allows no control over the length of compression they generates (Nomoto, 2007). We tackle the issues by harnessing CRFs with what we might call dependency truncation, whose goal is to restrict CRFs to working with candidates that conform to the grammar.

Thus, unlike McDonald (2006), Clarke and Lapata (2006) and Cohn and Lapata (2007), we do not insist on finding a globally optimal solution in the space of  $2^n$  possible compressions for an  $n$  word long sentence. Rather we insist on finding a most plausible compression among those that are explicitly warranted by the grammar.

Later in the paper, we will introduce an approach called the ‘Dependency Path Model’ (DPM) from the previous literature (Section 4), which purports to provide a robust framework for sentence compression.

sion in Japanese. We will look at how the present approach compares with that of DPM in Section 6.

## 2 A Sentence Trimmer with CRFs

Our idea on how to make CRFs comply with grammar is quite simple: we focus on only those label sequences that are associated with grammatically correct compressions, by making CRFs look at only those that comply with some grammatical constraints  $G$ , and ignore others, regardless of how probable they are.<sup>1</sup> But how do we find compressions that are grammatical? To address the issue, rather than resort to statistical generation models as in the previous literature (Cohn and Lapata, 2007; Galley and McKeown, 2007), we pursue a particular rule-based approach we call a ‘dependency truncation,’ which as we will see, gives us a greater control over the form that compression takes.

Let us denote a set of label assignments for  $S$  that satisfy constraints, by  $G(S)$ .<sup>2</sup> We seek to solve the following,

$$\mathbf{y}^* = \arg \max_{\mathbf{y} \in G(S)} p(\mathbf{y}|\mathbf{x}; \boldsymbol{\theta}). \quad (2)$$

There would be a number of ways to go about the problem. In the context of sentence compression, a linear programming based approach such as Clarke and Lapata (2006) is certainly one that deserves consideration. In this paper, however, we will explore a much simpler approach which does not require as involved formulation as Clarke and Lapata (2006) do.

We approach the problem *extensionally*, i.e., through generating sentences that are grammatical, or that conform to whatever constraints there are.

<sup>1</sup>Assume as usual that CRFs take the form,

$$\begin{aligned} p(\mathbf{y}|\mathbf{x}) &\propto \\ &\exp\left(\sum_{k,j} \lambda_j f_j(y_k, y_{k-1}, \mathbf{x}) + \sum_i \mu_i g_i(x_k, y_k, \mathbf{x})\right) \\ &= \exp[\mathbf{w}^\top \mathbf{f}(\mathbf{x}, \mathbf{y})] \end{aligned} \quad (1)$$

$f_j$  and  $g_i$  are ‘features’ associated with edges and vertices, respectively, and  $k \in \mathcal{C}$ , where  $\mathcal{C}$  denotes a set of cliques in CRFs.  $\lambda_j$  and  $\mu_i$  are the weights for corresponding features.  $\mathbf{w}$  and  $\mathbf{f}$  are vector representations of weights and features, respectively (Tasker, 2004).

<sup>2</sup>Note that a sentence compression can be represented as an array of binary labels, one of them marking words to be retained in compression and the other those to be dropped.

Figure 1: Syntactic structure in Japanese

Consider the following.

- (3) *Mushoku-no John -ga takai kuruma*  
 unemployed John SBJ expensive car  
*-wo kat-ta.*  
 ACC buy PAST  
 ‘John, who is unemployed, bought an expensive car.’

whose grammatically legitimate compressions would include:

- (4) (a) *John -ga takai kuruma -wo kat-ta.*  
 ‘John bought an expensive car.’  
 (b) *John -ga kuruma -wo kat-ta.*  
 ‘John bought a car.’  
 (c) *Mushoku-no John -ga kuruma -wo kat-ta.*  
 ‘John, who is unemployed, bought a car.’  
 (d) *John -ga kat-ta.*  
 ‘John bought.’  
 (e) *Mushoku-no John -ga kat-ta.*  
 ‘John, who is unemployed, bought.’  
 (f) *Takai kuruma-wo kat-ta.*  
 ‘Bought an expensive car.’  
 (g) *Kuruma-wo kat-ta.*  
 ‘Bought a car.’  
 (h) *Kat-ta.*  
 ‘Bought.’

This would give us  $G(S)=\{a, b, c, d, e, f, g, h\}$ , for the input 3. Whatever choice we make for compression among candidates in  $G(S)$ , should be grammatical, since they all are. One linguistic feature

Figure 2: Compressing an NP chunk

Figure 3: Trimming TDPs

of the Japanese language we need to take into account when generating compressions, is that the sentence, which is free of word order and verb-final, typically takes a left-branching structure as in Figure 1, consisting of an array of morphological units called *bunsetsu* (BS, henceforth). A BS, which we might regard as an inflected form (case marked in the case of nouns) of verb, adjective, and noun, could involve one or more independent linguistic elements such as noun, case particle, but acts as a morphological atom, in that it cannot be torn apart, or partially deleted, without compromising the grammaticality.<sup>3</sup>

Noting that a Japanese sentence typically consists of a sequence of case marked NPs and adjuncts, followed by a main verb at the end (or what would be called ‘matrix verb’ in linguistics), we seek to compress each of the major chunks in the sentence, leaving untouched the matrix verb, as its removal often leaves the sentence unintelligible. In particular, starting with the leftmost BS in a major constituent,

<sup>3</sup>Example 3 could be broken into BSs: / *Mushuku -no / John -ga / takai / kuruma -wo / kat-ta /*.

we work up the tree by pruning BSs on our way up, which in general gives rise to grammatically legitimate compressions of various lengths (Figure 2).

More specifically, we take the following steps to construct  $G(S)$ . Let  $S = ABCDE$ . Assume that it has a dependency structure as in Figure 3. We begin by locating terminal nodes, i.e., those which have no incoming edges, depicted as filled circles in Figure 3, and find a dependency (singly linked) path from each terminal node to the root, or a node labeled ‘E’ here, which would give us two paths  $p_1 = A-C-D-E$  and  $p_2 = B-C-D-E$  (call them *terminating dependency paths*, or TDPs). Now create a set  $\mathcal{T}$  of all trimmings, or suffixes of each TDP, including an empty string:

$$\begin{aligned} \mathcal{T}(p_1) &= \{ \langle A C D E \rangle, \langle C D E \rangle, \langle D E \rangle, \langle E \rangle, \langle \rangle \} \\ \mathcal{T}(p_2) &= \{ \langle B C D E \rangle, \langle C D E \rangle, \langle D E \rangle, \langle E \rangle, \langle \rangle \} \end{aligned}$$

Then we merge subpaths from the two sets in every possible way, i.e., for any two subpaths  $t_1 \in \mathcal{T}(p_1)$  and  $t_2 \in \mathcal{T}(p_2)$ , we take a union over nodes in  $t_1$  and  $t_2$ ; Figure 4 shows how this might be done. We remove duplicates if any. This would give us  $G(S) = \{ \{ A B C D E \}, \{ A C D E \}, \{ B C D E \}, \{ C D E \}, \{ D E \}, \{ E \}, \{ \} \}$ , a set of compressions over  $S$  based on TDPs.

What is interesting about the idea is that creating  $G(S)$  does not involve much of anything that is specific to a given language. Indeed this could be done on English as well. Take for instance a sentence at the top of Table 1, which is a slightly modified lead sentence from an article in the *New York Times*. Assume that we have a relevant dependency structure as shown in Figure 5, where we have three TDPs, i.e., one with *southern*, one with *British* and one with *lethal*. Then  $G(S)$  would include those listed in Table 1. A major difference from Japanese lies in the direction in which a tree is branching out: right versus left.<sup>4</sup>

Having said this, we need to address some language specific constraints: in Japanese, for instance, we should keep a topic marked NP in compression as its removal often leads to a decreased readability; and also it is grammatically wrong to start any compressed segment with sentence nominalizers such as

<sup>4</sup>We stand in a marked contrast to previous ‘grafting’ approaches which more or less rely on an ad-hoc collection of transformation rules to generate candidates (Riezler et al., 2003).

Table 1: Hedge-clipping English

An official was quoted yesterday as accusing Iran of supplying explosive technology used in lethal attacks on British troops in southern Iraq

An official was quoted yesterday as accusing Iran of supplying explosive technology

An official was quoted yesterday as accusing Iran of supplying technology

Figure 4: Combining TDP suffixes

*-koto* and *-no*. In English, we should keep a preposition from being left dangling, as in *An official was quoted yesterday as accusing Iran of supplying technology used in*. In any case, we need some extra rules on  $G(S)$  to take care of language specific issues (cf. Vandeghinste and Pan (2004) for English). An important point about the dependency truncation is that for most of the time, a compression it generates comes out reasonably grammatical, so the number of ‘extras’ should be small.

Finally, in order for CRFs to work with the compressions, we need to translate them into a sequence of binary labels, which involves labeling an element token, *bunsetsu* or a word, with some label, e.g., 0 for ‘remove’ and 1 for ‘retain,’ as in Figure 6.

Figure 5: An English dependency structure and TDPs

Consider following compressions  $y_1$  to  $y_4$  for  $x = \beta_1\beta_2\beta_3\beta_4\beta_5\beta_6$ .  $\beta_i$  denotes a *bunsetsu* (BS). ‘0’ marks a BS to be removed and ‘1’ that to be retained.

	$\beta_1$	$\beta_2$	$\beta_3$	$\beta_4$	$\beta_5$	$\beta_6$
$y_1$	0	1	1	1	1	1
$y_2$	0	0	1	1	1	1
$y_3$	0	0	0	0	0	1
$y_4$	0	0	1	0	0	0

Assume that  $G(S) = \{y_1, y_2, y_3\}$ . Because  $y_4$  is not part of  $G(S)$ , it is not considered a candidate for a compression for  $y$ , even if its likelihood may exceed those of others in  $G(S)$ . We note that the approach here does not rely on so much of CRFs as a discriminative classifier as CRFs as a strategy for ranking among a limited set of label sequences which correspond to syntactically plausible simplifications of input sentence.

Furthermore, we could dictate the length of compression by putting an additional constraint on out-

Figure 6: Compression in binary representation.

put, as in:

$$\mathbf{y}^* = \arg \max_{\mathbf{y} \in G'(S)} p(\mathbf{y}|\mathbf{x}; \boldsymbol{\theta}), \quad (5)$$

where  $G'(S) = \{\mathbf{y} : \mathbf{y} \in G(S), R(\mathbf{y}, \mathbf{x}) = r\}$ .  $R(\mathbf{y}, \mathbf{x})$  denotes a compression rate  $r$  for which  $\mathbf{y}$  is desired, where  $r = \frac{\# \text{ of } 1 \text{ in } \mathbf{y}}{\text{length of } \mathbf{x}}$ . The constraint forces the trimmer to look for the best solution among candidates that satisfy the constraint, ignoring those that do not.<sup>5</sup>

Another point to note is that  $G(S)$  is finite and relatively small – it was found, for our domain,  $G(S)$  usually runs somewhere between a few hundred and ten thousand in length – so in practice it suffices that we visit each compression in  $G(S)$ , and select one that gives the maximum value for the objective function. We will have more to say about the size of the search space in Section 6.

### 3 Features in CRFs

We use an array of features in CRFs which are either derived or borrowed from the taxonomy that a Japanese tokenizer called JUMAN and KNP,<sup>6</sup> a Japanese dependency parser (aka Kurohashi-Nagao Parser), make use of in characterizing the output they produce: both JUMAN and KNP are part of the compression model we build.

Features come in three varieties: semantic, morphological and syntactic. Semantic features are used for classifying entities into semantic types such as name of person, organization, or place, while syntactic features characterize the kinds of dependency

<sup>5</sup>It is worth noting that the present approach can be recast into one based on ‘constraint relaxation’ (Tromble and Eisner, 2006).

<sup>6</sup><http://nlp.kuee.kyoto-u.ac.jp/nl-resource/top-e.html>

relations that hold among BSs such as whether a BS is of the type that combines with the verb (*renyou*), or of the type that combines with the noun (*rentai*), etc.

A morphological feature could be thought of as something that broadly corresponds to an English POS, marking for some syntactic or morphological category such as noun, verb, numeral, etc. Also we included ngram features to encode the lexical context in which a given morpheme appears. Thus we might have something like: for some words (morphemes)  $w_1, w_2$ , and  $w_3$ ,  $f_{w_1 \cdot w_2}(w_3) = 1$  if  $w_3$  is preceded by  $w_1, w_2$ ; otherwise, 0. In addition, we make use of an IR-related feature, whose job is to indicate whether a given morpheme in the input appears in the title of an associated article. The motivation for the feature is obviously to identify concepts relevant to, or unique to the associated article. Also included was a feature on tfidf, to mark words that are conceptually more important than others. The number of features came to around 80,000 for the corpus we used in the experiment.

### 4 The Dependency Path Model

In what follows, we will describe somewhat in detail a prior approach to sentence compression in Japanese which we call the “dependency path model,” or DPM. DPM was first introduced in (Oguro et al., 2000), later explored by a number of people (Morooka et al., 2004; Yamagata et al., 2006; Fukutomi et al., 2007).<sup>7</sup>

DPM has the form:

$$h(\mathbf{y}) = \alpha f(\mathbf{y}) + (1 - \alpha)g(\mathbf{y}), \quad (6)$$

where  $\mathbf{y} = \beta_0, \beta_1, \dots, \beta_{n-1}$ , i.e., a compression consisting of any number of *bunsetsu*’s, or phrase-like elements.  $f(\cdot)$  measures the relevance of content in  $\mathbf{y}$ ; and  $g(\cdot)$  the fluency of text.  $\alpha$  is to provide a way of weighing up contributions from each component.

We further define:

$$f(\mathbf{y}) = \sum_{i=0}^{n-1} q(\beta_i), \quad (7)$$

<sup>7</sup>Kikuchi et al. (2003) explore an approach similar to DPM.

Figure 7: A dependency structure

and

$$g(\mathbf{y}) = \max_s \sum_{i=0}^{n-2} p(\beta_i, \beta_{s(i)}). \quad (8)$$

$q(\cdot)$  is meant to quantify how worthy of inclusion in compression, a given *bunsetsu* is; and  $p(\beta_i, \beta_j)$  represents the connectivity strength of dependency relation between  $\beta_i$  and  $\beta_j$ .  $s(\cdot)$  is a linking function that associates with a *bunsetsu* any one of those that follows it.  $g(\mathbf{y})$  thus represents a set of linked edges that, if combined, give the largest probability for  $\mathbf{y}$ .

*Dependency path length* (DL) refers to the number of (singly linked) dependency relations (or edges) that span two *bunsetsu*'s. Consider the dependency tree in Figure 7, which corresponds to a somewhat contrived sentence 'Three-legged dogs disappeared from sight.' Take an English word for a *bunsetsu* here. We have

$$\begin{aligned} \text{DL}(\text{three-legged}, \text{dogs}) &= 1 \\ \text{DL}(\text{three-legged}, \text{disappeared}) &= 2 \\ \text{DL}(\text{three-legged}, \text{from}) &= \infty \\ \text{DL}(\text{three-legged}, \text{sight}) &= \infty \end{aligned}$$

Since *dogs* is one edge away from *three-legged*, DL for them is 1; and we have DL of two for *three-legged* and *disappeared*, as we need to cross two edges in the direction of arrow to get from the former to the latter. In case there is no path between words as in the last two cases above, we take the DL to be infinite.

DPM takes a dependency tree to be a set of linked edges. Each edge is expressed as a triple  $\langle C_s(\beta_i), C_e(\beta_j), \text{DL}(\beta_i, \beta_j) \rangle$ , where  $\beta_i$  and  $\beta_j$

represent *bunsetsu*'s that the edge spans.  $C_s(\beta)$  denotes the class of a *bunsetsu* where the edge starts and  $C_e(\beta)$  that of a *bunsetsu* where the edge ends. What we mean by 'class of *bunsetsu*' is some sort of a classificatory scheme that concerns linguistic characteristics of *bunsetsu*, such as a part-of-speech of the head, whether it has an inflection, and if it does, what type of inflection it has, etc. Moreover, DPM uses two separate classificatory schemes for  $C_s(\beta)$  and  $C_e(\beta)$ .

In DPM, we define the connectivity strength  $p$  by:

$$p(\beta_i, \beta_j) = \begin{cases} \log S(t) & \text{if } \text{DL}(\beta_i, \beta_j) \neq \infty \\ -\infty & \text{otherwise} \end{cases} \quad (9)$$

where  $t = \langle C_s(\beta_i), C_e(\beta_j), \text{DL}(\beta_i, \beta_j) \rangle$ , and  $S(t)$  is the probability of  $t$  occurring in a compression, which is given by:

$$S(t) = \frac{\# \text{ of } t\text{'s found in compressions}}{\# \text{ of triples found in the training data}} \quad (10)$$

We complete the DPM formulation with:

$$q(\beta) = \log p_c(\beta) + \text{tfidf}(\beta) \quad (11)$$

$p_c(\beta)$  denotes the probability of having *bunsetsu*  $\beta$  in compression, calculated analogously to Eq. 10,<sup>8</sup> and  $\text{tfidf}(\beta)$  obviously denotes the  $\text{tfidf}$  value of  $\beta$ .

In DPM, a compression of a given sentence can be obtained by finding  $\arg \max_{\mathbf{y}} h(\mathbf{y})$ , where  $\mathbf{y}$  ranges over possible candidate compressions of a particular length one may derive from that sentence. In the experiment described later, we set  $\alpha = 0.1$  for DPM, following Morooka et al. (2004), who found the best performance with that setting for  $\alpha$ .

## 5 Evaluation Setup

We created a corpus of sentence summaries based on email news bulletins we had received over five to six months from an on-line news provider called Nikkei Net, which mostly deals with finance and politics.<sup>9</sup> Each bulletin consists of six to seven news briefs, each with a few sentences. Since a news brief contains nothing to indicate what its longer version

<sup>8</sup>DPM puts *bunsetsu*'s into some groups based on linguistic features associated with them, and uses the statistics of the groups for  $p_c$  rather than that of *bunsetsu*'s that actually appear in text.

<sup>9</sup><http://www.nikkei.co.jp>

Table 2: The rating scale on fluency

RATING	EXPLANATION
1	makes no sense
2	only partially intelligible/grammatical
3	makes sense; seriously flawed in grammar
4	makes good sense; only slightly flawed in grammar
5	makes perfect sense; no grammar flaws

might look like, we manually searched the news site for a full-length article that might reasonably be considered a long version of that brief.

We extracted lead sentences both from the brief and from its source article, and aligned them, using what is known as the Smith-Waterman algorithm (Smith and Waterman, 1981), which produced 1,401 pairs of summary and source sentence.<sup>10</sup> For the ease of reference, we call the corpus so produced ‘NICOM’ for the rest of the paper. A part of our system makes use of a modeling toolkit called GRMM (Sutton et al., 2004; Sutton, 2006). Throughout the experiments, we call our approach ‘Generic Sentence Trimmer’ or GST.

## 6 Results and Discussion

We ran DPM and GST on NICOM in the 10-fold cross validation format where we break the data into 10 blocks, use 9 of them for training and test on the remaining block. In addition, we ran the test at three different compression rates, 50%, 60% and 70%, to learn how they affect the way the models perform. This means that for each input sentence in NICOM, we have three versions of its compression created, corresponding to a particular rate at which the sentence is compressed. We call a set of compressions so generated ‘NICOM-g.’

In order to evaluate the quality of outputs GST and DPM generate, we asked 6 people, all Japanese natives, to make an intuitive judgment on how each compression fares in fluency and relevance to gold

<sup>10</sup>The Smith-Waterman algorithm aims at finding a best match between two sequences which may include gaps, such as A-C-D-E and A-B-C-D-E. The algorithm is based on an idea rather akin to dynamic programming.

Table 3: The rating scale on content overlap

RATING	EXPLANATION
1	no overlap with reference
2	poor or marginal overlap w. ref.
3	moderate overlap w. ref.
4	significant overlap w. ref.
5	perfect overlap w. ref.

standards (created by humans), on a scale of 1 to 5. To this end, we conducted evaluation in two separate formats; one concerns fluency and the other relevance. The fluency test consisted of a set of compressions which we created by randomly selecting 200 of them from NICOM-g, for each model at compression rates 50%, 60%, and 70%; thus we have 200 samples for each model and each compression rate.<sup>11</sup> The total number of test compressions came to 1,200.

The relevance test, on the other hand, consisted of *paired* compressions along with the associated gold standard compressions. Each pair contains compressions both from DPM and from GST at a given compression rate. We randomly picked 200 of them from NICOM-g, at each compression rate, and asked the participants to make a subjective judgment on how much of the content in a compression semantically overlap with that of the gold standard, on a scale of 1 to 5 (Table 3). Also included in the survey are 200 gold standard compressions, to get some idea of how fluent “ideal” compressions are, compared to those generated by machine.

Tables 4 and 5 summarize the results. Table 4 looks at the fluency of compressions generated by each of the models; Table 5 looks at how much of the content in reference is retained in compressions. In either table, CR stands for compression rate. All the results are averaged over samples.

We find in Table 4 a clear superiority of GST over DPM at every compression rate examined, with fluency improved by as much as 60% at 60%. However, GST fell short of what human compressions achieved in fluency – an issue we need to address

<sup>11</sup>As stated elsewhere, by compression rate, we mean  $r = \frac{\# \text{ of } 1 \text{ in } y}{\text{length of } x}$ .

Table 4: Fluency (Average)

MODEL/CR	50%	60%	70%
GST	<b>3.430</b>	<b>3.820</b>	<b>3.810</b>
DPM	2.222	2.372	2.660
Human	–	4.45	–

Table 5: Semantic (Content) Overlap (Average)

MODEL/CR	50%	60%	70%
GST	<b>2.720</b>	<b>3.181</b>	<b>3.405</b>
DPM	2.210	2.548	2.890

in the future. Since the average CR of gold standard compressions was 60%, we report their fluency at that rate only.

Table 5 shows the results in relevance of content. Again GST marks a superior performance over DPM, beating it at every compression rate. It is interesting to observe that GST manages to do well in the semantic overlap, despite the cutback on the search space we forced on GST.

As for fluency, we suspect that the superior performance of GST is largely due to the dependency truncation the model is equipped with; and its performance in content overlap owes a lot to CRFs. However, just how much improvement GST achieved over regular CRFs (with no truncation) in fluency and in relevance is something that remains to be seen, as the latter do not allow for variable length compression, which prohibits a straightforward comparison between the two kinds of models.

We conclude the section with a few words on the size of  $|G(S)|$ , i.e., the number of candidates generated per run of compression with GST.

Figure 8 shows the distribution of the numbers of candidates generated per compression, which looks like the familiar scale-free power curve. Over 99% of the time, the number of candidates or  $|G(S)|$  is found to be less than 500.

## 7 Conclusions

This paper introduced a novel approach to sentence compression in Japanese, which combines a syntactically motivated generation model and CRFs, in or-

Figure 8: The distribution of  $|G(S)|$ 

der to address fluency and relevance of compressions we generate. What distinguishes this work from prior research is its overt withdrawal from a search for global optima to a search for local optima that comply with grammar.

We believe that our idea was empirically borne out, as the experiments found that our approach outperforms, by a large margin, a previously known method called DPM, which employs a global search strategy. The results on semantic overlap indicates that the narrowing down of compressions we search obviously does not harm their relevance to references.

An interesting future exercise would be to explore whether it is feasible to rewrite Eq. 5 as a linear integer program. If it is, the whole scheme of ours would fall under what is known as ‘Linear Programming CRFs’ (Tasker, 2004; Roth and Yih, 2005). What remains to be seen, however, is whether GST is transferable to languages other than Japanese, notably, English. The answer is likely to be yes, but details have yet to be worked out.

## Abstract

Online reviews are often accompanied with numerical ratings provided by users for a set of service or product aspects. We propose a statistical model which is able to discover corresponding topics in text and extract textual evidence from reviews supporting each of these aspect ratings – a fundamental problem in aspect-based sentiment summarization (Hu and Liu, 2004a). Our model achieves high accuracy, without any explicitly labeled data except the user provided opinion ratings. The proposed approach is general and can be used for segmentation in other applications where sequential data is accompanied with correlated signals.

## 1 Introduction

User generated content represents a unique source of information in which user interface tools have facilitated the creation of an abundance of labeled content, e.g., topics in blogs, numerical product and service ratings in user reviews, and helpfulness rankings in online discussion forums. Many previous studies on user generated content have attempted to predict these labels automatically from the associated text. However, these labels are often present in the data already, which opens another interesting line of research: designing models leveraging these labelings to improve a wide variety of applications.

In this study, we look at the problem of *aspect-based sentiment summarization* (Hu and Liu, 2004a; Popescu and Etzioni, 2005; Gamon et al., 2005;

### Nikos' Fine Dining

Food	4/5	"Best fish in the city", "Excellent appetizers"
Decor	3/5	"Cozy with an old world feel", "Too dark"
Service	1/5	"Our waitress was rude", "Awful service"
Value	5/5	"Good Greek food for the \$", "Great price!"

Figure 1: An example aspect-based summary.

Carenini et al., 2006; Zhuang et al., 2006).<sup>1</sup> An aspect-based summarization system takes as input a set of user reviews for a specific product or service and produces a set of relevant aspects, the aggregated sentiment for each aspect, and supporting textual evidence. For example, figure 1 summarizes a restaurant using aspects *food*, *decor*, *service*, and *value* plus a numeric rating out of 5.

Standard aspect-based summarization consists of two problems. The first is *aspect identification and mention extraction*. Here the goal is to find the set of relevant aspects for a rated entity and extract all textual mentions that are associated with each. Aspects can be fine-grained, e.g., *fish*, *lamb*, *calamari*, or coarse-grained, e.g., *food*, *decor*, *service*. Similarly, extracted text can range from a single word to phrases and sentences. The second problem is *sentiment classification*. Once all the relevant aspects and associated pieces of texts are extracted, the system should aggregate sentiment over each aspect to provide the user with an average numeric or symbolic rating. Sentiment classification is a well studied problem (Wiebe, 2000; Pang et al., 2002; Turney, 2002) and in many domains users explicitly

<sup>1</sup>We use the term *aspect* to denote properties of an object that can be rated by a user as in Snyder and Barzilay (2007). Other studies use the term *feature* (Hu and Liu, 2004b).

Figure 2: Extraction problem: Produce aspect mentions from a corpus of aspect rated reviews.

provide ratings for each aspect making automated means unnecessary.<sup>2</sup> Aspect identification has also been thoroughly studied (Hu and Liu, 2004b; Gamon et al., 2005; Titov and McDonald, 2008), but again, ontologies and users often provide this information negating the need for automation.

Though it may be reasonable to expect a user to provide a rating for each aspect, it is unlikely that a user will annotate every sentence and phrase in a review as being relevant to some aspect. Thus, it can be argued that the most pressing challenge in an aspect-based summarization system is to extract all relevant mentions for each aspect, as illustrated in figure 2. When labeled data exists, this problem can be solved effectively using a wide variety of methods available for text classification and information extraction (Manning and Schutze, 1999). However, labeled data is often hard to come by, especially when one considers all possible domains of products and services. Instead, we propose an unsupervised model that leverages aspect ratings that frequently accompany an online review.

In order to construct such model, we make two assumptions. First, ratable aspects normally represent coherent topics which can be potentially discovered from co-occurrence information in the text. Second, we hypothesize that the most predictive features of an aspect rating are features derived from the text segments discussing the corresponding aspect. Motivated by these observations, we construct a joint statistical model of text and sentiment ratings. The model is at heart a topic model in that it assigns words to a set of induced *topics*, each of which may represent one particular aspect. The model is extended through a set of maximum entropy classifiers, one per each rated aspect, that are used to pre-

dict the sentiment rating towards each of the aspects. However, only the words assigned to an aspects corresponding topic are used in predicting the rating for that aspect. As a result, the model enforces that words assigned to an aspects' topic are predictive of the associated rating. Our approach is more general than the particular statistical model we consider in this paper. For example, other topic models can be used as a part of our model and the proposed class of models can be employed in other tasks beyond sentiment summarization, e.g., segmentation of blogs on the basis of topic labels provided by users, or topic discovery on the basis of tags given by users on social bookmarking sites.<sup>3</sup>

The rest of the paper is structured as follows. Section 2 begins with a discussion of the joint text-sentiment model approach. In Section 3 we provide both a qualitative and quantitative evaluation of the proposed method. We conclude in Section 4 with an examination of related work.

## 2 The Model

In this section we describe a new statistical model called the Multi-Aspect Sentiment model (MAS), which consists of two parts. The first part is based on Multi-Grain Latent Dirichlet Allocation (Titov and McDonald, 2008), which has been previously shown to build topics that are representative of ratable aspects. The second part is a set of sentiment predictors per aspect that are designed to force specific topics in the model to be directly correlated with a particular aspect.

### 2.1 Multi-Grain LDA

The Multi-Grain Latent Dirichlet Allocation model (MG-LDA) is an extension of Latent Dirichlet Allocation (LDA) (Blei et al., 2003). As was demon-

<sup>2</sup>E.g., <http://zagat.com> and <http://tripadvisor.com>.

<sup>3</sup>See e.g. [del.icio.us](http://del.icio.us) (<http://del.icio.us>).

strated in Titov and McDonald (2008), the topics produced by LDA do not correspond to ratable aspects of entities. In particular, these models tend to build topics that globally classify terms into product instances (e.g., Creative Labs Mp3 players versus iPods, or New York versus Paris Hotels). To combat this, MG-LDA models two distinct types of topics: global topics and local topics. As in LDA, the distribution of global topics is fixed for a document (a user review). However, the distribution of local topics is allowed to vary across the document.

A word in the document is sampled either from the mixture of global topics or from the mixture of local topics specific to the local context of the word. It was demonstrated in Titov and McDonald (2008) that ratable aspects will be captured by local topics and global topics will capture properties of reviewed items. For example, consider an extract from a review of a London hotel: “. . . public transport in London is straightforward, the tube station is about an 8 minute walk . . . or you can get a bus for £1.50”. It can be viewed as a mixture of topic *London* shared by the entire review (words: “London”, “tube”, “£”), and the ratable aspect *location*, specific for the local context of the sentence (words: “transport”, “walk”, “bus”). Local topics are reused between very different types of items, whereas global topics correspond only to particular types of items.

In MG-LDA a document is represented as a set of sliding windows, each covering  $T$  adjacent sentences within a document.<sup>4</sup> Each window  $v$  in document  $d$  has an associated distribution over local topics  $\theta_{d,v}^{loc}$  and a distribution defining preference for local topics versus global topics  $\pi_{d,v}$ . A word can be sampled using any window covering its sentence  $s$ , where the window is chosen according to a categorical distribution  $\psi_{d,s}$ . Importantly, the fact that windows overlap permits the model to exploit a larger co-occurrence domain. These simple techniques are capable of modeling local topics without more expensive modeling of topic transitions used in (Griffiths et al., 2004; Wang and McCallum, 2005; Wallach, 2006; Gruber et al., 2007). Introduction of a symmetrical Dirichlet prior  $Dir(\gamma)$  for the distribution  $\psi_{d,s}$  can control the smoothness of transitions.

<sup>4</sup>Our particular implementation is over sentences, but sliding windows in theory can be over any sized fragment of text.

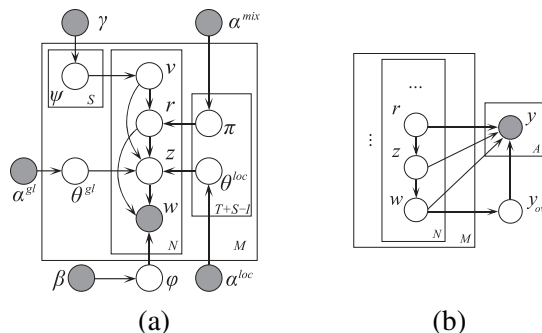

Figure 3: (a) MG-LDA model. (b) An extension of MG-LDA to obtain MAS.

The formal definition of the model with  $K^{gl}$  global and  $K^{loc}$  local topics is as follows: First, draw  $K^{gl}$  word distributions for global topics  $\varphi_z^{gl}$  from a Dirichlet prior  $Dir(\beta^{gl})$  and  $K^{loc}$  word distributions for local topics  $\varphi_z^{loc}$  - from  $Dir(\beta^{loc})$ . Then, for each document  $d$ :

- Choose a distribution of global topics  $\theta_d^{gl} \sim Dir(\alpha^{gl})$ .
- For each sentence  $s$  choose a distribution over sliding windows  $\psi_{d,s}(v) \sim Dir(\gamma)$ .
- For each sliding window  $v$ 
  - choose  $\theta_{d,v}^{loc} \sim Dir(\alpha^{loc})$ ,
  - choose  $\pi_{d,v} \sim Beta(\alpha^{mix})$ .
- For each word  $i$  in sentence  $s$  of document  $d$ 
  - choose window  $v_{d,i} \sim \psi_{d,s}$ ,
  - choose  $r_{d,i} \sim \pi_{d,v_{d,i}}$ ,
  - if  $r_{d,i} = gl$  choose global topic  $z_{d,i} \sim \theta_d^{gl}$ ,
  - if  $r_{d,i} = loc$  choose local topic  $z_{d,i} \sim \theta_{d,v_{d,i}}^{loc}$ ,
  - choose word  $w_{d,i}$  from the word distribution  $\varphi_{z_{d,i}}^{r_{d,i}}$ .

$Beta(\alpha^{mix})$  is a prior Beta distribution for choosing between local and global topics. In Figure 3a the corresponding graphical model is presented.

## 2.2 Multi-Aspect Sentiment Model

MG-LDA constructs a set of topics that ideally correspond to ratable aspects of an entity (often in a many-to-one relationship of topics to aspects). A major shortcoming of this model – and all other unsupervised models – is that this correspondence is not explicit, i.e., how does one say that topic  $X$  is really about aspect  $Y$ ? However, we can observe that numeric aspect ratings are often included in our data by users who left the reviews. We then make the assumption that the text of the review discussing an aspect is predictive of its rating. Thus, if we model the prediction of aspect ratings jointly with the construction of explicitly associated topics, then such a

model should benefit from both higher quality topics and a direct assignment from topics to aspects. This is the basic idea behind the Multi-Aspect Sentiment model (MAS).

In its simplest form, MAS introduces a classifier for each aspect, which is used to predict its rating. Each classifier is explicitly associated to a single topic in the model and only words assigned to that topic can participate in the prediction of the sentiment rating for the aspect. However, it has been observed that ratings for different aspects can be correlated (Snyder and Barzilay, 2007), e.g., very negative opinion about room cleanliness is likely to result not only in a low rating for the aspect *rooms*, but also is very predictive of low ratings for the aspects *service* and *dining*. This complicates discovery of the corresponding topics, as in many reviews the most predictive features for an aspect rating might correspond to another aspect. Another problem with this overly simplistic model is the presence of opinions about an item in general without referring to any particular aspect. For example, “this product is the worst I have ever purchased” is a good predictor of low ratings for every aspect. In such cases, non-aspect ‘background’ words will appear to be the most predictive. Therefore, the use of the aspect sentiment classifiers based only on the words assigned to the corresponding topics is problematic. Such a model will not be able to discover coherent topics associated with each aspect, because in many cases the most predictive fragments for each aspect rating will not be the ones where this aspect is discussed.

Our proposal is to estimate the distribution of possible values of an aspect rating on the basis of the *overall* sentiment rating and to use the words assigned to the corresponding topic to compute *corrections* for this aspect. An aspect rating is typically correlated to the overall sentiment rating<sup>5</sup> and the fragments discussing this particular aspect will help to correct the overall sentiment in the appropriate direction. For example, if a review of a hotel is generally positive, but it includes a sentence “the neighborhood is somewhat seedy” then this sentence is predictive of rating for an aspect *location* being below other ratings. This rectifies the aforementioned

<sup>5</sup>In the dataset used in our experiments all three aspect ratings are equivalent for 5,250 reviews out of 10,000.

problems. First, aspect sentiment ratings can often be regarded as conditionally independent given the overall rating, therefore the model will not be forced to include in an aspect topic any words from other aspect topics. Secondly, the fragments discussing overall opinion will influence the aspect rating only through the overall sentiment rating. The overall sentiment is almost always present in the real data along with the aspect ratings, but it can be coarsely discretized and we preferred to use a latent overall sentiment.

The MAS model is presented in Figure 3b. Note that for simplicity we decided to omit in the figure the components of the MG-LDA model other than variables  $r$ ,  $z$  and  $w$ , though they are present in the statistical model. MAS also allows for extra unassociated local topics in order to capture aspects not explicitly rated by the user. As in MG-LDA, MAS has global topics which are expected to capture topics corresponding to particular types of items, such *London hotels* or *seaside resorts* for the hotel domain. In figure 3b we shaded the aspect ratings  $y_a$ , assuming that every aspect rating is present in the data (though in practice they might be available only for some reviews). In this model the distribution of the overall sentiment rating  $y_{ov}$  is based on all the n-gram features of a review text. Then the distribution of  $y_a$ , for every rated aspect  $a$ , can be computed from the distribution of  $y_{ov}$  and from any n-gram feature where at least one word in the n-gram is assigned to the associated aspect topic ( $r = loc$ ,  $z = a$ ).

Instead of having a latent variable  $y_{ov}$ ,<sup>6</sup> we use a similar model which does not have an explicit notion of  $y_{ov}$ . The distribution of a sentiment rating  $y_a$  for each rated aspect  $a$  is computed from two scores. The first score is computed on the basis of all the n-grams, but using a common set of weights independent of the aspect  $a$ . Another score is computed only using n-grams associated with the related topic, but an aspect-specific set of weights is used in this computation. More formally, we consider the log-linear distribution:

$$P(y_a = y | \mathbf{w}, \mathbf{r}, \mathbf{z}) \propto \exp(b_y^a + \sum_{f \in \mathbf{w}} J_{f,y}^a + p_{f,\mathbf{r},\mathbf{z}}^a J_{f,y}^a), \quad (1)$$

where  $\mathbf{w}$ ,  $\mathbf{r}$ ,  $\mathbf{z}$  are vectors of all the words in a docu-

<sup>6</sup>Preliminary experiments suggested that this is also a feasible approach, but somewhat more computationally expensive.

ment, assignments of context (global or local) and topics for all the words in the document, respectively.  $b_y^a$  is the bias term which regulates the prior distribution  $P(y_a = y)$ ,  $f$  iterates through all the n-grams,  $J_{y,f}$  and  $J_{y,f}^a$  are common weights and aspect-specific weights for n-gram feature  $f$ .  $p_{f,r,z}^a$  is equal to a fraction of words in n-gram feature  $f$  assigned to the aspect topic ( $r = loc, z = a$ ).

### 2.3 Inference in MAS

Exact inference in the MAS model is intractable. Following Titov and McDonald (2008) we use a collapsed Gibbs sampling algorithm that was derived for the MG-LDA model based on the Gibbs sampling method proposed for LDA in (Griffiths and Steyvers, 2004). Gibbs sampling is an example of a Markov Chain Monte Carlo algorithm (Geman and Geman, 1984). It is used to produce a sample from a joint distribution when only conditional distributions of each variable can be efficiently computed. In Gibbs sampling, variables are sequentially sampled from their distributions conditioned on all other variables in the model. Such a chain of model states converges to a sample from the joint distribution. A naive application of this technique to LDA would imply that both assignments of topics to words  $\mathbf{z}$  and distributions  $\theta$  and  $\varphi$  should be sampled. However, (Griffiths and Steyvers, 2004) demonstrated that an efficient collapsed Gibbs sampler can be constructed, where only assignments  $\mathbf{z}$  need to be sampled, whereas the dependency on distributions  $\theta$  and  $\varphi$  can be integrated out analytically.

In the case of MAS we also use maximum a-posteriori estimates of the sentiment predictor parameters  $b_y^a$ ,  $J_{y,f}$  and  $J_{y,f}^a$ . The MAP estimates for parameters  $b_y^a$ ,  $J_{y,f}$  and  $J_{y,f}^a$  are obtained by using stochastic gradient ascent. The direction of the gradient is computed simultaneously with running a chain by generating several assignments at each step and averaging over the corresponding gradient estimates. For details on computing gradients for log-linear graphical models with Gibbs sampling we refer the reader to (Neal, 1992).

Space constraints do not allow us to present either the derivation or a detailed description of the sampling algorithm. However, note that the conditional distribution used in sampling decomposes into two

parts:

$$P(v_{d,i} = v, r_{d,i} = r, z_{d,i} = z | \mathbf{v}', \mathbf{r}', \mathbf{z}', \mathbf{w}, \mathbf{y}) \propto \eta_{v,r,z}^{d,i} \times \rho_{r,z}^{d,i}, \quad (2)$$

where  $\mathbf{v}'$ ,  $\mathbf{r}'$  and  $\mathbf{z}'$  are vectors of assignments of sliding windows, context (global or local) and topics for all the words in the collection except for the considered word at position  $i$  in document  $d$ ;  $y$  is the vector of sentiment ratings. The first factor  $\eta_{v,r,z}^{d,i}$  is responsible for modeling co-occurrences on the window and document level and coherence of the topics. This factor is proportional to the conditional distribution used in the Gibbs sampler of the MG-LDA model (Titov and McDonald, 2008). The last factor quantifies the influence of the assignment of the word  $(d, i)$  on the probability of the sentiment ratings. It appears only if ratings are known (observable) and equals:

$$\rho_{r,z}^{d,i} = \prod_a \frac{P(y_a^d | \mathbf{w}, \mathbf{r}', r_{d,i} = r, \mathbf{z}', z_{d,i} = z)}{P(y_a^d | \mathbf{w}, \mathbf{r}', \mathbf{z}', r_{d,i} = gl)},$$

where the probability distribution is computed as defined in expression (1),  $y_a^d$  is the rating for the  $a$ th aspect of review  $d$ .

## 3 Experiments

In this section we present qualitative and quantitative experiments. For the qualitative analysis we show that topics inferred by the MAS model correspond directly to the associated aspects. For the quantitative analysis we show that the MAS model induces a distribution over the rated aspects which can be used to accurately predict whether a text fragment is relevant to an aspect or not.

### 3.1 Qualitative Evaluation

To perform qualitative experiments we used a set of reviews of hotels taken from TripAdvisor.com<sup>7</sup> that contained 10,000 reviews (109,024 sentences, 2,145,313 words in total). Every review was rated with at least three aspects: *service*, *location* and *rooms*. Each rating is an integer from 1 to 5. The dataset was tokenized and sentence split automatically.

<sup>7</sup>(c) 2005-06, TripAdvisor, LLC All rights reserved

Table 2: Top words for aspect *rooms* with different number of topics  $K_{rooms}$ .

We ran the sampling chain for 700 iterations to produce a sample. Distributions of words in each topic were estimated as the proportion of words assigned to each topic, taking into account topic model priors  $\beta^{gl}$  and  $\beta^{loc}$ . The sliding windows were chosen to cover 3 sentences for all the experiments. All the priors were chosen to be equal to 0.1. We used 15 local topics and 30 global topics. In the model, the first three local topics were associated to the rating classifiers for each aspects. As a result, we would expect these topics to correspond to the *service*, *location*, and *rooms* aspects respectively. Unigram and bigram features were used in the sentiment predictors in the MAS model. Before applying the topic models we removed punctuation and also removed stop words using the standard list of stop words,<sup>8</sup> however, all the words and punctuation were used in the sentiment predictors.

It does not take many chain iterations to discover initial topics. This happens considerably faster than the appropriate weights of the sentiment predictor being learned. This poses a problem, because, in the beginning, the sentiment predictors are not accurate enough to force the model to discover appropriate topics associated with each of the rated aspects. And as soon as topic are formed, aspect sentiment predictors cannot affect them anymore because they do not

<sup>8</sup>[http://www.dcs.gla.ac.uk/idom/ir\\_resources/linguistic\\_utils/stop\\_words](http://www.dcs.gla.ac.uk/idom/ir_resources/linguistic_utils/stop_words)

have access to the true words associated with their aspects. To combat this problem we first train the sentiment classifiers by assuming that  $p_{f,r,z}^a$  is equal for all the local topics, which effectively ignores the topic model. Then we use the estimated parameters within the topic model.<sup>9</sup> Secondly, we modify the sampling algorithm. The conditional probability used in sampling, expression (2), is proportional to the product of two factors. The first factor,  $\eta_{v,r,z}^{d,i}$ , expresses a preference for topics likely from the co-occurrence information, whereas the second one,  $\rho_{r,z}^{d,i}$ , favors the choice of topics which are predictive of the observable sentiment ratings. We used  $(\rho_{r,z}^{d,i})^{1+0.95^t q}$  in the sampling distribution instead of  $\rho_{r,z}^{d,i}$ , where  $t$  is the iteration number.  $q$  was chosen to be 4, though the quality of the topics seemed to be indistinguishable with any  $q$  between 3 and 10. This can be thought of as having  $1 + 0.95^t q$  ratings instead of a single vector assigned to each review, i.e., focusing the model on prediction of the ratings rather than finding the topic labels which are good at explaining co-occurrences of words. These heuristics influence sampling only during the first iterations of the chain.

Top words for some of discovered local topics, in-

<sup>9</sup>Initial experiments suggested that instead of doing this ‘pre-training’ we could start with very large priors  $\alpha^{loc}$  and  $\alpha^{mix}$ , and then reduce them through the course of training. However, this is significantly more computationally expensive.

Figure 4: (a) Aspect *service*. (b) Aspect *location*. (c) Aspect *rooms*.

cluding the first 3 topics associated with the rated aspects, and also top words for some of global topics are presented in Table 1. We can see that the model discovered as its first three topics the correct associated aspects: *service*, *location*, and *rooms*. Other local topics, as for the MG-LDA model, correspond to other aspects discussed in reviews (*breakfast*, *prices*, *noise*), and as it was previously shown in Titov and McDonald (2008), aspects for global topics correspond to the types of reviewed items (*hotels in Russia*, *Paris hotels*) or background words.

Notice though, that the 3rd local topic induced for the rating *rooms* is slightly narrow. This can be explained by the fact that the aspect *rooms* is a central aspect of hotel reviews. A very significant fraction of text in every review can be thought of as a part of the aspect *rooms*. These portions of reviews discuss different coherent sub-aspects related to the aspect *rooms*, e.g., the previously discovered topic *noise*. Therefore, it is natural to associate several topics to such central aspects. To test this we varied the number of topics associated with the sentiment predictor for the aspect *rooms*. Top words for resulting topics are presented in Table 2. It can be observed that the topic model discovered appropriate topics while the number of topics was below 4. With 4 topics a semantically unrelated topic (*check-in/arrival*) is induced. Manual selection of the number of topics is undesirable, but this problem can be potentially tackled with Dirichlet Process priors or a topic split criterion based on the accuracy of the sentiment predictor in the MAS model. We found that both *service* and *location* did not benefit by the assignment of additional topics to their sentiment rating models.

The experimental results suggest that the MAS model is reliable in the discovery of topics corresponding to the rated aspects. In the next section we will show that the induced topics can be used to accurately extract fragments for each aspect.

### 3.2 Sentence Labeling

A primary advantage of MAS over unsupervised models, such as MG-LDA or clustering, is that topics are linked to a rated aspect, i.e., we know exactly which topics model which aspects. As a result, these topics can be directly used to extract textual mentions that are relevant for an aspect. To test this, we hand labeled 779 random sentences from the dataset considered in the previous set of experiments. The sentences were labeled with one or more aspects. Among them, 164, 176 and 263 sentences were labeled as related to aspects *service*, *location* and *rooms*, respectively. The remaining sentences were not relevant to any of the rated aspects.

We compared two models. The first model uses the first three topics of MAS to extract relevant mentions based on the probability of that topic/aspect being present in the sentence. To obtain these probabilities we used estimators based on the proportion of words in the sentence assigned to an aspects' topic and normalized within local topics. To improve the reliability of the estimator we produced 100 samples for each document while keeping assignments of the topics to all other words in the collection fixed. The probability estimates were then obtained by averaging over these samples. We did not perform any model selection on the basis of the hand-labeled data, and tested only a single model of each type.

For the second model we trained a maximum entropy classifier, one per each aspect, using 10-fold cross validation and unigram/bigram features. Note that this is a *supervised* system and as such represents an upper-bound in performance one might expect when comparing an unsupervised model such as MAS. We chose this comparison to demonstrate that our model can find relevant text mentions with high accuracy relative to a supervised model. It is difficult to compare our model to other unsupervised systems such as MG-LDA or LDA. Again, this is because those systems have no mechanism for directly correlating topics or clusters to corresponding aspects, highlighting the benefit of MAS.

The resulting precision-recall curves for the aspects *service*, *location* and *rooms* are presented in Figure 4. In Figure 4c, we varied the number of topics associated with the aspect *rooms*.<sup>10</sup> The average precision we obtained (the standard measure proportional to the area under the curve) is 75.8%, 85.5% for aspects *service* and *location*, respectively. For the aspect *rooms* these scores are equal to 75.0%, 74.5%, 87.6%, 79.8% with 1–4 topics per aspect, respectively. The logistic regression models achieve 80.8%, 94.0% and 88.3% for the aspects *service*, *location* and *rooms*. We can observe that the topic model, which does not use any explicitly aspect-labeled text, achieves accuracies lower than, but comparable to a supervised model.

## 4 Related Work

There is a growing body of work on summarizing sentiment by extracting and aggregating sentiment over ratable aspects and providing corresponding textual evidence. Text excerpts are usually extracted through string matching (Hu and Liu, 2004a; Popescu and Etzioni, 2005), sentence clustering (Gamon et al., 2005), or through topic models (Mei et al., 2007; Titov and McDonald, 2008). String extraction methods are limited to fine-grained aspects whereas clustering and topic model approaches must resort to ad-hoc means of labeling clusters or topics. However, this is the first work we are aware of that uses a pre-defined set of aspects plus an associated signal to learn a mapping from text to an aspect for

<sup>10</sup>To improve readability we smoothed the curve for the aspect *rooms*.

the purpose of extraction.

A closely related model to ours is that of Mei et al. (2007) which performs joint topic and sentiment modeling of collections. Our model differs from theirs in many respects: Mei et al. only model sentiment predictions for the entire document and not on the aspect level; They treat sentiment predictions as unobserved variables, whereas we treat them as observed signals that help to guide the creation of topics; They model co-occurrences solely on the document level, whereas our model is based on MG-LDA and models both local and global contexts.

Recently, Blei and McAuliffe (2008) proposed an approach for joint sentiment and topic modeling that can be viewed as a supervised LDA (sLDA) model that tries to infer topics appropriate for use in a given classification or regression problem. MAS and sLDA are similar in that both use sentiment predictions as an observed signal that is predicted by the model. However, Blei et al. do not consider multi-aspect ranking or look at co-occurrences beyond the document level, both of which are central to our model. Parallel to this study Branavan et al. (2008) also showed that joint models of text and user annotations benefit extractive summarization. In particular, they used signals from pros-cons lists whereas our models use aspect rating signals.

## 5 Conclusions

In this paper we presented a joint model of text and aspect ratings for extracting text to be displayed in sentiment summaries. The model uses aspect ratings to discover the corresponding topics and can thus extract fragments of text discussing these aspects without the need of annotated data. We demonstrated that the model indeed discovers corresponding coherent topics and achieves accuracy in sentence labeling comparable to a standard supervised model. The primary area of future work is to incorporate the model into an end-to-end sentiment summarization system in order to evaluate it at that level.

## Abstract

To date, parsers have made limited use of semantic information, but there is evidence to suggest that semantic features can enhance parse disambiguation. This paper shows that semantic classes help to obtain significant improvement in both parsing and PP attachment tasks. We devise a gold-standard sense- and parse tree-annotated dataset based on the intersection of the Penn Treebank and SemCor, and experiment with different approaches to both semantic representation and disambiguation. For the Bikel parser, we achieved a maximal error reduction rate over the baseline parser of 6.9% and 20.5%, for parsing and PP-attachment respectively, using an unsupervised WSD strategy. This demonstrates that word sense information can indeed enhance the performance of syntactic disambiguation.

## 1 Introduction

Traditionally, parse disambiguation has relied on structural features extracted from syntactic parse trees, and made only limited use of semantic information. There is both empirical evidence and linguistic intuition to indicate that semantic features can enhance parse disambiguation performance, however. For example, a number of different parsers have been shown to benefit from lexicalisation, that is, the conditioning of structural features on the lexical head of the given constituent (Magerman, 1995; Collins, 1996; Charniak, 1997; Charniak, 2000; Collins, 2003). As an example of lexicalisation, we may observe in our training data that *knife* often occurs as the manner adjunct of *open* in prepositional phrases headed by *with* (c.f. *open with*

*a knife*), which would provide strong evidence for *with (a) knife* attaching to *open* and not *box* in *open the box with a knife*. It would not, however, provide any insight into the correct attachment of *with scissors* in *open the box with scissors*, as the disambiguation model would not be able to predict that *knife* and *scissors* are semantically similar and thus likely to have the same attachment preferences.

In order to deal with this limitation, we propose to integrate directly the semantic classes of words into the process of training the parser. This is done by substituting the original words with semantic codes that reflect semantic classes. For example, in the above example we could substitute both *knife* and *scissors* with the semantic class TOOL, thus relating the training and test instances directly. We explore several models for semantic representation, based around WordNet (Fellbaum, 1998).

Our approach to exploring the impact of lexical semantics on parsing performance is to take two state-of-the-art statistical treebank parsers and preprocess the inputs variously. This simple method allows us to incorporate semantic information into the parser without having to reimplement a full statistical parser, and also allows for maximum comparability with existing results in the treebank parsing community. We test the parsers over both a PP attachment and full parsing task.

In experimenting with different semantic representations, we require some strategy to disambiguate the semantic class of polysemous words in context (e.g. determining for each instance of *crane* whether it refers to an animal or a lifting device). We explore a number of disambiguation strategies, including the use of hand-annotated (gold-standard) senses, the

use of the most frequent sense, and an unsupervised word sense disambiguation (WSD) system.

This paper shows that semantic classes help to obtain significant improvements for both PP attachment and parsing. We attain a 20.5% error reduction for PP attachment, and 6.9% for parsing. These results are achieved using most frequent sense information, which surprisingly outperforms both gold-standard senses and automatic WSD.

The results are notable in demonstrating that very simple preprocessing of the parser input facilitates significant improvements in parser performance. We provide the first definitive results that word sense information can enhance Penn Treebank parser performance, building on earlier results of Bikel (2000) and Xiong et al. (2005). Given our simple procedure for incorporating lexical semantics into the parsing process, our hope is that this research will open the door to further gains using more sophisticated parsing models and richer semantic options.

## 2 Background

This research is focused on applying lexical semantics in parsing and PP attachment tasks. Below, we outline these tasks.

### Parsing

As our baseline parsers, we use two state-of-the-art lexicalised parsing models, namely the Bikel parser (Bikel, 2004) and Charniak parser (Charniak, 2000). While a detailed description of the respective parsing models is beyond the scope of this paper, it is worth noting that both parsers induce a context free grammar as well as a generative parsing model from a training set of parse trees, and use a development set to tune internal parameters. Traditionally, the two parsers have been trained and evaluated over the WSJ portion of the Penn Treebank (PTB; Marcus et al. (1993)). We diverge from this norm in focusing exclusively on a sense-annotated subset of the Brown Corpus portion of the Penn Treebank, in order to investigate the upper bound performance of the models given gold-standard sense information.

### PP attachment in a parsing context

Prepositional phrase attachment (PP attachment) is the problem of determining the correct attachment site for a PP, conventionally in the form of the noun

or verb in a V NP PP structure (Ratnaparkhi et al., 1994; Mitchell, 2004). For instance, in *I ate a pizza with anchovies*, the PP *with anchovies* could attach either to the verb (c.f. *ate with anchovies*) or to the noun (c.f. *pizza with anchovies*), of which the noun is the correct attachment site. With *I ate a pizza with friends*, on the other hand, the verb is the correct attachment site. PP attachment is a structural ambiguity problem, and as such, a subproblem of parsing.

Traditionally the so-called RRR data (Ratnaparkhi et al., 1994) has been used to evaluate PP attachment algorithms. RRR consists of 20,081 training and 3,097 test quadruples of the form  $(v, n1, p, n2)$ , where the attachment decision is either  $v$  or  $n1$ . The best published results over RRR are those of Stetina and Nagao (1997), who employ WordNet sense predictions from an unsupervised WSD method within a decision tree classifier. Their work is particularly inspiring in that it significantly outperformed the plethora of lexicalised probabilistic models that had been proposed to that point, and has not been beaten in later attempts.

In a recent paper, Atterer and Schütze (2007) criticised the RRR dataset because it assumes that an oracle parser provides the two hypothesised structures to choose between. This is needed to derive the fact that there are two possible attachment sites, as well as information about the lexical phrases, which are typically extracted heuristically from gold standard parses. Atterer and Schütze argue that the only meaningful setting for PP attachment is within a parser, and go on to demonstrate that in a parser setting, the Bikel parser is competitive with the best-performing dedicated PP attachment methods. Any improvement in PP attachment performance over the baseline Bikel parser thus represents an advancement in state-of-the-art performance.

That we specifically present results for PP attachment in a parsing context is a combination of us supporting the new research direction for PP attachment established by Atterer and Schütze, and us wishing to reinforce the findings of Stetina and Nagao that word sense information significantly enhances PP attachment performance in this new setting.

### Lexical semantics in parsing

There have been a number of attempts to incorporate word sense information into parsing tasks. The

most closely related research is that of Bikel (2000), who merged the Brown portion of the Penn Treebank with SemCor (similarly to our approach in Section 4.1), and used this as the basis for evaluation of a generative bilexical model for joint WSD and parsing. He evaluated his proposed model in a parsing context both with and without WordNet-based sense information, and found that the introduction of sense information either had no impact or degraded parse performance.

The only successful applications of word sense information to parsing that we are aware of are Xiong et al. (2005) and Fujita et al. (2007). Xiong et al. (2005) experimented with first-sense and hypernym features from HowNet and CiLin (both WordNets for Chinese) in a generative parse model applied to the Chinese Penn Treebank. The combination of word sense and first-level hypernyms produced a significant improvement over their basic model. Fujita et al. (2007) extended this work in implementing a discriminative parse selection model incorporating word sense information mapped onto upper-level ontologies of differing depths. Based on gold-standard sense information, they achieved large-scale improvements over a basic parse selection model in the context of the Hinoki treebank.

Other notable examples of the successful incorporation of lexical semantics into parsing, not through word sense information but indirectly via selectional preferences, are Dowding et al. (1994) and Hektoen (1997). For a broader review of WSD in NLP applications, see Resnik (2006).

### 3 Integrating Semantics into Parsing

Our approach to providing the parsers with sense information is to make available the semantic denotation of each word in the form of a semantic class. This is done simply by substituting the original words with semantic codes. For example, in the earlier example of *open with a knife* we could substitute both *knife* and *scissors* with the class TOOL, and thus directly facilitate semantic generalisation within the parser. There are three main aspects that we have to consider in this process: (i) the semantic representation, (ii) semantic disambiguation, and (iii) morphology.

There are many ways to represent semantic re-

lationships between words. In this research we opt for a class-based representation that will map semantically-related words into a common semantic category. Our choice for this work was the WordNet 2.1 lexical database, in which synonyms are grouped into synsets, which are then linked via an IS-A hierarchy. WordNet contains other types of relations such as meronymy, but we did not use them in this research. With any lexical semantic resource, we have to be careful to choose the appropriate level of granularity for a given task: if we limit ourselves to synsets we will not be able to capture broader generalisations, such as the one between *knife* and *scissors*;<sup>1</sup> on the other hand by grouping words related at a higher level in the hierarchy we could find that we make overly coarse groupings (e.g. *mallet*, *square* and *steel-wool pad* are also descendants of TOOL in WordNet, none of which would conventionally be used as the manner adjunct of *cut*). We will test different levels of granularity in this work.

The second problem we face is semantic disambiguation. The more fine-grained our semantic representation, the higher the average polysemy and the greater the need to distinguish between these senses. For instance, if we find the word *crane* in a context such as *demolish a house with the crane*, the ability to discern that this corresponds to the DEVICE and not ANIMAL sense of word will allow us to avoid erroneous generalisations. This problem of identifying the correct sense of a word in context is known as word sense disambiguation (WSD: Agirre and Edmonds (2006)). Disambiguating each word relative to its context of use becomes increasingly difficult for fine-grained representations (Palmer et al., 2006). We experiment with different ways of tackling WSD, using both gold-standard data and automatic methods.

Finally, when substituting words with semantic tags we have to decide how to treat different word forms of a given lemma. In the case of English, this pertains most notably to verb inflection and noun number, a distinction which we lose if we opt to map all word forms onto semantic classes. For our current purposes we choose to substitute all word

---

<sup>1</sup>In WordNet 2.1, *knife* and *scissors* are sister synsets, both of which have TOOL as their 4th hypernym. Only by mapping them onto their 1st hypernym or higher would we be able to capture the semantic generalisation alluded to above.

forms, but we plan to look at alternative representations in the future.

## 4 Experimental setting

We evaluate the performance of our approach in two settings: (1) full parsing, and (2) PP attachment within a full parsing context. Below, we outline the dataset used in this research and the parser evaluation methodology, explain the methodology used to perform PP attachment, present the different options for semantic representation, and finally detail the disambiguation methods.

### 4.1 Dataset and parser evaluation

One of the main requirements for our dataset is the availability of gold-standard sense and parse tree annotations. The gold-standard sense annotations allow us to perform upper bound evaluation of the relative impact of a given semantic representation on parsing and PP attachment performance, to contrast with the performance in more realistic semantic disambiguation settings. The gold-standard parse tree annotations are required in order to carry out evaluation of parser and PP attachment performance.

The only publicly-available resource with these two characteristics at the time of this work was the subset of the Brown Corpus that is included in both SemCor (Landes et al., 1998) and the Penn Treebank (PTB).<sup>2</sup> This provided the basis of our dataset. After sentence- and word-aligning the SemCor and PTB data (discarding sentences where there was a difference in tokenisation), we were left with a total of 8,669 sentences containing 151,928 words. Note that this dataset is smaller than the one described by Bikel (2000) in a similar exercise, the reason being our simple and conservative approach taken when merging the resources.

We relied on this dataset alone for all the experiments in this paper. In order to maximise reproducibility and encourage further experimentation in the direction pioneered in this research, we partitioned the data into 3 sets: 80% training, 10% development and 10% test data. This dataset is available on request to the research community.

<sup>2</sup>OntoNotes (Hovy et al., 2006) includes large-scale treebank and (selective) sense data, which we plan to use for future experiments when it becomes fully available.

We evaluate the parsers via labelled bracketing recall ( $\mathcal{R}$ ), precision ( $\mathcal{P}$ ) and F-score ( $\mathcal{F}_1$ ). We use Bikel’s randomized parsing evaluation comparator<sup>3</sup> (with  $p < 0.05$  throughout) to test the statistical significance of the results using word sense information, relative to the respective baseline parser using only lexical features.

### 4.2 PP attachment task

Following Atterer and Schütze (2007), we wrote a script that, given a parse tree, identifies instances of PP attachment ambiguity and outputs the  $(v, n1, p, n2)$  quadruple involved and the attachment decision. This extraction system uses Collins’ rules (based on TREEP (Chiang and Bikel, 2002)) to locate the heads of phrases. Over the combined gold-standard parsing dataset, our script extracted a total of 2,541 PP attachment quadruples. As with the parsing data, we partitioned the data into 3 sets: 80% training, 10% development and 10% test data. Once again, this dataset and the script used to extract the quadruples are available on request to the research community.

In order to evaluate the PP attachment performance of a parser, we run our extraction script over the parser output in the same manner as for the gold-standard data, and compare the extracted quadruples to the gold-standard ones. Note that there is no guarantee of agreement in the quadruple membership between the extraction script and the gold standard, as the parser may have produced a parse which is incompatible with either attachment possibility. A quadruple is deemed correct if: (1) it exists in the gold standard, and (2) the attachment decision is correct. Conversely, it is deemed incorrect if: (1) it exists in the gold standard, and (2) the attachment decision is incorrect. Quadruples not found in the gold standard are discarded. Precision was measured as the number of correct quadruples divided by the total number of correct and incorrect quadruples (i.e. all quadruples which are not discarded), and recall as the number of correct quadruples divided by the total number of gold-standard quadruples in the test set. This evaluation methodology coincides with that of Atterer and Schütze (2007).

Statistical significance was calculated based on

<sup>3</sup>[www.cis.upenn.edu/~dbikel/software.html](http://www.cis.upenn.edu/~dbikel/software.html)

a modified version of the Bikel comparator (see above), once again with  $p < 0.05$ .

### 4.3 Semantic representation

We experimented with a range of semantic representations, all of which are based on WordNet 2.1. As mentioned above, words in WordNet are organised into sets of synonyms, called **synsets**. Each synset in turn belongs to a unique **semantic file** (SF). There are a total of 45 SFs (1 for adverbs, 3 for adjectives, 15 for verbs, and 26 for nouns), based on syntactic and semantic categories. A selection of SFs is presented in Table 1 for illustration purposes.

We experiment with both full synsets and SFs as instances of fine-grained and coarse-grained semantic representation, respectively. As an example of the difference in these two representations, *knife* in its tool sense is in the EDGE TOOL USED AS A CUTTING INSTRUMENT singleton synset, and also in the ARTIFACT SF along with thousands of other words including *cutter*. Note that these are the two extremes of semantic granularity in WordNet, and we plan to experiment with intermediate representation levels in future research (c.f. Li and Abe (1998), McCarthy and Carroll (2003), Xiong et al. (2005), Fujita et al. (2007)).

As a hybrid representation, we tested the effect of merging words with their corresponding SF (e.g. *knife*+ARTIFACT). This is a form of semantic specialisation rather than generalisation, and allows the parser to discriminate between the different senses of each word, but not generalise across words.

For each of these three semantic representations, we experimented with substituting each of: (1) all open-class POSs (nouns, verbs, adjectives and adverbs), (2) nouns only, and (3) verbs only. There are thus a total of 9 combinations of representation type and target POS.

### 4.4 Disambiguation methods

For a given semantic representation, we need some form of WSD to determine the semantics of each token occurrence of a target word. We experimented with three options:

1. **Gold-standard:** Gold-standard annotations from SemCor. This gives us the upper bound performance of the semantic representation.

SF ID	DEFINITION
adj.all	all adjective clusters
adj.pert	relational adjectives (pertainyms)
adj.ppl	participial adjectives
adv.all	all adverbs
noun.act	nouns denoting acts or actions
noun.animal	nouns denoting animals
noun.artifact	nouns denoting man-made objects
...	
verb.consumption	verbs of eating and drinking
verb.emotion	verbs of feeling
verb.perception	verbs of seeing, hearing, feeling
...	

Table 1: A selection of WordNet SFs

2. **First Sense (1ST):** All token instances of a given word are tagged with their most frequent sense in WordNet.<sup>4</sup> Note that the first sense predictions are based largely on the same dataset as we use in our evaluation, such that the predictions are tuned to our dataset and not fully unsupervised.
3. **Automatic Sense Ranking (ASR):** First sense tagging as for First Sense above, except that an unsupervised system is used to automatically predict the most frequent sense for each word based on an independent corpus. The method we use to predict the first sense is that of McCarthy et al. (2004), which was obtained using a thesaurus automatically created from the British National Corpus (BNC) applying the method of Lin (1998), coupled with WordNet-based similarity measures. This method is fully unsupervised and completely unreliant on any annotations from our dataset.

In the case of SFs, we perform full synset WSD based on one of the above options, and then map the prediction onto the corresponding (unique) SF.

## 5 Results

We present the results for each disambiguation approach in turn, analysing the results for parsing and PP attachment separately.

<sup>4</sup>There are some differences with the most frequent sense in SemCor, due to extra corpora used in WordNet development, and also changes in WordNet from the original version used for the SemCor tagging.

Table 2: Parsing results with gold-standard senses (\* indicates that the recall or precision is significantly better than baseline; the best performing method in each column is shown in **bold**)

## 5.1 Gold standard

We disambiguated each token instance in our corpus according to the gold-standard sense data, and trained both the Charniak and Bikel parsers over each semantic representation. We evaluated the parsers in full parsing and PP attachment contexts.

The results for parsing are given in Table 2. The rows represent the three semantic representations (including whether we substitute only nouns, only verbs or all POS). We can see that in almost all cases the semantically-enriched representations improve over the baseline parsers. These results are statistically significant in some cases (as indicated by \*). The SF<sub>v</sub> representation produces the best results for Bikel (F-score 0.010 above baseline), while for Charniak the best performance is obtained with word+SF (F-score 0.007 above baseline). Comparing the two baseline parsers, Bikel achieves better precision and Charniak better recall. Overall, Bikel obtains a superior F-score in all configurations.

The results for the PP attachment experiments using gold-standard senses are given in Table 3, both for the Charniak and Bikel parsers. Again, the F-score for the semantic representations is better than the baseline in all cases. We see that the improvement is significant for recall in most cases (particularly when using verbs), but not for precision (only Charniak over Syn<sub>v</sub> and word+SF<sub>v</sub> for Bikel). For both parsers the best results are achieved with SF<sub>v</sub>, which was also the best configuration for parsing with Bikel. The performance gain obtained here is larger than in parsing, which is in accordance with the findings of Stetina and Nagao that lexical semantics has a considerable effect on PP attachment

performance. As in full-parsing, Bikel outperforms Charniak, but in this case the difference in the baselines is not statistically significant.

## 5.2 First sense (1ST)

For this experiment, we use the first sense data from WordNet for disambiguation. The results for full parsing are given in Table 4. Again, the performance is significantly better than baseline in most cases, and surprisingly the results are even better than gold-standard in some cases. We hypothesise that this is due to the avoidance of excessive fragmentation, as occurs with fine-grained senses. The results are significantly better for nouns, with SF<sub>n</sub> performing best. Verbs seem to suffer from lack of disambiguation precision, especially for Bikel. Here again, Charniak trails behind Bikel.

The results for the PP attachment task are shown in Table 5. The behaviour is slightly different here, with Charniak obtaining better results than Bikel in most cases. As was the case for parsing, the performance with 1ST reaches and in many instances surpasses gold-standard levels, achieving statistical significance over the baseline in places. Comparing the semantic representations, the best results are achieved with SF<sub>v</sub>, as we saw in the gold-standard PP-attachment case.

## 5.3 Automatic sense ranking (ASR)

The final option for WSD is automatic sense ranking, which indicates how well our method performs in a completely unsupervised setting.

The parsing results are given in Table 6. We can see that the scores are very similar to those from

1ST, with improvements in some cases, particularly for Charniak. Again, the results are better for nouns, except for the case of SF<sub>v</sub> with Bikel. Bikel outperforms Charniak in terms of F-score in all cases.

The PP attachment results are given in Table 7. The results are similar to 1ST, with significant improvements for verbs. In this case, synsets slightly outperform SF. Charniak performs better than Bikel, and the results for Syn<sub>v</sub> are higher than the best obtained using gold-standard senses.

## 6 Discussion

The results of the previous section show that the improvements in parsing results are small but significant, for all three word sense disambiguation strategies (gold-standard, 1ST and ASR). Table 8 summarises the results, showing that the error reduction rate (ERR) over the parsing F-score is up to 6.9%, which is remarkable given the relatively superficial strategy for incorporating sense information into the parser. Note also that our baseline results for the

dataset are almost the same as previous work parsing the Brown corpus with similar models (Gildea, 2001), which suggests that our dataset is representative of this corpus.

The improvement in PP attachment was larger (20.5% ERR), and also statistically significant. The results for PP attachment are especially important, as we demonstrate that the sense information has high utility when embedded within a parser, where the parser needs to first identify the ambiguity and heads correctly. Note that Atterer and Schütze (2007) have shown that the Bikel parser performs as well as the state-of-the-art in PP attachment, which suggests our method improves over the current state-of-the-art. The fact that the improvement is larger for PP attachment than for full parsing is suggestive of PP attachment being a parsing subtask where lexical semantic information is particularly important, supporting the findings of Stetina and Nagao (1997) over a standalone PP attachment task. We also observed that while better PP-attachment usually improves parsing, there is some small variation. This

Table 8: Summary of F-score results with error reduction rates and the best semantic representation(s) for each setting (C = Charniak, B = Bikel)

means that the best configuration for PP-attachment does not always produce the best results for parsing

One surprising finding was the strong performance of the automatic WSD systems, actually outperforming the gold-standard annotation overall. Our interpretation of this result is that the approach of annotating all occurrences of the same word with the same sense allows the model to avoid the data sparseness associated with the gold-standard distinctions, as well as supporting the merging of different words into single semantic classes. While the results for gold-standard senses were intended as an upper bound for WordNet-based sense information, in practice there was very little difference between gold-standard senses and automatic WSD in all cases barring the Bikel parser and PP attachment.

Comparing the two parsers, Charniak performs better than Bikel on PP attachment when automatic WSD is used, while Bikel performs better on parsing overall. Regarding the choice of WSD system, the results for both approaches are very similar, showing that ASR performs well, even if it does not require sense frequency information.

The analysis of performance according to the semantic representation is not so clear cut. Generalising only verbs to semantic files (SF<sub>v</sub>) was the best option in most of the experiments, particularly for PP-attachment. This could indicate that semantic generalisation is particularly important for verbs, more so than nouns.

Our hope is that this paper serves as the bridge-head for a new line of research into the impact of lexical semantics on parsing. Notably, more could be done to fine-tune the semantic representation be-

tween the two extremes of full synsets and SFs. One could also imagine that the appropriate level of generalisation differs across POS and even the relative syntactic role, e.g. finer-grained semantics are needed for the objects than subjects of verbs.

On the other hand, the parsing strategy is very simple, as we just substitute words by their semantic class and then train statistical parsers on the transformed input. The semantic class should be an information source that the parsers take into account in addition to analysing the actual words used. Tighter integration of semantics into the parsing models, possibly in the form of discriminative reranking models (Collins and Koo, 2005; Charniak and Johnson, 2005; McClosky et al., 2006), is a promising way forward in this regard.

## 7 Conclusions

In this work we have trained two state-of-the-art statistical parsers on semantically-enriched input, where content words have been substituted with their semantic classes. This simple method allows us to incorporate lexical semantic information into the parser, without having to reimplement a full statistical parser. We tested the two parsers in both a full parsing and a PP attachment context.

This paper shows that semantic classes achieve significant improvement both on full parsing and PP attachment tasks relative to the baseline parsers. PP attachment achieves a 20.5% ERR, and parsing 6.9% without requiring hand-tagged data.

The results are highly significant in demonstrating that a simplistic approach to incorporating lexical semantics into a parser significantly improves parser performance. As far as we know, these are the first results over both WordNet and the Penn Treebank to show that semantic processing helps parsing.

## Acknowledgements

We wish to thank Diana McCarthy for providing us with the sense rank for the target words. This work was partially funded by the Education Ministry (project KNOW TIN2006-15049), the Basque Government (IT-397-07), and the Australian Research Council (grant no. DP0663879). Eneko Agirre participated in this research while visiting the University of Melbourne, based on joint funding from the Basque Government and HCSNet.

# A Logical Basis for the D Combinator and Normal Form in CCG

Frederick Hoyt and Jason Baldridge

The Department of Linguistics

The University of Texas at Austin

{fmhoyt, jbaldrid}@mail.utexas.edu

## Abstract

The standard set of rules defined in Combinatory Categorical Grammar (CCG) fails to provide satisfactory analyses for a number of syntactic structures found in natural languages. These structures can be analyzed elegantly by augmenting CCG with a class of rules based on the combinator **D** (Curry and Feys, 1958). We show two ways to derive the **D** rules: one based on unary composition and the other based on a logical characterization of CCG’s rule base (Baldridge, 2002). We also show how Eisner’s (1996) normal form constraints follow from this logic, ensuring that the **D** rules do not lead to spurious ambiguities.

## 1 Introduction

Combinatory Categorical Grammar (CCG, Steedman (2000)) is a compositional, semantically transparent formalism that is both linguistically expressive and computationally tractable. It has been used for a variety of tasks, such as wide-coverage parsing (Hockenmaier and Steedman, 2002; Clark and Curran, 2007), sentence realization (White, 2006), learning semantic parsers (Zettlemoyer and Collins, 2007), dialog systems (Kruijff et al., 2007), grammar engineering (Beavers, 2004; Baldridge et al., 2007), and modeling syntactic priming (Reitter et al., 2006).

A distinctive aspect of CCG is that it provides a very flexible notion of constituency. This supports elegant analyses of several phenomena (e.g., coordination, long-distance extraction, and intonation) and allows incremental parsing with the competence grammar (Steedman, 2000). Here, we argue

that even with its flexibility, CCG as standardly defined is not permissive enough for certain linguistic constructions and greater incrementality. Following Wittenburg (1987), we remedy this by adding a set of rules based on the **D** combinator of combinatory logic (Curry and Feys, 1958).

$$(1) \quad x/(y/z):f \quad y/w:g \Rightarrow x/(w/z):\lambda h.f(\lambda x.g h x)$$

We show that CCG augmented with this rule improves CCG’s empirical coverage by allowing better analyses of modal verbs in English and causatives in Spanish, and certain coordinate constructions.

The **D** rules are well-behaved; we show this by deriving them both from unary composition and from the logic defined by Baldridge (2002). Both perspectives on **D** ensure that the new rules are compatible with normal form constraints (Eisner, 1996) for controlling spurious ambiguity. The logic also ensures that the new rules are subject to modalities consistent with those defined by Baldridge and Kruijff (2003). Furthermore, we define a logic that produces Eisner’s constraints as grammar internal theorems rather than parsing stipulations.

## 2 Combinatory Categorical Grammar

CCG uses a universal set of syntactic rules based on the **B**, **T**, and **S** combinators of combinatory logic (Curry and Feys, 1958):

$$(2) \quad \mathbf{B}: ((\mathbf{B}f)g)x = f(gx)$$

$$\mathbf{T}: \mathbf{T}x f = f x$$

$$\mathbf{S}: ((\mathbf{S}f)g)x = f x(gx)$$

CCG functors are functions over strings of symbols, so different linearized versions of each of the combinators have to be specified (ignoring **S** here):

- (3) **FA:** ( $>$ )  $x/_*y \ y \Rightarrow x$   
 ( $<$ )  $y \ x\_*y \Rightarrow x$
- B:** ( $>\mathbf{B}$ )  $x/_\diamond y \ y/_\diamond z \Rightarrow x/_\diamond z$   
 ( $<\mathbf{B}$ )  $y\_ \diamond z \ x\_ \diamond y \Rightarrow x\_ \diamond z$   
 ( $>\mathbf{B}_\times$ )  $x/_\times y \ y\_ \times z \Rightarrow x\_ \times z$   
 ( $<\mathbf{B}_\times$ )  $y\_ \times z \ x\_ \times y \Rightarrow x\_ \times z$
- T:** ( $>\mathbf{T}$ )  $x \Rightarrow t/_i(t\_i x)$   
 ( $<\mathbf{T}$ )  $x \Rightarrow t\_i(t/_i x)$

The symbols  $\{*, \diamond, \times, \cdot\}$  are modalities that allow subtypes of slashes to be defined; this in turn allows the slashes on categories to be defined in a way that allows them to be used (or not) with specific subsets of the above rules. The rules of this multimodal version of CCG (Baldrige, 2002; Baldrige and Kruijff, 2003) are derived as theorems of a Categorical Type Logic (CTL, Moortgat (1997)).

This treats CCG as a compilation of CTL proofs, providing a principled, grammar-internal basis for restrictions on the CCG rules, transferring language-particular restrictions on rule application to the lexicon, and allowing the CCG rules to be viewed as grammatical universals (Baldrige and Kruijff, 2003; Steedman and Baldrige, To Appear).

These rules—especially the **B** rules—allow derivations to be *partially* associative: given appropriate type assignments, a string ABC can be analyzed as either A(BC) or (AB)C. This associativity leads to elegant analyses of phenomena that demand more effort in less flexible frameworks. One of the best known is “odd constituent” coordination:

- (4) Bob gave **Stan a beer** and **Max a coke**.  
 (5) **I will buy** and **you will eat** a cheeseburger.

The coordinated constituents are challenging because they are at odds with standardly assumed phrase structure constituents. In CCG, such constituents simply follow from the associativity added by the **B** and **T** rules. For example, given the category assignments in (6) and the abbreviations in (7), (4) is analyzed as in (8) and (9). Each conjunct is a pair of type-raised NPs combined by means of the  $>\mathbf{B}$ -rule, deriving two composed constituents that are arguments to the conjunction:<sup>1</sup>

- (6) i. **Bob**  $\vdash s/(s\_np)$

<sup>1</sup>We follow (Steedman, 2000) in assuming that type-raising applies in the lexicon, and therefore that nominals such as *Stan*

- ii. **Stan, Max**  $\vdash$   
 $((s\_np)/np)\(((s\_np)/np)/np)$
- iii. **a beer, a coke**  $\vdash (s\_np)\((s\_np)/np)$
- iv. **and**  $\vdash (x\_x)/_x x$
- v. **gave**  $\vdash ((s\_np)/np)/np$
- (7) i.  $vp = s\_np$   
 ii.  $tv = (s\_np)/np$   
 iii.  $dtv = ((s\_np)/np)/np$

(8) **Stan a beer and Max a coke**

$$\frac{\frac{tv\_dt \quad vp\_tv}{vp\_dt} \leftarrow \mathbf{B} \quad \frac{(x\_x)/_x x \quad tv\_dt \quad vp\_tv}{vp\_dt} \leftarrow \mathbf{B}}{\frac{(vp\_dt)\(vp\_dt)}{vp\_dt} \rightarrow}$$

(9) **Bill gave Stan a beer and Max a coke**

$$\frac{\frac{s\_vp \quad dt \quad vp\_dt}{vp} \leftarrow \quad \frac{vp\_dt}{s} \rightarrow}{s}$$

Similarly, *I will buy* is derived with category  $s\_np$  by assuming the category (6i) for *I* and composing that with both verbs in turn.

CCG’s approach is appealing because such constituents are not odd at all: they simply follow from the fact that CCG is a system of type-based grammatical inference that allows left associativity.

### 3 Linguistic Motivation for D

CCG is only *partially* associative. Here, we discuss several situations which require greater associativity and thus cannot be given an adequate analysis with CCG as standardly defined. These structures have in common that a category of the form  $x|(y|z)$  must combine with one of the form  $y|w$ —exactly the configuration handled by the **D** schemata in (1).

#### 3.1 Cross-Conjunct Extraction

In the first situation, a question word is distributed across auxiliary or subordinating verb categories:

- (10) ... **what you can** and **what you must not** base your verdict on.

We call this *cross-conjunct extraction*. It was noted by Pickering and Barry (1993) for English, but to the best of our knowledge it has not been treated in the

have type-raised lexical assignments. We also suppress semantic representations in the derivations for the sake of space.

CCG literature, nor noted in other languages. The problem it presents to CCG is clear in (11), which shows the necessary derivation of (10) using standard multimodal category assignments. For the tokens of *what* to form constituents with *you can* and *you must not*, they must combine directly. The problem is that these constituents (in bold) cannot be created with the standard CCG combinators in (3).

The category for *and* is marked for non-associativity with  $*$ , and thus combines with other expressions only by function application (Baldrige, 2002). This ensures that each conjunct is a discrete constituent.

Cross-conjunct extraction occurs in other languages as well, including Dutch (12), German (13), Romanian (14), and Spanish (15):

- (12) *dat ik haar wil en dat ik haar moet helpen.*  
that I her want and that I her can help  
“... that I want to and that I can help her.”
- (13) *Wen kann ich und wen darf ich noch wählen?*  
who can I and who may I still choose  
“Whom can I and whom may I still chose?”
- (14) *Gandeste-te cui ce vrei,*  
consider.imper.2s-refl.2s who.dat what want.2s  
*și cui ce poți, să dai.*  
and who.dat what can.2s to give.subj.2s  
“Consider to whom you want and to whom you are able to give what.”
- (15) *Me lo puedes y me lo debes explicar*  
me it can.2s and me it must.2s ask  
“You can and should explain it to me.”

It is thus a general phenomenon, not just a quirk of English. While it could be handled with extra categories, such as  $(s/(vp/np))/(s/np)$  for *what*, this is exactly the sort of strong-arm tactic that inclusion of the standard **B**, **T**, and **S** rules is meant to avoid.

### 3.2 English Auxiliary Verbs

The standard CCG analysis for English auxiliary verbs is the type exemplified in (16) (Steedman, 2000, 68), interpreted as a unary operator over sentence meanings (Gamut, 1991; Kratzer, 1991):

$$(16) \text{ can} \vdash (s \backslash np) / (s \backslash np) : \lambda P_{et} \lambda x. \diamond P(x)$$

However, this type is empirically underdetermined, given a widely-noted set of generalizations suggesting that auxiliaries and raising verbs take no subject argument at all (Jacobson, 1990, a.o.).

- (17) i. Lack of syntactic restrictions on the subject;  
ii. Lack of semantic restrictions on the subject;  
iii. Inheritance of selectional restrictions from the subordinate predicate.

Two arguments are made for (16). First, it is necessary so that type-raised subjects can compose with the auxiliary in extraction contexts, as in (18):

$$(18) \begin{array}{cccc} \text{what} & \text{I} & \text{can} & \text{eat} \\ \hline s/(s/np) & s/vp & vp/vp & tv \\ \hline & & \xrightarrow{B} & \\ & & s/vp & \\ \hline & & & \xrightarrow{B} \\ & & & s/np \\ \hline & & & \xrightarrow{S} \\ & & & s \end{array}$$

Second, it is claimed to be necessary in order to account for subject-verb agreement, on the assumption that agreement features are domain restrictions on functors of type  $s \backslash np$  (Steedman, 1992, 1996).

The first argument is the topic of this paper, and, as we show below, is refuted by the use of the **D**-combinator. The second argument is undermined by examples like (19):

- (19) There **appear** to have been [ neither [ **any catastrophic consequences** ], nor [ **a drastic change** in the average age of retirement ] ] .

In (19), *appear* agrees with two negative-polarity-sensitive NPs trapped inside a *neither-nor* coordinate structure in which they are licensed. *Appear* therefore does not combine with them directly, showing that the agreement relation need not be mediated by direct application of a subject argument.

We conclude, therefore, that the assignment of the  $vp/vp$  type to English auxiliaries and modal verbs is unsupported on both formal and linguistic grounds.

Following Jacobson (1990), a more empirically-motivated assignment is (20):

(20)  $\text{can} \vdash s/s : \lambda p_t. \diamond p$

Combining (20) with a type-raised subject presents another instance of the structure in (1), where that question words are represented as variable-binding operators (Groenendijk and Stokhof, 1997):

(21) 
$$\frac{\text{what} \quad \text{I} \quad \text{can}}{s/(s/np) : \lambda Q_{et} ?yQy \quad \frac{s/vp : \lambda P_{et}. P'i'}{***} \quad \frac{s/s : \lambda p_t. \diamond p}{***}}{>B ***}$$

### 3.3 The Spanish Causative Construction

The schema in (1) is also found in the widely-studied Romance causative construction (Andrews and Manning, 1999, a.m.o), illustrated in (22):

(22) *Nos hizo leer El Señor de los Anillos.*  
cl.1p made.3s read the Lord of the Rings  
“He made us read *The Lord of the Rings*.”

The aspect of the construction that is relevant here is that the causative verb *hacer* appears to take an object argument understood as the subject or agent of the subordinate verb (the *causee*). However, it has been argued that Spanish causative verbs do not in fact take objects (Ackerman and Moore, 1999, and refs therein). There are two arguments for this.

First, syntactic alternations that apply to object-taking verbs, such as passivization and periphrasis with subjunctive complements, do not apply to *hacer* (Luján, 1980). Second, *hacer* specifies neither the case form of the *causee*, nor any semantic entailments with respect to it. These are instead determined by syntactic, semantic, and pragmatic factors, such as transitivity, word order, animacy, gender, social prestige, and referential specificity (Finnemann, 1982, a.o). Thus, there is neither syntactic nor semantic evidence that *hacer* takes an object argument.

On this basis, we assign *hacer* the category (23):

(23)  $\text{hacer} \vdash (s \setminus np)/s : \lambda P \lambda x. \text{cause}' P x$

However, Spanish has examples of cross-conjunct extraction in which *hacer* hosts clitics:

(24) *No solo le ordenaron, sino que*  
not only cl.dat.3ms ordered.3p but  
*le hicieron barrer la verada.*  
cl.dat.3ms made.3p sweep the sidewalk  
“They not only ordered him to, but also made him sweep the sidewalk.”

This shows another instance of the schema in (1), which is undefined for any of the combinators in (3):

(25) 
$$\frac{\text{le} \quad \text{hicieron} \quad \text{barrer la verada}}{\frac{(s \setminus np)/((s \setminus np)/np) \quad (s \setminus np)/s}{***} \quad (s \setminus np)}{>B ***}$$

### 3.4 Analyses Based on D

The preceding data motivates adding **D** rules (we return to the distribution of the modalities below):

(26) 
$$\begin{aligned} >D & \quad x/o(y/o/z) \quad y/o/w \Rightarrow x/o(w/o/z) \\ >D_x & \quad x/x(y/x/z) \quad y \setminus_x w \Rightarrow x \setminus_x (w/x/z) \\ >D_{ox} & \quad x/o(y \setminus_x z) \quad y/w \Rightarrow x/o(w \setminus_x z) \\ >D_{xo} & \quad x/x(y \setminus_o z) \quad y \setminus_w \Rightarrow x \setminus_x (w \setminus_o z) \end{aligned}$$

(27) 
$$\begin{aligned} <D & \quad y \setminus_o w \quad x \setminus_o (y \setminus_o z) \Rightarrow x \setminus_o (w \setminus_o z) \\ <D_x & \quad y/xw \quad x \setminus_x (y \setminus_x z) \Rightarrow x \setminus_x (w \setminus_x z) \\ <D_{ox} & \quad y \setminus_w \quad x \setminus_o (y/xz) \Rightarrow x \setminus_o (w/xz) \\ <D_{xo} & \quad y/w \quad x \setminus_x (y/o/z) \Rightarrow x \setminus_x (w/o/z) \end{aligned}$$

To illustrate with example (10), one application of  $>D$  allows *you* and *can* to combine when the auxiliary is given the principled type assignment  $s/s$ , and another combines *what* with the result.

(28) 
$$\frac{\text{what} \quad \text{you} \quad \text{can}}{\frac{s/o(s/np) \quad \frac{s/o(s \setminus_x np) \quad s/s}{>D_{ox}}}{s/o(s \setminus_x np)}}{s/o((s \setminus_x np)/np)}{>D}$$

The derivation then proceeds in the usual way.

Likewise, **D** handles the Spanish causative constructions (29) straightforwardly :

(29) 
$$\frac{\text{lo} \quad \text{hice} \quad \text{dormir}}{\frac{(s \setminus np)/o((s \setminus np)/o np) \quad (s \setminus np)/o s \quad s/np}{>D}}{s \setminus np}$$

The **D**-rules thus provide straightforward analyses of such constructions by delivering flexible constituency while maintaining CCG’s commitment to low categorial ambiguity and semantic transparency.

## 4 Deriving Eisner Normal Form

Adding new rules can have implications for parsing efficiency. In this section, we show that the **D** rules fit naturally within standard normal form constraints for CCG parsing (Eisner, 1996), by providing both

combinatory and logical bases for **D**. This additionally allows Eisner’s normal form constraints to be derived as grammar internal theorems.

#### 4.1 The Spurious Ambiguity Problem

CCG’s flexibility is useful for linguistic analyses, but leads to *spurious ambiguity* (Wittenburg, 1987) due to the associativity introduced by the **B** and **T** rules. This can incur a high computational cost which parsers must deal with. Several techniques have been proposed for the problem (Wittenburg, 1987; Karttunen, 1989; Hepple and Morrill, 1989; Eisner, 1996). The most commonly used are Karttunen’s chart subsumption check (White and Baldrige, 2003; Hockenmaier and Steedman, 2002) and Eisner’s normal-form constraints (Bozsahin, 1998; Clark and Curran, 2007).

Eisner’s normal form, referred to here as *Eisner NF* and paraphrased in (30), has the advantage of not requiring comparisons of logical forms: it functions purely on the syntactic types being combined.

- (30) For a set  $S$  of semantically equivalent<sup>2</sup> parse trees for a string  $ABC$ , admit the unique parse tree such that at least one of (i) or (ii) holds:
- i.  $C$  is not the argument of  $(AB)$  resulting from application of  $>\mathbf{B}^{1+}$ .
  - ii.  $A$  is not the argument of  $(BC)$  resulting from application of  $<\mathbf{B}^{1+}$ .

The implication is that outputs of  $\mathbf{B}^{1+}$  rules are *inert*, using the terminology of Baldrige (2002). Inert slashes are Baldrige’s (2002) encoding in OpenCCG<sup>3</sup> of his CTL interpretation of Steedman’s (2000) *antecedent-government* feature.

Eisner derives (30) from two theorems about the set of semantically equivalent parses that a CCG parser will generate for a given string (see (Eisner, 1996) for proofs and discussion of the theorems):

- (31) *Theorem 1*: For every parse tree  $\alpha$ , there is a semantically equivalent parse-tree  $NF(\alpha)$  in which no node resulting from application of **B** or **S** functions as the primary functor in a rule application.
- (32) *Theorem 2*: If  $NF(\alpha)$  and  $NF(\alpha')$  are distinct parse trees, then their model-theoretic interpretations are distinct.

<sup>2</sup>Two parse trees are semantically equivalent if: (i) their leaf nodes have equivalent interpretations, and (ii) equivalent scope relations hold between their respective leaf-node meanings.

<sup>3</sup><http://openccg.sourceforge.net>

Eisner uses a generalized form  $\mathbf{B}^n$  ( $n \geq 0$ ) of composition that subsumes function application.<sup>4</sup>

$$(33) \quad >\mathbf{B}^n: x/y \quad y\$^n \Rightarrow x\$^n$$

$$(34) \quad <\mathbf{B}^n: y\$^n \quad x \backslash y \Rightarrow x\$^n$$

Based on these theorems, Eisner defines NF as follows (for  $R, S, T$  as  $\mathbf{B}^n$  or **S**, and  $Q = \mathbf{B}^{n \geq 1}$ ):

- (35) Given a parse tree  $\alpha$ :
- i. If  $\alpha$  is a lexical item, then  $\alpha$  is in Eisner-NF.
  - ii. If  $\alpha$  is a parse tree  $\langle R, \beta, \gamma \rangle$  and  $NF(\beta)$ ,  $NF(\gamma)$ , then  $NF(\alpha)$ .
  - iii. If  $\beta$  is not in Eisner-NF, then  $NF(\beta) = \langle Q, \beta_1, \beta_2 \rangle$ , and  $NF(\alpha) = \langle S, \beta_1, NF(\langle T, \beta_2, \gamma \rangle) \rangle$ .

As a parsing constraint, (30) is a filter on the set of parses produced for a given string. It preserves all the unique semantic forms generated for the string while eliminating all spurious ambiguities: it is both *safe* and *complete*.

Given the utility of Eisner NF for practical CCG parsing, the **D** rules we propose should be compatible with (30). This requires that the generalizations underlying (30) apply to **D** as well. In the remainder of this section, we show this in two ways.

#### 4.2 Deriving D from B

The first is to derive the binary **B** rules from a unary rule based on the unary combinator  $\hat{\mathbf{B}}$ :<sup>5</sup>

$$(36) \quad x/y : f_{xy} \Rightarrow (x/z)/(y/z) : \lambda h_{zy} \lambda x_z. f(hx)$$

We then derive **D** from  $\hat{\mathbf{B}}$  and show that clause (iii) of (35) holds of  $Q$  schematized over both **B** and **D**.

Applying **D** to an argument sequence is equivalent to compound application of binary **B**:

$$(37) \quad (((\mathbf{D}f)g)h)x = (fg)(hx)$$

$$(38) \quad (((\mathbf{B}\mathbf{B})f)g)h)x = ((\mathbf{B}(fg))h)x = (fg)(hx)$$

Syntactically, binary **B** is equivalent to application of unary  $\hat{\mathbf{B}}$  to the primary functor  $\Delta$ , followed by applying the secondary functor  $\Gamma$  to the output of  $\hat{\mathbf{B}}$  by means of function application (Jacobson, 1999):

<sup>4</sup>We use Steedman’s (Steedman, 1996) “\$”-convention for representing argument stacks of length  $n$ , for  $n \geq 0$ .

<sup>5</sup>This is Lambek’s (1958) *Division* rule, also known as the “*Geach* rule” (Jacobson, 1999).

$$(39) \quad \frac{\frac{\Delta}{x/y} \quad \frac{\Gamma}{y/z}}{\frac{(x/z)/(y/z)}{x/z} \hat{\mathbf{B}}} \hat{\mathbf{B}}$$

$\mathbf{B}^n$  ( $n \geq 1$ ) is derived by applying  $\hat{\mathbf{B}}$  to the primary functor  $n$  times. For example,  $\mathbf{B}^2$  is derived by 2 applications of  $\hat{\mathbf{B}}$  to the primary functor:

$$(40) \quad \frac{\frac{\frac{\Delta}{x/y} \quad \frac{\Gamma}{(y/w)/z}}{(x/w)/(y/w)} \hat{\mathbf{B}}}{\frac{((x/w)/z)/((y/w)/z)}{(x/w)/z} \hat{\mathbf{B}}} \hat{\mathbf{B}}$$

The rules for  $\mathbf{D}$  correspond to application of  $\hat{\mathbf{B}}$  to *both* the primary and secondary functors, followed by function application:

$$(41) \quad \frac{\frac{\Delta}{x/(y/z)} \quad \frac{\Gamma}{y/w}}{\frac{(x/(w/z))/((y/z)/(w/z))}{x/(w/z)} \hat{\mathbf{B}}} \hat{\mathbf{B}}$$

As with  $\mathbf{B}^n$ ,  $\mathbf{D}^{n \geq 1}$  can be derived by iterative application of  $\hat{\mathbf{B}}$  to both primary and secondary functors.

Because  $\mathbf{B}$  can be derived from  $\hat{\mathbf{B}}$ , clause (iii) of (35) is equivalent to the following:

$$(42) \quad \text{If } \beta \text{ is not in Eisner-NF, then} \\ NF(\beta) = \langle FA, \langle \hat{\mathbf{B}}, \beta_1 \rangle, \beta_2 \rangle, \text{ such that} \\ NF(\alpha) = \langle S, \beta_1, NF(\langle T, \beta_2, \gamma \rangle) \rangle$$

Interpreted in terms of  $\hat{\mathbf{B}}$ , both  $\mathbf{B}$  and  $\mathbf{D}$  involve application of  $\hat{\mathbf{B}}$  to the primary functor. It follows that Theorem I applies directly to  $\mathbf{D}$  simply by virtue of the equivalence between binary  $\mathbf{B}$  and unary- $\hat{\mathbf{B}}$ +FA.

Eisner's NF constraints can then be reinterpreted as a constraint on  $\hat{\mathbf{B}}$  requiring its output to be an inert result category. We represent this in terms of the  $\hat{\mathbf{B}}$ -rules introducing an inert slash, indicated with “!” (adopting the convention from OpenCCG):

$$(43) \quad x/y : f_{xy} \Rightarrow (x/!z)/(y/!z) : \lambda h_{zy} \lambda x_z f h x$$

Hence, both binary  $\mathbf{B}$  and  $\mathbf{D}$  return inert functors:

$$(44) \quad \frac{\frac{\Delta}{x/y} \quad \frac{\Gamma}{y/z}}{\frac{(x/!z)/(y/!z)}{x/!z} \hat{\mathbf{B}}} \hat{\mathbf{B}}$$

$$(45) \quad \frac{\frac{\Delta}{x/(y/z)} \quad \frac{\Gamma}{y/w}}{\frac{(x/!(w/z))/((y/z)/!(w/z))}{x/!(w/z)} \hat{\mathbf{B}}} \hat{\mathbf{B}}$$

The binary substitution ( $\mathbf{S}$ ) combinator can be similarly incorporated into the system. Unary substitution  $\hat{\mathbf{S}}$  is like  $\hat{\mathbf{B}}$  except that it introduces a slash on only the argument-side of the input functor. We stipulate that  $\hat{\mathbf{S}}$  returns a category with inert slashes:

$$(46) \quad (\hat{\mathbf{S}}) \quad (x/y)/z \Rightarrow (x/!z)/(y/!z)$$

$\mathbf{T}$  is by definition unary. It follows that all the binary rules in CCG (including the  $\mathbf{D}$ -rules) can be reduced to (iterated) instantiations of the unary combinators  $\hat{\mathbf{B}}$ ,  $\hat{\mathbf{S}}$ , or  $\mathbf{T}$  plus function application.

This provides a basis for CCG in which all combinatory rules are derived from unary  $\hat{\mathbf{B}}$ ,  $\hat{\mathbf{S}}$ , and  $\mathbf{T}$ .

### 4.3 A Logical Basis for Eisner Normal Form

The previous section shows that deriving CCG rules from unary combinators allows us to derive the  $\mathbf{D}$ -rules while preserving Eisner NF. In this section, we present an alternate formulation of Eisner NF with Baldridge's (2002) CTL basis for CCG. This formulation allows us to derive the  $\mathbf{D}$ -rules as before, and does so in a way that seamlessly integrates with Baldridge's system of modalized functors.

In CTL,  $\mathbf{B}_\diamond$  and  $\mathbf{B}_\times$  are proofs derived via structural rules that allow associativity and permutation of symbols within a sequent, in combination with the slash introduction and elimination rules of the base logic. To control application of these rules, Baldridge keys them to binary modal operators  $\diamond$  (for associativity) and  $\times$  (for permutation). Given these,  $\mathbf{B}$  is proven in (47):

$$(47) \quad \frac{\frac{\Delta \vdash x/\diamond y \quad \Gamma \vdash y/\diamond z \quad [a \vdash z]}{(\Gamma \circ_\diamond a_i) \vdash y} [\diamond E]}{(\Delta \circ_\diamond (\Gamma \circ_\diamond a_i)) \vdash x} [\diamond E]}{((\Delta \circ_\diamond \Gamma) \circ_\diamond a_i) \vdash x} [RA]}{(\Delta \circ_\diamond \Gamma) \vdash x/\diamond z} [\diamond I]$$

In a CCG ruleset compiled from such logics, a category must have an appropriately decorated slash in order to be the input to a rule. This means that rules apply universally, without language-specific

restrictions. Instead, restrictions can only be declared via modalities marked on lexical categories.

Unary  $\hat{\mathbf{B}}$  and the  $\mathbf{D}$  rules in 4.2 can be derived using the same logic. For example,  $>\hat{\mathbf{B}}$  can be derived as in (48):

$$(48) \quad \frac{\frac{\frac{\frac{\frac{\Delta \vdash x/y \quad [f \vdash y/z]^1 \quad [a \vdash z]^2}{(f_1 \circ_\circ a_2) \vdash y} [/E]}{(\Delta \circ_\circ (f_1 \circ_\circ a_2)) \vdash x} [/E]}{((\Delta \circ_\circ f_1) \circ_\circ a_2) \vdash x} [RA]}{(\Delta \circ_\circ f_1) \vdash x/z} [/I]}{\Delta \vdash (x/z)/\circ(y/z)} [/I]$$

The  $\mathbf{D}$  rules are also theorems of this system. For example, the proof for  $>\mathbf{D}$  applies (48) as a lemma to each of the primary and secondary functors:

$$(49) \quad \frac{\frac{\Delta \vdash x/\circ(y/z) \quad \Gamma \vdash y/w}{\Delta \vdash (x/\circ(w/z))/\circ((y/z)/\circ(w/z))} >\hat{\mathbf{B}} \quad \frac{\Gamma \vdash y/w}{\Gamma \vdash (y/z)/\circ(w/z)} >\hat{\mathbf{B}}}{(\Delta \circ_\circ \Gamma) \vdash x/\circ(w/z)} [\hat{\mathbf{D}}]$$

$>\mathbf{D}_{\circ_\times}$  involves an associative version of  $\hat{\mathbf{B}}$  applied to the primary functor (50), and a permutative version to the secondary functor (51).

$$(50) \quad \frac{\frac{\frac{\frac{\Delta \vdash x/\circ(y \setminus_\times z) \quad [f \vdash (y \setminus_\times z)]^1 \quad [g \vdash w \setminus_\times z]^2}{(f_1 \circ_\circ g_2) \vdash y \setminus_\times z} [/E]}{(\Delta \circ_\circ (f_1 \circ_\circ g_2)) \vdash x} [/E]}{((\Delta \circ_\circ f_1) \circ_\circ g_2) \vdash x} [RA]}{(\Delta \circ_\circ f_1) \vdash x/(w \setminus_\times z)} [/I]}{\Delta \vdash (x/(w \setminus_\times z))/\circ((y \setminus_\times z)/(w \setminus_\times z))} [/I]$$

$$(51) \quad \frac{\frac{\frac{\frac{\Gamma \vdash y/w \quad [a \vdash z]^1 \quad [f \vdash w \setminus_\times z]^2}{(a_1 \circ_\times f_2) \vdash w} [\setminus_\times E]}{(\Gamma \circ_\circ (a_1 \circ_\times f_2)) \vdash y} [LP]}{(a_1 \circ_\times (\Gamma \circ_\circ f_2)) \vdash y} [\setminus_\times I]}{(\Gamma \circ_\circ f_2) \vdash y \setminus_\times z} [/I]}{\Gamma \vdash (y \setminus_\times z)/(w \setminus_\times z)} [/I]$$

Rules for  $\mathbf{D}$  with appropriate modalities can therefore be incorporated seamlessly into CCG.

In the preceding subsection, we encoded Eisner NF with inert slashes. In Baldridge’s CTL basis for CCG, inert slashes are represented as functors seeking non-lexical arguments, represented as categories marked with an *antecedent-governed* feature,

reflecting the intuition that non-lexical arguments have to be “bound” by a superordinate functor.

This is based on an interpretation of antecedent-government as a unary modality  $\diamond_{ant}$  that allows structures marked by it to permute to the left or right periphery of a structure:<sup>6</sup>

$$(52) \quad \frac{((\Delta_a \circ_\times \diamond_{ant} \Delta_b) \circ_\times \Delta_c) \vdash x}{((\Delta_a \circ_\times \Delta_c) \circ_\times \diamond_{ant} \Delta_b) \vdash x} \quad [ARP]}{(\Delta_a \circ_\times (\diamond_{ant} \Delta_b \circ_\times \Delta_c)) \vdash x} \quad [ALP]}{(\diamond_{ant} \Delta_b \circ_\times (\Delta_a \circ_\times \Delta_c)) \vdash x}$$

Unlike permutation rules without  $\diamond_{ant}$ , these permutation rules can only be used in a proof when preceded by a hypothetical category marked with the  $\square_{ant}^\downarrow$  modality. The elimination rule for  $\square_{ant}^\downarrow$ -modalities introduces a corresponding  $\diamond$ -marked object in the resulting structure, feeding the rule:

$$(53) \quad \frac{\frac{\frac{\frac{[a \vdash \square_{ant}^\downarrow z]^1}{\diamond_{ant} a_1 \vdash z} [\square_{ant}^\downarrow E]}{\Delta \vdash x/y \quad (\diamond_{ant} a_1 \circ_\times \Gamma) \vdash y} [\setminus_\times E]}{(\Delta \circ_\times (\diamond_{ant} a_1 \circ_\times \Gamma)) \vdash x} [ALP]}{(\diamond_{ant} a_1 \circ_\times (\Delta \circ_\times \Gamma)) \vdash x} [ALP]}{(\Delta \circ_\times \Gamma) \vdash x \setminus_\times \diamond_{ant} \square_{ant}^\downarrow z} [\diamond E]}{(\Delta \circ_\times \Gamma) \vdash x \setminus_\times \diamond_{ant} \square_{ant}^\downarrow z} [\setminus_\times I]^2$$

Re-introduction of the  $[a \vdash \diamond_{ant} \square_{ant}^\downarrow z]^k$  hypothesis results in a functor the argument of which is marked with  $\diamond_{ant} \square_{ant}^\downarrow$ . Because lexical categories are not marked as such, the functor cannot take a lexical argument, and so is effectively an inert functor.

In Baldridge’s (2002) system, only proofs involving the ARP and ALP rules produce inert categories. In Eisner NF, all instances of  $\mathbf{B}$ -rules result in inert categories. This can be reproduced in Baldridge’s system simply by keying *all* structural rules to the *ant*-modality, the result being that all proofs involving structural rules result in inert functors.

As desired, the  $\mathbf{D}$ -rules result in inert categories as well. For example,  $>\mathbf{D}$  is derived as follows ( $\square_{ant}^\downarrow$  and  $\diamond_{ant}$  are abbreviated as  $\square^\downarrow$  and  $\diamond$ ):

<sup>6</sup>Note that the diamond operator used here is a syntactic operator, rather than a semantic operator as used in (16) above. The unary modalities used in CTL describe accessibility relationships between subtypes and supertypes of particular categories: in effect, they define feature hierarchies. See Moortgat (1997) and Oehrle (To Appear) for further explanation.

$$(54) \quad \frac{\frac{\Gamma \vdash y/\diamond w \quad \frac{[a \vdash \square^\downarrow(w/\diamond z)]^1}{\diamond a \vdash w/\diamond z} [\square^\downarrow E] \quad \frac{[b \vdash \square^\downarrow z]^2}{\diamond b \vdash z} [\square^\downarrow E]}{\diamond a \circ_\diamond \diamond b \vdash w} [\circ E]}{\frac{\Gamma \circ_\diamond (\diamond a \circ_\diamond \diamond b) \vdash y} [RA]}{((\Gamma \circ_\diamond \diamond a) \circ_\diamond \diamond b) \vdash y} [\circ E]} \frac{[c \vdash \diamond \square^\downarrow z]^3}{((\Gamma \circ_\diamond \diamond a) \circ_\diamond c) \vdash y} [\circ E]^2} {(\Gamma \circ_\diamond \diamond a) \vdash y/\diamond \diamond \square^\downarrow z} [\circ I]^3$$

$$(55) \quad \frac{\frac{\Delta \vdash x/\diamond (y/\diamond \diamond \square^\downarrow z) \quad \frac{\Gamma \circ_\diamond \diamond a \vdash y/\diamond \diamond \square^\downarrow z}{(\Delta \circ_\diamond (\Gamma \circ_\diamond \diamond a)) \vdash x} [RA]}{((\Delta \circ_\diamond \Gamma) \circ_\diamond \diamond a) \vdash x} [\circ E]^1}{((\Delta \circ_\diamond \Gamma) \circ_\diamond d) \vdash x} [\circ E]^1} {(\Delta \circ_\diamond \Gamma) \vdash x/\diamond \diamond \square^\downarrow (w/\diamond z)} [\circ I]^4$$

(54)-(55) can be used as a lemma corresponding to the CCG rule in (57):

$$(56) \quad \frac{\Delta \vdash x/\diamond (y/\diamond \diamond \square^\downarrow z) \quad \Gamma \vdash y/\diamond w}{(\Delta \circ_\diamond \Gamma) \vdash x/\diamond \diamond \square^\downarrow (w/\diamond z)} [D]$$

$$(57) \quad x/\diamond (y/\diamond^\downarrow z) \quad y/\diamond w \Rightarrow x/\diamond^\downarrow (w/\diamond z)$$

This means that all CCG rules compiled from the logic—which requires  $\diamond_{ant}$  to licence the structural rules necessary to prove the rules—return inert functors. Eisner NF thus falls out of the logic because all instances of **B**, **D**, and **S** produce inert categories. This in turns allows us to view Eisner NF as part of a theory of grammatical competence, in addition to being a useful technique for constraining parsing.

## 5 Conclusion

Including the **D**-combinator rules in the CCG rule set lets us capture several linguistic generalizations that lack satisfactory analyses in standard CCG. Furthermore, CCG augmented with **D** is compatible with Eisner NF (Eisner, 1996), a standard technique for controlling derivational ambiguity in CCG-parsers, and also with the modalized version of CCG (Baldrige and Kruijff, 2003). A consequence is that both the **D** rules and the NF constraints can be derived from a grammar-internal perspective. This extends CCG’s linguistic applicability without sacrificing efficiency.

Wittenburg (1987) originally proposed using rules based on **D** as a way to reduce spurious ambiguity, which he achieved by eliminating **B** rules entirely and replacing them with variations on **D**. Wittenburg notes that doing so produces as many instances of **D** as there are rules in the standard rule set. Our proposal retains **B** and **S**, but, thanks to Eisner NF, eliminates spurious ambiguity, a result that Wittenburg was not able to realize at the time.

Our approach can be incorporated into Eisner NF straightforwardly. However, Eisner NF disprefers incremental analyses by forcing right-corner analyses of long-distance dependencies, such as in (58):

$$(58) \quad (\text{What (does (Grommet (think (Tottie (said (Victor (knows (Wallace ate))))))))))?)$$

For applications that call for increased incrementality (e.g., aligning visual and spoken input incrementally (Kruijff et al., 2007)), CCG rules that do not produce inert categories can be derived a CTL basis that does not require  $\diamond_{ant}$  for associativity and permutation. The **D**-rules derived from this kind of CTL specification would allow for left-corner analyses of such dependencies with the competence grammar. An extracted element can “wrap around” the words intervening between it and its extraction site. For example, **D** would allow the following bracketing for the same example (while producing the same logical form):

$$(59) \quad ((((((((((\text{What does}) \text{Grommet}) \text{think}) \text{Tottie}) \text{said}) \text{Victor}) \text{knows}) \text{Wallace}) \text{ate})))))?)$$

Finally, the unary combinator basis for CCG provides an interesting additional specification for generating CCG rules. Like the CTL basis, the unary combinator basis can produce a much wider range of possible rules, such as **D** rules, that may be relevant for linguistic applications. Whichever basis is used, inclusion of the **D**-rules increases empirical coverage, while at the same time preserving CCG’s computational attractiveness.

## Acknowledgments

Thanks Mark Steedman for extensive comments and suggestions, and particularly for noting the relationship between the **D**-rules and unary  $\hat{\mathbf{B}}$ . Thanks also to Emmon Bach, Cem Bozsahin, Jason Eisner, Geert-Jan Kruijff and the ACL reviewers.

# Parsing Noun Phrase Structure with CCG

David Vadas and James R. Curran

School of Information Technologies

University of Sydney

NSW 2006, Australia

{dvadas1, james}@it.usyd.edu.au

## Abstract

Statistical parsing of noun phrase (NP) structure has been hampered by a lack of gold-standard data. This is a significant problem for CCGbank, where binary branching NP derivations are often incorrect, a result of the automatic conversion from the Penn Treebank.

We correct these errors in CCGbank using a gold-standard corpus of NP structure, resulting in a much more accurate corpus. We also implement novel NER features that generalise the lexical information needed to parse NPs and provide important semantic information. Finally, evaluating against DepBank demonstrates the effectiveness of our modified corpus and novel features, with an increase in parser performance of 1.51%.

## 1 Introduction

Internal noun phrase (NP) structure is not recovered by a number of widely-used parsers, e.g. Collins (2003). This is because their training data, the Penn Treebank (Marcus et al., 1993), does not fully annotate NP structure. The flat structure described by the Penn Treebank can be seen in this example:

```
(NP (NN lung) (NN cancer) (NNS deaths))
```

CCGbank (Hockenmaier and Steedman, 2007) is the primary English corpus for Combinatory Categorical Grammar (CCG) (Steedman, 2000) and was created by a semi-automatic conversion from the Penn Treebank. However, CCG is a binary branching grammar, and as such, cannot leave NP structure underspecified. Instead, *all* NPs were made right-branching, as shown in this example:

```
(N  
  (N/N lung)  
  (N  
    (N/N cancer) (N deaths) ) )
```

This structure is correct for most English NPs and is the best solution that doesn't require manual re-annotation. However, the resulting derivations often contain errors. This can be seen in the previous example, where *lung cancer* should form a constituent, but does not.

The first contribution of this paper is to correct these CCGbank errors. We apply an automatic conversion process using the gold-standard NP data annotated by Vadas and Curran (2007a). Over a quarter of the sentences in CCGbank need to be altered, demonstrating the magnitude of the NP problem and how important it is that these errors are fixed.

We then run a number of parsing experiments using our new version of the CCGbank corpus. In particular, we implement new features using NER tags from the BBN Entity Type Corpus (Weischedel and Brunstein, 2005). These features are targeted at improving the recovery of NP structure, increasing parser performance by 0.64% F-score.

Finally, we evaluate against DepBank (King et al., 2003). This corpus annotates internal NP structure, and so is particularly relevant for the changes we have made to CCGbank. The CCG parser now recovers additional structure learnt from our NP corrected corpus, increasing performance by 0.92%. Applying the NER features results in a total increase of 1.51%.

This work allows parsers trained on CCGbank to model NP structure accurately, and then pass this crucial information on to downstream systems.

Figure 1: (a) Incorrect CCG derivation from Hockenmaier and Steedman (2007) (b) The correct derivation

## 2 Background

Parsing of NPs is typically framed as NP bracketing, where the task is limited to discriminating between left and right-branching NPs of three nouns only:

- *(crude oil) prices* – left-branching
- *world (oil prices)* – right-branching

Lauer (1995) presents two models to solve this problem: the adjacency model, which compares the association strength between words 1–2 to words 2–3; and the dependency model, which compares words 1–2 to words 1–3. Lauer (1995) experiments with a data set of 244 NPs, and finds that the dependency model is superior, achieving 80.7% accuracy.

Most NP bracketing research has used Lauer’s data set. Because it is a very small corpus, most approaches have been unsupervised, measuring association strength with counts from a separate large corpus. Nakov and Hearst (2005) use search engine hit counts and extend the query set with typographical markers. This results in 89.3% accuracy.

Recently, Vadas and Curran (2007a) annotated internal NP structure for the entire Penn Treebank, providing a large gold-standard corpus for NP bracketing. Vadas and Curran (2007b) carry out supervised experiments using this data set of 36,584 NPs, outperforming the Collins (2003) parser.

The Vadas and Curran (2007a) annotation scheme inserts NML and JJP brackets to describe the correct NP structure, as shown below:

```
(NP (NML (NN lung) (NN cancer) )
  (NNS deaths) )
```

We use these brackets to determine new gold-standard CCG derivations in Section 3.

### 2.1 Combinatory Categorical Grammar

Combinatory Categorical Grammar (CCG) (Steedman, 2000) is a type-driven, lexicalised theory of

grammar. Lexical categories (also called *supertags*) are made up of basic atoms such as *S* (Sentence) and *NP* (Noun Phrase), which can be combined to form complex categories. For example, a transitive verb such as *bought* (as in *IBM bought the company*) would have the category:  $(S \setminus NP) / NP$ . The slashes indicate the directionality of arguments, here two arguments are expected: an NP subject on the left; and an NP object on the right. Once these arguments are filled, a sentence is produced.

Categories are combined using combinatory rules such as forward and backward application:

$$X / Y \ Y \Rightarrow X \ (>) \quad (1)$$

$$Y \ X \setminus Y \Rightarrow X \ (<) \quad (2)$$

Other rules such as composition and type-raising are used to analyse some linguistic constructions, while retaining the canonical categories for each word. This is an advantage of CCG, allowing it to recover long-range dependencies without the need for post-processing, as is the case for many other parsers.

In Section 1, we described the incorrect NP structures in CCGbank, but a further problem that highlights the need to improve NP derivations is shown in Figure 1. When a conjunction occurs in an NP, a non-CCG rule is required in order to reach a parse:

$$conj \ N \Rightarrow N \quad (3)$$

This rule treats the conjunction in the same manner as a modifier, and results in the incorrect derivation shown in Figure 1(a). Our work creates the correct CCG derivation, shown in Figure 1(b), and removes the need for the grammar rule in (3).

Honnibal and Curran (2007) have also made changes to CCGbank, aimed at better differentiating between complements and adjuncts. PropBank (Palmer et al., 2005) is used as a gold-standard to inform these decisions, similar to the way that we use the Vadas and Curran (2007a) data.

Figure 2: (a) Original right-branching CCGbank (b) Left-branching (c) Left-branching with new supertags

## 2.2 CCG parsing

The C&C CCG parser (Clark and Curran, 2007b) is used to perform our experiments, and to evaluate the effect of the changes to CCGbank. The parser uses a two-stage system, first employing a supertagger (Bangalore and Joshi, 1999) to propose lexical categories for each word, and then applying the CKY chart parsing algorithm. A log-linear model is used to identify the most probable derivation, which makes it possible to add the novel features we describe in Section 4, unlike a PCFG.

The C&C parser is evaluated on predicate-argument dependencies derived from CCGbank. These dependencies are represented as 5-tuples:  $\langle h_f, f, s, h_a, l \rangle$ , where  $h_f$  is the head of the predicate;  $f$  is the supertag of  $h_f$ ;  $s$  describes which argument of  $f$  is being filled;  $h_a$  is the head of the argument; and  $l$  encodes whether the dependency is local or long-range. For example, the dependency encoding *company* as the object of *bought* (as in *IBM bought the company*) is represented by:

$$\langle \text{bought}, (S \setminus NP_1) / NP_2, 2, \text{company}, - \rangle \quad (4)$$

This is a local dependency, where *company* is filling the second argument slot, the object.

## 3 Conversion Process

This section describes the process of converting the Vadas and Curran (2007a) data to CCG derivations. The tokens dominated by NML and JJP brackets in the source data are formed into constituents in the corresponding CCGbank sentence. We generate the two forms of output that CCGbank contains: AUTO files, which represent the tree structure of each sentence; and PARG files, which list the word–word dependencies (Hockenmaier and Steedman, 2005).

We apply one preprocessing step on the Penn Treebank data, where if multiple tokens are enclosed by brackets, then a NML node is placed around those

tokens. For example, we would insert the NML bracket shown below:

```
(NP (DT a) (-LRB- -LRB-)
  (NML (RB very) (JJ negative) )
  (-RRB- -RRB-) (NN reaction) )
```

This simple heuristic captures NP structure not explicitly annotated by Vadas and Curran (2007a).

The conversion algorithm applies the following steps for each NML or JJP bracket:

1. Identify the CCGbank *lowest spanning node*, the lowest constituent that covers all of the words in the NML or JJP bracket;
2. flatten the lowest spanning node, to remove the right-branching structure;
3. insert new left-branching structure;
4. identify heads;
5. assign supertags;
6. generate new dependencies.

As an example, we will follow the conversion process for the NML bracket below:

```
(NP (NML (NN lung) (NN cancer) )
  (NNS deaths) )
```

The corresponding lowest spanning node, which incorrectly has *cancer deaths* as a constituent, is shown in Figure 2(a). To flatten the node, we recursively remove brackets that partially overlap the NML bracket. Nodes that don't overlap at all are left intact. This process results in a list of nodes (which may or may not be leaves), which in our example is [*lung, cancer, deaths*]. We then insert the correct left-branching structure, shown in Figure 2(b). At this stage, the supertags are still incomplete.

Heads are then assigned using heuristics adapted from Hockenmaier and Steedman (2007). Since we are applying these to CCGbank NP structures rather than the Penn Treebank, the POS tag based heuristics are sufficient to determine heads accurately.

Finally, we assign supertags to the new structure. We want to make the minimal number of changes to the entire sentence derivation, and so the supertag of the dominating node is fixed. Categories are then propagated recursively down the tree. For a node with category  $X$ , its head child is also given the category  $X$ . The non-head child is always treated as an adjunct, and given the category  $X/X$  or  $X\backslash X$  as appropriate. Figure 2(c) shows the final result of this step for our example.

### 3.1 Dependency generation

The changes described so far have generated the new tree structure, but the last step is to generate new dependencies. We recursively traverse the tree, at each level creating a dependency between the heads of the left and right children. These dependencies are never long-range, and therefore easy to deal with. We may also need to change dependencies reaching from inside to outside the NP, if the head(s) of the NP have changed. In these cases we simply replace the old head(s) with the new one(s) in the relevant dependencies. The number of heads may change because we now analyse conjunctions correctly.

In our example, the original dependencies were:

$$\langle lung, N/N_1, 1, deaths, - \rangle \quad (5)$$

$$\langle cancer, N/N_1, 1, deaths, - \rangle \quad (6)$$

while after the conversion process, (5) becomes:

$$\langle lung, (N/N_1)/(N/N)_2, 2, cancer, - \rangle \quad (7)$$

To determine that the conversion process worked correctly, we manually inspected its output for unique tree structures in Sections 00–07. This identified problem cases to correct, such as those described in the following section.

### 3.2 Exceptional cases

Firstly, when the lowest spanning node covers the NML or JJP bracket exactly, no changes need to be made to CCGbank. These cases occur when CCGbank already received the correct structure during the original conversion process. For example, brackets separating a possessive from its possessor were detected automatically.

A more complex case is conjunctions, which do not follow the simple head/adjunct method of assigning supertags. Instead, conjuncts are identified

during the head-finding stage, and then assigned the supertag dominating the entire coordination. Intervening non-conjunct nodes are given the same category with the *conj* feature, resulting in a derivation that can be parsed with the standard CCGbank binary coordination rules:

$$conj\ X \Rightarrow X[conj] \quad (8)$$

$$X\ X[conj] \Rightarrow X \quad (9)$$

The derivation in Figure 1(b) is produced by these corrections to coordination derivations. As a result, applications of the non-CCG rule shown in (3) have been reduced from 1378 to 145 cases.

Some POS tags require special behaviour. Determiners and possessive pronouns are both usually given the supertag  $NP[nb]/N$ , and this should not be changed by the conversion process. Accordingly, we do not alter tokens with POS tags of DT and PRP\$. Instead, their sibling node is given the category  $N$  and their parent node is made the head. The parent's sibling is then assigned the appropriate adjunct category (usually  $NP\backslash NP$ ). Tokens with punctuation POS tags<sup>1</sup> do not have their supertag changed either.

Finally, there are cases where the lowest spanning node covers a constituent that should not be changed. For example, in the following NP:

```
(NP
  (NML (NN lower) (NN court) )
  (JJ final) (NN ruling) )
```

with the original CCGbank lowest spanning node:

```
(N (N/N lower)
  (N (N/N court)
    (N (N/N final) (N ruling) ) ) )
```

the final ruling node should not be altered.

It may seem trivial to process in this case, but consider a similarly structured NP: lower court ruling that the U.S. can bar the use of... Our minimalist approach avoids reanalysing the many linguistic constructions that can be dominated by NPs, as this would reinvent the creation of CCGbank. As a result, we only flatten those constituents that partially overlap the NML or JJP bracket. The existing structure and dependencies of other constituents are retained. Note that we are still converting every NML and JJP bracket, as even in the subordinate clause example, only the structure around lower court needs to be altered.

<sup>1</sup>period, comma, colon, and left and right bracket.

DT	22	4.30
NML/JJP bracket is an error	12	2.34
Other	17	3.32
Total	512	100.00

Table 1: Manual analysis

### 3.3 Manual annotation

A handful of problems that occurred during the conversion process were corrected manually. The first indicator of a problem was the presence of a possessive. This is unexpected, because possessives were already bracketed properly when CCGbank was originally created (Hockenmaier, 2003, §3.6.4). Secondly, a non-flattened node should not be assigned a supertag that it did not already have. This is because, as described previously, a non-leaf node could dominate any kind of structure. Finally, we expect the lowest spanning node to cover only the NML or JJP bracket and one more constituent to the right. If it doesn't, because of unusual punctuation or an incorrect bracket, then it may be an error. In all these cases, which occur throughout the corpus, we manually analysed the derivation and fixed any errors that were observed.

512 cases were flagged by this approach, or 1.90% of the 26,993 brackets converted to CCG. Table 1 shows the causes of these problems. The most common cause of errors was possessives, as the con-

version process highlighted a number of instances where the original CCGbank analysis was incorrect. An example of this error can be seen in Figure 3(a), where the possessive doesn't take any arguments. Instead, *largest aid donor* incorrectly modifies the NP one word at a time. The correct derivation after manual analysis is in (b).

The second-most common cause occurs when there is apposition inside the NP. This can be seen in Figure 4. As there is no punctuation on which to coordinate (which is how CCGbank treats most appositions) the best derivation we can obtain is to have *Victor Borge* modify the preceding NP.

The final step in the conversion process was to validate the corpus against the CCG grammar, first by those productions used in the existing CCGbank, and then against those actually licensed by CCG (with pre-existing ungrammaticalities removed). Sixteen errors were identified by this process and subsequently corrected by manual analysis.

In total, we have altered 12,475 CCGbank sentences (25.5%) and 20,409 dependencies (1.95%).

## 4 NER features

Named entity recognition (NER) provides information that is particularly relevant for NP parsing, simply because entities are nouns. For example, knowing that *Air Force* is an entity tells us that *Air Force contract* is a left-branching NP.

Vadas and Curran (2007a) describe using NE tags during the annotation process, suggesting that NER-based features will be helpful in a statistical model. There has also been recent work combining NER and parsing in the biomedical field. Lewin (2007) experiments with detecting base-NPs using NER information, while Buyko et al. (2007) use a CRF to identify

Figure 4: CCGbank derivations for apposition with DT

coordinate structure in biological named entities.

We draw NE tags from the BBN Entity Type Corpus (Weischedel and Brunstein, 2005), which describes 28 different entity types. These include the standard person, location and organization classes, as well person descriptions (generally occupations), NORP (National, Other, Religious or Political groups), and works of art. Some classes also have finer-grained subtypes, although we use only the coarse tags in our experiments.

Clark and Curran (2007b) has a full description of the C&C parser’s pre-existing features, to which we have added a number of novel NER-based features. Many of these features generalise the head words and/or POS tags that are already part of the feature set. The results of applying these features are described in Sections 5.3 and 6.

The first feature is a simple lexical feature, describing the NE tag of each token in the sentence. This feature, and all others that we describe here, are not active when the NE tag(s) are **O**, as there is no NER information from tokens that are not entities.

The next group of features is based on the local tree (a parent and two child nodes) formed by every grammar rule application. We add a feature where the rule being applied is combined with the parent’s NE tag. For example, when joining two constituents<sup>2</sup>:  $\langle \text{five}, \text{CD}, \text{CARD}, N/N \rangle$  and  $\langle \text{Europeans}, \text{NNPS}, \text{NORP}, N \rangle$ , the feature is:

$$N \rightarrow N/N N + \text{NORP}$$

as the head of the constituent is *Europeans*.

In the same way, we implement features that combine the grammar rule with the child nodes. There are already features in the model describing each combination of the children’s head words and POS tags, which we extend to include combinations with

<sup>2</sup>These 4-tuples are the node’s head, POS, NE, and supertag.

the NE tags. Using the same example as above, one of the new features would be:

$$N \rightarrow N/N N + \text{CARD} + \text{NORP}$$

The last group of features is based on the NE category spanned by each constituent. We identify constituents that dominate tokens that all have the same NE tag, as these nodes will not cause a “crossing bracket” with the named entity. For example, the constituent *Force contract*, in the NP *Air Force contract*, spans two different NE tags, and should be penalised by the model. *Air Force*, on the other hand, only spans **ORG** tags, and should be preferred accordingly.

We also take into account whether the constituent spans the *entire* named entity. Combining these nodes with others of different NE tags should *not* be penalised by the model, as the NE must combine with the rest of the sentence at some point.

These NE spanning features are implemented as the grammar rule in combination with the parent node or the child nodes. For the former, one feature is active when the node spans the entire entity, and another is active in other cases. Similarly, there are four features for the child nodes, depending on whether neither, the left, the right or both nodes span the entire NE. As an example, if the *Air Force* constituent were being joined with *contract*, then the child feature would be:

$$N \rightarrow N/N N + \text{LEFT} + \text{ORG} + \text{O}$$

assuming that there are more **O** tags to the right.

## 5 Experiments

Our experiments are run with the C&C CCG parser (Clark and Curran, 2007b), and will evaluate the changes made to CCGbank, as well as the effectiveness of the NER features. We train on Sections 02-21, and test on Section 00.

	PREC	RECALL	F-SCORE

Original	85.34	84.55	84.94
NP corrected	85.08	84.17	84.63

Table 3: Parsing results with gold-standard POS tags

## 5.1 Supertagging

Before we begin full parsing experiments, we evaluate on the supertagger alone. The supertagger is an important stage of the CCG parsing process, its results will affect performance in later experiments.

Table 2 shows that F-score has dropped by 0.61%. This is not surprising, as the conversion process has increased the ambiguity of supertags in NPs. Previously, a bare NP could only have a sequence of  $N/N$  tags followed by a final  $N$ . There are now more complex possibilities, equal to the Catalan number of the length of the NP.

## 5.2 Initial parsing results

We now compare parser performance on our NP corrected version of the corpus to that on original CCGbank. We are using the normal-form parser model and report labelled precision, recall and F-score for all dependencies. The results are shown in Table 3.

The F-score drops by 0.31% in our new version of the corpus. However, this comparison is not entirely fair, as the original CCGbank test data does not include the NP structure that the NP corrected model is being evaluated on. Vadas and Curran (2007a) experienced a similar drop in performance on Penn Treebank data, and noted that the F-score for  $NML$  and  $JJP$  brackets was about 20% lower than the overall figure. We suspect that a similar effect is causing the drop in performance here.

Unfortunately, there are no explicit  $NML$  and  $JJP$  brackets to evaluate on in the CCG corpus, and so an NP structure only figure is difficult to compute. Recall can be calculated by marking those dependencies altered in the conversion process, and evaluating only on them. Precision cannot be measured in this

NP corrected	85.71	84.83	85.27

Table 5: Parsing results with NER features

way, as NP dependencies remain undifferentiated in parser output. The result is a recall of 77.03%, which is noticeably lower than the overall figure.

We have also experimented with using automatically assigned POS tags. These tags are accurate with an F-score of 96.34%, with precision 96.20% and recall 96.49%. Table 4 shows that, unsurprisingly, performance is lower without the gold-standard data. The NP corrected model drops an additional 0.1% F-score over the original model, suggesting that POS tags are particularly important for recovering internal NP structure. Evaluating NP dependencies only, in the same manner as before, results in a recall figure of 75.21%.

## 5.3 NER features results

Table 5 shows the results of adding the NER features we described in Section 4. Performance has increased by 0.64% on both versions of the corpora. It is surprising that the NP corrected increase is not larger, as we would expect the features to be less effective on the original CCGbank. This is because incorrect right-branching NPs such as *Air Force contract* would introduce noise to the NER features.

Table 6 presents the results of using automatically assigned POS and NE tags, i.e. parsing raw text. The NER tagger achieves 84.45% F-score on all non-O classes, with precision being 78.35% and recall 91.57%. We can see that parsing F-score has dropped by about 2% compared to using gold-standard POS and NER data, however, the NER features still improve performance by about 0.3%.

	PREC	RECALL	F-SCORE
Original	83.92	83.06	83.49
NP corrected	83.62	82.65	83.14

Table 6: Parsing results with automatic POS and NE tags

## 6 DepBank evaluation

One problem with the evaluation in the previous section, is that the original CCGbank is not expected to recover internal NP structure, making its task easier and inflating its performance. To remove this variable, we carry out a second evaluation against the Briscoe and Carroll (2006) reannotation of DepBank (King et al., 2003), as described in Clark and Curran (2007a). Parser output is made similar to the grammatical relations (GRs) of the Briscoe and Carroll (2006) data, however, the conversion remains complex. Clark and Curran (2007a) report an upper bound on performance, using gold-standard CCGbank dependencies, of 84.76% F-score.

This evaluation is particularly relevant for NPs, as the Briscoe and Carroll (2006) corpus *has* been annotated for internal NP structure. With our new version of CCGbank, the parser will be able to recover these GRs correctly, where before this was unlikely.

Firstly, we show the figures achieved using gold-standard CCGbank derivations in Table 7. In the NP corrected version of the corpus, performance has increased by 1.02% F-score. This is a reversal of the results in Section 5, and demonstrates that correct NP structure improves parsing performance, rather than reduces it. Because of this increase to the upper bound of performance, we are now even closer to a true formalism-independent evaluation.

We now move to evaluating the C&C parser itself and the improvement gained by the NER features. Table 8 show our results, with the NP corrected version outperforming original CCGbank by 0.92%. Using the NER features has also caused an increase in F-score, giving a total improvement of 1.51%. These results demonstrate how successful the correcting of NPs in CCGbank has been.

Furthermore, the performance increase of 0.59% on the NP corrected corpus is more than the 0.25% increase on the original. This demonstrates that NER features are particularly helpful for NP structure.

## 7 Conclusion

The first contribution of this paper is the application of the Vadas and Curran (2007a) data to Combinatory Categorical Grammar. Our experimental results have shown that this more accurate representation of CCGbank’s NP structure increases parser performance. Our second major contribution is the introduction of novel NER features, a source of semantic information previously unused in parsing.

As a result of this work, internal NP structure is now recoverable by the C&C parser, a result demonstrated by our total performance increase of 1.51% F-score. Even when parsing raw text, without gold standard POS and NER tags, our approach has resulted in performance gains.

In addition, we have made possible further increases to NP structure accuracy. New features can now be implemented and evaluated in a CCG parsing context. For example, bigram counts from a very large corpus have already been used in NP bracketing, and could easily be applied to parsing. Similarly, additional supertagging features can now be created to deal with the increased ambiguity in NPs.

Downstream NLP components can now exploit the crucial information in NP structure.

## Acknowledgements

We would like to thank Mark Steedman and Matthew Honnibal for help with converting the NP data to CCG; and the anonymous reviewers for their helpful feedback. This work has been supported by the Australian Research Council under Discovery Project DP0665973.

# Sentence Simplification for Semantic Role Labeling

David Vickrey and Daphne Koller

Stanford University

Stanford, CA 94305-9010

{dvickrey, koller}@cs.stanford.edu

## Abstract

Parse-tree paths are commonly used to incorporate information from syntactic parses into NLP systems. These systems typically treat the paths as atomic (or nearly atomic) features; these features are quite sparse due to the immense variety of syntactic expression. In this paper, we propose a general method for learning how to iteratively simplify a sentence, thus decomposing complicated syntax into small, easy-to-process pieces. Our method applies a series of hand-written transformation rules corresponding to basic syntactic patterns — for example, one rule “depassivizes” a sentence. The model is parameterized by *learned* weights specifying preferences for some rules over others. After applying all possible transformations to a sentence, we are left with a set of candidate simplified sentences. We apply our simplification system to semantic role labeling (SRL). As we do not have labeled examples of correct simplifications, we use labeled training data for the SRL task to jointly learn both the weights of the simplification model and of an SRL model, treating the simplification as a hidden variable. By extracting and labeling simplified sentences, this combined simplification/SRL system better generalizes across syntactic variation. It achieves a statistically significant 1.2% F1 measure increase over a strong baseline on the Conll-2005 SRL task, attaining near-state-of-the-art performance.

## 1 Introduction

In *semantic role labeling* (SRL), given a sentence containing a *target verb*, we want to label the semantic arguments, or roles, of that verb. For the verb “eat”, a correct labeling of “Tom ate a salad” is {ARG0(Eater)=“Tom”, ARG1(Food)=“salad”}.

Current semantic role labeling systems rely primarily on syntactic features in order to identify and

Figure 1: Parse with path features for verb “eat”.

classify roles. Features derived from a syntactic parse of the sentence have proven particularly useful (Gildea & Jurafsky, 2002). For example, the syntactic subject of “give” is nearly always the Giver. Path features allow systems to capture both general patterns, e.g., that the ARG0 of a sentence tends to be the subject of the sentence, and specific usage, e.g., that the ARG2 of “give” is often a post-verbal prepositional phrase headed by “to”. An example sentence with extracted path features is shown in Figure 1.

A major problem with this approach is that the path from an argument to the verb can be quite complicated. In the sentence “He expected to receive a prize for winning,” the path from “win” to its ARG0, “he”, involves the verbs “expect” and “receive” and the preposition “for.” The corresponding path through the parse tree likely occurs a relatively small number of times (or not at all) in the training corpus. If the test set contained exactly the same sentence but with “expected” replaced by “did not expect” we would extract a different parse path feature; therefore, as far as the classifier is concerned, the syntax of the two sentences is totally unrelated.

In this paper we learn a mapping from full, complicated sentences to simplified sentences. For example, given a correct parse, our system simplifies the above sentence with target verb “win” to “He won.” Our method combines hand-written syntactic simplification rules with machine learning, which

determines which rules to prefer. We then use the output of the simplification system as input to a SRL system that is trained to label simplified sentences.

Compared to previous SRL models, our model has several qualitative advantages. First, we believe that the simplification process, which represents the syntax as a set of local syntactic transformations, is more linguistically satisfying than using the entire parse path as an atomic feature. Improving the simplification process mainly involves adding more linguistic knowledge in the form of simplification rules. Second, labeling simple sentences is much easier than labeling raw sentences and allows us to generalize more effectively across sentences with differing syntax. This is particularly important for verbs with few labeled training instances; using training examples as efficiently as possible can lead to considerable gains in performance. Third, our model is very effective at sharing information across verbs, since most of our simplification rules apply equally well regardless of the target verb.

A major difficulty in learning to simplify sentences is that we do not have labeled data for this task. To address this problem, we simultaneously train our simplification system and the SRL system. We treat the correct simplification as a hidden variable, using labeled SRL data to guide us towards “more useful” simplifications. Specifically, we train our model discriminatively to predict the correct role labeling assignment given an input sentence, treating the simplification as a hidden variable.

Applying our combined simplification/SRL model to the Conll 2005 task, we show a significant improvement over a strong baseline model. Our model does best on verbs with little training data and on instances with paths that are rare or have never been seen before, matching our intuitions about the strengths of the model. Our model outperforms all but the best few Conll 2005 systems, each of which uses multiple different automatically-generated parses (which would likely improve our model).

## 2 Sentence Simplification

We will begin with an example before describing our model in detail. Figure 2 shows a series of transformations applied to the sentence “I was not given a chance to eat,” along with the interpretation of each transformation. Here, the target verb is “eat.”

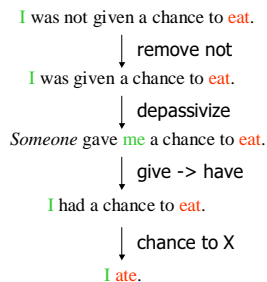

Figure 2: Example simplification

Figure 3: Shared simplification structure

There are several important things to note. First, many of the steps do lose some semantic information; clearly, having a chance to eat is not the same as eating. However, since we are interested only in labeling the core arguments of the verb (which in this case is simply the Eater, “I”), it is not important to maintain this information. Second, there is more than one way to choose a set of rules which lead to the desired final sentence “I ate.” For example, we could have chosen to include a rule which went directly from the second step to the fourth. In general, the rules were designed to allow as much reuse of rules as possible. Figure 3 shows the simplification of “Sam’s chance to eat has passed” (again with target verb “eat”); by simplifying both of these sentences as “X had a chance to Y”, we are able to use the same final rule in both cases.

Of course, there may be more than one way to simplify a sentence for a given rule set; this ambiguity is handled by learning which rules to prefer.

In this paper, we use simplification to mean something which is closer to *canonicalization* than *summarization*. Thus, given an input sentence, our goal is not to produce a single shortened sentence which contains as much information from the original sentence as possible. Rather, the goal is, for *each* verb in the sentence, to produce a “simple” sentence which is in a particular canonical form (described below) relative to that verb.

## 3 Transformation Rules

A *transformation rule* takes as input a parse tree and produces as output a different, changed parse tree. Since our goal is to produce a simplified version of the sentence, the rules are designed to bring all sentences toward the same common format.

A rule (see left side of Figure 4) consists of two

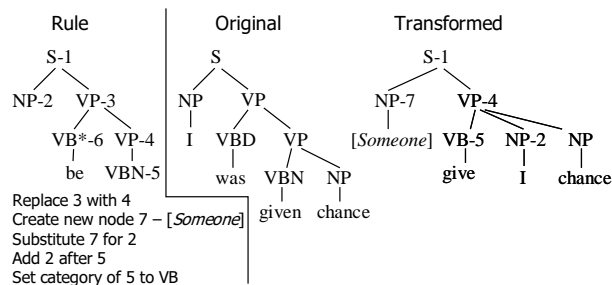

Figure 4: Rule for depassivizing a sentence

parts. The first is a “tree regular expression” which is most simply viewed as a tree fragment with optional constraints at each node. The rule assigns numbers to each node which are referred to in the second part of the rule. Formally, a rule node  $X$  matches a parse-tree node  $A$  if: (1) All constraints of node  $X$  (e.g., constituent category, head word, etc.) are satisfied by node  $A$ . (2) For each child node  $Y$  of  $X$ , there is a child  $B$  of  $A$  that matches  $Y$ ; two children of  $X$  cannot be matched to the same child  $B$ . There are no other requirements.  $A$  can have other children besides those matched, and leaves of the rule pattern can match to internal nodes of the parse (corresponding to entire phrases in the original sentence). For example, the same rule is used to simplify both “I had a chance to eat,” and “I had a chance to eat a sandwich,” (into “I ate,” and “I ate a sandwich,”). The insertion of the phrase “a sandwich” does not prevent the rule from matching.

The second part of the rule is a series of simple steps that are applied to the matched nodes. For example, one type of simple step applied to the pair of nodes  $(X,Y)$  removes  $X$  from its current parent and adds it as the final child of  $Y$ . Figure 4 shows the depassivizing rule and the result of applying it to the sentence “I was given a chance.” The transformation steps are applied sequentially from top to bottom. Note that any nodes not matched are unaffected by the transformation; they remain where they are relative to their parents. For example, “chance” is not matched by the rule, and thus remains as a child of the VP headed by “give.”

There are two significant pieces of “machinery” in our current rule set. The first is the idea of a *floating node*, used for locating an argument within a subordinate clause. For example, in the phrases “The cat that ate the mouse”, “The seed that the mouse ate”, and “The person we gave the gift to”, the modified nouns (“cat”, “seed”, and “person”, respectively) all

Rule Category	#	Original	Simplified
Sentence normalization	24	Thursday, I <u>slept</u> .	I <u>slept</u> Thursday.
Sentence extraction	4	I said he <u>slept</u> .	He <u>slept</u> .
Passive	5	I was <u>hit</u> by a car.	A car <u>hit</u> me.
Misc Collapsing/Rewriting	20	John, a lawyer, ...	John is a lawyer.
Conjunctions	8	I <u>ate</u> and slept.	I <u>ate</u> .
Verb Collapsing/Rewriting	14	I must <u>eat</u> .	I <u>eat</u> .
Verb Raising/Control (basic)	17	I <u>want</u> to eat.	I <u>eat</u> .
Verb RC (ADJP/ADVP)	6	I am likely to <u>eat</u> .	I <u>eat</u> .
Verb RC (Noun)	7	I have a chance to <u>eat</u> .	I <u>eat</u> .
Modified nouns	8	The food I <u>ate</u> ...	Float(The food) I <u>ate</u> .
Floating nodes	5	Float(The food) I <u>ate</u> .	I <u>ate</u> the food.
Inverted sentences	7	Nor will I <u>eat</u> .	I will <u>eat</u> .
Questions	7	Will I <u>eat</u> ?	I will <u>eat</u> .
Possessive	7	John’s chance to <u>eat</u> ...	John has a chance to <u>eat</u> .
Verb acting as PP/NP	7	<u>Including</u> tax, the total...	The total <u>includes</u> tax.
“Make” rewrites	8	Salt makes food tasty.	Food is tasty.

Table 1: Rule categories with sample simplifications. Target verbs are underlined.

should be placed in different positions in the subordinate clauses (subject, direct object, and object of “to”) to produce the phrases “The cat ate the mouse,” “The mouse ate the seed”, and “We gave the gift to the person.” We handle these phrases by placing a floating node in the subordinate clause which points to the argument; other rules try to place the floating node into each possible position in the sentence.

The second construct is a system for keeping track of whether a sentence has a subject, and if so, what it is. A subset of our rule set normalizes the input sentence by moving modifiers after the verb, leaving either a single phrase (the subject) or nothing before the verb. For example, the sentence “Before leaving, I ate a sandwich,” is rewritten as “I ate a sandwich before leaving.” In many cases, keeping track of the presence or absence of a subject greatly reduces the set of possible simplifications.

Altogether, we currently have 154 (mostly unlexicalized) rules. Our general approach was to write very conservative rules, i.e., avoid making rules with low precision, as these can quickly lead to a large blowup in the number of generated simple sentences. Table 1 shows a summary of our rule-set, grouped by type. Note that each row lists only one possible sentence and simplification rule from that

Figure 5: Simple sentence constraints for “eat”

category; many of the categories handle a variety of syntax patterns. The two examples without target verbs are helper transformations; in more complex sentences, they can enable further simplifications. Another thing to note is that we use the terms Raising/Control (RC) very loosely to mean situations where the subject of the target verb is displaced, appearing as the subject of another verb (see table).

Our rule set was developed by analyzing performance and coverage on the PropBank WSJ training set; neither the development set nor (of course) the test set were used during rule creation.

#### 4 Simple Sentence Production

We now describe how to take a set of rules and produce a set of candidate simple sentences. At a high level, the algorithm is very simple. We maintain a set of derived parses  $S$  which is initialized to contain only the original, untransformed parse. One iteration of the algorithm consists of applying every possible matching transformation rule to every parse in  $S$ , and adding all resulting parses to  $S$ . With carefully designed rules, repeated iterations are guaranteed to converge; that is, we eventually arrive at a set  $\hat{S}$  such that if we apply an iteration of rule application to  $\hat{S}$ , no new parses will be added. Note that we simplify the whole sentence without respect to a particular verb. Thus, this process only needs to be done once per sentence (not once per verb).

To label arguments of a particular target verb, we remove any parse from our set which does not match one of the two templates in Figure 5 (for verb “eat”). These select simple sentences that have all non-subject modifiers moved to the predicate and “eat” as the main verb. Note that the constraint VB\* indicates any terminal verb category (e.g., VBN, VBD, etc.) A parse that matches one of these templates is called a *valid simple sentence*; this is exactly the canonicalized version of the sentence which our simplification rules are designed to produce.

This procedure is quite expensive; we have to copy the entire parse tree at each step, and in general, this procedure could generate an exponential number of transformed parses. The first issue can be solved, and the second alleviated, using a dynamic-programming data structure similar to the one used to store parse forests (as in a chart parser). This data structure is not essential for exposition; we delay discussion until Section 7.

#### 5 Labeling Simple Sentences

For a particular sentence/target verb pair  $s, v$ , the output from the previous section is a set  $S^{sv} = \{t_i^{sv}\}_i$  of valid simple sentences. Although labeling a simple sentence is easier than labeling the original sentence, there are still many choices to be made. There is one key assumption that greatly reduces the search space: in a simple sentence, only the subject (if present) and direct modifiers of the target verb can be arguments of that verb.

On the training set, we now extract a set of *role patterns*  $G^v = \{g_j^v\}_j$  for each verb  $v$ . For example, a common role pattern for “give” is that of “I gave him a sandwich”. We represent this pattern as  $g_1^{give} = \{ARG0 = Subject NP, ARG1 = Postverb NP2, ARG2 = Postverb NP1\}$ . Note that this is one atomic pattern; thus, we are keeping track not just of occurrences of particular roles in particular places in the simple sentence, but also how those roles co-occur with other roles.

For a particular simple sentence  $t_i^{sv}$ , we apply all extracted role patterns  $g_j^v$  to  $t_i^{sv}$ , obtaining a set of possible role labelings. We call a simple sentence/role labeling pair a *simple labeling* and denote the set of candidate simple labelings  $C^{sv} = \{c_k^{sv}\}_k$ . Note that a given pair  $t_i^{sv}, g_j^v$  may generate more than one simple labeling, if there is more than one way to assign the elements of  $g_j^v$  to constituents in  $t_i^{sv}$ . Also, for a sentence  $s$  there may be several simple labelings that lead to the same role labeling. In particular, there may be several simple labelings which assign the correct labels to all constituents; we denote this set  $K^{sv} \subseteq C^{sv}$ .

#### 6 Probabilistic Model

We now define our probabilistic model. Given a (possibly large) set of candidate simple labelings  $C^{sv}$ , we need to select a correct one. We assign a score to each candidate based on its features:

Rule = Depassivize  
 Pattern = { ARG0 = Subj NP, ARG1 = PV NP2, ARG2 = PV NP1 }  
 Role = ARG0, Head Word = John  
 Role = ARG1, Head Word = sandwich  
 Role = ARG2, Head Word = I  
 Role = ARG0, Category = NP  
 Role = ARG1, Category = NP  
 Role = ARG2, Category = NP  
 Role = ARG0, Position = Subject NP  
 Role = ARG1, Position = Postverb NP2  
 Role = ARG2, Position = Postverb NP1

Figure 6: Features for “John gave me a sandwich.”

which rules were used to obtain the simple sentence, which role pattern was used, and features about the assignment of constituents to roles. A log-linear model then assigns probability to each simple labeling equal to the normalized exponential of the score.

The first type of feature is which rules were used to obtain the simple sentence. These features are indicator functions for each possible rule. Thus, we do not currently learn anything about interactions between different rules. The second type of feature is an indicator function of the role pattern used to generate the labeling. This allows us to learn that “give” has a preference for the labeling {*ARG0 = Subject NP, ARG1 = Postverb NP2, ARG2 = Postverb NP1*}. Our final features are analogous to those used in semantic role labeling, but greatly simplified due to our use of simple sentences: head word of the constituent; category (i.e., constituent label); and position in the simple sentence. Each of these features is combined with the role assignment, so that each feature indicates a preference for a particular role assignment (i.e., for “give”, head word “sandwich” tends to be ARG1). For each feature, we have a verb-specific and a verb-independent version, allowing sharing across verbs while still permitting different verbs to learn different preferences. The set of extracted features for the sentence “I was given a sandwich by John” with simplification “John gave me a sandwich” is shown in Figure 6. We omit verb-specific features to save space. Note that we “stem” all pronouns (including possessive pronouns).

For each candidate simple labeling  $c_k^{sv}$  we extract a vector of features  $\mathbf{f}_k^{sv}$  as described above. We now define the probability of a simple labeling  $c_k^{sv}$  with respect to a weight vector  $\mathbf{w}$   $P(c_k^{sv}) = \frac{e^{\mathbf{w}^T \mathbf{f}_k^{sv}}}{\sum_{k'} e^{\mathbf{w}^T \mathbf{f}_{k'}^{sv}}}$ .

Our goal is to maximize the total probability assigned to any correct simple labeling; therefore, for each sentence/verb pair  $(s, v)$ , we want to increase

$\sum_{c_k^{sv} \in K^{sv}} P(c_k^{sv})$ . This expression treats the simple labeling (consisting of a simple sentence and a role assignment) as a hidden variable that is summed out. Taking the log, summing across all sentence/verb pairs, and adding L2 regularization on the weights, we have our final objective  $F(\mathbf{w})$ :

$$\sum_{s,v} \left( \log \frac{\sum_{c_k^{sv} \in K^{sv}} e^{\mathbf{w}^T \mathbf{f}_k^{sv}}}{\sum_{c_{k'}^{sv} \in C^{sv}} e^{\mathbf{w}^T \mathbf{f}_{k'}^{sv}}} \right) - \frac{\mathbf{w}^T \mathbf{w}}{2\sigma^2}$$

We train our model by optimizing the objective using standard methods, specifically BFGS. Due to the summation over the hidden variable representing the choice of simple sentence (not observed in the training data), our objective is not convex. Thus, we are not guaranteed to find a global optimum; in practice we have gotten good results using the default initialization of setting all weights to 0.

Consider the derivative of the likelihood component with respect to a single weight  $w_l$ :

$$\sum_{c_k^{sv} \in K^{sv}} \mathbf{f}_k^{sv}(l) \frac{P(c_k^{sv})}{\sum_{c_{k'}^{sv} \in K^{sv}} P(c_{k'}^{sv})} - \sum_{c_{k'}^{sv} \in C^{sv}} \mathbf{f}_{k'}^{sv}(l) P(c_{k'}^{sv})$$

where  $\mathbf{f}_k^{sv}(l)$  denotes the  $l^{\text{th}}$  component of  $\mathbf{f}_k^{sv}$ . This formula is positive when the expected value of the  $l^{\text{th}}$  feature is higher on the set of correct simple labelings  $K^{sv}$  than on the set of all simple labelings  $C^{sv}$ . Thus, the optimization procedure will tend to be self-reinforcing, increasing the score of correct simple labelings which already have a high score.

## 7 Simplification Data Structure

Our representation of the set of possible simplifications of a sentence addresses two computational bottlenecks. The first is the need to repeatedly copy large chunks of the sentence. For example, if we are depassivizing a sentence, we can avoid copying the subject and object of the original sentence by simply referring back to them in the depassivized version. At worst, we only need to add one node for each numbered node in the transformation rule. The second issue is the possible exponential blowup of the number of generated sentences. Consider “I want to eat and I want to drink and I want to play and ...” Each subsentence can be simplified, yielding two possibilities for each subsentence. The number of simplifications of the entire sentence is then exponential in the length of the sentence. However,

Figure 7: Data structure after applying the depassivize rule to “I was given (a) chance.” Circular nodes are OR-nodes, rectangular nodes are AND-nodes.

we can store these simplifications compactly as a set of independent decisions, “I {want to eat OR eat} and I {want to drink OR drink} and ...”

Both issues can be addressed by representing the set of simplifications using an AND-OR tree, a general data structure also used to store parse forests such as those produced by a chart parser. In our case, the AND nodes are similar to constituent nodes in a parse tree – each has a category (e.g. NP) and (if it is a leaf) a word (e.g. “chance”), but instead of having a list of child constituents, it instead has a list of child OR nodes. Each OR node has one or more constituent children that correspond to the different options at this point in the tree. Figure 7 shows the resulting AND-OR tree after applying the depassivize rule to the original parse of “I was given a chance.” Because this AND-OR tree represents only two different parses, the original parse and the depassivized version, only one OR node in the tree has more than one child – the root node, which has two choices, one for each parse. However, the AND nodes immediately above “I” and “chance” each have more than one OR-node parent, since they are shared by the original and depassivized parses<sup>1</sup>. To extract a parse from this data structure, we apply the following recursive algorithm: starting at the root OR node, each time we reach an OR node, we choose and recurse on exactly one of its children; each time we reach an AND node, we recurse on all of its children. In Figure 7, we have only one choice: if we go left at the root, we generate the original parse; otherwise, we generate the depassivized version.

Unfortunately, it is difficult to find the optimal AND-OR tree. We use a greedy but smart proce-

<sup>1</sup>In this particular example, both of these nodes are leaves, but in general shared nodes can be entire tree fragments

dure to try to produce a small tree. We omit details for lack of space. Using our rule set, the compact representation is usually (but not always) small.

For our compact representation to be useful, we need to be able to optimize our objective without expanding all possible simple sentences. A relatively straight-forward extension of the inside-outside algorithm for chart-parses allows us to learn and perform inference in our compact representation (a similar algorithm is presented in (Geman & Johnson, 2002)). We omit details for lack of space.

## 8 Experiments

We evaluated our system using the setup of the Conll 2005 semantic role labeling task.<sup>2</sup> Thus, we trained on Sections 2-21 of PropBank and used Section 24 as development data. Our test data includes both the selected portion of Section 23 of PropBank, plus the extra data on the Brown corpus. We used the Charniak parses provided by the Conll distribution.

We compared to a strong **Baseline** SRL system that learns a logistic regression model using the features of Pradhan et al. (2005). It has two stages. The first filters out nodes that are unlikely to be arguments. The second stage labels each remaining node either as a particular role (e.g. “ARGO”) or as a non-argument. Note that the baseline feature set includes a feature corresponding to the subcategorization of the verb (specifically, the sequence of nonterminals which are children of the predicate’s parent node). Thus, **Baseline** does have access to something similar to our model’s role pattern feature, although the **Baseline** subcategorization feature only includes post-verbal modifiers and is generally much noisier because it operates on the original sentence.

Our **Transforms** model takes as input the Charniak parses supplied by the Conll release, and labels every node with Core arguments (ARG0-ARG5). Our rule set does not currently handle either referent arguments (such as “who” in “The man who ate ...”) or non-core arguments (such as ARGM-TMP). For these arguments, we simply filled in using our baseline system (specifically, any non-core argument which did not overlap an argument predicted by our model was added to the labeling). Also, on some sentences, our system did not generate any predictions because no valid simple sen-

<b>Combined</b>	<b>76.0</b>	<b>78.0</b>	66.4	<b>76.5</b>
Punyakanok	77.35	79.44	67.75	77.92

Table 2: F1 Measure using Charniak parses

tences were produced by the simplification system . Again, we used the baseline to fill in predictions (for all arguments) for these sentences.

**Baseline** and **Transforms** were regularized using a Gaussian prior; for both models,  $\sigma^2 = 1.0$  gave the best results on the development set.

For generating role predictions from our model, we have two reasonable options: use the labeling given by the single highest scoring simple labeling; or compute the distribution over predictions for each node by summing over all simple labelings. The latter method worked slightly better, particularly when combined with the baseline model as described below, so all reported results use this method.

We also evaluated a hybrid model that combines the **Baseline** with our simplification model. For a given sentence/verb pair  $(s, v)$ , we find the set of constituents  $N^{sv}$  that made it past the first (filtering) stage of **Baseline**. For each candidate simple sentence/labeling pair  $c_k^{sv} = (t_i^{sv}, g_j^v)$  proposed by our model, we check to see which of the constituents in  $N^{sv}$  are already present in our simple sentence  $t_i^{sv}$ . Any constituents that are *not* present are then assigned a probability distribution over possible roles according to **Baseline**. Thus, we fall back **Baseline** whenever the current simple sentence does not have an “opinion” about the role of a particular constituent. The **Combined** model is thus able to correctly label sentences when the simplification process drops some of the arguments (generally due to unusual syntax). Each of the two components was trained separately and combined only at testing time.

Table 2 shows results of these three systems on the Conll-2005 task, plus the top-performing system (Punyakanok et al., 2005) for reference. **Baseline** already achieves good performance on this task, placing at about 75<sup>th</sup> percentile among evaluated systems. Our **Transforms** model outperforms **Baseline** on all sets. Finally, our **Combined** model improves over **Transforms** on all but the test Brown corpus,

Model	Test WSJ
<b>Baseline</b>	87.6
<b>Transforms</b>	88.2
<b>Combined</b>	<b>88.5</b>

Table 3: F1 Measure using gold parses

achieving a statistically significant increase over the **Baseline** system (according to confidence intervals calculated for the Conll-2005 results).

The **Combined** model still does not achieve the performance levels of the top several systems. However, these systems all use information from multiple parses, allowing them to fix many errors caused by incorrect parses. We return to this issue in Section 10. Indeed, as shown in Table 3, performance on gold standard parses is (as expected) much better than on automatically generated parses, for all systems. Importantly, the **Combined** model again achieves a significant improvement over **Baseline**.

We expect that by labeling simple sentences, our model will generalize well even on verbs with a small number of training examples. Figure 8 shows F1 measure on the WSJ test set as a function of training set size. Indeed, both the **Transforms** model and the **Combined** model significantly outperform the **Baseline** model when there are fewer than 20 training examples for the verb. While the **Baseline** model has higher accuracy than the **Transforms** model for verbs with a very large number of training examples, the **Combined** model is at or above both of the other models in all but the rightmost bucket, suggesting that it gets the best of both worlds.

We also found, as expected, that our model improved on sentences with very long parse paths. For example, in the sentence “Big investment banks refused to step up to the plate to support the beleaguered floor traders by buying blocks of stock, traders say,” the parse path from “buy” to its ARG0, “Big investment banks,” is quite long. The **Transforms** model correctly labels the arguments of “buy”, while the **Baseline** system misses the ARG0.

To understand the importance of different types of rules, we performed an ablation analysis. For each major rule category in Figure 1, we deleted those rules from the rule set, retrained, and evaluated using the **Combined** model. To avoid parse-related issues, we trained and evaluated on gold-standard parses. Most important were rules relating to (ba-

Figure 8: F1 Measure on the WSJ test set as a function of training set size. Each bucket on the X-axis corresponds to a group of verbs for which the number of training examples fell into the appropriate range; the value is the average performance for verbs in that bucket.

sic) verb raising/control, “make” rewrites, modified nouns, and passive constructions. Each of these rule categories when removed lowered the F1 score by approximately .4%. In contrast, removing rules for non-basic control, possessives, and inverted sentences caused a negligible reduction in performance. This may be because the relevant syntactic structures occur rarely; because **Baseline** does well on those constructs; or because the simplification model has trouble learning when to apply these rules.

## 9 Related Work

One area of current research which has similarities with this work is on Lexical Functional Grammars (LFGs). Both approaches attempt to abstract away from the surface level syntax of the sentence (e.g., the XLE system<sup>3</sup>). The most obvious difference between the approaches is that we use SRL data to train our system, avoiding the need to have labeled data specific to our simplification scheme.

There have been a number of works which model verb subcategorization. Approaches include incorporating a subcategorization feature (Gildea & Jurafsky, 2002; Xue & Palmer, 2004), such as the one used in our baseline; and building a model which jointly classifies all arguments of a verb (Toutanova et al., 2005). Our method differs from past work in that it extracts its role pattern feature from the simplified sentence. As a result, the feature is less noisy

<sup>3</sup><http://www2.parc.com/isl/groups/nltt/xle/>

and generalizes better across syntactic variation than a feature extracted from the original sentence.

Another group of related work focuses on summarizing sentences through a series of deletions (Jing, 2000; Dorr et al., 2003; Galley & McKeown, 2007). In particular, the latter two works iteratively simplify the sentence by deleting a phrase at a time. We differ from these works in several important ways. First, our transformation language is not context-free; it can reorder constituents and then apply transformation rules to the reordered sentence. Second, we are focusing on a somewhat different task; these works are interested in obtaining a single summary of each sentence which maintains all “essential” information, while in our work we produce a simplification that may lose semantic content, but aims to contain all arguments of a verb. Finally, training our model on SRL data allows us to avoid the relative scarcity of parallel simplification corpora and the issue of determining what is “essential” in a sentence.

Another area of related work in the semantic role labeling literature is that on tree kernels (Moschitti, 2004; Zhang et al., 2007). Like our method, tree kernels decompose the parse path into smaller pieces for classification. Our model can generalize better across verbs because it first simplifies, then classifies based on the simplified sentence. Also, through iterative simplifications we can discover structure that is not immediately apparent in the original parse.

## 10 Future Work

There are a number of improvements that could be made to the current simplification system, including augmenting the rule set to handle more constructions and doing further sentence normalizations, e.g., identifying whether a direct object exists. Another interesting extension involves incorporating parser uncertainty into the model; in particular, our simplification system is capable of seamlessly accepting a parse forest as input.

There are a variety of other tasks for which sentence simplification might be useful, including summarization, information retrieval, information extraction, machine translation and semantic entailment. In each area, we could either use the simplification system as learned on SRL data, or retrain the simplification model to maximize performance on the particular task.

# Summarizing Emails with Conversational Cohesion and Subjectivity

Giuseppe Carenini, Raymond T. Ng and Xiaodong Zhou

Department of Computer Science

University of British Columbia

Vancouver, BC, Canada

{carenini, rng, xdzhou}@cs.ubc.ca

## Abstract

In this paper, we study the problem of summarizing email conversations. We first build a sentence quotation graph that captures the conversation structure among emails. We adopt three cohesion measures: clue words, semantic similarity and cosine similarity as the weight of the edges. Second, we use two graph-based summarization approaches, Generalized ClueWordSummarizer and Page-Rank, to extract sentences as summaries. Third, we propose a summarization approach based on subjective opinions and integrate it with the graph-based ones. The empirical evaluation shows that the basic clue words have the highest accuracy among the three cohesion measures. Moreover, subjective words can significantly improve accuracy.

## 1 Introduction

With the ever increasing popularity of emails, it is very common nowadays that people discuss specific issues, events or tasks among a group of people by emails (Fisher and Moody, 2002). Those discussions can be viewed as conversations via emails and are valuable for the user as a personal information repository (Ducheneaut and Bellotti, 2001). In this paper, we study the problem of *summarizing email conversations*. Solutions to this problem can help users access the information embedded in emails more effectively. For instance, 10 minutes before a meeting, a user may want to quickly go through a previous discussion via emails that is going to be discussed soon. In that case, rather than

reading each individual email one by one, it would be preferable to read a concise summary of the previous discussion with the major information summarized. Email summarization is also helpful for mobile email users on a small screen.

Summarizing email conversations is challenging due to the characteristics of emails, especially the conversational nature. Most of the existing methods dealing with email conversations use the email *thread* to represent the email conversation structure, which is not accurate in many cases (Yeh and Harnly, 2006). Meanwhile, most existing email summarization approaches use quantitative features to describe the conversation structure, e.g., number of recipients and responses, and apply some general multi-document summarization methods to extract some sentences as the summary (Rambow et al., 2004) (Wan and McKeown, 2004). Although such methods consider the conversation structure somehow, they simplify the conversation structure into several features and do not fully utilize it into the summarization process.

In contrast, in this paper, we propose new summarization approaches by sentence extraction, which rely on a fine-grain representation of the conversation structure. We first build a *sentence quotation graph* by content analysis. This graph not only captures the conversation structure more accurately, especially for selective quotations, but it also represents the conversation structure at the finer granularity of sentences. As a second contribution of this paper, we study several ways to measure the cohesion between parent and child sentences in the quotation graph: *clue words* (re-occurring words in the reply)

(Carenini et al., 2007), *semantic similarity* and *cosine similarity*. Hence, we can directly evaluate the importance of each sentence in terms of its cohesion with related ones in the graph. The extractive summarization problem can be viewed as a node ranking problem. We apply two summarization algorithms, Generalized ClueWordSummarizer and Page-Rank to rank nodes in the sentence quotation graph and to select the corresponding most highly ranked sentences as the summary.

Subjective opinions are often critical in many conversations. As a third contribution of this paper, we study how to make use of the subjective opinions expressed in emails to support the summarization task. We integrate our best cohesion measure together with the subjective opinions. Our empirical evaluations show that subjective words and phrases can significantly improve email summarization.

To summarize, this paper is organized as follows. In Section 2, we discuss related work. After building a sentence quotation graph to represent the conversation structure in Section 3, we apply two summarization methods in Section 4. In Section 5, we study summarization approaches with subjective opinions. Section 6 presents the empirical evaluation of our methods. We conclude this paper and propose future work in Section 7.

## 2 Related Work

Rambow et al. proposed a sentence extraction summarization approach for email threads (Rambow et al., 2004). They described each sentence in an email conversations by a set of features and used machine learning to classify whether or not a sentence should be included into the summary. Their experiments showed that features about emails and the email thread could significantly improve the accuracy of summarization.

Wan et al. proposed a summarization approach for decision-making email discussions (Wan and McKeown, 2004). They extracted the issue and response sentences from an email thread as a summary. Similar to the issue-response relationship, Shrestha et al. (Shrestha and McKeown, 2004) proposed methods to identify the question-answer pairs from an email thread. Once again, their results showed that including features about the email

thread could greatly improve the accuracy. Similar results were obtained by Corston-Oliver et al. They studied how to identify “action” sentences in email messages and use those sentences as a summary (Corston-Oliver et al., 2004). All these approaches used the email thread as a coarse representation of the underlying conversation structure.

In our recent study (Carenini et al., 2007), we built a fragment quotation graph to represent an email conversation and developed a ClueWordSummarizer (CWS) based on the concept of clue words. Our experiments showed that CWS had a higher accuracy than the email summarization approach in (Rambow et al., 2004) and the generic multi-document summarization approach MEAD (Radev et al., 2004). Though effective, the CWS method still suffers from the following four substantial limitations. First, we used a fragment quotation graph to represent the conversation, which has a coarser granularity than the sentence level. For email summarization by sentence extraction, the fragment granularity may be inadequate. Second, we only adopted one cohesion measure (clue words that are based on stemming), and did not consider more sophisticated ones such as semantically similar words. Third, we did not consider subjective opinions. Finally, we did not compare CWS to other possible graph-based approaches as we propose in this paper.

Other than for email summarization, other document summarization methods have adopted graph-ranking algorithms for summarization, e.g., (Wan et al., 2007), (Mihalcea and Tarau, 2004) and (Erkan and Radev, 2004). Those methods built a complete graph for all sentences in one or multiple documents and measure the similarity between every pair of sentences. Graph-ranking algorithms, e.g., Page-Rank (Brin and Page, 1998), are then applied to rank those sentences. Our method is different from them. First, instead of using the complete graph, we build the graph based on the conversation structure. Second, we try various ways to compute the similarity among sentences and the ranking of the sentences.

Several studies in the NLP literature have explored the reoccurrence of similar words within one document due to text cohesion. The idea has been formalized in the construct of *lexical chains* (Barzilay and Elhadad, 1997). While our approach and lexical chains both rely on lexical cohesion, they are

quite different with respect to the kind of linkages considered. Lexical chain is only based on similarities between lexical items in contiguous sentences. In contrast, in our approach, the linkage is based on the existing conversation structure. In our approach, the “chain” is not only “lexical” but also “conversational”, and typically spans over several emails.

### 3 Extracting Conversations from Multiple Emails

In this section, we first review how to build a fragment quotation graph through an example. Then we extend this structure into a sentence quotation graph, which can allow us to capture the conversational relationship at the level of sentences.

#### 3.1 Building the Fragment Quotation Graph

(a) Conversation involving 6 Emails

(b) Fragment Quotation Graph

Figure 1: A Real Example

Figure 1(a) shows a real example of a conversation from a benchmark data set involving 6 emails. For the ease of representation, we do not show the original content but abbreviate them as a sequence of fragments. In the first step, all new and quoted fragments are identified. For instance, email  $E_3$  is decomposed into 3 fragments: new fragment  $c$  and quoted fragments  $b$ , which in turn quoted  $a$ .  $E_4$  is decomposed into  $de$ ,  $c$ ,  $b$  and  $a$ . Then, in the second step, to identify distinct fragments (nodes), fragments are compared with each other and overlaps are identified. Fragments are split if necessary (e.g., fragment  $gh$  in  $E_5$  is split into  $g$  and  $h$  when matched with  $E_6$ ), and duplicates are removed. At the end, 10 distinct fragments  $a, \dots, j$  give rise to 10 nodes in the graph shown in Figure 1(b).

As the third step, we create edges, which represent the replying relationship among fragments. In

general, it is difficult to determine whether one fragment is actually replying to another fragment. We assume that *any new fragment is a potential reply to neighboring quotations – quoted fragments immediately preceding or following it*. Let us consider  $E_6$  in Figure 1(a). there are two edges from node  $i$  to  $g$  and  $h$ , while there is only a single edge from  $j$  to  $h$ . For  $E_3$ , there are the edges  $(c, b)$  and  $(c, a)$ . Because of the edge  $(b, a)$ , the edge  $(c, a)$  is not included in Figure 1(b). Figure 1(b) shows the fragment quotation graph of the conversation shown in Figure 1(a) with all the redundant edges removed. In contrast, if threading is done at the coarse granularity of entire emails, as adopted in many studies, the threading would be a simple chain from  $E_6$  to  $E_5$ ,  $E_5$  to  $E_4$  and so on. Fragment  $f$  reflects a special and important phenomenon, where the original email of a quotation does not exist in the user’s folder. We call this as the *hidden email* problem. This problem and its influence on email summarization were studied in (Carenini et al., 2005) and (Carenini et al., 2007).

#### 3.2 Building the Sentence Quotation Graph

A fragment quotation graph can only represent the conversation in the fragment granularity. We notice that some sentences in a fragment are more relevant to the conversation than the remaining ones. The fragment quotation graph is not capable of representing this difference. Hence, in the following, we describe how to build a sentence quotation graph from the fragment quotation graph and introduce several ways to give weight to the edges.

In a sentence quotation graph  $GS$ , each node represents a distinct sentence in the email conversation, and each edge  $(u, v)$  represents the replying relationship between node  $u$  and  $v$ . The algorithm to create the sentence quotation graph contains the following 3 steps: create nodes, create edges and assign weight to edges. In the following, we first illustrate how to create nodes and edges. In Section 3.3, we discuss different ways to assign weight to edges.

Given a fragment quotation graph  $GF$ , we first split each fragment into a set of sentences. For each sentence, we create a node in the sentence quotation graph  $GS$ . In this way, each sentence in the email conversation is represented by a distinct node in  $GS$ .

As the second step, we create the edges in  $GS$ . The edges in  $GS$  are based on the edges in  $GF$

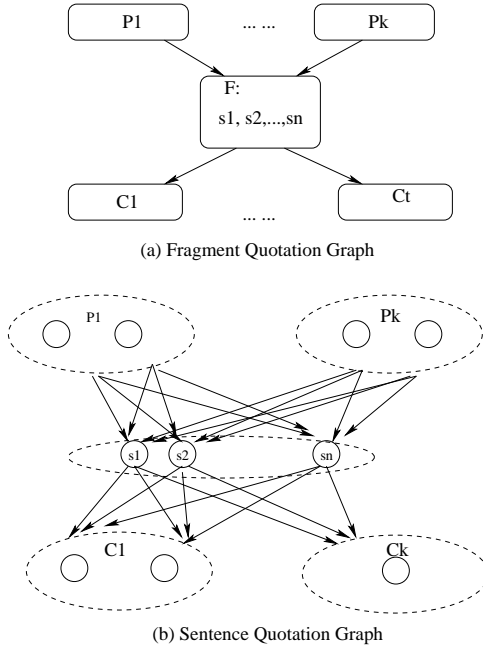

Figure 2: Create the Sentence Quotation Graph from the Fragment Quotation Graph

because the edges in  $GF$  already reflect the replying relationship among fragments. For each edge  $(u, v) \in GF$ , we create edges from each sentence of  $u$  to each sentence of  $v$  in the sentence quotation graph  $GS$ . This is illustrated in Figure 2.

Note that when each distinct sentence in an email conversation is represented as one node in the sentence quotation graph, the extractive email summarization problem is transformed into a standard node ranking problem within the sentence quotation graph. Hence, general node ranking algorithms, e.g., Page-Rank, can be used for email summarization as well.

### 3.3 Measuring the Cohesion Between Sentences

After creating the nodes and edges in the sentence quotation graph, a key technical question is how to measure the degree that two sentences are related to each other, e.g., a sentence  $s_u$  is replying to or being replied by  $s_v$ . In this paper, we use text cohesion between two sentences  $s_u$  and  $s_v$  to make this assessment and assign this as the weight of the corresponding edge  $(s_u, s_v)$ . We explore three types of cohesion measures: (1) clue words that are based on stems, (2) semantic distance based on WordNet

and (3) cosine similarity that is based on the word TFIDF vector. In the following, we discuss these three methods separately in detail.

#### 3.3.1 Clue Words

Clue words were originally defined as re-occurring words with the same stem between two adjacent fragments in the fragment quotation graph. In this section, we re-define clue words based on the sentence quotation graph as follows. A clue word in a sentence  $S$  is a non-stop word that also appears (modulo stemming) in a parent or a child node (sentence) of  $S$  in the sentence quotation graph.

The frequency of clue words in the two sentences measures their cohesion as described in Equation 1.

$$weight(s_u, s_v) = \sum_{w_i \in s_u} freq(w_i, s_v) \quad (1)$$

#### 3.3.2 Semantic Similarity Based on WordNet

Other than stems, when people reply to previous messages they may also choose some semantically related words, such as synonyms and antonyms, e.g., “talk” vs. “discuss”. Based on this observation, we propose to use semantic similarity to measure the cohesion between two sentences. We use the well-known lexical database WordNet to get the semantic similarity of two words. Specifically, we use the package by (Pedersen et al., 2004), which includes several methods to compute the semantic similarity. Among those methods, we choose “lesk” and “jcn”, which are considered two of the best methods in (Jurafsky and Martin, 2008). Similar to the clue words, we measure the semantic similarity of two sentences by the total semantic similarity of the words in both sentences. This is described in the following equation.

$$weight(s_u, s_v) = \sum_{w_i \in s_u} \sum_{w_j \in s_v} \sigma(w_i, w_j), \quad (2)$$

#### 3.3.3 Cosine Similarity

Cosine similarity is a popular metric to compute the similarity of two text units. To do so, each sentence is represented as a word vector of TFIDF values. Hence, the cosine similarity of two sentences  $s_u$  and  $s_v$  is then computed as  $\frac{\vec{s}_u \cdot \vec{s}_v}{\|\vec{s}_u\| \cdot \|\vec{s}_v\|}$ .

## 4 Summarization Based on the Sentence Quotation Graph

Having built the sentence quotation graph with different measures of cohesion, in this section, we develop two summarization approaches. One is the generalization of the CWS algorithm in (Carenini et al., 2007) and one is the well-known Page-Rank algorithm. Both algorithms compute a score,  $SentScore(s)$ , for each sentence (node)  $s$ , which is used to select the top- $k\%$  sentences as the summary.

### 4.1 Generalized ClueWordSummarizer

Given the sentence quotation graph, since the weight of an edge  $(s, t)$  represents the extent that  $s$  is related to  $t$ , a natural assumption is that the more relevant a sentence (node)  $s$  is to its parents and children, the more important  $s$  is. Based on this assumption, we compute the weight of a node  $s$  by summing up the weight of all the outgoing and incoming edges of  $s$ . This is described in the following equation.

$$SentScore(s) = \sum_{(s,t) \in GS} weight(s,t) + \sum_{(p,s) \in GS} weight(p,s) \quad (3)$$

The weight of an edge  $(s, t)$  can be any of the three metrics described in the previous section. Particularly, when the weight of the edge is based on clue words as in Equation 1, this method is equivalent to Algorithm CWS in (Carenini et al., 2007). In the rest of this paper, let CWS denote the Generalized ClueWordSummarizer when the edge weight is based on clue words, and let *CWS-Cosine* and *CWS-Semantic* denote the summarizer when the edge weight is cosine similarity and semantic similarity respectively. *Semantic* can be either “lesk” or “jcn”.

### 4.2 Page-Rank-based Summarization

The Generalized ClueWordSummarizer only considers the weight of the edges without considering the importance (weight) of the nodes. This might be incorrect in some cases. For example, a sentence replied by an important sentence should get some of its importance. This intuition is similar to the one inspiring the well-known Page-Rank algorithm. The traditional Page-Rank algorithm only considers the outgoing edges. In email conversations, what we want to measure is the cohesion between sentences no matter which one is being replied to. Hence, we

need to consider both incoming and outgoing edges and the corresponding sentences.

Given the sentence quotation graph  $G_s$ , the Page-Rank-based algorithm is described in Equation 4.  $PR(s)$  is the Page-Rank score of a node (sentence)  $s$ .  $d$  is the dumping factor, which is initialized to 0.85 as suggested in the Page-Rank algorithm. In this way, the rank of a sentence is evaluated globally based on the graph.

## 5 Summarization with Subjective Opinions

Other than the conversation structure, the measures of cohesion and the graph-based summarization methods we have proposed, the importance of a sentence in emails can be captured from other aspects. In many applications, it has been shown that sentences with subjective meanings are paid more attention than factual ones (Pang and Lee, 2004) (Esuli and Sebastiani, 2006). We evaluate whether this is also the case in emails, especially when the conversation is about decision making, giving advice, providing feedbacks, etc.

A large amount of work has been done on determining the level of subjectivity of text (Shanahan et al., 2005). In this paper we follow a very simple approach that, if successful, could be extended in future work. More specifically, in order to assess the degree of subjectivity of a sentence  $s$ , we count the frequency of words and phrases in  $s$  that are likely to bear subjective opinions. The assumption is that the more subjective words  $s$  contains, the more likely that  $s$  is an important sentence for the purpose of email summarization. Let  $SubjScore(s)$  denote the number of words with a subjective meaning. Equation 5 illustrates how  $SubjScore(s)$  is computed.  $SubjList$  is a list of words and phrases that indicate subjective opinions.

$$SubjScore(s) = \sum_{w_i \in SubjList, w_i \in s} freq(w_i) \quad (5)$$

The  $SubjScore(s)$  alone can be used to evaluate the importance of a sentence. In addition, we can combine  $SubjScore$  with any of the sentence scores based on the sentence quotation graph. In this paper, we use a simple approach by adding them up as the final sentence score.

$$PR(s) = (1 - d) + d * \frac{\sum_{s_i \in \text{child}(s)} \text{weight}(s, s_i) * PR(s_i) + \sum_{s_j \in \text{parent}(s)} \text{weight}(s_j, s) * PR(s_j)}{\sum_{s_i \in \text{child}(s)} \text{weight}(s, s_i) + \sum_{s_j \in \text{parent}(s)} \text{weight}(s_j, s)} \quad (4)$$

As to the subjective words and phrases, we consider the following two lists generated by researchers in this area.

- *OpFind*: The list of subjective words in (Wilson et al., 2005). The major source of this list is from (Riloff and Wiebe, 2003) with additional words from other sources. This list contains 8,220 words or phrases in total.
- *OpBear*: The list of opinion bearing words in (Kim and Hovy, 2005). This list contains 27,193 words or phrases in total.

## 6 Empirical Evaluation

### 6.1 Dataset Setup

There are no publicly available annotated corpora to test email summarization techniques. So, the first step in our evaluation was to develop our own corpus. We use the Enron email dataset, which is the largest public email dataset. In the 10 largest *inbox* folders in the Enron dataset, there are 296 email conversations. Since we are studying summarizing email conversations, we required that each selected conversation contained at least 4 emails. In total, 39 conversations satisfied this requirement. We use the MEAD package to segment the text into 1,394 sentences (Radev et al., 2004).

We recruited 50 human summarizers to review those 39 selected email conversations. Each email conversation was reviewed by 5 different human summarizers. For each given email conversation, human summarizers were asked to generate a summary by directly selecting important sentences from the original emails in that conversation. We asked the human summarizers to select 30% of the total sentences in their summaries.

Moreover, human summarizers were asked to classify each selected sentence as either *essential* or *optional*. The essential sentences are crucial to the email conversation and have to be extracted in any case. The optional sentences are not critical but

are useful to help readers understand the email conversation if the given summary length permits. By classifying essential and optional sentences, we can distinguish the core information from the supporting ones and find the most convincing sentences that most human summarizers agree on.

As essential sentences are more important than the optional ones, we give more weight to the essential selections. We compute a *GSValue* for each sentence to evaluate its importance according to the human summarizers' selections. The score is designed as follows: for each sentence  $s$ , one essential selection has a score of 3, one optional selection has a score of 1. Thus, the *GSValue* of a sentence ranges from 0 to 15 (5 human summarizers  $\times$  3). The *GSValue* of 8 corresponds to 2 essential and 2 optional selections. If a sentence has a *GSValue* no less than 8, we take it as an *overall essential* sentence. In the 39 conversations, we have about 12% overall essential sentences.

### 6.2 Evaluation Metrics

Evaluation of summarization is believed to be a difficult problem in general. In this paper, we use two metrics to measure the accuracy of a system generated summary. One is *sentence pyramid precision*, and the other is *ROUGE recall*. As to the statistical significance, we use the 2-tail pairwise student t-test in all the experiments to compare two specific methods. We also use ANOVA to compare three or more approaches together.

The sentence pyramid precision is a relative precision based on the *GSValue*. Since this idea is borrowed from the pyramid metric by Nenkova et al. (Nenkova et al., 2007), we call it the *sentence pyramid precision*. In this paper, we simplify it as the *pyramid precision*. As we have discussed above, with the reviewers' selections, we get a *GSValue* for each sentence, which ranges from 0 to 15. With this *GSValue*, we rank all sentences in a descendant order. We also group all sentences with the same *GSValue* together as one tier  $T_i$ , where  $i$  is the corre-

sponding GSValue;  $i$  is called the *level* of the tier  $T_i$ . In this way, we organize all sentences into a pyramid: a sequence of tiers with a descendant order of levels. With the pyramid of sentences, the accuracy of a summary is evaluated over the best summary we can achieve under the same summary length. The best summary of  $k$  sentences are the top  $k$  sentences in terms of GSValue.

Other than the sentence pyramid precision, we also adopt the ROUGE recall to evaluate the generated summary with a finer granularity than sentences, e.g., n-gram and longest common subsequence. Unlike the pyramid method which gives more weight to sentences with a higher GSValue, ROUGE is not sensitive to the difference between essential and optional selections (it considers all sentences in one summary equally). Directly applying ROUGE may not be accurate in our experiments. Hence, we use the overall essential sentences as the gold standard summary for each conversation, i.e., sentences in tiers no lower than  $T_8$ . In this way, the ROUGE metric measures the similarity of a system generated summary to a gold standard summary that is considered important by most human summarizers. Specifically, we choose ROUGE-2 and ROUGE-L as the evaluation metric.

### 6.3 Evaluating the Weight of Edges

In Section 3.3, we developed three ways to compute the weight of an edge in the sentence quotation graph, i.e., clue words, semantic similarity based on WordNet and cosine similarity. In this section, we compare them together to see which one is the best. It is well-known that the accuracy of the summarization method is affected by the length of the summary. In the following experiments, we choose the summary length as 10%, 12%, 15%, 20% and 30% of the total sentences and use the aggregated average accuracy to evaluate different algorithms.

Table 1 shows the aggregated pyramid precision over all five summary lengths of CWS, CWS-Cosine, two semantic similarities, i.e., CWS-lesk and CWS-jcn. We first use ANOVA to compare the four methods. For the pyramid precision, the  $F$  ratio is 50, and the p-value is  $2.1E-29$ . This shows that the four methods are significantly different in the average accuracy. In Table 1, by comparing CWS with the other methods, we can see that CWS obtains the

	CWS	CWS-Cosine	CWS-lesk	CWS-jcn
Pyramid	0.60	0.39	0.57	0.57
p-value		<0.0001	0.02	0.005
ROUGE-2	0.46	0.31	0.39	0.35
p-value		<0.0001	<0.001	<0.001
ROUGE-L	0.54	0.43	0.49	0.45
p-value		<0.0001	<0.001	<0.001

Table 1: Generalized CWS with Different Edge Weights

highest precision (0.60). The widely used cosine similarity does not perform well. Its precision (0.39) is about half of the precision of CWS with a p-value less than 0.0001. This clearly shows that CWS is significantly better than CWS-Cosine. Meanwhile, both semantic similarities have lower accuracy than CWS, and the differences are also statistically significant even with the conservative Bonferroni adjustment (i.e., the p-values in Table 1 are multiplied by three).

The above experiments show that the widely used cosine similarity and the more sophisticated semantic similarity in WordNet are less accurate than the basic CWS in the summarization framework. This is an interesting result and can be viewed at least from the following two aspects. First, clue words, though straight forward, are good at capturing the important sentences within an email conversation. The higher accuracy of CWS may suggest that people tend to use the same words to communicate in email conversations. Some related words in the previous emails are adopted exactly or in another similar format (modulo stemming). This is different from other documents such as newspaper articles and formal reports. In those cases, the authors are usually professional in writing and choose their words carefully, even intentionally avoid repeating the same words to gain some diversity. However, for email conversation summarization, this does not appear to be the case.

Moreover, in the previous discussion we only considered the accuracy in precision without considering the runtime issue. In order to have an idea of the runtime of the two methods, we did the following comparison. We randomly picked 1000 pairs of words from the 20 conversations and compute their semantic distance in “jcn”. It takes about 0.056 seconds to get the semantic similarity for one pair on the

average. In contrast, when the weight of edges are computed based on clue words, the average runtime to compute the SentScore for all sentences in a conversation is only 0.05 seconds, which is even a little less than the time to compute the semantic similarity of one pair of words. In other words, when CWS has generated the summary of one conversation, we can only get the semantic distance between one pair of words. Note that for each edge in the sentence quotation graph, we need to compute the distance for every pair of words in each sentence. Hence, the empirical results do not support the use of semantic similarity. In addition, we do not discuss the runtime performance of CWS-cosine here because of its extremely low accuracy.

#### 6.4 Comparing Page-Rank and CWS

Table 2 compares Page-Rank and CWS under different edge weights. We compare Page-Rank only with CWS because CWS is better than the other Generalized CWS methods as shown in the previous section. This table shows that Page-Rank has a lower accuracy than that of CWS and the difference is significant in all four cases. Moreover, when we compare Table 1 and 2 together, we can find that, for each kind of edge weight, Page-Rank has a lower accuracy than the corresponding Generalized CWS. Note that Page-Rank computes a node’s rank based on all the nodes and edges in the graph. In contrast, CWS only considers the similarity between neighboring nodes. The experimental result indicates that for email conversation, the local similarity based on clue words is more consistent with the human summarizers’ selections.

#### 6.5 Evaluating Subjective Opinions

Table 3 shows the result of using subjective opinions described in Section 5. The first 3 columns in this table are pyramid precision of CWS and using 2 lists of subjective words and phrases alone. We can see that by using subjective words alone, the precision of each subjective list is lower than that of CWS. However, when we integrate CWS and subjective words together, as shown in the remaining 2 columns, the precisions get improved consistently for both lists. The increase in precision is at least 0.04 with statistical significance. A natural question to ask is whether clue words and subjective words overlap much. Our

	CWS	PR-Clue	PR-Cosine	PR-lesk	PR-jcn
Pyramid	0.60	0.51	0.37	0.54	0.50
p-value		< 0.0001	< 0.0001	< 0.0001	< 0.0001
ROUGE-2	0.46	0.4	0.26	0.36	0.39
p-value		0.05	< 0.0001	0.001	0.02
ROUGE-L	0.54	0.49	0.36	0.44	0.48
p-value		0.06	< 0.0001	0.0005	0.02

Table 2: Compare Page-Rank with CWS

	CWS	OpFind	OpBear	CWS+OpFind	CWS+OpBear
Pyramid	0.60	0.52	0.59	<b>0.65</b>	<b>0.64</b>
p-value		0.0003	0.8	<0.0001	0.0007
ROUGE-2	0.46	0.37	0.44	<b>0.50</b>	<b>0.49</b>
p-value		0.0004	0.5	0.004	0.06
ROUGE-L	0.54	0.48	0.56	<b>0.60</b>	<b>0.59</b>
p-value		0.01	0.6	0.0002	0.002

Table 3: Accuracy of Using Subjective Opinions

analysis shows that the overlap is minimal. For the list of OpFind, the overlapped words are about 8% of clue words and 4% of OpFind that appear in the conversations. This result clearly shows that clue words and subjective words capture the importance of sentences from different angles and can be used together to gain a better accuracy.

## 7 Conclusions

We study how to summarize email conversations based on the conversational cohesion and the subjective opinions. We first create a sentence quotation graph to represent the conversation structure on the sentence level. We adopt three cohesion metrics, clue words, semantic similarity and cosine similarity, to measure the weight of the edges. The Generalized ClueWordSummarizer and Page-Rank are applied to this graph to produce summaries. Moreover, we study how to include subjective opinions to help identify important sentences for summarization.

The empirical evaluation shows the following two discoveries: (1) The basic CWS (based on clue words) obtains a higher accuracy and a better runtime performance than the other cohesion measures. It also has a significant higher accuracy than the Page-Rank algorithm. (2) By integrating clue words and subjective words (phrases), the accuracy of CWS is improved significantly. This reveals an interesting phenomenon and will be further studied.

# Ad Hoc Treebank Structures

**Markus Dickinson**

Department of Linguistics

Indiana University

md7@indiana.edu

## Abstract

We outline the problem of ad hoc rules in treebanks, rules used for specific constructions in one data set and unlikely to be used again. These include ungeneralizable rules, erroneous rules, rules for ungrammatical text, and rules which are not consistent with the rest of the annotation scheme. Based on a simple notion of rule equivalence and on the idea of finding rules unlike any others, we develop two methods for detecting ad hoc rules in flat treebanks and show they are successful in detecting such rules. This is done by examining evidence across the grammar and without making any reference to context.

## 1 Introduction and Motivation

When extracting rules from constituency-based treebanks employing flat structures, grammars often limit the set of rules (e.g., Charniak, 1996), due to the large number of rules (Krotov et al., 1998) and “leaky” rules that can lead to mis-analysis (Foth and Menzel, 2006). Although frequency-based criteria are often used, these are not without problems because low-frequency rules can be valid and potentially useful rules (see, e.g., Daelemans et al., 1999), and high-frequency rules can be erroneous (see, e.g., Dickinson and Meurers, 2005). A key issue in determining the rule set is rule generalizability: will these rules be needed to analyze new data? This issue is of even more importance when considering the task of porting a parser trained on one genre to another genre (e.g., Gildea, 2001). Infrequent rules in one genre may be quite frequent in

another (Sekine, 1997) and their frequency may be unrelated to their usefulness for parsing (Foth and Menzel, 2006). Thus, we need to carefully consider the applicability of rules in a treebank to new text.

Specifically, we need to examine *ad hoc* rules, rules used for particular constructions specific to one data set and unlikely to be used on new data. This is why low-frequency rules often do not extend to new data: if they were only used once, it was likely for a specific reason, not something we would expect to see again. Ungeneralizable rules, however, do not extend to new text for a variety of reasons, not all of which can be captured strictly by frequency.

While there are simply phenomena which, for various reasons, are rarely used (e.g., long coordinated lists), other ungeneralizable phenomena are potentially more troubling. For example, when ungrammatical or non-standard text is used, treebanks employ rules to cover it, but do not usually indicate ungrammaticality in the annotation. These rules are only to be used in certain situations, e.g., for typographical conventions such as footnotes, and the fact that the situation is irregular would be useful to know if the purpose of an induced grammar is to support robust parsing. And these rules are outright damaging if the set of treebank rules is intended to accurately capture the grammar of a language. This is true of precision grammars, where analyses can be more or less preferred (see, e.g., Wagner et al., 2007), and in applications like intelligent computer-aided language learning, where learner input is parsed to detect what is correct or not (see, e.g., Vandeventer Faltin, 2003, ch. 2). If a treebank grammar is used (e.g., Metcalf and Boyd,

2006), then one needs to isolate rules for ungrammatical data, to be able to distinguish grammatical from ungrammatical input.

Detecting ad hoc rules can also reveal issues related to rule quality. Many ad hoc rules exist because they are erroneous. Not only are errors inherently undesirable for obtaining an accurate grammar, but training on data with erroneous rules can be detrimental to parsing performance (e.g., Dickinson and Meurers, 2005; Hogan, 2007). As annotation schemes are not guaranteed to be completely consistent, other ad hoc rules point to non-uniform aspects of the annotation scheme. Thus, identifying ad hoc rules can also provide feedback on annotation schemes, an especially important step if one is to use the treebank for specific applications (see, e.g., Vadas and Curran, 2007), or if one is in the process of developing a treebank.

Although statistical techniques have been employed to detect anomalous annotation (Ule and Simov, 2004; Eskin, 2000), these methods do not account for linguistically-motivated generalizations across rules, and no full evaluation has been done on a treebank. Our starting point for detecting ad hoc rules is also that they are dissimilar to the rest of the grammar, but we rely on a notion of equivalence which accounts for linguistic generalizations, as described in section 2. We generalize equivalence in a corpus-independent way in section 3 to detect ad hoc rules, using two different methods to determine when rules are dissimilar. The results in section 4 show the success of the method in identifying all types of ad hoc rules.

## 2 Background

### 2.1 Equivalence classes

To define dissimilarity, we need a notion of similarity, and, a starting point for this is the error detection method outlined in Dickinson and Meurers (2005). Since most natural language expressions are endocentric, i.e., a category projects to a phrase of the same category (e.g., X-bar Schema, Jackendoff, 1977), daughters lists with more than one possible mother are flagged as potentially containing an error. For example, IN NP<sup>1</sup> has nine different mothers in the Wall Street Journal (WSJ) portion of the Penn

<sup>1</sup>Appendix A lists all categories used in this paper.

Treebank (Marcus et al., 1993), six of which are errors.

This method can be extended to increase recall, by treating similar daughters lists as equivalent (Dickinson, 2006, 2008). For example, the daughters lists ADVP RB ADVP and ADVP , RB ADVP in (1) can be put into the same equivalence class, because they predict the same mother category. With this equivalence, the two different mothers, PP and ADVP, point to an error (in PP).

- (1) a. to slash its work force in the U.S. , [*PP* [*ADVP* as] soon/*RB* [*ADVP* as next month]]
- b. to report ... [*ADVP* [*ADVP* immediately] ,/ not/*RB* [*ADVP* a month later]]

Anything not contributing to predicting the mother is ignored in order to form equivalence classes. Following the steps below, 15,989 daughters lists are grouped into 3783 classes in the WSJ.

1. Remove daughter categories that are always non-predictive to phrase categorization, i.e., always adjuncts, such as punctuation and the parenthetical (PRN) category.
2. Group head-equivalent lexical categories, e.g., NN (common noun) and NNS (plural noun).
3. Model adjacent identical elements as a single element, e.g., NN NN becomes NN.

While the sets of non-predictive and head-equivalent categories are treebank-specific, they require only a small amount of manual effort.

### 2.2 Non-equivalence classes

Rules in the same equivalence class not only predict the same mother, they provide support that the daughters list is accurate—the more rules within a class, the better evidence that the annotation scheme legitimately licenses that sequence. A lack of similar rules indicates a potentially anomalous structure.

Of the 3783 equivalence classes for the whole WSJ, 2141 are unique, i.e., have only one unique daughters list. For example, in (2), the daughters list RB TO JJ NNS is a daughters list with no correlates in the treebank; it is erroneous because *close to wholesale* needs another layer of structure, namely adjective phrase (ADJP) (Bies et al., 1995, p. 179).

(2) they sell [merchandise] for [ $NP$  close/RB to/TO wholesale/JJ prices/NNS ]

Using this strict equivalence to identify ad hoc rules is quite successful (Dickinson, 2008), but it misses a significant number of generalizations. These equivalences were not designed to assist in determining linguistic patterns from non-linguistic patterns, but to predict the mother category, and thus many correct rules are incorrectly flagged. To provide support for the correct rule  $NP \rightarrow DT CD JJS NNP JJ NNS$  in (3), for instance, we need to look at some highly similar rules in the treebank, e.g., the three instances of  $NP \rightarrow DT CD JJ NNP NNS$ , which are not strictly equivalent to the rule in (3).

(3) [ $NP$  the/DT 100/CD largest/JJS Nasdaq/NNP financial/JJ stocks/NNS ]

### 3 Rule dissimilarity and generalizability

#### 3.1 Criteria for rule equivalence

With a notion of (non-)equivalence as a heuristic, we can begin to detect ad hoc rules. First, however, we need to redefine equivalence to better reflect syntactic patterns.

Firstly, in order for two rules to be in the same equivalence class—or even to be similar—the mother must also be the same. This captures the property that identical daughters lists with different mothers are distinct (cf. Dickinson and Meurers, 2005). For example, looking back at (1), the one occurrence of  $ADVP \rightarrow ADVP, RB ADVP$  is very similar to the 4 instances of  $ADVP \rightarrow RB ADVP$ , whereas the one instance of  $PP \rightarrow ADVP RB ADVP$  is not and is erroneous. Daughters lists are thus now only compared to rules with the same mother.

Secondly, we use only two steps to determine equivalence: 1) remove non-predictive daughter categories, and 2) group head-equivalent lexical categories.<sup>2</sup> While useful for predicting the same mother, the step of Kleene reduction is less useful for our purposes since it ignores potential differences in argument structure. It is important to know how many identical categories can appear within a given rule, to tell whether it is reliable;  $VP \rightarrow VB$

$NP$  and  $VP \rightarrow VB NP NP$ , for example, are two different rules.<sup>3</sup>

Thirdly, we base our scores on token counts, in order to capture the fact that the more often we observe a rule, the more reliable it seems to be. This is not entirely true, as mentioned above, but this prevents frequent rules such as  $NP \rightarrow EX$  (1075 occurrences) from being seen as an anomaly.

With this new notion of equivalence, we can now proceed to accounting for similar rules in detecting ad hoc rules.

#### 3.2 Reliability scores

In order to devise a scoring method to reflect similar rules, the simplest way is to use a version of edit distance between rules, as we do under the *Whole daughters scoring* below. This reflects the intuition that rules with similar lists of daughters reflect the same properties. This is the “positive” way of scoring rules, in that we start with a basic notion of equivalence and look for more positive evidence that the rule is legitimate. Rules without such evidence are likely ad hoc.

Our goal, though, is to take the results and examine the anomalous rules, i.e., those which lack strong evidence from other rules. We can thus more directly look for “negative” evidence that a rule is ad hoc. To do this, we can examine the weakest parts of each rule and compare those across the corpus, to see which anomalous patterns emerge; we do this in the *Bigram scoring* section below.

Because these methods exploit different properties of rules and use different levels of abstraction, they have complementary aspects. Both start with the same assumptions about what makes rules equivalent, but diverge in how they look for rules which do not fit well into these equivalences.

**Whole daughters scoring** The first method to detect ad hoc rules directly accounts for similar rules across equivalence classes. Each rule type is assigned a reliability score, calculated as follows:

1. Map a rule to its equivalence class.
2. For every rule token within the equivalence class, add a score of 1.

<sup>2</sup>See Dickinson (2006) for the full mappings.

<sup>3</sup>Experiments done with Kleene reduction show that the results are indeed worse.

3. For every rule token within a highly similar equivalence class, add a score of  $\frac{1}{2}$ .

Positive evidence that a rule is legitimate is obtained by looking at similar classes in step #3, and then rules with the lowest scores are flagged as potentially ad hoc (see section 4.1). To determine similarity, we use a modified Levenshtein distance, where only insertions and deletions are allowed; a distance of one qualifies as *highly similar*.<sup>4</sup> Allowing two or more changes would be problematic for unary rules (e.g., (4a), and in general, would allow us to add and subtract dissimilar categories. We thus remain conservative in determining similarity.

Also, we do not utilize substitutions: while they might be useful in some cases, it is too problematic to include them, given the difference in meaning of each category. Consider the problematic rules in (4). In (4a), which occurs once, if we allow substitutions, then we will find 760 “comparable” instances of VP → VB, despite the vast difference in category (verb vs. adverb). Likewise, the rule in (4b), which occurs 8 times, would be “comparable” to the 602 instances of PP → IN PP, used for multi-word prepositions like *because of*.<sup>5</sup> To maintain these true differences, substitutions are not allowed.

- (4) a. VP → RB  
 b. PP → JJ PP

This notion of similarity captures many generalizations, e.g., that adverbial phrases are optional. For example, in (5), the rule reduces to S → PP ADVP NP ADVP VP. With a strict notion of equivalence, there are no comparable rules. However, the class S → PP NP ADVP VP, with 198 members, is highly similar, indicating more confidence in this correct rule.

- (5) [<sub>S</sub> [<sub>PP</sub> During his years in Chiriqui] ,/ , [<sub>ADVP</sub> however] ,/ , [<sub>NP</sub> Mr. Noriega] [<sub>ADVP</sub> also] [<sub>VP</sub> revealed himself as an officer as perverse as he was ingenious] ./ .]

<sup>4</sup>The score is thus more generally  $\frac{1}{1+distance}$ , although we ascribe no theoretical meaning to this

<sup>5</sup>Rules like PP → JJ PP might seem to be correct, but this depends upon the annotation scheme. Phrases starting with *due to* are sometimes annotated with this rule, but they also occur as ADJP or ADVP or with *due* as RB. If PP → JJ PP is correct, identifying this rule actually points to other erroneous rules.

**Bigram scoring** The other method of detecting ad hoc rules calculates reliability scores by focusing specifically on what the classes do not have in common. Instead of examining and comparing rules in their entirety, this method abstracts a rule to its component parts, similar to features using information about *n*-grams of daughter nodes in parse reranking models (e.g., Collins and Koo, 2005).

We abstract to bigrams, including added *START* and *END* tags, as longer sequences risk missing generalizations; e.g., unary rules would have no comparable rules. We score rule types as follows:

1. Map a rule to its equivalence class, resulting in a *reduced rule*.
2. Calculate the frequency of each <mother,bigram> pair in a reduced rule: for every reduced rule token with the same pair, add a score of 1 for that bigram pair.
3. Assign the score of the least-frequent bigram as the score of the rule.

We assign the score of the lowest-scoring bigram because we are interested in anomalous sequences. This is in the spirit of Květon and Oliva (2002), who define invalid bigrams for POS annotation sequences in order to detect annotation errors..

As one example, consider (6), where the reduced rule NP → NP DT NNP is composed of the bigrams START NP, NP DT, DT NNP, and NNP END. All of these are relatively common (more than a hundred occurrences each), except for NP DT, which appears in only two other rule types. Indeed, DT is an incorrect tag (NNP is correct): when NP is the first daughter of NP, it is generally a possessive, precluding the use of a determiner.

- (6) (NP (NP ABC 's) ( ' ' ' ' ) (DT This) (NNP Week))

The whole daughters scoring misses such problematic structures because it does not explicitly look for anomalies. The disadvantage of the bigram scoring, however, is its missing of the big picture: for example, the erroneous rule NP → NNP CC NP gets a large score (1905) because each subsequence is quite common. But this exact sequence is rather rare (NNP and NP are not generally coordinated), so the whole daughters scoring assigns a low score (4.0).

## 4 Evaluation

To gauge our success in detecting ad hoc rules, we evaluate the reliability scores in two main ways: 1) whether unreliable rules generalize to new data (section 4.1), and, more importantly, 2) whether the unreliable rules which do generalize are ad hoc in other ways—e.g., erroneous (section 4.2). To measure this, we use sections 02-21 of the WSJ corpus as training data to derive scores, section 23 as testing data, and section 24 as development data.

### 4.1 Ungeneralizable rules

To compare the effectiveness of the two scoring methods in identifying ungeneralizable rules, we examine how many rules from the training data do not appear in the heldout data, for different thresholds. In figure 1, for example, the method identifies 3548 rules with scores less than or equal to 50, 3439 of which do not appear in the development data, resulting in an ungeneralizability rate of 96.93%.

To interpret the figures below, we first need to know that of the 15,246 rules from the training data, 1832 occur in the development data, or only 12.02%, corresponding to 27,038 rule tokens. There are also 396 new rules in the development data, making for a total of 2228 rule types and 27,455 rule tokens.

#### 4.1.1 Development data results

The results are shown in figure 1 for the whole daughters scoring method and in figure 2 for the bigram method. Both methods successfully identify rules with little chance of occurring in new data, the whole daughters method performing slightly better.

Thresh.	Rules	Unused	Ungen.
1	311	311	100.00%
25	2683	2616	97.50%
50	3548	3439	96.93%
100	4596	4419	96.15%

Figure 1: Whole daughter ungeneralizability (devo.)

#### 4.1.2 Comparing across data

Is this ungeneralizability consistent over different data sets? To evaluate this, we use the whole daughters scoring method, since it had a higher ungeneralizability rate in the development data, and we use

Thresh.	Rules	Unused	Ungen.
1	599	592	98.83%
5	1661	1628	98.01%
10	2349	2289	97.44%
15	2749	2657	96.65%
20	3120	2997	96.06%

Figure 2: Bigram ungeneralizability (devo.)

section 23 of the WSJ and the Brown corpus portion of the Penn Treebank.

Given different data sizes, we now report the coverage of rules in the heldout data, for both type and token counts. For instance, in figure 3, for a threshold of 50, 108 rule types appear in the development data, and they appear 141 times. With 2228 total rule types and 27,455 rule tokens, this results in coverages of 4.85% and 0.51%, respectively.

In figures 3, 4, and 5, we observe the same trends for all data sets: low-scoring rules have little generalizability to new data. For a cutoff of 50, for example, rules at or below this mark account for approximately 5% of the rule types used in the data and half a percent of the tokens.

Thresh.	Types		Tokens	
	Used	Cov.	Used	Cov.
10	23	1.03%	25	0.09%
25	67	3.01%	78	0.28%
50	108	4.85%	141	0.51%
100	177	7.94%	263	0.96%
All	1832	82.22%	27,038	98.48%

Figure 3: Coverage of rules in WSJ, section 24

Thresh.	Types		Tokens	
	Used	Cov.	Used	Cov.
10	33	1.17%	39	0.08%
25	82	2.90%	117	0.25%
50	155	5.49%	241	0.51%
100	242	8.57%	416	0.88%
All	2266	80.24%	46,375	98.74%

Figure 4: Coverage of rules in WSJ, section 23

Note in the results for the larger Brown corpus that the percentage of overall rule types from the

Thresh.	Types		Tokens	
	Used	Cov.	Used	Cov.
10	187	1.51%	603	0.15%
25	402	3.25%	1838	0.45%
50	562	4.54%	2628	0.64%
100	778	6.28%	5355	1.30%
All	4675	37.75%	398,136	96.77%

Figure 5: Coverage of rules in Brown corpus

training data is only 37.75%, vastly smaller than the approximately 80% from either WSJ data set. This illustrates the variety of the grammar needed to parse this data versus the grammar used in training.

We have isolated thousands of rules with little chance of being observed in the evaluation data, and, as we will see in the next section, many of the rules which appear are problematic in other ways. The ungeneralizability results make sense, in light of the fact that reliability scores are based on token counts. Using reliability scores, however, has the advantage of being able to identify infrequent but correct rules (cf. example (5)) and also frequent but unhelpful rules. For example, in (7), we find erroneous cases from the development data of the rules  $WHNP \rightarrow WHNP WHPP$  (*five* should be NP) and  $VP \rightarrow NNP NP$  (*OKing* should be VBG). These rules appear 27 and 16 times, respectively, but have scores of only 28.0 and 30.5, showing their unreliability. Future work can separate the effect of frequency from the effect of similarity (see also section 4.3).

- (7) a. [ $WHNP$  [ $WHNP$  five] [ $WHPP$  of whom]]  
 b. received hefty sums for \* [ $VP$  OKing/NNP [ $NP$  the purchase of ...]]

## 4.2 Other ad hoc rules

The results in section 4.1 are perhaps unsurprising, given that many of the identified rules are simply rare. What is important, therefore, is to figure out why some rules appeared in the heldout data at all. As this requires qualitative analysis, we hand-examined the rules appearing in the development data. We set out to examine about 100 rules, and so we report only for the corresponding threshold, finding that ad hoc rules are predominant.

For the whole daughters scoring, at the 50 threshold, 55 (50.93%) of the 108 rules in the development

data are errors. Adding these to the ungeneralizable rules, 98.48% (3494/3548) of the 3548 rules are unhelpful for parsing, at least for this data set. An additional 12 rules cover non-English or fragmented constructions, making for 67 clearly ad hoc rules.

For the bigram scoring, at the 20 threshold, 67 (54.47%) of the 123 rules in the development data are erroneous, and 8 more are ungrammatical. This means that 97.88% (3054/3120) of the rules at this threshold are unhelpful for parsing this data, still slightly lower than the whole daughters scoring.

### 4.2.1 Problematic cases

But what about the remaining rules for both methods which are not erroneous or ungrammatical? First, as mentioned at the outset, there are several cases which reveal non-uniformity in the annotation scheme or guidelines. This may be justifiable, but it has an impact on grammars using the annotation scheme. Consider the case of NAC (not a constituent), used for complex NP premodifiers. The description for tagging titles in the guidelines (Bies et al., 1995, p. 208-209) covers the exact case found in section 24, shown in (8a). This rule,  $NAC \rightarrow NP PP$ , is one of the lowest-scoring rules which occurs, with a whole daughters score of 2.5 and a bigram score of 3, yet it is correct. Examining the guidelines more closely, however, we find examples such as (8b). Here, no extra NP layer is added, and it is not immediately clear what the criteria are for having an intermediate NP.

- (8) a. a “ [ $NAC$  [ $NP$  Points] [ $PP$  of Light]] ” foundation  
 b. The Wall Street Journal “ [ $NAC$  American Way [ $PP$  of Buying]] ” Survey

Secondly, rules with mothers which are simply rare are prone to receive lower scores, regardless of their generalizability. For example, the rules dominated by SINV, SQ, or SBARQ are all correct (6 in whole daughters, 5 in bigram), but questions are not very frequent in this news text: SQ appears only 350 times and SBARQ 222 times in the training data. One might thus consider normalizing the scores based on the overall frequency of the parent.

Finally, and most prominently, there are issues with coordinate structures. For example,  $NP \rightarrow NN CC DT$  receives a low whole daughters score of 7.0,

despite the fact that  $NP \rightarrow NN$  and  $NP \rightarrow DT$  are very common rules. This is a problem for both methods: for the whole daughters scoring, of the 108, 28 of them had a conjunct (CC or CONJP) in the daughters list, and 18 of these were correct. Likewise, for the bigram scoring, 18 had a conjunct, and 12 were correct. Reworking similarity scores to reflect coordinate structures and handle each case separately would require treebank-specific knowledge: the Penn Treebank, for instance, distinguishes unlike coordinated phrases (UCP) from other coordinated phrases, each behaving differently.

#### 4.2.2 Comparing the methods

There are other cases in which one method outperforms the other, highlighting their strengths and weaknesses. In general, both methods fare badly with clausal rules, i.e., those dominated by S, SBAR, SINV, SQ, or SBARQ, but the effect is slightly greater on the bigram scoring, where 20 of the 123 rules are clausal, and 16 of these are correct (i.e., 80% of them are misclassified). To understand this, we have to realize that most modifiers are adjoined at the sentence level when there is any doubt about their attachment (Bies et al., 1995, p. 13), leading to correct but rare subsequences. In sentence (9), for example, the reduced rule  $S \rightarrow SBAR PP NP VP$  arises because both the introductory SBAR and the PP are at the same level. This SBAR PP sequence is fairly rare, resulting in a bigram score of 13.

- (9) [ $S$  [ $SBAR$  As the best opportunities for corporate restructurings are exhausted \* of course] /, [ $PP$  at some point] [ $NP$  the market] [ $VP$  will start \* to reject them] /.]

Whole daughters scoring, on the other hand, assigns this rule a high reliability score of 2775.0, due to the fact that both SBAR NP VP and PP NP VP sequences are common. For rules with long modifier sequences, whole daughters scoring seems to be more effective since modifiers are easily skipped over in comparing to other rules. Whole daughters scoring is also imprecise with clausal rules (10/12 are misclassified), but identifies less of them, and they tend to be for rare mothers (see above).

Various cases are worse for the whole daughters scoring. First are quantifier phrases (QPs), which have a highly varied set of possible heads and argu-

ments. QP is “used for multiword numerical expressions that occur within NP (and sometimes ADJP), where the QP corresponds frequently to some kind of complex determiner phrase” (Bies et al., 1995, p. 193). This definition leads to rules which look different from QP to QP. Some of the lowest-scoring, correct rules are shown in (10). We can see that there is not a great deal of commonality about what comprises quantifier phrases, even if subparts are common and thus not flagged by the bigram method.

- (10) a. [ $QP$  only/RB three/CD of/IN the/DT nine/CD] justices  
 b. [ $QP$  too/RB many/JJ] cooks  
 c. 10 % [ $QP$  or/CC more/JJR]

Secondly, whole daughters scoring relies on complete sequences, and thus whether Kleene reduction (step #3 in section 2) is used makes a marked difference. For example, in (11), the rule  $NP \rightarrow DT JJ NNP NNP JJ NN NN$  is completely correct, despite its low whole daughters score of 15.5 and one occurrence. This rule is similar to the 10 occurrences of  $NP \rightarrow DT JJ NNP JJ NN$  in the training set, but we cannot see this without performing Kleene reduction. For noun phrases at least, using Kleene reduction might more accurately capture comparability. This is less of an issue for bigram scoring, as all the bigrams are perfectly valid, resulting here in a relatively high score (556).

- (11) [ $NP$  the/DT basic/JJ Macintosh/NNP Plus/NNP central/JJ processing/NN unit/NN ]

#### 4.3 Discriminating rare rules

In an effort to determine the effectiveness of the scores on isolating structures which are not linguistically sound, in a way which factors out frequency, we sampled 50 rules occurring only once in the training data. We marked for each whether it was correct or how it was ad hoc, and we did this blindly, i.e., without knowledge of the rule scores. Of these 50, only 9 are errors, 2 cover ungrammatical constructions, and 8 more are unclear. Looking at the bottom 25 scores, we find that the whole daughters and bigrams methods both find 6 errors, or 67% of them, additionally finding 5 unclear cases for the whole daughters and 6 for the bigrams method. Erroneous rules in the top half appear to be ones which

happened to be errors, but could actually be correct in other contexts (e.g., NP → NN NNP NNP CD). Although it is a small data set, the scores seem to be effectively sorting rare rules.

## 5 Summary and Outlook

We have outlined the problem of ad hoc rules in treebanks—ungeneralizable rules, erroneous rules, rules for ungrammatical text, and rules which are not necessarily consistent with the rest of the annotation scheme. Based on the idea of finding rules unlike any others, we have developed methods for detecting ad hoc rules in flat treebanks, simply by examining properties across the grammar and without making any reference to context.

We have been careful not to say how to use the reliability scores. First, without 100% accuracy, it is hard to know what their removal from a parsing model would mean. Secondly, assigning confidence scores to rules, as we have done, has a number of other potential applications. Parse reranking techniques, for instance, rely on knowledge about features other than those found in the core parsing model in order to determine the best parse (e.g., Collins and Koo, 2005; Charniak and Johnson, 2005). Active learning techniques also require a scoring function for parser confidence (e.g., Hwa et al., 2003), and often use uncertainty scores of parse trees in order to select representative samples for learning (e.g., Tang et al., 2002). Both could benefit from more information about rule reliability.

Given the success of the methods, we can strive to make them more corpus-independent, by removing the dependence on equivalence classes. In some ways, comparing rules to similar rules already naturally captures equivalences among rules. In this process, it will also be important to sort out the impact of similarity from the impact of frequency on identifying ad hoc structures.

## Abstract

Morphological processes in Semitic languages deliver space-delimited words which introduce multiple, distinct, syntactic units into the structure of the input sentence. These words are in turn highly ambiguous, breaking the assumption underlying most parsers that the yield of a tree for a given sentence is known in advance. Here we propose a single joint model for performing both morphological segmentation and syntactic disambiguation which bypasses the associated circularity. Using a tree-bank grammar, a data-driven lexicon, and a linguistically motivated unknown-tokens handling technique our model outperforms previous pipelined, integrated or factorized systems for Hebrew morphological and syntactic processing, yielding an error reduction of 12% over the best published results so far.

## 1 Introduction

Current state-of-the-art broad-coverage parsers assume a direct correspondence between the lexical items ingrained in the proposed syntactic analyses (the *yields* of syntactic *parse-trees*) and the space-delimited tokens (henceforth, ‘tokens’) that constitute the unanalyzed surface forms (*utterances*). In Semitic languages the situation is very different.

In Modern Hebrew (Hebrew), a Semitic language with very rich morphology, particles marking conjunctions, prepositions, complementizers and relativizers are bound elements prefixed to the word (Glinert, 1989). The Hebrew token ‘*bcl*’<sup>1</sup>, for example, stands for the complete prepositional phrase

<sup>1</sup>We adopt here the transliteration of (Sima’an et al., 2001).

“in the shadow”. This token may further embed into a larger utterance, e.g., ‘*bcl hneim*’ (literally “in-the-shadow the-pleasant”, meaning roughly “in the pleasant shadow”) in which the dominated Noun is modified by a preceding space-delimited adjective. It should be clear from the onset that the particle *b* (“in”) in ‘*bcl*’ may then attach higher than the bare noun *cl* (“shadow”). This leads to word- and constituent-boundaries discrepancy, which breaks the assumptions underlying current state-of-the-art statistical parsers.

One way to approach this discrepancy is to assume a preceding phase of *morphological segmentation* for extracting the different lexical items that exist at the token level (as is done, to the best of our knowledge, in all parsing related work on Arabic and its dialects (Chiang et al., 2006)). The input for the segmentation task is however highly ambiguous for Semitic languages, and surface forms (tokens) may admit multiple possible analyses as in (Bar-Haim et al., 2007; Adler and Elhadad, 2006). The aforementioned surface form *bcl*, for example, may also stand for the lexical item “onion”, a Noun. The implication of this ambiguity for a parser is that the yield of syntactic trees no longer consists of space-delimited tokens, and the expected number of leaves in the syntactic analysis is not known in advance.

Tsarfaty (2006) argues that for Semitic languages determining the correct morphological segmentation is dependent on syntactic context and shows that increasing information sharing between the morphological and the syntactic components leads to improved performance on the joint task. Cohen and Smith (2007) followed up on these results and pro-

posed a system for joint inference of morphological and syntactic structures using factored models each designed and trained on its own.

Here we push the single-framework conjecture across the board and present a single model that performs morphological segmentation and syntactic disambiguation in a fully generative framework. We claim that no particular morphological segmentation is a-priori more likely for surface forms before exploring the compositional nature of syntactic structures, including manifestations of various long-distance dependencies. Morphological segmentation decisions in our model are delegated to a *lexeme-based* PCFG and we show that using a simple treebank grammar, a data-driven lexicon, and a linguistically motivated unknown-tokens handling our model outperforms (Tsarfaty, 2006) and (Cohen and Smith, 2007) on the joint task and achieves state-of-the-art results on a par with current respective standalone models.<sup>2</sup>

## 2 Modern Hebrew Structure

**Segmental morphology** Hebrew consists of seven particles *m* (“from”) *f* (“when”/“who”/“that”) *h* (“the”) *w* (“and”) *k* (“like”) *l* (“to”) and *b* (“in”). which may never appear in isolation and must always attach as prefixes to the following open-class category item we refer to as *stem*. Several such particles may be prefixed onto a single stem, in which case the affixation is subject to strict linear precedence constraints. Co-occurrences among the particles themselves are subject to further syntactic and lexical constraints relative to the stem.

While the linear precedence of segmental morphemes within a token is subject to constraints, the dominance relations among their mother and sister constituents is rather free. The relativizer *f* (“that”) for example, may attach to an arbitrarily long relative clause that goes beyond token boundaries. The attachment in such cases encompasses a long distance dependency that cannot be captured by Markovian processes that are typically used for morphological disambiguation. The same argument holds for resolving PP attachment of a prefixed preposition or marking conjunction of elements of any kind.

A less canonical representation of segmental mor-

phology is triggered by a morpho-phonological process of omitting the definite article *h* when occurring after the particles *b* or *l*. This process triggers ambiguity as for the definiteness status of Nouns following these particles. We refer to such cases in which the concatenation of elements does not strictly correspond to the original surface form as *super-segmental morphology*. An additional case of super-segmental morphology is the case of Pronominal Clitics. Inflectional features marking pronominal elements may be attached to different kinds of categories marking their pronominal complements. The additional morphological material in such cases appears *after* the stem and realizes the extended meaning. The current work treats both segmental and super-segmental phenomena, yet we note that there may be more adequate ways to treat super-segmental phenomena assuming Word-Based morphology as we explore in (Tsarfaty and Goldberg, 2008).

**Lexical and Morphological Ambiguity** The rich morphological processes for deriving Hebrew stems give rise to a high degree of ambiguity for Hebrew space-delimited tokens. The form *fmnh*, for example, can be understood as the verb “lubricated”, the possessed noun “her oil”, the adjective “fat” or the verb “got fat”. Furthermore, the systematic way in which particles are prefixed to one another and onto an open-class category gives rise to a distinct sort of morphological ambiguity: space-delimited tokens may be ambiguous between several different segmentation possibilities. The same form *fmnh* can be segmented as *f-mnh*, *f* (“that”) functioning as a relativizer with the form *mnh*. The form *mnh* itself can be read as at least three different verbs (“counted”, “appointed”, “was appointed”), a noun (“a portion”), and a possessed noun (“her kind”).

Such ambiguities cause discrepancies between token boundaries (indexed as white spaces) and constituent boundaries (imposed by syntactic categories) with respect to a surface form. Such discrepancies can be aligned via an intermediate level of PoS tags. PoS tags impose a unique morphological segmentation on surface tokens and present a unique valid yield for syntactic trees. The correct ambiguity resolution of the syntactic level therefore helps to resolve the morphological one, and vice versa.

<sup>2</sup>Standalone parsing models assume a segmentation Oracle.

### 3 Previous Work on Hebrew Processing

Morphological analyzers for Hebrew that analyze a surface form in isolation have been proposed by Segal (2000), Yona and Wintner (2005), and recently by the knowledge center for processing Hebrew (Itai et al., 2006). Such analyzers propose multiple segmentation possibilities and their corresponding analyses for a token in isolation but have no means to determine the most likely ones. Morphological disambiguators that consider a token in context (an utterance) and propose the most likely morphological analysis of an utterance (including segmentation) were presented by Bar-Haim et al. (2005), Adler and Elhadad (2006), Shacham and Wintner (2007), and achieved good results (the best segmentation result so far is around 98%).

The development of the very first Hebrew Treebank (Sima'an et al., 2001) called for the exploration of general statistical parsing methods, but the application was at first limited. Sima'an et al. (2001) presented parsing results for a DOP tree-gram model using a small data set (500 sentences) and semi-automatic morphological disambiguation. Tsarfaty (2006) was the first to demonstrate that fully automatic Hebrew parsing is feasible using the newly available 5000 sentences treebank. Tsarfaty and Sima'an (2007) have reported state-of-the-art results on Hebrew unlexicalized parsing (74.41%) albeit assuming oracle morphological segmentation.

The joint morphological and syntactic hypothesis was first discussed in (Tsarfaty, 2006; Tsarfaty and Sima'an, 2004) and empirically explored in (Tsarfaty, 2006). Tsarfaty (2006) used a morphological analyzer (Segal, 2000), a PoS tagger (Bar-Haim et al., 2005), and a general purpose parser (Schmid, 2000) in an integrated framework in which morphological and syntactic components interact to share information, leading to improved performance on the joint task. Cohen and Smith (2007) later on based a system for joint inference on factored, independent, morphological and syntactic components of which scores are combined to cater for the joint inference task. Both (Tsarfaty, 2006; Cohen and Smith, 2007) have shown that a single integrated framework outperforms a completely streamlined implementation, yet neither has shown a single generative model which handles both tasks.

### 4 Model Preliminaries

#### 4.1 The Status Space-Delimited Tokens

A Hebrew surface token may have several readings, each of which corresponding to a sequence of segments and their corresponding PoS tags. We refer to different readings as different *analyses* whereby the segments are deterministic given the sequence of PoS tags. We refer to a segment and its assigned PoS tag as a *lexeme*, and so analyses are in fact sequences of lexemes. For brevity we omit the segments from the analysis, and so analysis of the form “*f*/REL *mnh*/VB is represented simply as REL VB.

Such tag sequences are often treated as “complex tags” (e.g. REL+VB) (cf. (Bar-Haim et al., 2007; Habash and Rambow, 2005)) and probabilities are assigned to different analyses in accordance with the likelihood of their tags (e.g., “*f**mnh* is 30% likely to be tagged NN and 70% likely to be tagged REL+VB”). Here we do not submit to this view. When a token *f**mnh* is to be interpreted as the lexeme sequence *f*/REL *mnh*/VB, the analysis introduces two distinct entities, the relativizer *f* (“that”) and the verb *mnh* (“counted”), and not as the complex entity “that counted”. When the same token is to be interpreted as a single lexeme *f**mnh*, it may function as a single adjective “fat”. There is no relation between these two interpretations other than the fact that their surface forms coincide, and we argue that the only reason to prefer one analysis over the other is compositional. A possible probabilistic model for assigning probabilities to complex analyses of a surface form may be

$$P(\text{REL, VB}|f\text{mnh, context}) = P(\text{REL}|f)P(\text{VB}|mnh, \text{REL})P(\text{REL, VB}| \text{context})$$

and indeed recent sequential disambiguation models for Hebrew (Adler and Elhadad, 2006) and Arabic (Smith et al., 2005) present similar models.

We suggest that in unlexicalized PCFGs the syntactic context may be explicitly modeled in the derivation probabilities. Hence, we take the probability of the event *f**mnh* analyzed as REL VB to be

$$P(\text{REL} \rightarrow f|\text{REL}) \times P(\text{VB} \rightarrow mnh|\text{VB})$$

This means that we generate *f* and *mnh* independently depending on their corresponding PoS tags,

and the context (as well as the syntactic relation between the two) is modeled via the derivation resulting in a sequence REL VB spanning the form *fmnh*.

## 4.2 Lattice Representation

We represent all morphological analyses of a given utterance using a lattice structure. Each lattice arc corresponds to a segment and its corresponding PoS tag, and a path through the lattice corresponds to a specific morphological segmentation of the utterance. This is by now a fairly standard representation for multiple morphological segmentation of Hebrew utterances (Adler, 2001; Bar-Haim et al., 2005; Smith et al., 2005; Cohen and Smith, 2007; Adler, 2007). Figure 1 depicts the lattice for a 2-words sentence *bclm hneim*. We use double-circles to indicate the space-delimited token boundaries. Note that in our construction arcs can never cross token boundaries. Every token is independent of the others, and the sentence lattice is in fact a concatenation of smaller lattices, one for each token. Furthermore, some of the arcs represent lexemes not present in the input tokens (e.g. *h/DT*, *fl/POS*), however these are parts of valid analyses of the token (cf. *super-segmental morphology* section 2). Segments with the same surface form but different PoS tags are treated as different lexemes, and are represented as separate arcs (e.g. the two arcs labeled *neim* from node 6 to 7).

Figure 1: The Lattice for the Hebrew Phrase *bclm hneim*

A similar structure is used in speech recognition. There, a lattice is used to represent the possible sentences resulting from an interpretation of an acoustic model. In speech recognition the arcs of the lattice are typically weighted in order to indicate the probability of specific transitions. Given that weights on all outgoing arcs sum up to one, weights induce a probability distribution on the lattice paths. In sequential tagging models such as (Adler and Elhadad, 2006; Bar-Haim et al., 2007; Smith et al., 2005) weights are assigned according to a language model

based on linear context. In our model, however, all lattice paths are taken to be a-priori equally likely.

## 5 A Generative PCFG Model

The input for the joint task is a sequence  $W = w_1, \dots, w_n$  of space-delimited tokens. Each token may admit multiple analyses, each of which a sequence of one or more lexemes (we use  $l_i$  to denote a lexeme) belonging a presupposed Hebrew lexicon  $LEX$ . The entries in such a lexicon may be thought of as meaningful surface segments paired up with their PoS tags  $l_i = \langle s_i, p_i \rangle$ , but note that a surface segment  $s$  need not be a space-delimited token.

**The Input** The set of analyses for a token is thus represented as a lattice in which every arc corresponds to a specific lexeme  $l$ , as shown in Figure 1. A morphological analyzer  $M : \mathcal{W} \rightarrow \mathcal{L}$  is a function mapping sentences in Hebrew ( $W \in \mathcal{W}$ ) to their corresponding lattices ( $M(W) = L \in \mathcal{L}$ ). We define the lattice  $L$  to be the concatenation of the lattices  $L_i$  corresponding to the input words  $w_i$  (s.t.  $M(w_i) = L_i$ ). Each connected path  $\langle l_1 \dots l_k \rangle \in L$  corresponds to one morphological segmentation possibility of  $W$ .

**The Parser** Given a sequence of input tokens  $W = w_1 \dots w_n$  and a morphological analyzer, we look for the most probable parse tree  $\pi$  s.t.

$$\hat{\pi} = \arg \max_{\pi} P(\pi|W, M)$$

Since the lattice  $L$  for a given sentence  $W$  is determined by the morphological analyzer  $M$  we have

$$\hat{\pi} = \arg \max_{\pi} P(\pi|W, M, L)$$

Hence, our parser searches for a parse tree  $\pi$  over lexemes  $\langle l_1 \dots l_k \rangle$  s.t.  $l_i = \langle s_i, p_i \rangle \in LEX$ ,  $\langle l_1 \dots l_k \rangle \in L$  and  $M(W) = L$ . So we remain with

$$\hat{\pi} = \arg \max_{\pi} P(\pi|L)$$

which is precisely the formula corresponding to the so-called lattice parsing familiar from speech recognition. Every parse  $\pi$  selects a specific morphological segmentation  $\langle l_1 \dots l_k \rangle$  (a path through the lattice). This is akin to PoS tags sequences induced by different parses in the setup familiar from English and explored in e.g. (Charniak et al., 1996).

Our use of an unweighted lattice reflects our belief that all the segmentations of the given input sentence are a-priori equally likely; the only reason to prefer one segmentation over the another is due to the overall syntactic context which is modeled via the PCFG derivations. A compatible view is presented by Charniak et al. (1996) who consider the kind of probabilities a generative parser should get from a PoS tagger, and concludes that these should be  $P(w|t)$  “and nothing fancier”.<sup>3</sup> In our setting, therefore, the Lattice is *not* used to induce a probability distribution on a linear context, but rather, it is used as a common-denominator of state-indexation of all segmentations possibilities of a surface form. This is a unique object for which we are able to define a proper probability model. Thus our proposed model is a proper model assigning probability mass to all  $\langle \pi, L \rangle$  pairs, where  $\pi$  is a parse tree and  $L$  is the one and only lattice that a sequence of characters (and spaces)  $W$  over our alpha-beth gives rise to.

$$\sum_{\pi, L} P(\pi, L) = 1; L \text{ uniquely index } W$$

**The Grammar** Our parser looks for the most likely tree spanning a single path through the lattice of which the yield is a sequence of lexemes. This is done using a simple PCFG which is *lexeme-based*. This means that the rules in our grammar are of two kinds: (a) syntactic rules relating non-terminals to a sequence of non-terminals and/or PoS tags, and (b) lexical rules relating PoS tags to lattice arcs (lexemes). The possible analyses of a surface token pose constraints on the analyses of specific segments. In order to pass these constraints onto the parser, the lexical rules in the grammar are of the form  $p_i \rightarrow \langle s_i, p_i \rangle$

**Parameter Estimation** The grammar probabilities are estimated from the corpus using simple relative frequency estimates. Lexical rules are estimated in a similar manner. We smooth  $P_{rf}(p \rightarrow \langle s, p \rangle)$  for rare and OOV segments ( $s \in l, l \in L, s$  unseen) using a “per-tag” probability distribution over rare segments which we estimate using relative frequency estimates for once-occurring segments.

<sup>3</sup>An English sentence with ambiguous PoS assignment can be trivially represented as a lattice similar to our own, where every pair of consecutive nodes correspond to a word, and every possible PoS assignment for this word is a connecting arc.

**Handling Unknown tokens** When handling unknown *tokens* in a language such as Hebrew various important aspects have to be borne in mind. Firstly, Hebrew unknown tokens are doubly unknown: each unknown token may correspond to several segmentation possibilities, and each segment in such sequences may be able to admit multiple PoS tags. Secondly, some segments in a proposed segment sequence may in fact be *seen* lexical events, i.e., for some  $p$  tag  $P_{rf}(p \rightarrow \langle s, p \rangle) > 0$ , while other segments have never been observed as a lexical event before. The latter arcs correspond to OOV words in English. Finally, the assignments of PoS tags to OOV segments is subject to language specific constraints relative to the token it was originated from.

Our smoothing procedure takes into account all the aforementioned aspects and works as follows. We first make use of our morphological analyzer to find all segmentation possibilities by chopping off all prefix sequence possibilities (including the empty prefix) and construct a lattice off of them. The remaining arcs are marked OOV. At this stage the lattice path corresponds to segments only, with no PoS assigned to them. In turn we use two sorts of heuristics, orthogonal to one another, to prune segmentation possibilities based on *lexical* and *grammatical* constraints. We simulate *lexical* constraints by using an external lexical resource against which we verify whether OOV segments are in fact valid Hebrew lexemes. This heuristics is used to prune all segmentation possibilities involving “lexically improper” segments. For the remaining arcs, if the segment is in fact a known lexeme it is tagged as usual, but for the OOV arcs which are valid Hebrew entries lacking tags assignment, we assign all possible tags and then simulate a *grammatical* constraint. Here, all token-internal collocations of tags unseen in our training data are pruned away. From now on all lattice arcs are tagged segments and the assignment of probability  $P(p \rightarrow \langle s, p \rangle)$  to lattice arcs proceeds as usual.<sup>4</sup>

A rather pathological case is when our lexical heuristics prune away all segmentation possibilities and we remain with an empty lattice. In such cases we use the non-pruned lattice including all (possibly ungrammatical) segmentation, and let the statistics (including OOV) decide. We empirically control for

<sup>4</sup>Our heuristics may slightly alter  $\sum_{\pi, L} P(\pi, L) \approx 1$

the effect of our heuristics to make sure our pruning does not undermine the objectives of our joint task.

## 6 Experimental Setup

Previous work on morphological and syntactic disambiguation in Hebrew used different sets of data, different splits, differing annotation schemes, and different evaluation measures. Our experimental setup therefore is designed to serve two goals. Our primary goal is to exploit the resources that are most appropriate for the task at hand, and our secondary goal is to allow for comparison of our models’ performance against previously reported results. When a comparison against previous results requires additional pre-processing, we state it explicitly to allow for the reader to replicate the reported results.

**Data** We use the Hebrew Treebank, (Sima’an et al., 2001), provided by the knowledge center for processing Hebrew, in which sentences from the daily newspaper “Ha’aretz” are morphologically segmented and syntactically annotated. The treebank has two versions, v1.0 and v2.0, containing 5001 and 6501 sentences respectively. We use v1.0 mainly because previous studies on joint inference reported results w.r.t. v1.0 only.<sup>5</sup> We expect that using the same setup on v2.0 will allow a cross-treebank comparison.<sup>6</sup> We used the first 500 sentences as our dev set and the rest 4500 for training and report our main results on this split. To facilitate the comparison of our results to those reported by (Cohen and Smith, 2007) we use their data set in which 177 empty and “malformed”<sup>7</sup> were removed. The first 3770 trees of the resulting set then were used for training, and the last 418 are used testing. (we ignored the 419 trees in their development set.)

**Morphological Analyzer** Ideally, we would use an of-the-shelf morphological analyzer for mapping each input token to its possible analyses. Such resources exist for Hebrew (Itai et al., 2006), but unfortunately use a tagging scheme which is incom-

<sup>5</sup>The comparison to performance on version 2.0 is meaningless not only because of the change in size, but also conceptual changes in the annotation scheme

<sup>6</sup>Unfortunately running our setup on the v2.0 data set is currently not possible due to missing tokens-morphemes alignment in the v2.0 treebank.

<sup>7</sup>We thank Shay Cohen for providing us with their data set and evaluation Software.

patible with the one of the Hebrew Treebank.<sup>8</sup> For this reason, we use a data-driven morphological analyzer derived from the training data similar to (Cohen and Smith, 2007). We construct a mapping from all the space-delimited tokens seen in the training sentences to their corresponding analyses.

**Lexicon and OOV Handling** Our data-driven morphological-analyzer proposes analyses for unknown tokens as described in Section 5. We use the HSPELL<sup>9</sup> (Har’el and Kenigsberg, 2004) wordlist as a lexeme-based lexicon for pruning segmentations involving invalid segments. Models that employ this strategy are denoted **hsp**. To control for the effect of the HSPELL-based pruning, we also experimented with a morphological analyzer that does not perform this pruning. For these models we limit the options provided for OOV words by not considering the entire token as a valid segmentation in case at least some prefix segmentation exists. This analyzer setting is similar to that of (Cohen and Smith, 2007), and models using it are denoted **nohsp**,

**Parser and Grammar** We used BitPar (Schmid, 2004), an efficient general purpose parser,<sup>10</sup> together with various treebank grammars to parse the input sentences and propose compatible morphological segmentation and syntactic analysis.

We experimented with increasingly rich grammars read off of the treebank. Our first model is **GT<sub>plain</sub>**, a PCFG learned from the treebank after removing all functional features from the syntactic categories. In our second model **GT<sub>vpi</sub>** we also distinguished finite and non-finite verbs and VPs as

<sup>8</sup>Mapping between the two schemes involves non-deterministic many-to-many mappings, and in some cases require a change in the syntactic trees.

<sup>9</sup>An open-source Hebrew spell-checker.

<sup>10</sup>Lattice parsing can be performed by special initialization of the chart in a CKY parser (Chappelier et al., 1999). We currently simulate this by crafting a WCFG and feeding it to BitPar. Given a PCFG grammar  $G$  and a lattice  $L$  with nodes  $n_1 \dots n_k$ , we construct the weighted grammar  $G_L$  as follows: for every arc (lexeme)  $l \in L$  from node  $n_i$  to node  $n_j$ , we add to  $G_L$  the rule  $[l \rightarrow t_{n_i}, t_{n_{i+1}}, \dots, t_{n_j-1}]$  with a probability of 1 (this indicates the lexeme  $l$  spans from node  $n_i$  to node  $n_j$ ).  $G_L$  is then used to parse the string  $t_{n_1} \dots t_{n_{k-1}}$ , where  $t_{n_i}$  is a terminal corresponding to the lattice span between node  $n_i$  and  $n_{i+1}$ . Removing the leaves from the resulting tree yields a parse for  $L$  under  $G$ , with the desired probabilities. We use a patched version of BitPar allowing for direct input of probabilities instead of counts. We thank Felix Hageloh (Hageloh, 2006) for providing us with this version.

proposed in (Tsarfaty, 2006). In our third model  $\mathbf{GT}_{\text{ppp}}$  we also add the distinction between general PPs and possessive PPs following Goldberg and Elhadad (2007). In our fourth model  $\mathbf{GT}_{\text{nph}}$  we add the definiteness status of constituents following Tsarfaty and Sima'an (2007). Finally, model  $\mathbf{GT}_v = 2$  includes parent annotation on top of the various state-splits, as is done also in (Tsarfaty and Sima'an, 2007; Cohen and Smith, 2007). For all grammars, we use fine-grained PoS tags indicating various morphological features annotated therein.

**Evaluation** We use 8 different measures to evaluate the performance of our system on the joint disambiguation task. To evaluate the performance on the segmentation task, we report  $SEG$ , the standard harmonic means for segmentation Precision and Recall  $F_1$  (as defined in Bar-Haim *et al.* (2005); Tsarfaty (2006)) as well as the segmentation accuracy  $SEG_{Tok}$  measure indicating the percentage of input tokens assigned the correct exact segmentation (as reported by Cohen and Smith (2007)).  $SEG_{Tok}(noH)$  is the segmentation accuracy ignoring mistakes involving the implicit definite article  $h$ .<sup>11</sup> To evaluate our performance on the tagging task we report  $CPOS$  and  $FPOS$  corresponding to coarse- and fine-grained PoS tagging results ( $F_1$ ) measure. Evaluating parsing results in our joint framework, as argued by Tsarfaty (2006), is not trivial under the joint disambiguation task, as the hypothesized yield need not coincide with the correct one. Our parsing performance measures ( $SYN$ ) thus report the PARSEVAL extension proposed in Tsarfaty (2006). We further report  $SYN^{CS}$ , the parsing metric of Cohen and Smith (2007), to facilitate the comparison. We report the  $F_1$  value of both measures. Finally, our  $U$  (unparsed) measure is used to report the number of sentences to which our system could not propose a joint analysis.

## 7 Results and Analysis

The accuracy results for segmentation, tagging and parsing using our different models and our standard data split are summarized in Table 1. In addition we report for each model its performance on gold-segmented input ( $GS$ ) to indicate the upper bound

<sup>11</sup>Overt definiteness errors may be seen as a wrong feature rather than as wrong constituent and it is by now an accepted standard to report accuracy with and without such errors.

for the grammars' performance on the parsing task.

The table makes clear that enriching our grammar improves the syntactic performance as well as morphological disambiguation (segmentation and POS tagging) accuracy. This supports our main thesis that decisions taken by single, improved, grammar are beneficial for both tasks. When using the segmentation pruning (using HSPELL) for unseen tokens, performance improves for all tasks as well. Yet we note that the better grammars without pruning outperform the poorer grammars using this technique, indicating that the syntactic context aids, to some extent, the disambiguation of unknown tokens.

Table 2 compares the performance of our system on the setup of Cohen and Smith (2007) to the best results reported by them for the same tasks.

Model	$SEG_{Tok}$	$CPOS$	$FPOS$	$SYN^{CS}$
$\mathbf{GT}_{\text{nohsp/pln}}$	89.50	81.00	77.65	62.22
$\mathbf{GT}_{\text{nohsp}/\dots+\text{nph}}$	89.58	81.26	77.82	64.30
$CS_{\text{pln}}$	91.10	80.40	75.60	64.00
$CS_{v=2}$	90.90	80.50	75.40	64.40
$\mathbf{GT}_{\text{hsp/pln}}$	93.13	83.12	79.12	64.46
$\mathbf{GT}_{\text{nohsp}/\dots+v=2}$	89.66	82.85	78.92	66.31
Oracle $CS_{\text{pln}}$	91.80	83.20	79.10	66.50
Oracle $CS_{v=2}$	91.70	83.00	78.70	67.40
$\mathbf{GT}_{\text{hsp}/\dots+v=2}$	93.38	85.08	80.11	69.11

Table 2: Segmentation, Parsing and Tagging Results using the Setup of (Cohen and Smith, 2007) (sentence length  $\leq 40$ ). The Models' are Ordered by Performance.

We first note that the accuracy results of our system are overall higher on their setup, on all measures, indicating that theirs may be an easier dataset. Secondly, for all our models we provide better fine- and coarse-grained POS-tagging accuracy, and all pruned models outperform the Oracle results reported by them.<sup>12</sup> In terms of syntactic disambiguation, even the simplest grammar pruned with HSPELL outperforms their non-Oracle results. Without HSPELL-pruning, our simpler grammars are somewhat lagging behind, but as the grammars improve the gap is bridged. The addition of vertical markovization enables non-pruned models to outperform all previously reported re-

<sup>12</sup>Cohen and Smith (2007) make use of a parameter ( $\alpha$ ) which is tuned separately for each of the tasks. This essentially means that their model does not result in a true joint inference, as executions for different tasks involve tuning a parameter separately. In our model there are no such hyper-parameters, and the performance is the result of truly joint disambiguation.

Table 1: Segmentation, tagging and parsing results on the Standard dev/train Split, for all Sentences

sults. Furthermore, the combination of pruning and vertical markovization of the grammar outperforms the Oracle results reported by Cohen and Smith. This essentially means that a better grammar tunes the joint model for optimized syntactic disambiguation at least in as much as their hyper parameters do. An interesting observation is that while vertical markovization benefits all our models, its effect is less evident in Cohen and Smith.

On the surface, our model may seem as a special case of Cohen and Smith in which  $\alpha = 0$ . However, there is a crucial difference: the morphological probabilities in their model come from discriminative models based on linear context. Many morphological decisions are based on long distance dependencies, and when the global syntactic evidence disagrees with evidence based on local linear context, the two models compete with one another, despite the fact that the PCFG takes also local context into account. In addition, as the CRF and PCFG look at similar sorts of information from within two inherently different models, they are far from independent and optimizing their product is meaningless. Cohen and Smith approach this by introducing the  $\alpha$  hyperparameter, which performs best when optimized independently for each sentence (cf. Oracle results).

In contrast, our morphological probabilities are based on a *unigram*, *lexeme*-based model, and all other (local and non-local) contextual considerations are delegated to the PCFG. This fully generative model caters for real interaction between the syntactic and morphological levels as a part of a single coherent process.

## 8 Discussion and Conclusion

Employing a PCFG-based generative framework to make both syntactic and morphological disambiguation decisions is not only theoretically clean and

linguistically justified and but also probabilistically appropriate and empirically sound. The overall performance of our joint framework demonstrates that a probability distribution obtained over mere syntactic contexts using a Treebank grammar and a data-driven lexicon outperforms upper bounds proposed by previous joint disambiguation systems and achieves segmentation and parsing results on a par with state-of-the-art standalone applications results.

Better grammars are shown here to improve performance on both morphological and syntactic tasks, providing support for the advantage of a joint framework over pipelined or factorized ones. We conjecture that this trend may continue by incorporating additional information, e.g., three-dimensional models as proposed by Tsarfaty and Sima'an (2007). In the current work morphological analyses and lexical probabilities are derived from a small Treebank, which is by no means the best way to go. Using a wide-coverage morphological analyzer based on (Itai et al., 2006) should cater for a better coverage, and incorporating lexical probabilities learned from a big (unannotated) corpus (cf. (Levinger et al., 1995; Goldberg et al., ; Adler et al., 2008)) will make the parser more robust and suitable for use in more realistic scenarios.

# Which words are hard to recognize?

## Prosodic, lexical, and disfluency factors that increase ASR error rates

Sharon Goldwater, Dan Jurafsky and Christopher D. Manning

Department of Linguistics and Computer Science

Stanford University

{sgwater, jurafsky, manning}@stanford.edu

### Abstract

Many factors are thought to increase the chances of misrecognizing a word in ASR, including low frequency, nearby disfluencies, short duration, and being at the start of a turn. However, few of these factors have been formally examined. This paper analyzes a variety of lexical, prosodic, and disfluency factors to determine which are likely to increase ASR error rates. Findings include the following. (1) For disfluencies, effects depend on the type of disfluency: errors *increase* by up to 15% (absolute) for words near fragments, but *decrease* by up to 7.2% (absolute) for words near repetitions. This decrease seems to be due to longer word duration. (2) For prosodic features, there are more errors for words with *extreme* values than words with *typical* values. (3) Although our results are based on output from a system with speaker adaptation, speaker differences are a major factor influencing error rates, and the effects of features such as frequency, pitch, and intensity may vary between speakers.

### 1 Introduction

In order to improve the performance of automatic speech recognition (ASR) systems on conversational speech, it is important to understand the factors that cause problems in recognizing words. Previous work on recognition of spontaneous monologues and dialogues has shown that infrequent words are more likely to be misrecognized (Fosler-Lussier and Morgan, 1999; Shinozaki and Furui, 2001) and that fast speech increases error rates (Siegler and Stern, 1995; Fosler-Lussier and Morgan, 1999; Shinozaki

and Furui, 2001). Siegler and Stern (1995) and Shinozaki and Furui (2001) also found higher error rates in very slow speech. Word length (in phones) has also been found to be a useful predictor of higher error rates (Shinozaki and Furui, 2001). In Hirschberg et al.'s (2004) analysis of two human-computer dialogue systems, misrecognized turns were found to have (on average) higher maximum pitch and energy than correctly recognized turns. Results for speech rate were ambiguous: faster utterances had higher error rates in one corpus, but lower error rates in the other. Finally, Adda-Decker and Lamel (2005) demonstrated that both French and English ASR systems had more trouble with male speakers than female speakers, and found several possible explanations, including higher rates of disfluencies and more reduction.

Many questions are left unanswered by these previous studies. In the word-level analyses of Fosler-Lussier and Morgan (1999) and Shinozaki and Furui (2001), only substitution and deletion errors were considered, so we do not know how including insertions might affect the results. Moreover, these studies primarily analyzed lexical, rather than prosodic, factors. Hirschberg et al.'s (2004) work suggests that prosodic factors can impact error rates, but leaves open the question of which factors are important at the word level and how they influence recognition of natural conversational speech. Adda-Decker and Lamel's (2005) suggestion that higher rates of disfluency are a cause of worse recognition for male speakers presupposes that disfluencies raise error rates. While this assumption seems natural, it has yet to be carefully tested, and in particular we do not

know whether disfluent words are associated with errors in adjacent words, or are simply more likely to be misrecognized themselves. Other factors that are often thought to affect a word’s recognition, such as its status as a content or function word, and whether it starts a turn, also remain unexamined.

The present study is designed to address all of these questions by analyzing the effects of a wide range of lexical and prosodic factors on the accuracy of an English ASR system for conversational telephone speech. In the remainder of this paper, we first describe the data set used in our study and introduce a new measure of error, *individual word error rate* (IWER), that allows us to include insertion errors in our analysis, along with deletions and substitutions. Next, we present the features we collected for each word and the effects of those features individually on IWER. Finally, we develop a joint statistical model to examine the effects of each feature while controlling for possible correlations.

## 2 Data

For our analysis, we used the output from the SRI/ICSI/UW RT-04 CTS system (Stolcke et al., 2006) on the NIST RT-03 development set. This system’s performance was state-of-the-art at the time of the 2004 evaluation. The data set contains 36 telephone conversations (72 speakers, 38477 reference words), half from the Fisher corpus and half from the Switchboard corpus.<sup>1</sup>

The standard measure of error used in ASR is *word error rate* (WER), computed as  $100(I + D + S)/R$ , where  $I$ ,  $D$  and  $S$  are the number of insertions, deletions, and substitutions found by aligning the ASR hypotheses with the reference transcriptions, and  $R$  is the number of reference words. Since we wish to know what features of a reference word increase the probability of an error, we need a way to measure the errors attributable to individual words — an *individual word error rate* (IWER). We assume that a substitution or deletion error can be assigned to its corresponding reference word, but for insertion errors, there may be two adjacent reference words that could be responsible. Our solution is to assign any insertion errors to each of

<sup>1</sup>These conversations are not part of the standard Fisher and Switchboard corpora used to train most ASR systems.

	Ins	Del	Sub	Total	% data
Full word	1.6	6.9	10.5	19.0	94.2
Filled pause	0.6	–	16.4	17.0	2.8
Fragment	2.3	–	17.3	19.6	2.0
Backchannel	0.3	30.7	5.0	36.0	0.6
Guess	1.6	–	30.6	32.1	0.4
Total	1.6	6.7	10.9	19.7	100

Table 1: Individual word error rates for different word types, and the proportion of words belonging to each type. Deletions of filled pauses, fragments, and guesses are not counted as errors in the standard scoring method.

the adjacent words. We could then define IWER as  $100(n_i + n_d + n_s)/R$ , where  $n_i$ ,  $n_d$ , and  $n_s$  are the insertion, deletion, and substitution counts for individual words (with  $n_d = D$  and  $n_s = S$ ). In general, however,  $n_i > I$ , so that the IWER for a given data set would be larger than the WER. To facilitate comparisons with standard WER, we therefore discount insertions by a factor  $\alpha$ , such that  $\alpha n_i = I$ . In this study,  $\alpha = .617$ .

## 3 Analysis of individual features

### 3.1 Features

The reference transcriptions used in our analysis distinguish between five different types of words: filled pauses (*um*, *uh*), fragments (*wh-*, *redistr-*), backchannels (*uh-huh*, *mm-hm*), guesses (where the transcribers were unsure of the correct words), and full words (everything else). Error rates for each of these types can be found in Table 1. The remainder of our analysis considers only the 36159 invocabularly full words in the reference transcriptions (70 OOV full words are excluded). We collected the following features for these words:

**Speaker sex** Male or female.

**Broad syntactic class** Open class (e.g., nouns and verbs), closed class (e.g., prepositions and articles), or discourse marker (e.g., *okay*, *well*). Classes were identified using a POS tagger (Ratnaparkhi, 1996) trained on the tagged Switchboard corpus.

**Log probability** The unigram log probability of each word, as listed in the system’s language model.

**Word length** The length of each word (in phones), determined using the most frequent pronunciation

BefRep	FirRep	MidRep	LastRep	AfRep	BefFP	AfFP	BefFr	AfFr
yeah	i	i	i	think	you	should	um	ask for the ref- recommendation

Figure 1: Example illustrating disfluency features: words occurring before and after repetitions, filled pauses, and fragments; first, middle, and last words in a repeated sequence.

found for that word in the recognition lattices.

**Position near disfluency** A collection of features indicating whether a word occurred before or after a filled pause, fragment, or repeated word; or whether the word itself was the first, last, or other word in a sequence of repetitions. Figure 1 illustrates. Only identical repeated words with no intervening words or filled pauses were considered repetitions.

**First word of turn** Turn boundaries were assigned automatically at the beginning of any utterance following a pause of at least 100 ms during which the other speaker spoke.

**Speech rate** The average speech rate (in phones per second) was computed for each utterance using the pronunciation dictionary extracted from the lattices and the utterance boundary timestamps in the reference transcriptions.

In addition to the above features, we used Praat (Boersma and Weenink, 2007) to collect the following additional prosodic features on a subset of the data obtained by excluding all contractions:<sup>2</sup>

**Pitch** The minimum, maximum, mean, and range of pitch for each word.

**Intensity** The minimum, maximum, mean, and range of intensity for each word.

**Duration** The duration of each word.

31017 words (85.8% of the full-word data set) remain in the no-contractions data set after removing words for which pitch and/or intensity features could not be extracted.

<sup>2</sup>Contractions were excluded before collecting prosodic features for the following reason. In the reference transcriptions and alignments used for scoring ASR systems, contractions are treated as two separate words. However, aside from speech rate, our prosodic features were collected using word-by-word timestamps from a forced alignment that used a transcription where contractions are treated as single words. Thus, the start and end times for a contraction in the forced alignment correspond to two words in the alignments used for scoring, and it is not clear how to assign prosodic features appropriately to those words.

## 3.2 Results and discussion

Results of our analysis of individual features can be found in Table 2 (for categorical features) and Figure 2 (for numeric features). Comparing the error rates for the full-word and the no-contractions data sets in Table 2 verifies that removing contractions does not create systematic changes in the patterns of errors, although it does lower error rates (and significance values) slightly overall. (First and middle repetitions are combined as non-final repetitions in the table, because only 52 words were middle repetitions, and their error rates were similar to initial repetitions.)

### 3.2.1 Disfluency features

Perhaps the most interesting result in Table 2 is that the effects of disfluencies are highly variable depending on the type of disfluency and the position of a word relative to it. Non-final repetitions and words next to fragments have an IWER up to 15% (absolute) *higher* than the average word, while final repetitions and words following repetitions have an IWER up to 7.2% *lower*. Words occurring before repetitions or next to filled pauses do not have significantly different error rates than words not in those positions. Our results for repetitions support Shriberg’s (1995) hypothesis that the final word of a repeated sequence is in fact fluent.

### 3.2.2 Other categorical features

Our results support the common wisdom that open class words have lower error rates than other words (although the effect we find is small), and that words at the start of a turn have higher error rates. Also, like Adda-Decker and Lamel (2005), we find that male speakers have higher error rates than females, though in our data set the difference is more striking (3.6% absolute, compared to their 2.0%).

### 3.2.3 Word probability and word length

Turning to Figure 2, we find (consistent with previous results) that low-probability words have dramatically higher error rates than high-probability

		Filled Pau.		Fragment		Repetition				Syntactic Class			Sex		All	
		Bef	Aft	Bef	Aft	Bef	Aft	NonF	Fin	Clos	Open	Disc	1st	M		F

Table 2: IWER by feature and percentage of words exhibiting each feature for (a) the full-word data set and (b) the no-contractions data set. Error rates that are significantly different for words with and without a given feature (computed using 10,000 samples in a Monte Carlo permutation test) are in **bold** ( $p < .05$ ) or **bold italics** ( $p < .005$ ). Features shown are whether a word occurs before or after a filled pause, fragment, or repetition; is a non-final or final repetition; is open class, closed class, or a discourse marker; is the first word of a turn; or is spoken by a male or female. *All* is the IWER for the entire data set. (Overall IWER is slightly lower than in Table 1 due to the removal of OOV words.)

words. More surprising is that word length in phones does *not* seem to have a consistent effect on IWER. Further analysis reveals a possible explanation: word length is correlated with duration, but anti-correlated to the same degree with log probability (the Kendall  $\tau$  statistics are .50 and -.49). Figure 2 shows that words with longer duration have lower IWER. Since words with more phones tend to have longer duration, but lower frequency, there is no overall effect of length.

### 3.2.4 Prosodic features

Figure 2 shows that means of pitch and intensity have relatively little effect except at extreme values, where more errors occur. In contrast, pitch and intensity range show clear linear trends, with greater range of pitch or intensity leading to lower IWER.<sup>3</sup> As noted above, decreased duration is associated with increased IWER, and (as in previous work), we find that IWER increases dramatically for fast speech. We also see a tendency towards higher IWER for very slow speech, consistent with Shinozaki and Furui (2001) and Siegler and Stern (1995). The effects of pitch minimum and maximum are not shown for reasons of space, but are similar to pitch mean. Also not shown are intensity minimum (with more errors at higher values) and intensity maximum (with more errors at lower values).

For most of our prosodic features, as well as log probability, extreme values seem to be associated

<sup>3</sup>Our decision to use the log transform of pitch range was originally based on the distribution of pitch range values in the data set. Exploratory data analysis also indicated that using the transformed values would likely lead to a better model fit (Section 4) than using the raw values.

with worse recognition than average values. We explore this possibility further in Section 4.

## 4 Analysis using a joint model

In the previous section, we investigated the effects of various individual features on ASR error rates. However, there are many correlations between these features – for example, words with longer duration are likely to have a larger range of pitch and intensity. In this section, we build a single model with all of our features as potential predictors in order to determine the effects of each feature after controlling for the others. We use the no-contractions data set so that we can include prosodic features in our model. Since only 1% of tokens have an IWER  $> 1$ , we simplify modeling by predicting only whether each token is responsible for an error or not. That is, our dependent variable is binary, taking on the value 1 if IWER  $> 0$  for a given token and 0 otherwise.

### 4.1 Model

To model data with a binary dependent variable, a logistic regression model is an appropriate choice. In logistic regression, we model the *log odds* as a linear combination of feature values  $x_0 \dots x_n$ :

$$\log \frac{p}{1-p} = \beta_0 x_0 + \beta_1 x_1 + \dots + \beta_n x_n$$

where  $p$  is the probability that the outcome occurs (here, that a word is misrecognized) and  $\beta_0 \dots \beta_n$  are coefficients (feature weights) to be estimated. Standard logistic regression models assume that all categorical features are *fixed effects*, meaning that all possible values for these features are known in advance, and each value may have an arbitrarily different effect on the outcome. However, features

Figure 2: Effects of numeric features on IWER of the SRI system for the no-contractors data set. All feature values were binned, and the average IWER for each bin is plotted, with the area of the surrounding circle proportional to the number of points in the bin. Dotted lines show the average IWER over the entire data set.

such as speaker identity do not fit this pattern. Instead, we control for speaker differences by assuming that speaker identity is a *random effect*, meaning that the speakers observed in the data are a random sample from a larger population. The baseline probability of error for each speaker is therefore assumed to be a normally distributed random variable, with mean equal to the population mean, and variance to be estimated by the model. Stated differently, a random effect allows us to add a factor to the model for speaker identity, without allowing arbitrary variation in error rates between speakers. Models such as ours, with both fixed and random effects, are known as *mixed-effects models*, and are becoming a standard method for analyzing linguistic data (Baayen, 2008). We fit our models using the lme4 package (Bates, 2007) of R (R Development Core Team, 2007).

To analyze the joint effects of all of our features, we initially built as large a model as possible, and used *backwards elimination* to remove features one at a time whose presence did not contribute significantly (at  $p \leq .05$ ) to model fit. All of the features shown in Table 2 were converted to binary variables and included as predictors in our initial model, along with a binary feature controlling for corpus (Fisher or Switchboard), and all numeric features in Figure 2. We did not include minimum and maximum values for pitch and intensity because they are highly

correlated with the mean values, making parameter estimation in the combined model difficult. Preliminary investigation indicated that using the mean values would lead to the best overall fit to the data.

In addition to these basic fixed effects, our initial model included quadratic terms for all of the numeric features, as suggested by our analysis in Section 3, as well as random effects for speaker identity and word identity. All numeric features were rescaled to values between 0 and 1 so that coefficients are comparable.

## 4.2 Results and discussion

Figure 3 shows the estimated coefficients and standard errors for each of the fixed effect categorical features remaining in the reduced model (i.e., after backwards elimination). Since all of the features are binary, a coefficient of  $\beta$  indicates that the corresponding feature, when present, adds a weight of  $\beta$  to the log odds (i.e., multiplies the odds of an error by a factor of  $e^\beta$ ). Thus, features with positive coefficients *increase* the odds of an error, and features with negative coefficients *decrease* the odds of an error. The magnitude of the coefficient corresponds to the size of the effect.

Interpreting the coefficients for our numeric features is less intuitive, since most of these variables have both linear and quadratic effects. The contribution to the log odds of a particular numeric feature

Figure 3: Estimates and standard errors of the coefficients for the categorical predictors in the reduced model.

$x_i$ , with linear and quadratic coefficients  $a$  and  $b$ , is  $ax_i + bx_i^2$ . We plot these curves for each numeric feature in Figure 4. Values on the  $x$  axes with positive  $y$  values indicate increased odds of an error, and negative  $y$  values indicate decreased odds of an error. The  $x$  axes in these plots reflect the rescaled values of each feature, so that 0 corresponds to the minimum value in the data set, and 1 to the maximum value.

#### 4.2.1 Disfluencies

In our analysis of individual features, we found that different types of disfluencies have different effects: non-final repeated words and words near fragments have higher error rates, while final repetitions and words following repetitions have lower error rates. After controlling for other factors, a different picture emerges. There is no longer an effect for final repetitions or words after repetitions; all other disfluency features increase the odds of an error by a factor of 1.3 to 2.9. These differences from Section 3 can be explained by noting that words near filled pauses and repetitions have longer durations than other words (Bell et al., 2003). Longer duration lowers IWER, so controlling for duration reveals the negative effect of the nearby disfluencies. Our results are also consistent with Shriberg’s (1995) findings on fluency in repeated words, since final repetitions have no significant effect in our combined model, while non-final repetitions incur a penalty.

#### 4.2.2 Other categorical features

Without controlling for other lexical or prosodic features, we found that a word is more likely to be misrecognized at the beginning of a turn, and less likely to be misrecognized if it is an open class word. According to our joint model, these effects still hold even after controlling for other features.

Similarly, male speakers still have higher error rates than females. This last result sheds some light on the work of Adda-Decker and Lamel (2005), who suggested several factors that could explain males’ higher error rates. In particular, they showed that males have higher rates of disfluency, produce words with slightly shorter durations, and use more alternate (“sloppy”) pronunciations. Our joint model controls for the first two of these factors, suggesting that the third factor or some other explanation must account for the remaining differences between males and females. One possibility is that female speech is more easily recognized because females tend to have expanded vowel spaces (Diehl et al., 1996), a factor that is associated with greater intelligibility (Bradlow et al., 1996) and is characteristic of genres with lower ASR error rates (Nakamura et al., 2008).

#### 4.2.3 Prosodic features

Examining the effects of pitch and intensity individually, we found that increased range for these features is associated with lower IWER, while higher pitch and extremes of intensity are associated with higher IWER. In the joint model, we see the same effect of pitch mean and an even stronger effect for intensity, with the predicted odds of an error dramatically higher for extreme intensity values. Meanwhile, we no longer see a benefit for increased pitch range and intensity; rather, we see small quadratic effects for both features, i.e. words with average ranges of pitch and intensity are recognized more easily than words with extreme values for these features. As with disfluencies, we hypothesize that the linear trends observed in Section 3 are primarily due to effects of duration, since duration is moderately correlated with both log pitch range ( $\tau = .35$ ) and intensity range ( $\tau = .41$ ).

Our final two prosodic features, duration and speech rate, showed strong linear and weak quadratic trends when analyzed individually. According to our model, both duration and speech rate are still important predictors of error after controlling for other features. However, as with the other prosodic features, predictions of the joint model are dominated by quadratic trends, i.e., predicted error rates are lower for average values of duration and speech rate than for extreme values.

Overall, the results from our joint analysis suggest

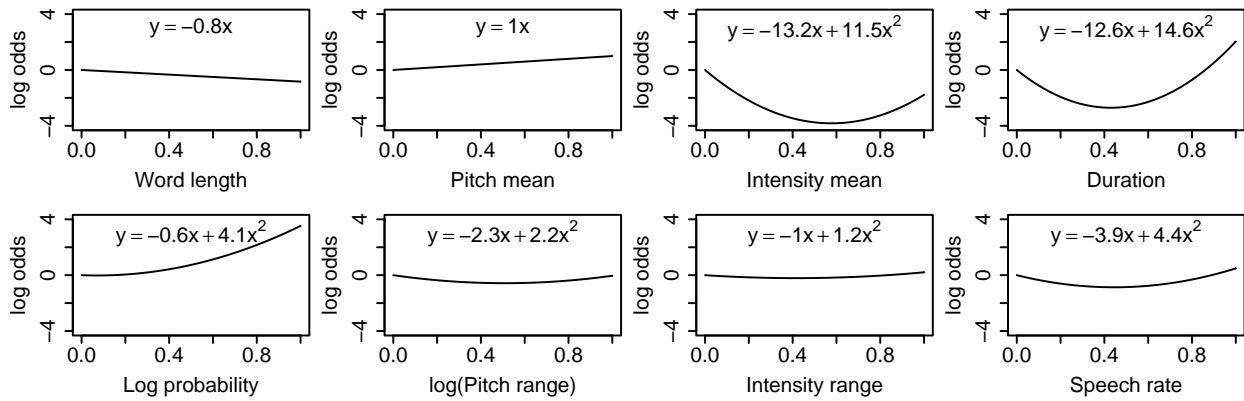

Figure 4: Predicted effect on the log odds of each numeric feature, including linear and (if applicable) quadratic terms.

Model	Neg. log lik.	Diff.	df
Full	12932	0	32
Reduced	12935	3	26
No lexical	13203	271	16
No prosodic	13387	455	20
No speaker	13432	500	31
No word	13267	335	31
Baseline	14691	1759	1

Table 3: Fit to the data of various models. Degrees of freedom (df) for each model is the number of fixed effects plus the number of random effects plus 1 (for the intercept). *Full* model contains all predictors; *Reduced* contains only predictors contributing significantly to fit; *Baseline* contains only intercept. Other models are obtained by removing features from *Full*. *Diff* is the difference in log likelihood between each model and *Full*.

that, after controlling for other factors, *extreme* values for prosodic features are associated with worse recognition than *typical* values.

#### 4.2.4 Differences between lexical items

As discussed above, our model contains a random effect for word identity, to control for the possibility that certain lexical items have higher error rates that are not explained by any of the other factors in the model. It is worth asking whether this random effect is really necessary. To address this question, we compared the fit to the data of two models, each containing all of our fixed effects and a random effect for speaker identity. One model also contained a random effect for word identity. Results are shown in Table 3. The model without a random effect for word identity is significantly worse than the

full model; in fact, this single parameter is more important than all of the lexical features combined. To see which lexical items are causing the most difficulty, we examined the items with the highest estimated increases in error. The top 20 items on this list include *yup*, *yep*, *yes*, *buy*, *then*, *than*, and *r*, all of which are acoustically similar to each other or to other high-frequency words, as well as the words *after*, *since*, *now*, and *though*, which occur in many syntactic contexts, making them difficult to predict based on the language model.

#### 4.2.5 Differences between speakers

We examined the importance of the random effect for speaker identity in a similar fashion to the effect for word identity. As shown in Table 3, speaker identity is a very important factor in determining the probability of error. That is, the lexical and prosodic variables examined here are not sufficient to fully explain the differences in error rates between speakers. In fact, the speaker effect is the single most important factor in the model.

Given that the differences in error rates between speakers are so large (average IWER for different speakers ranges from 5% to 51%), we wondered whether our model is sufficient to capture the kinds of speaker variation that exist. The model assumes that each speaker has a different baseline error rate, but that the effects of each variable are the same for each speaker. Determining the extent to which this assumption is justified is beyond the scope of this paper, however we present some suggestive results in Figure 5. This figure illustrates some of the dif-

Figure 5: Estimated effects of various features on the error rates of two different speakers (top and bottom). Dashed lines illustrate the baseline probability of error for each speaker. Solid lines were obtained by fitting a logistic regression model to each speaker’s data, with the variable labeled on the  $x$ -axis as the only predictor.

ferences between two speakers chosen fairly arbitrarily from our data set. Not only are the baseline error rates different for the two speakers, but the effects of various features appear to be very different, in one case even reversed. The rest of our data set exhibits similar kinds of variability for many of the features we examined. These differences in ASR behavior between speakers are particularly interesting considering that the system we investigated here already incorporates speaker adaptation models.

## 5 Conclusion

In this paper, we introduced the *individual word error rate* (IWER) for measuring ASR performance on individual words, including insertions as well as deletions and substitutions. Using IWER, we analyzed the effects of various word-level lexical and prosodic features, both individually and in a joint model. Our analysis revealed the following effects. (1) Words at the start of a turn have slightly higher IWER than average, and open class (content) words have slightly lower IWER. These effects persist even after controlling for other lexical and prosodic factors. (2) Disfluencies heavily impact error rates: IWER for non-final repetitions and words adjacent to fragments rises by up to 15% absolute, while IWER for final repetitions and words following repetitions decreases by up to 7.2% absolute. Controlling for prosodic features eliminates the latter benefit, and reveals a negative effect of adjacent filled pauses, suggesting that the effects of these disfluen-

cies are normally obscured by the greater duration of nearby words. (3) For most acoustic-prosodic features, words with extreme values have worse recognition than words with average values. This effect becomes much more pronounced after controlling for other factors. (4) After controlling for lexical and prosodic characteristics, the lexical items with the highest error rates are primarily homophones or near-homophones (e.g., *buy* vs. *by*, *then* vs. *than*). (5) Speaker differences account for much of the variance in error rates between words. Moreover, the direction and strength of effects of different prosodic features may vary between speakers.

While we plan to extend our analysis to other ASR systems in order to determine the generality of our findings, we have already gained important insights into a number of factors that increase ASR error rates. In addition, our results suggest a rich area for future research in further analyzing the variability of both lexical and prosodic effects on ASR behavior for different speakers.

## Acknowledgments

This work was supported by the Edinburgh-Stanford LINK and ONR MURI award N000140510388. We thank Andreas Stolcke for providing the ASR output, language model, and forced alignments used here, and Raghunandan Kumaran and Katrin Kirchhoff for earlier datasets and additional help.

### Abstract

We present a method to transliterate names in the framework of end-to-end statistical machine translation. The system is trained to learn when to transliterate. For Arabic to English MT, we developed and trained a transliterator on a bitext of 7 million sentences and Google’s English terabyte ngrams and achieved better name translation accuracy than 3 out of 4 professional translators. The paper also includes a discussion of challenges in name translation evaluation.

## 1 Introduction

State-of-the-art statistical machine translation (SMT) is bad at translating names that are not very common, particularly across languages with different character sets and sound systems. For example, consider the following automatic translation:<sup>1</sup>

**Arabic input** موسيقيين مثل باخ وموزار وشوبان  
وبيتهوفن وشومان ورحمانينوف ورافيل  
وبروكوفيف

**SMT output** musicians such as Bach

**Correct translation** composers such as Bach,  
Mozart, Chopin, Beethoven, Schumann,  
Rachmaninoff, Ravel and Prokofiev

The SMT system drops most names in this example. “Name dropping” and mis-translation happens when the system encounters an unknown word, mistakes a name for a common noun, or trains on noisy parallel data. The state-of-the-art is poor for

two reasons. First, although names are important to human readers, automatic MT scoring metrics (such as BLEU) do not encourage researchers to improve name translation in the context of MT. Names are vastly outnumbered by prepositions, articles, adjectives, common nouns, etc. Second, name translation is a hard problem — even professional human translators have trouble with names. Here are four reference translations taken from the same corpus, with mistakes underlined:

**Ref1** composers such as Bach, missing name Chopin, Beethoven, Shumann, Rakmaninov, Ravel and Prokoviev

**Ref2** musicians such as Bach, Mozart, Chopin, Bethoven, Shuman, Rachmaninoff, Rafael and Brokoviev

**Ref3** composers including Bach, Mozart, Schopen, Beethoven, missing name Raphael, Rahmaniev and Brokofien

**Ref4** composers such as Bach, Mozart, missing name Beethoven, Schumann, Rachmaninov, Raphael and Prokofiev

The task of transliterating names (independent of end-to-end MT) has received a significant amount of research, e.g., (Knight and Graehl, 1997; Chen et al., 1998; Al-Onaizan, 2002). One approach is to “sound out” words and create new, plausible target-language spellings that preserve the sounds of the source-language name as much as possible. Another approach is to phonetically match source-language names against a large list of target-language words

<sup>1</sup>taken from NIST02-05 corpora

and phrases. Most of this work has been disconnected from end-to-end MT, a problem which we address head-on in this paper.

The simplest way to integrate name handling into SMT is: (1) run a named-entity identification system on the source sentence, (2) transliterate identified entities with a special-purpose transliteration component, and (3) run the SMT system on the source sentence, as usual, but when looking up phrasal translations for the words identified in step 1, instead use the transliterations from step 2.

Many researchers have attempted this, and it does not work. Typically, translation quality is degraded rather than improved, for the following reasons:

- Automatic named-entity identification makes errors. Some words and phrases that should not be transliterated are nonetheless sent to the transliteration component, which returns a bad translation.
- Not all named entities should be transliterated. Many named entities require a mix of transliteration and translation. For example, in the pair جنوب كاليفورنيا /jnuub kalyfurnya/Southern California, the first Arabic word is translated, and the second word is transliterated.
- Transliteration components make errors. The base SMT system may translate a commonly-occurring name just fine, due to the bitext it was trained on, while the transliteration component can easily supply a worse answer.
- Integration hobbles SMT's use of longer phrases. Even if the named-entity identification and transliteration components operate perfectly, adopting their translations means that the SMT system may no longer have access to longer phrases that include the name. For example, our base SMT system translates رئيس الوزراء لي بنغ (as a whole phrase) to "Premier Li Peng", based on its bitext knowledge. However, if we force لي بنغ to translate as a separate phrase to "Li Peng", then the term رئيس الوزراء becomes ambiguous (with translations including "Prime Minister", "Premier", etc.), and we observe incorrect choices being subsequently made.

To spur better work in name handling, an ACE entity-translation pilot evaluation was recently developed (Day, 2007). This evaluation involves a mixture of entity identification and translation concerns—for example, the scoring system asks for coreference determination, which may or may not be of interest for improving machine translation output.

In this paper, we adopt a simpler metric. We ask: *what percentage of source-language named entities are translated correctly?* This is a precision metric. We can readily apply it to any base SMT system, and to human translations as well. Our goal in augmenting a base SMT system is to increase this percentage. A secondary goal is to make sure that our overall translation quality (as measured by BLEU) does not degrade as a result of the name-handling techniques we introduce. We make all our measurements on an Arabic/English newswire translation task.

Our overall technical approach is summarized here, along with references to sections of this paper:

- We build a component for transliterating between Arabic and English (Section 3).
- We automatically learn to tag those words and phrases in Arabic text, which we believe the transliteration component will translate correctly (Section 4).
- We integrate suggested transliterations into the base SMT search space, with their use controlled by a feature function (Section 5).
- We evaluate both the base SMT system and the augmented system in terms of entity translation accuracy and BLEU (Sections 2 and 6).

## 2 Evaluation

In this section we present the evaluation method that we use to measure our system and also discuss challenges in name transliteration evaluation.

### 2.1 NEWA Evaluation Metric

General MT metrics such as BLEU, TER, METEOR are not suitable for evaluating named entity translation and transliteration, because they are not focused on named entities (NEs). Dropping a comma or a *the* is penalized as much as dropping a name. We therefore use another metric, jointly developed with BBN and LanguageWeaver.

The general idea of the Named Entity Weak Accuracy (NEWA) metric is to

- Count number of NEs in source text: N
- Count number of correctly translated NEs: C
- Divide C/N to get an accuracy figure

In NEWA, an NE is counted as correctly translated if the target reference NE is found in the MT output. The metric has the advantage that it is easy to compute, has no special requirements on an MT system (such as depending on source-target word alignment) and is tokenization independent.

In the result section of this paper, we will use the NEWA metric to measure and compare the accuracy of NE translations in our end-to-end SMT translations and four human reference translations.

## 2.2 Annotated Corpus

BBN kindly provided us with an annotated Arabic text corpus, in which named entities were marked up with their type (e.g. GPE for Geopolitical Entity) and one or more English translations. Example:

عبد الله <PER alt="Abdullah II | Abdallah II">  
<GPE alt="Termoli"> تيرمولى </GPE> فى  
الشانى </PER>

The BBN annotations exhibit a number of issues. For the English translations of the NEs, BBN annotators looked at human reference translations, which may introduce a bias towards those human translations. Specifically, the BBN annotations are sometimes wrong, because the reference translations were wrong. Consider for example the Arabic phrase مصنع بورتران فى تيرمولي (mSn‘ burtran fY tyrmulY), which means *Powertrain plant in Termoli*. The mapping from *tyrmulY* to *Termoli* is not obvious, and even less the one from *burtran* to *Powertrain*. The human reference translations for this phrase are

1. Portran site in Tremolo
2. Termoli plant (*one name dropped*)
3. Portran in Tirnoli
4. Portran assembly plant, in Tirmoli

The BBN annotators adopted the correct translation *Termoli*, but also the incorrect *Portran*. In

other cases the BBN annotators adopted both a correct (Khatami) and an incorrect translation (Khatimi) when referring to the former Iranian president, which would reward a translation with such an incorrect spelling.

- <PER alt="Khatami|Khatimi"> خاتمي </PER>
- <GPE alt="the American"> الاميركية </GPE>

In other cases, all translations are correct, but additional correct translations are missing, as for “the American” above, for which “the US” is an equally valid alternative in the specific sentence it was annotated in.

All this raises the question of what **is** a correct answer. For most Western names, there is normally only one correct spelling. We follow the same conventions as standard media, paying attention to how an organization or individual spells its own name, e.g. Senator Jon Kyl, not Senator John Kyle. For Arabic names, variation is generally acceptable if there is no one clearly dominant spelling in English, e.g. Gaddafi|Gadhafi|Qaddafi|Qadhafi, as long as a given variant is not radically rarer than the most conventional or popular form.

## 2.3 Re-Annotation

Based on the issues we found with the BBN annotations, we re-annotated a sub-corpus of 637 sentences of the BBN gold standard.

We based this re-annotation on detailed annotation guidelines and sample annotations that had previously been developed in cooperation with LanguageWeaver, building on three iterations of test annotations with three annotators.

We checked each NE in every sentence, using human reference translations, automatic transliterator output, performing substantial Web research for many rare names, and checked Google ngrams and counts for the general Web and news archives to determine whether a variant form met our threshold of occurring at least 20% as often as the most dominant form.

## 3 Transliterator

This section describes how we transliterate Arabic words or phrases. Given a word such as رحمانينوف or a phrase such as موريس رافيل, we want to find the English transliteration for it. This is not just a

romanization like *rHmanyuf* and *murys rafyl* for the examples above, but a properly spelled English name such as *Rachmaninoff* and *Maurice Ravel*. The transliteration result can contain several alternatives, e.g. *Rachmaninoff*|*Rachmaninov*. Unlike various generative approaches (Knight and Graehl, 1997; Stalls and Knight, 1998; Li et al., 2004; Matthews, 2007; Sherif and Kondrak, 2007; Kashani et al., 2007), we do not synthesize an English spelling from scratch, but rather find a translation in very large lists of English words (3.4 million) and phrases (47 million).

We develop a similarity metric for Arabic and English words. Since matching against millions of candidates is computationally prohibitive, we store the English words and phrases in an index, such that given an Arabic word or phrase, we quickly retrieve a much smaller set of likely candidates and apply our similarity metric to that smaller list.

We divide the task of transliteration into two steps: given an Arabic word or phrase to transliterate, we (1) identify a list of English transliteration candidates from indexed lists of English words and phrases with counts (section 3.1) and (2) compute for each English name candidate the cost for the Arabic/English name pair (transliteration scoring model, section 3.2).

We then combine the count information with the transliteration cost according to the formula:

$$\text{score}(e) = \log(\text{count}(e))/20 - \text{translit\_cost}(e,f)$$

### 3.1 Indexing with consonant skeletons

We identify a list of English transliteration candidates through what we call a *consonant skeleton* index. Arabic consonants are divided into 11 classes, represented by letters b,f,g,j,k,l,m,n,r,s,t. In a one-time pre-processing step, all 3,420,339 (unique) English words from our English unigram language model (based on Google’s Web terabyte ngram collection) that might be names or part of names (mostly based on capitalization) are mapped to one or more skeletons, e.g.

Rachmaninoff → rkmnnf, rmnnf, rsmnnf, rtsmnnf  
This yields 10,381,377 skeletons (average of 3.0 per word) for which a reverse index is created (with counts). At run time, an Arabic word to be transliterated is mapped to its skeleton, e.g.

رحمانينوف → rmnnf

This skeleton serves as a key for the previously built reverse index, which then yields the list of English candidates with counts:

rmnnf → Rachmaninov (186,216), Rachmaninoff (179,666), Armenonville (3,445), Rachmaninow (1,636), plus 8 others.

Shorter words tend to produce more candidates, resulting in slower transliteration, but since there are relatively few unique short words, this can be addressed by caching transliteration results.

The same consonant skeleton indexing process is applied to name bigrams (47,700,548 unique with 167,398,054 skeletons) and trigrams (46,543,712 unique with 165,536,451 skeletons).

### 3.2 Transliteration scoring model

The cost of an Arabic/English name pair is computed based on 732 rules that assign a cost to a pair of Arabic and English substrings, allowing for one or more context restrictions.

1. ق::q == ::0
2. وف::ough == ::0
3. ح::ch == :[aou],:0.1
4. ق::k == ,\$, \$::0.1 ; ::0.2
5. ء:: == ,EC::0.1

The first example rule above assigns to the straightforward pair ق/q a cost of 0. The second rule includes 2 letters on the Arabic and 4 on the English side. The third rule restricts application to substring pairs where the English side is preceded by the letters a, o, or u. The fourth rule specifies a cost of 0.1 if the substrings occur at the end of (both) names, 0.2 otherwise. According to the fifth rule, the Arabic letter ء may match an empty string on the English side, if there is an English consonant (EC) in the right context of the English side.

The total cost is computed by always applying the longest applicable rule, without branching, resulting in a linear complexity with respect to word-pair length. Rules may include left and/or right context for both Arabic and English. The match fails if no rule applies or the accumulated cost exceeds a preset limit.

Names may have  $n$  words on the English and  $m$  on the Arabic side. For example, *New York* is one word in Arabic and *Abdullah* is two words in Arabic. The

rules handle spaces (as well as digits, apostrophes and other non-alphabetic material) just like regular alphabetic characters, so that our system can handle cases like where words in English and Arabic names do not match one to one.

The French name *Beaujolais* (بوجولييه/bujulyh) deviates from standard English spelling conventions in several places. The accumulative cost from the rules handling these deviations could become prohibitive, with each cost element penalizing the same underlying offense — being French. We solve this problem by allowing for additional context in the form of *style flags*. The rule for matching *eau/و* specifies, in addition to a cost, an (output) style flag +fr (as in French), which in turn serves as an additional context for the rule that matches *ais/يه* at a much reduced cost. Style flags are also used for some Arabic dialects. Extended characters such as é, ö, and § and spelling idiosyncrasies in names on the English side of the bitext that come from various third languages account for a significant portion of the rule set.

Casting the transliteration model as a scoring problem thus allows for very powerful rules with strong contexts. The current set of rules has been built by hand based on a bitext development corpus; future work might include deriving such rules automatically from a training set of transliterated names.

This transliteration scoring model described in this section is used in two ways: (1) to transliterate names at SMT decoding time, and (2) to identify transliteration pairs in a bitext.

## 4 Learning what to transliterate

As already mentioned in the introduction, named entity (NE) identification followed by MT is a bad idea. We don't want to identify NEs per se anyway — we want to identify things that our transliterator will be good at handling, i.e., things that should be transliterated. This might even include loanwords like *bnk* (*bank*) and *brlman* (*parliament*), but would exclude names such as *National Basketball Association* that are often translated rather transliterated.

Our method follows these steps:

1. Take a bitext.
2. Mark the Arabic words and phrases that have a recognizable transliteration on the English side.

3. Remove the English side of the bitext.
4. Divide the annotated Arabic corpus into a training and test corpus.
5. Train a monolingual Arabic tagger to identify which words and phrases (in running Arabic) are good candidates for transliteration (section 4.2)
6. Apply the tagger to test data and evaluate its accuracy.

### 4.1 Mark-up of bitext

Given a tokenized (but unaligned and mixed-case) bitext, we mark up that bitext with links between Arabic and English words that appear to be transliterations. In the following example, linked words are underlined, with numbers indicating what is linked.

**English** The meeting was attended by Omani (1) Secretary of State for Foreign Affairs Yusif (2) bin (3) Alawi (6) bin (8) Abdallah (10) and Special Advisor to Sultan (12) Qabus (13) for Foreign Affairs Umar (14) bin (17) Abdul Munim (19) al-Zawawi (21).

**Arabic (translit.)** uHDr allqa' uzyr aldule al'manY (1) llsh'uun alkhariye yusf (2) bn (3) 'luY (6) bn (8) 'bd allh (10) ualmstshar alkhaS llslTan (12) qabus (13) ll'laqat alkhariye 'mr (14) bn (17) 'bd almn'm (19) alzuauY (21) .

For each Arabic word, the linking algorithm tries to find a matching word on the English side, using the transliteration scoring model described in section 3. If the matcher reaches the end of an Arabic or English word before reaching the end of the other, it continues to “consume” additional words until a word-boundary observing match is found or the cost threshold exceeded.

When there are several viable linking alternatives, the algorithm considers the cost provided by the transliteration scoring model, as well as context to eliminate inferior alternatives, so that for example the different occurrences of the name particle *bin* in the example above are linked to the proper Arabic words, based on the names next to them. The number of links depends, of course, on the specific corpus, but we typically identify about 3.0 links per sentence.

The algorithm is enhanced by a number of heuristics:

- English match candidates are restricted to capitalized words (with a few exceptions).
- We use a list of about 200 Arabic and English stopwords and stopword pairs.
- We use lists of countries and their adjective forms to bridge cross-POS translations such as *Italy's president* on the English and رئيس الايطالي (*Italian president*) on the Arabic side.
- Arabic prefixes such as لـ/ (“to”) are treated in a special way, because they are translated, not transliterated like the rest of the word. Link (12) above is an example.

In this bitext mark-up process, we achieve 99.5% precision and 95% recall based on a manual visualization-tool based evaluation. Of the 5% recall error, 3% are due to noisy data in the bitext such as typos, incorrect translations, or names missing on one side of the bitext.

#### 4.2 Training of Arabic name tagger

The task of the Arabic name tagger (or more precisely, “transliterate-me” tagger) is to predict whether or not a word in an Arabic text should be transliterated, and if so, whether it includes a prefix. Prefixes such as و/u- (“and”) have to be translated rather than transliterated, so it is important to split off any prefix from a name before transliterating that name. This monolingual tagging task is not trivial, as many Arabic words can be both a name and a non-name. For example, الجزيرة (aljzyre) can mean both *Al-Jazeera* and *the island (or peninsula)*.

Features include the word itself plus two words to the left and right, along with various prefixes, suffixes and other characteristics of all of them, totalling about 250 features.

Some of our features depend on large corpus statistics. For this, we divide the tagged Arabic side of our training corpus into a *stat section* and a *core training section*. From the *stat section* we collect statistics as to how often every word, bigram or trigram occurs, and what distribution of name/non-name patterns these ngrams have. The name distribution bigram

الجزيرة الكورية 3327 00:133 01:3193 11:1  
(aljzyre alkurye/“peninsula Korean”) for example tells us that in 3193 out of 3327 occurrences in the

stat corpus bitext, the first word is marked up as a non-name (“0”) and the second as a name (“1”), which strongly suggests that in such a bigram context, *aljzyre* better be **translated** as *island* or *peninsula*, and not be **transliterated** as *Al-Jazeera*.

We train our system on a corpus of 6 million *stat* sentences, and 500,000 *core* training sentences. We employ a sequential tagger trained using the SEARN algorithm (Daumé III et al., 2006) with aggressive updates ( $\beta = 1$ ). Our base learning algorithm is an averaged perceptron, as implemented in the MEGAM package<sup>2</sup>.

Reference	Precision	Recall	F-meas.
Raw test corpus	87.4%	95.7%	91.4%
Adjusted for GS deficiencies	92.1%	95.9%	94.0%

Table 1: Accuracy of “transliterate-me” tagger

Testing on 10,000 sentences, we achieve precision of 87.4% and a recall of 95.7% with respect to the automatically marked-up Gold Standard as described in section 4.1. A manual error analysis of 500 sentences shows that a large portion are not errors after all, but have been marked as errors because of noise in the bitext and errors in the bitext mark-up. After adjusting for these deficiencies in the gold standard, we achieve precision of 92.1% and recall of 95.9% in the name tagging task.

## 5 Integration with SMT

We use the following method to integrate our transliterator into the overall SMT system:

1. We tag the Arabic source text using the tagger described in the previous section.
2. We apply the transliterator described in section 3 to the tagged items. We limit this transliteration to words that occur up to 50 times in the training corpus for single token names (or up to 100 and 150 times for two and three-word names). We do this because the general SMT mechanism tends to do well on more common names, but does poorly on rare names (and will

<sup>2</sup>Freely available at <http://hal3.name/megam>

always drop names it has never seen in the training bitext).

3. On the fly, we add transliterations to SMT phrase table. Instead of a phrasal probability, the transliterations have a special binary feature set to 1. In a tuning step, the Minimum Error Rate Training component of our SMT system iteratively adjusts the set of rule weights, including the weight associated with the transliteration feature, such that the English translations are optimized with respect to a set of known reference translations according to the BLEU translation metric.
4. At run-time, the transliterations then compete with the translations generated by the general SMT system. This means that the MT system will not always use the transliterator suggestions, depending on the combination of language model, translation model, and other component scores.

### 5.1 Multi-token names

We try to transliterate names as much as possible in context. Consider for example the Arabic name:

يوسف أبو صفية ("yusf abu Sfy")

If transliterated as single words without context, the top results would be Joseph|Josef|Yusuf|Yosef|Youssef, Abu|Abo|Ivo|Apo|Ibo, and Sephia|Sofia|Sophia|Safieh|Safia respectively. However, when transliterating the three words together against our list of 47 million English trigrams (section 3), the transliterator will select the (correct) translation *Yousef Abu Safieh*. Note that *Yousef* was not among the top 5 choices, and that *Safieh* was only choice 4.

Similarly, when transliterating وموزار وشوبان ("and Mozart and Chopin") without context, the top results would be Moser|Mauser|Mozer|Mozart|Mouser and Shuppan|Shopping|Schwaben|Schuppan|Shobana (with *Chopin* way down on place 22). Checking our large English lists for a matching *name, name* pattern, the transliterator identifies the correct translation "*Mozart, Chopin*". Note that the transliteration module provides the overall SMT system with up to 5 alternatives, augmented with a choice of English translations for the Arabic prefixes like the comma and the conjunction *and* in the last example.

## 6 End-to-End results

We applied the NEWA metric (section 2) to both our SMT translations as well as the four human reference translations, using both the original named-entity translation annotation and the re-annotation:

Gold Standard	BBN GS	Re-annotated GS
Human 1	87.0%	85.0%
Human 2	85.3%	86.9%
Human 3	90.4%	91.8%
Human 4	86.5%	88.3%
SMT System	80.4%	89.7%

Table 2: Name translation accuracy with respect to BBN and re-annotated Gold Standard on 1730 named entities in 637 sentences.

Almost all scores went up with re-annotations, because the re-annotations more properly reward correct answers.

Based on the original annotations, all human name translations were much better than our SMT system. However, based on our re-annotation, the results are quite different: our system has a higher NEWA score and better name translations than 3 out of 4 human annotators.

The evaluation results confirm that the original annotation method produced a relative bias towards the human translation its annotations were largely based on, compared to other translations.

Table 3 provides more detailed NEWA results. The addition of the transliteration module improves our overall NEWA score from 87.8% to 89.7%, a relative gain of 16% over base SMT system. For names of persons (PER) and facilities (FAC), our system outperforms all human translators. Humans performed much better on Person Nominals (PER.Nom) such as *Swede, Dutchmen, Americans*. Note that name translation quality varies greatly between human translators, with error rates ranging from 8.2-15.0% (absolute).

To make sure our name transliterator does not degrade the overall translation quality, we evaluated our base SMT system with BLEU, as well as our transliteration-augmented SMT system. Our standard newswire training set consists of 10.5 million words of bitext (English side) and 1491 test sen-

NE Type	Count	Baseline SMT	SMT with Transliteration	Human 1	Human 2	Human 3	Human 4
PER	342	266 (77.8%)	280 (81.9%)	210 (61.4%)	265 (77.5%)	278 (81.3%)	275 (80.4%)
GPE	910	863 (94.8%)	877 (96.4%)	867 (95.3%)	849 (93.3%)	885 (97.3%)	852 (93.6%)
ORG	332	280 (84.3%)	282 (84.9%)	263 (79.2%)	265 (79.8%)	293 (88.3%)	281 (84.6%)
FAC	27	18 (66.7%)	24 (88.9%)	21 (77.8%)	20 (74.1%)	22 (81.5%)	20 (74.1%)

## 7 Discussion

We have shown that a state-of-the-art statistical machine translation system can benefit from a dedicated transliteration module to improve the transla-

tion of rare names. Improved named entity translation accuracy as measured by the NEWA metric in general, and a reduction in dropped names in particular is clearly valuable to the human reader of machine translated documents as well as for systems using machine translation for further information processing. At the same time, there has been no negative impact on overall quality as measured by BLEU.

We believe that all components can be further improved, e.g.

- Automatically retune the weights in the transliteration scoring model.
- Improve robustness with respect to typos, incorrect or missing translations, and badly aligned sentences when marking up bitexts.
- Add more features for learning whether or not a word should be transliterated, possibly using source language morphology to better identify non-name words never or rarely seen during training.

Additionally, our transliteration method could be applied to other language pairs.

We find it encouraging that we already outperform some professional translators in name translation accuracy. The potential to exceed human translator performance arises from the patience required to translate names right.

# Using adaptor grammars to identify synergies in the unsupervised acquisition of linguistic structure

Mark Johnson

Brown University

Mark\_Johnson@Brown.edu

## Abstract

Adaptor grammars (Johnson et al., 2007b) are a non-parametric Bayesian extension of Probabilistic Context-Free Grammars (PCFGs) which in effect learn the probabilities of entire subtrees. In practice, this means that an adaptor grammar learns the structures useful for generating the training data as well as their probabilities. We present several different adaptor grammars that learn to segment phonemic input into words by modeling different linguistic properties of the input. One of the advantages of a grammar-based framework is that it is easy to combine grammars, and we use this ability to compare models that capture different kinds of linguistic structure. We show that incorporating both unsupervised syllabification and collocation-finding into the adaptor grammar significantly improves unsupervised word-segmentation accuracy over that achieved by adaptor grammars that model only one of these linguistic phenomena.

## 1 Introduction

How humans acquire language is arguably the central issue in the scientific study of language. Human language is richly structured, but it is still hotly debated as to whether this structure can be learnt, or whether it must be innately specified. Computational linguistics can contribute to this debate by identifying which aspects of language can potentially be learnt from the input available to a child. Here we try to identify linguistic properties that convey information useful for learning to segment

streams of phonemes into words. We show that simultaneously learning syllable structure and collocations improves word segmentation accuracy compared to models that learn these independently. This suggests that there might be a synergistic interaction in learning several aspects of linguistic structure simultaneously, as compared to learning each kind of linguistic structure independently.

Because learning collocations and word-initial syllable onset clusters requires the learner to be able to identify word boundaries, it might seem that we face a chicken-and-egg problem here. One of the important properties of the adaptor grammar inference procedure is that it gives us a way of learning these interacting linguistic structures simultaneously.

Adaptor grammars are also interesting because they can be viewed as directly inferring linguistic structure. Most well-known machine-learning and statistical inference procedures are parameter estimation procedures, i.e., the procedure is designed to find the values of a finite vector of parameters. Standard methods for learning linguistic structure typically try to reduce structure learning to parameter estimation, say, by using an iterative generate-and-prune procedure in which each iteration consists of a rule generation step that proposes new rules according to some scheme, a parameter estimation step that estimates the utility of these rules, and pruning step that removes low utility rules. For example, the Bayesian unsupervised PCFG estimation procedure devised by Stolcke (1994) uses a model-merging procedure to propose new sets of PCFG rules and a Bayesian version of the EM procedure to estimate their weights.

Recently, methods have been developed in the statistical community for Bayesian inference of increasingly sophisticated non-parametric models. (“Non-parametric” here means that the models are not characterized by a finite vector of parameters, so the complexity of the model can vary depending on the data it describes). Adaptor grammars are a framework for specifying a wide range of such models for grammatical inference. They can be viewed as a nonparametric extension of PCFGs.

Informally, there seem to be at least two natural ways to construct non-parametric extensions of a PCFG. First, we can construct an infinite number of more specialized PCFGs by splitting or refining the PCFG’s nonterminals into increasingly finer states; this leads to the iPCFG or “infinite PCFG” (Liang et al., 2007). Second, we can generalize over arbitrary subtrees rather than local trees in much the way done in DOP or tree substitution grammar (Bod, 1998; Joshi, 2003), which leads to adaptor grammars.

Informally, the units of generalization of adaptor grammars are entire subtrees, rather than just local trees, as in PCFGs. Just as in tree substitution grammars, each of these subtrees behaves as a new context-free rule that expands the subtree’s root node to its leaves, but unlike a tree substitution grammar, in which the subtrees are specified in advance, in an adaptor grammar the subtrees, as well as their probabilities, are learnt from the training data. In order to make parsing and inference tractable we require the leaves of these subtrees to be terminals, as explained in section 2. Thus adaptor grammars are simple models of structure learning, where the subtrees that constitute the units of generalization are in effect new context-free rules learnt during the inference process. (In fact, the inference procedure for adaptor grammars described in Johnson et al. (2007b) relies on a PCFG approximation that contains a rule for each subtree generalization in the adaptor grammar).

This paper applies adaptor grammars to word segmentation and morphological acquisition. Linguistically, these exhibit considerable cross-linguistic variation, and so are likely to be learned by human learners. It’s also plausible that semantics and contextual information is less important for their acquisition than, say, syntax.

## 2 From PCFGs to Adaptor Grammars

This section introduces adaptor grammars as an extension of PCFGs; for a more detailed exposition see Johnson et al. (2007b). Formally, an adaptor grammar is a PCFG in which a subset  $M$  of the nonterminals are *adapted*. An adaptor grammar generates the same set of trees as the CFG with the same rules, but instead of defining a fixed probability distribution over these trees as a PCFG does, it defines a distribution over distributions over trees. An adaptor grammar can be viewed as a kind of PCFG in which each subtree of each adapted nonterminal  $A \in M$  is a potential rule, with its own probability, so an adaptor grammar is nonparametric if there are infinitely many possible adapted subtrees. (An adaptor grammar can thus be viewed as a tree substitution grammar with infinitely many initial trees). But any finite set of sample parses for any finite corpus can only involve a finite number of such subtrees, so the corresponding PCFG approximation only involves a finite number of rules, which permits us to build MCMC samplers for adaptor grammars.

A PCFG can be viewed as a set of recursively-defined mixture distributions  $G_A$  over trees, one for each nonterminal and terminal in the grammar. If  $A$  is a terminal then  $G_A$  is the distribution that puts all of its mass on the unit tree (i.e., tree consisting of a single node) labeled  $A$ . If  $A$  is a nonterminal then  $G_A$  is the distribution over trees with root labeled  $A$  that satisfies:

$$G_A = \sum_{A \rightarrow B_1 \dots B_n \in R_A} \theta_{A \rightarrow B_1 \dots B_n} \text{TD}_A(G_{B_1}, \dots, G_{B_n})$$

where  $R_A$  is the set of rules expanding  $A$ ,  $\theta_{A \rightarrow B_1, \dots, B_n}$  is the PCFG “probability” parameter associated with the rule  $A \rightarrow B_1 \dots B_n$  and  $\text{TD}_A(G_{B_1}, \dots, G_{B_n})$  is the distribution over trees with root label  $A$  satisfying:

$$\text{TD}_A(G_1, \dots, G_n) \left( \begin{array}{c} A \\ \diagdown \quad \diagup \\ t_1 \quad \dots \quad t_n \end{array} \right) = \prod_{i=1}^n G_i(t_i).$$

That is,  $\text{TD}_A(G_1, \dots, G_n)$  is the distribution over trees whose root node is labeled  $A$  and each subtree  $t_i$  is generated *independently* from the distribution  $G_i$ . This independence assumption is what makes a PCFG “context-free” (i.e., each subtree is independent given its label). Adaptor grammars relax

this independence assumption by in effect learning the probability of the subtrees rooted in a specified subset  $M$  of the nonterminals known as the *adapted nonterminals*.

Adaptor grammars achieve this by associating each adapted nonterminal  $A \in M$  with a Dirichlet Process (DP). A DP is a function of a *base distribution*  $H$  and a *concentration parameter*  $\alpha$ , and it returns a distribution over distributions  $\text{DP}(\alpha, H)$ . There are several different ways to define DPs; one of the most useful is the characterization of the conditional or sampling distribution of a draw from  $\text{DP}(\alpha, H)$  in terms of the Polya urn or Chinese Restaurant Process (Teh et al., 2006). The Polya urn initially contains  $\alpha H(x)$  balls of color  $x$ . We sample a distribution from  $\text{DP}(\alpha, H)$  by repeatedly drawing a ball at random from the urn and then returning it plus an additional ball of the same color to the urn.

In an adaptor grammar there is one DP for each adapted nonterminal  $A \in M$ , whose base distribution  $H_A$  is the distribution over trees defined using  $A$ 's PCFG rules. This DP ‘‘adapts’’  $A$ 's PCFG distribution by moving mass from the infrequently to the frequently occurring subtrees. An adaptor grammar associates a distribution  $G_A$  that satisfies the following constraints with each nonterminal  $A$ :

$$\begin{aligned} G_A &\sim \text{DP}(\alpha_A, H_A) && \text{if } A \in M \\ G_A &= H_A && \text{if } A \notin M \\ H_A &= \sum_{A \rightarrow B_1 \dots B_n, B_i \in R_A} \theta_{A \rightarrow B_1 \dots B_n} \text{TD}_A(G_{B_1}, \dots, G_{B_n}) \end{aligned}$$

Unlike a PCFG, an adaptor grammar does not define a single distribution over trees; rather, each set of draws from the DPs defines a different distribution. In the adaptor grammars used in this paper there is no recursion amongst adapted nonterminals (i.e., an adapted nonterminal never expands to itself); it is currently unknown whether there are tree distributions that satisfy the adaptor grammar constraints for recursive adaptor grammars.

Inference for an adaptor grammar involves finding the rule probabilities  $\theta$  and the adapted distributions over trees  $G$ . We put Dirichlet priors over the rule probabilities, i.e.:

$$\theta_A \sim \text{DIR}(\beta_A)$$

where  $\theta_A$  is the vector of probabilities for the rules

expanding the nonterminal  $A$  and  $\beta_A$  are the corresponding Dirichlet parameters.

The applications described below require unsupervised estimation, i.e., the training data consists of terminal strings alone. Johnson et al. (2007b) describe an MCMC procedure for inferring the adapted tree distributions  $G_A$ , and Johnson et al. (2007a) describe a Bayesian inference procedure for the PCFG rule parameters  $\theta$  using a Metropolis-Hastings MCMC procedure; implementations are available from the author’s web site.

Informally, the inference procedure proceeds as follows. We initialize the sampler by randomly assigning each string in the training corpus a random tree generated by the grammar. Then we randomly select a string to resample, and sample a parse of that string with a PCFG approximation to the adaptor grammar. This PCFG contains a production for each adapted subtree in the parses of the other strings in the training corpus. A final accept-reject step corrects for the difference in the probability of the sampled tree under the adaptor grammar and the PCFG approximation.

### 3 Word segmentation with adaptor grammars

We now turn to linguistic applications of adaptor grammars, specifically, to models of unsupervised word segmentation. We follow previous work in using the Brent corpus consists of 9790 transcribed utterances (33,399 words) of child-directed speech from the Bernstein-Ratner corpus (Bernstein-Ratner, 1987) in the CHILDES database (MacWhinney and Snow, 1985). The utterances have been converted to a phonemic representation using a phonemic dictionary, so that each occurrence of a word has the same phonemic transcription. Utterance boundaries are given in the input to the system; other word boundaries are not. We evaluated the f-score of the recovered word constituents (Goldwater et al., 2006b). Using the adaptor grammar software available on the author’s web site, samplers were run for 10,000 epochs (passes through the training data). We scored the parses assigned to the training data at the end of sampling, and for the last two epochs we annealed at temperature 0.5 (i.e., squared the probability) during sampling in or-

	1	10	100	1000

der to concentrate mass on high probability parses. In all experiments below we set  $\beta = 1$ , which corresponds to a uniform prior on PCFG rule probabilities  $\theta$ . We tied the Dirichlet Process concentration parameters  $\alpha$ , and performed runs with  $\alpha = 1, 10, 100$  and 1000; apart from this, no attempt was made to optimize the hyperparameters. Table 1 summarizes the word segmentation f-scores for all models described in this paper.

### 3.1 Unigram word adaptor grammar

Johnson et al. (2007a) presented an adaptor grammar that defines a unigram model of word segmentation and showed that it performs as well as the unigram DP word segmentation model presented by (Goldwater et al., 2006a). The adaptor grammar that encodes a unigram word segmentation model shown in Figure 1.

In this grammar and the grammars below, underlining indicates an adapted nonterminal. Phoneme is a nonterminal that expands to each of the 50 distinct phonemes present in the Brent corpus. This grammar defines a Sentence to consist of a sequence of Words, where a Word consists of a sequence of Phonemes. The category Word is adapted, which means that the grammar learns the words that occur in the training corpus. We present our adap-

Sentence  $\rightarrow$  Words

Figure 3: A parse of the phonemic representation of “you want to see the book” produced by unigram word adaptor grammar of Figure 1. Only nonterminal nodes labeled with adapted nonterminals and the start symbol are shown.

tor grammars using regular expressions for clarity, but since our implementation does not handle regular expressions in rules, in the grammars actually used by the program they are expanded using new non-adapted nonterminals that rewrite in a uniform right-branching manner. That is, the adaptor grammar used by the program is shown in Figure 2.

The unigram word adaptor grammar generates parses such as the one shown in Figure 3. With  $\alpha = 1$  and  $\alpha = 10$  we obtained a word segmentation f-score of 0.55. Depending on the run, between 1, 100 and 1, 400 subtrees (i.e., new rules) were found for Word. As reported in Goldwater et al. (2006a) and Goldwater et al. (2007), a unigram word segmentation model tends to undersegment and misanalyse collocations as individual words. This is presumably because the unigram model has no way to capture dependencies between words in collocations except to make the collocation into a single word.

### 3.2 Unigram morphology adaptor grammar

This section investigates whether learning morphology together with word segmentation improves word segmentation accuracy. Johnson et al. (2007a) presented an adaptor grammar for segmenting verbs into stems and suffixes that implements the DP-

Sentence  $\rightarrow$  Word<sup>+</sup>  
 Word  $\rightarrow$  Stem (Suffix)  
 Stem  $\rightarrow$  Phoneme<sup>+</sup>  
 Suffix  $\rightarrow$  Phoneme<sup>+</sup>

Figure 4: The unigram morphology adaptor grammar, which generates each Sentence as a sequence of Words, and each Word as a Stem optionally followed by a Suffix. Parentheses indicate optional constituents.

Figure 5: Parses of “wanna close it” and “you have to tell me” produced by the unigram morphology grammar of Figure 4. The first parse was chosen because it demonstrates how the grammar is intended to analyse “wanna” into a Stem and Suffix, while the second parse shows how the grammar tends to use Stem and Suffix to capture collocations.

based unsupervised morphological analysis model presented by Goldwater et al. (2006b). Here we combine that adaptor grammar with the unigram word segmentation grammar to produce the adaptor grammar shown in Figure 4, which is designed to simultaneously learn both word segmentation and morphology.

Parentheses indicate optional constituents in these rules, so this grammar says that a Sentence consists of a sequence of Words, and each Word consists of a Stem followed by an optional Suffix. The categories Word, Stem and Suffix are adapted, which means that the grammar learns the Words, Stems and Suffixes that occur in the training corpus. Technically this grammar implements a *Hierarchical Dirichlet Process* (HDP) (Teh et al., 2006) because the base distribution for the Word DP is itself constructed from the Stem and Suffix distributions, which are

themselves generated by DPs.

This grammar recovers words with an f-score of only 0.46 with  $\alpha = 1$  or  $\alpha = 10$ , which is considerably less accurate than the unigram model of section 3.1. Typical parses are shown in Figure 5. The unigram morphology grammar tends to misanalyse even longer collocations as words than the unigram word grammar does. Inspecting the parses shows that rather than capturing morphological structure, the Stem and Suffix categories typically expand to words themselves, so the Word category expands to a collocation. It may be possible to correct this by “tuning” the grammar’s hyperparameters, but we did not attempt this here.

These results are not too surprising, since the kind of regular stem-suffix morphology that this grammar can capture is not common in the Brent corpus. It is possible that a more sophisticated model of morphology, or even a careful tuning of the Bayesian prior parameters  $\alpha$  and  $\beta$ , would produce better results.

### 3.3 Unigram syllable adaptor grammar

PCFG estimation procedures have been used to model the supervised and unsupervised acquisition of syllable structure (Müller, 2001; Müller, 2002); and the best performance in unsupervised acquisition is obtained using a grammar that encodes linguistically detailed properties of syllables whose rules are inferred using a fairly complex algorithm (Goldwater and Johnson, 2005). While that work studied the acquisition of syllable structure from isolated words, here we investigate whether learning syllable structure together with word segmentation improves word segmentation accuracy. Modeling syllable structure is a natural application of adaptor grammars, since the grammar can learn the possible onset and coda clusters, rather than requiring them to be stipulated in the grammar.

In the unigram syllable adaptor grammar shown in Figure 7, Consonant expands to any consonant and Vowel expands to any vowel. This grammar defines a Word to consist of up to three Syllables, where each Syllable consists of an Onset and a Rhyme and a Rhyme consists of a Nucleus and a Coda. Following Goldwater and Johnson (2005), the grammar differentiates between OnsetI, which expands to word-initial onsets, and Onset,

Figure 6: A parse of “what’s this” produced by the unigram syllable adaptor grammar of Figure 7. (Only adapted non-root nonterminals are shown in the parse).

which expands to non-word-initial onsets, and between CodaF, which expands to word-final codas, and Coda, which expands to non-word-final codas. Note that we do not need to distinguish specific positions within the Onset and Coda clusters as Goldwater and Johnson (2005) did, since the adaptor grammar learns these clusters directly. Just like the unigram morphology grammar, the unigram syllable grammar also defines a HDP because the base distribution for Word is defined in terms of the Onset and Rhyme distributions.

The unigram syllable grammar achieves a word segmentation f-score of 0.52 at  $\alpha = 1$ , which is also lower than the unigram word grammar achieves. Inspection of the parses shows that the unigram syllable grammar also tends to misanalyse long collocations as Words. Specifically, it seems to misanalyse function words as associated with the content words next to them, perhaps because function words tend to have simpler initial and final clusters.

We cannot compare our syllabification accuracy with Goldwater’s and others’ previous work because that work used different, supervised training data and phonological representations based on British rather than American pronunciation.

### 3.4 Collocation word adaptor grammar

Goldwater et al. (2006a) showed that modeling dependencies between adjacent words dramatically improves word segmentation accuracy. It is not possible to write an adaptor grammar that directly implements Goldwater’s bigram word segmentation model because an adaptor grammar has one DP per adapted nonterminal (so the number of DPs is fixed in advance) while Goldwater’s bigram model has one DP per word type, and the number of word types is not known in advance. However it is pos-

- Sentence  $\rightarrow$  Word<sup>+</sup>
- Word  $\rightarrow$  SyllableIF
- Word  $\rightarrow$  SyllableI SyllableF
- Word  $\rightarrow$  SyllableI Syllable SyllableF
- Syllable  $\rightarrow$  (Onset) Rhyme
- SyllableI  $\rightarrow$  (OnsetI) Rhyme
- SyllableF  $\rightarrow$  (Onset) RhymeF
- SyllableIF  $\rightarrow$  (OnsetI) RhymeF
- Rhyme  $\rightarrow$  Nucleus (Coda)
- RhymeF  $\rightarrow$  Nucleus (CodaF)
- Onset  $\rightarrow$  Consonant<sup>+</sup>
- OnsetI  $\rightarrow$  Consonant<sup>+</sup>
- Coda  $\rightarrow$  Consonant<sup>+</sup>
- CodaF  $\rightarrow$  Consonant<sup>+</sup>
- Nucleus  $\rightarrow$  Vowel<sup>+</sup>

Figure 7: The unigram syllable adaptor grammar, which generates each word as a sequence of up to three Syllables. Word-initial Onsets and word-final Codas are distinguished using the suffixes “I” and “F” respectively; these are propagated through the grammar to ensure that these appear in the correct positions.

- Sentence  $\rightarrow$  Colloc<sup>+</sup>
- Colloc  $\rightarrow$  Word<sup>+</sup>
- Word  $\rightarrow$  Phoneme<sup>+</sup>

Figure 8: The collocation word adaptor grammar, which generates a Sentence as sequence of Colloc(ations), each of which consists of a sequence of Words.

sible for an adaptor grammar to generate a sentence as a sequence of *collocations*, each of which consists of a sequence of words. These collocations give the grammar a way to model dependencies between words.

With the DP concentration parameters  $\alpha = 1000$  we obtained a f-score of 0.76, which is approximately the same as the results reported by Goldwater et al. (2006a) and Goldwater et al. (2007). This suggests that the collocation word adaptor grammar can capture inter-word dependencies similar to those that improve the performance of Goldwater’s bigram segmentation model.

### 3.5 Collocation morphology adaptor grammar

One of the advantages of working within a grammatical framework is that it is often easy to combine

Figure 9: A parse of “you want to see the book” produced by the collocation word adaptor grammar of Figure 8.

$$\begin{aligned}
 \text{Sentence} &\rightarrow \text{Colloc}^+ \\
 \text{Colloc} &\rightarrow \text{Word}^+ \\
 \text{Word} &\rightarrow \text{Stem (Suffix)} \\
 \text{Stem} &\rightarrow \text{Phoneme}^+ \\
 \text{Suffix} &\rightarrow \text{Phoneme}^+
 \end{aligned}$$

Figure 10: The collocation morphology adaptor grammar, which generates each Sentence as a sequence of Colloc(ations), each Colloc as a sequence of Words, and each Word as a Stem optionally followed by a Suffix.

different grammar fragments into a single grammar. In this section we combine the collocation aspect of the previous grammar with the morphology component of the grammar presented in section 3.2 to produce a grammar that generates Sentences as sequences of Colloc(ations), where each Colloc consists of a sequence of Words, and each Word consists of a Stem followed by an optional Suffix, as shown in Figure 10.

This grammar achieves a word segmentation f-score of 0.73 at  $\alpha = 100$ , which is much better than the unigram morphology grammar of section 3.2, but not as good as the collocation word grammar of the previous section. Inspecting the parses shows

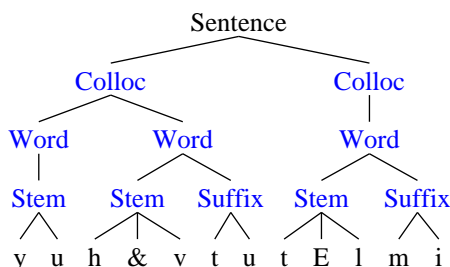

Figure 11: A parse of the phonemic representation of “you have to tell me” using the collocation morphology adaptor grammar of Figure 10.

Figure 12: A parse of “have a drink” produced by the collocation syllable adaptor grammar. (Only adapted non-root nonterminals are shown in the parse).

that while the ability to directly model collocations reduces the number of collocations misanalysed as words, function words still tend to be misanalysed as morphemes of two-word collocations. In fact, some of the misanalyses have a certain plausibility to them (e.g., “to” is often analysed as the suffix of verbs such as “have”, “want” and “like”, while “me” is often analysed as a suffix of verbs such as “show” and “tell”), but they lower the word f-score considerably.

### 3.6 Collocation syllable adaptor grammar

The collocation syllable adaptor grammar is the same as the unigram syllable adaptor grammar of Figure 7, except that the first production is replaced with the following pair of productions.

$$\begin{aligned}
 \text{Sentence} &\rightarrow \text{Colloc}^+ \\
 \text{Colloc} &\rightarrow \text{Word}^+
 \end{aligned}$$

This grammar generates a Sentence as a sequence of Colloc(ations), each of which is composed of a sequence of Words, each of which in turn is composed of a sequence of Syll(ables).

This grammar achieves a word segmentation f-score of 0.78 at  $\alpha = 100$ , which is the highest f-score of any of the grammars investigated in this paper, including the collocation word grammar, which models collocations but not syllables. To confirm that the difference is significant, we ran a Wilcoxon test to compare the f-scores obtained from 8 runs of the collocation syllable grammar with  $\alpha = 100$  and the collocation word grammar with  $\alpha = 1000$ , and found that the difference is significant at  $p = 0.006$ .

## 4 Conclusion and future work

This paper has shown how adaptor grammars can be used to study a variety of different linguistic hy-

potheses about the interaction of morphology and syllable structure with word segmentation. Technically, adaptor grammars are a way of specifying a variety of Hierarchical Dirichlet Processes (HDPs) that can spread their support over an unbounded number of distinct subtrees, giving them the ability to learn which subtrees are most useful for describing the training corpus. Thus adaptor grammars move beyond simple parameter estimation and provide a principled approach to the Bayesian estimation of at least some types of linguistic structure. Because of this, less linguistic structure needs to be “built in” to an adaptor grammar compared to a comparable PCFG. For example, the adaptor grammars for syllable structure presented in sections 3.3 and 3.6 learn more information about syllable onsets and codas than the PCFGs presented in Goldwater and Johnson (2005).

We used adaptor grammars to study the effects of modeling morphological structure, syllabification and collocations on the accuracy of a standard unsupervised word segmentation task. We showed how adaptor grammars can implement a previously investigated model of unsupervised word segmentation, the unigram word segmentation model. We then investigated adaptor grammars that incorporate one additional kind of information, and found that modeling collocations provides the greatest improvement in word segmentation accuracy, resulting in a model that seems to capture many of the same interword dependencies as the bigram model of Goldwater et al. (2006b).

We then investigated grammars that combine these kinds of information. There does not seem to be a straight forward way to design an adaptor grammar that models both morphology and syllable structure, as morpheme boundaries typically do not align with syllable boundaries. However, we showed that an adaptor grammar that models collocations and syllable structure performs word segmentation more accurately than an adaptor grammar that models either collocations or syllable structure alone. This is not surprising, since syllable onsets and codas that occur word-peripherally are typically different to those that appear word-internally, and our results suggest that by tracking these onsets and codas, it is possible to learn more accurate word segmentation.

There are a number of interesting directions for future work. In this paper all of the hyperparameters  $\alpha_A$  were tied and varied simultaneously, but it is desirable to learn these from data as well. Just before the camera-ready version of this paper was due we developed a method for estimating the hyperparameters by putting a vague Gamma hyper-prior on each  $\alpha_A$  and sampled using Metropolis-Hastings with a sequence of increasingly narrow Gamma proposal distributions, producing results for each model that are as good or better than the best ones reported in Table 1.

The adaptor grammars presented here barely scratch the surface of the linguistically interesting models that can be expressed as Hierarchical Dirichlet Processes. The models of morphology presented here are particularly naive—they only capture regular concatenative morphology consisting of one paradigm class—which may partially explain why we obtained such poor results using morphology adaptor grammars. It’s straight forward to design an adaptor grammar that can capture a finite number of concatenative paradigm classes (Goldwater et al., 2006b; Johnson et al., 2007a). We’d like to learn the number of paradigm classes from the data, but doing this would probably require extending adaptor grammars to incorporate the kind of adaptive state-splitting found in the iHMM and iPCFG (Liang et al., 2007). There is no principled reason why this could not be done, i.e., why one could not design an HDP framework that simultaneously learns both the fragments (as in an adaptor grammar) and the states (as in an iHMM or iPCFG).

However, inference with these more complex models will probably itself become more complex. The MCMC sampler of Johnson et al. (2007a) used here is satisfactory for small and medium-sized problems, but it would be very useful to have more efficient inference procedures. It may be possible to adapt efficient split-merge samplers (Jain and Neal, 2007) and Variational Bayes methods (Teh et al., 2008) for DPs to adaptor grammars and other linguistic applications of HDPs.

## Abstract

We propose using large-scale clustering of dependency relations between verbs and multi-word nouns (MNs) to construct a gazetteer for named entity recognition (NER). Since dependency relations capture the semantics of MNs well, the MN clusters constructed by using dependency relations should serve as a good gazetteer. However, the high level of computational cost has prevented the use of clustering for constructing gazetteers. We parallelized a clustering algorithm based on expectation-maximization (EM) and thus enabled the construction of large-scale MN clusters. We demonstrated with the IREX dataset for the Japanese NER that using the constructed clusters as a gazetteer (*cluster gazetteer*) is an effective way of improving the accuracy of NER. Moreover, we demonstrate that the combination of the cluster gazetteer and a gazetteer extracted from Wikipedia, which is also useful for NER, can further improve the accuracy in several cases.

## 1 Introduction

*Gazetteers*, or entity dictionaries, are important for performing named entity recognition (NER) accurately. Since building and maintaining high-quality gazetteers by hand is very expensive, many methods have been proposed for automatic extraction of gazetteers from texts (Riloff and Jones, 1999; Thelen and Riloff, 2002; Etzioni et al., 2005; Shinzato et al., 2006; Talukdar et al., 2006; Nadeau et al., 2006).

Most studies using gazetteers for NER are based on the assumption that a gazetteer is a mapping

from a multi-word noun (MN)<sup>1</sup> to named entity categories such as “Tokyo Stock Exchange → {ORGANIZATION}”.<sup>2</sup> However, since the correspondence between the labels and the NE categories can be learned by tagging models, a gazetteer will be useful as long as it returns consistent labels even if those returned are not the NE categories. By changing the perspective in such a way, we can explore more broad classes of gazetteers. For example, we can use automatically extracted hyponymy relations (Hearst, 1992; Shinzato and Torisawa, 2004), or automatically induced MN clusters (Rooth et al., 1999; Torisawa, 2001).

For instance, Kazama and Torisawa (2007) used the hyponymy relations extracted from Wikipedia for the English NER, and reported improved accuracies with such a gazetteer.

We focused on the automatically induced clusters of multi-word nouns (MNs) as the source of gazetteers. We call the constructed gazetteers *cluster gazetteers*. In the context of tagging, there are several studies that utilized *word* clusters to prevent the data sparseness problem (Kazama et al., 2001; Miller et al., 2004). However, these methods cannot produce the MN clusters required for constructing gazetteers. In addition, the clustering methods used, such as HMMs and Brown’s algorithm (Brown et al., 1992), seem unable to adequately capture the semantics of MNs since they are based only on the information of adjacent words. We utilized richer

<sup>1</sup>We used the term, “multi-word”, to emphasize that a gazetteer includes not only one-word expressions but also multi-word expressions.

<sup>2</sup>Although several categories can be associated in general, we assume that only one category is associated.

syntactic/semantic structures, i.e., verb-MN dependencies to make clean MN clusters. Rooth et al. (1999) and Torisawa (2001) showed that the EM-based clustering using verb-MN dependencies can produce semantically clean MN clusters. However, the clustering algorithms, especially the EM-based algorithms, are computationally expensive. Therefore, performing the clustering with a vocabulary that is large enough to cover the many named entities required to improve the accuracy of NER is difficult. We enabled such large-scale clustering by parallelizing the clustering algorithm, and we demonstrate the usefulness of the gazetteer constructed.

We parallelized the algorithm of (Torisawa, 2001) using the Message Passing Interface (MPI), with the prime goal being to distribute parameters and thus enable clustering with a large vocabulary. Applying the parallelized clustering to a large set of dependencies collected from Web documents enabled us to construct gazetteers with up to 500,000 entries and 3,000 classes.

In our experiments, we used the IREX dataset (Sekine and Isahara, 2000) to demonstrate the usefulness of cluster gazetteers. We also compared the cluster gazetteers with the Wikipedia gazetteer constructed by following the method of (Kazama and Torisawa, 2007). The improvement was larger for the cluster gazetteer than for the Wikipedia gazetteer. We also investigated whether these gazetteers improve the accuracies further when they are used in combination. The experimental results indicated that the accuracy improved further in several cases and showed that these gazetteers complement each other.

The paper is organized as follows. In Section 2, we explain the construction of cluster gazetteers and its parallelization, along with a brief explanation of the construction of the Wikipedia gazetteer. In Section 3, we explain how to use these gazetteers as features in an NE tagger. Our experimental results are reported in Section 4.

## 2 Gazetteer Induction

### 2.1 Induction by MN Clustering

Assume we have a probabilistic model of a multi-word noun (MN) and its class:  $p(n, c) = p(n|c)p(c)$ , where  $n \in \mathcal{N}$  is an MN and  $c \in \mathcal{C}$  is a class. We can use this model to construct a gazetteer in several ways. The method we used in this study

constructs a gazetteer:  $n \rightarrow \operatorname{argmax}_c p(c|n)$ . This computation can be re-written by the Bayes rule as  $\operatorname{argmax}_c p(n|c)p(c)$  using  $p(n|c)$  and  $p(c)$ .

Note that we do not exclude non-NEs when we construct the gazetteer. We expect that tagging models (CRFs in our case) can learn an appropriate weight for each gazetteer match regardless of whether it is an NE or not.

### 2.2 EM-based Clustering using Dependency Relations

To learn  $p(n|c)$  and  $p(c)$  for Japanese, we use the EM-based clustering method presented by Torisawa (2001). This method assumes a probabilistic model of verb-MN dependencies with hidden semantic classes:<sup>3</sup>

$$p(v, r, n) = \sum_c p(\langle v, r \rangle | c) p(n|c) p(c), \quad (1)$$

where  $v \in \mathcal{V}$  is a verb and  $n \in \mathcal{N}$  is an MN that depends on verb  $v$  with relation  $r$ . A relation,  $r$ , is represented by Japanese postpositions attached to  $n$ . For example, from the following Japanese sentence, we extract the following dependency:  $v =$  飲む (drink),  $r =$  を ("wo" postposition),  $n =$  ビール (beer).

ビール (beer) を (wo) 飲む (drink) ( $\approx$  drink beer)

In the following, we let  $vt \equiv \langle v, r \rangle \in \mathcal{VT}$  for the simplicity of explanation.

To be precise, we attach various auxiliary verb suffixes, such as “れる (reru)”, which is for passivization, into  $v$ , since these greatly change the type of  $n$  in the dependent position. In addition, we also treated the MN-MN expressions, “ $MN_1$  の  $MN_2$ ” ( $\approx$  “ $MN_2$  of  $MN_1$ ”), as dependencies  $v = MN_2$ ,  $r =$  の,  $n = MN_1$ , since these expressions also characterize the dependent MNs well.

Given  $L$  training examples of verb-MN dependencies  $\{(vt_i, n_i, f_i)\}_{i=1}^L$ , where  $f_i$  is the number of dependency  $(vt_i, n_i)$  in a corpus, the EM-based clustering tries to find  $p(vt|c)$ ,  $p(n|c)$ , and  $p(c)$  that maximize the (log)-likelihood of the training examples:

$$LL(p) = \sum_i f_i \log \left( \sum_c p(vt_i|c) p(n_i|c) p(c) \right). \quad (2)$$

<sup>3</sup>This formulation is based on the formulation presented in Rooth et al. (1999) for English.

We iteratively update the probabilities using the EM algorithm. For the update procedures used, see Torisawa (2001).

The corpus we used for collecting dependencies was a large set (76 million) of Web documents, that were processed by a dependency parser, KNP (Kurohashi and Kawahara, 2005).<sup>4</sup> From this corpus, we extracted about 380 million dependencies of the form  $\{(vt_i, n_i, f_i)\}_i^L$ .

### 2.3 Parallelization for Large-scale Data

The disadvantage of the clustering algorithm described above is the computational costs. The space requirements are  $O(|\mathcal{VT}||\mathcal{C}| + |\mathcal{N}||\mathcal{C}| + |\mathcal{C}|)$  for storing the parameters,  $p(vt|c)$ ,  $p(n|c)$ , and  $p(c)$ <sup>5</sup>, plus  $O(L)$  for storing the training examples. The time complexity is mainly  $O(L \times |\mathcal{C}| \times I)$ , where  $I$  is the number of update iterations. The space requirements are the main limiting factor. Assume that a floating-point number consumes 8 bytes. With the setting,  $|\mathcal{N}| = 500,000$ ,  $|\mathcal{VT}| = 500,000$ , and  $|\mathcal{C}| = 3,000$ , the algorithm requires more than 44 GB for the parameters and 4 GB of memory for the training examples. A machine with more than 48 GB of memory is not widely available even today.

Therefore, we parallelized the clustering algorithm, to make it suitable for running on a cluster of PCs with a moderate amount of memory (e.g., 8 GB). First, we decided to store the training examples on a file since otherwise each node would need to store all the examples when we use the data splitting described below, and having every node consume 4 GB of memory is memory-consuming. Since the access to the training data is sequential, this does not slow down the execution when we use a buffering technique appropriately.<sup>6</sup>

We then split the matrix for the model parameters,  $p(n|c)$  and  $p(vt|c)$ , along with the class coordinate. That is, each cluster node is responsible for storing only a part of classes  $\mathcal{C}_l$ , i.e.,  $1/|P|$  of the parameter matrix, where  $P$  is the number of cluster nodes. This data splitting enables linear scalability of memory sizes. However, doing so complicates the update procedure and, in terms of execution speed, may

<sup>4</sup>**Acknowledgements:** This corpus was provided by Dr. Daisuke Kawahara of NICT.

<sup>5</sup>To be precise, we need two copies of these.

<sup>6</sup>Each node has a copy of the training data on a local disk.

localZ = 0, Z = 0
for  $c_l \in \mathcal{C}_l$  do
   $\begin{cases} d = p(vt_i|c)p(n_i|c)p(c) \\ p(c_l|vt_i, n_i) = d \\ localZ += d \end{cases}$ 
MPI_Allreduce(localZ, Z, 1, MPI.DOUBLE,
MPI.SUM, MPI.COMM_WORLD)
for  $c_l \in \mathcal{C}_l$  do  $p(c_l|vt_i, n_i) /= Z$ 

```

Figure 1: Parallelized inner-most routine of EM clustering algorithm. Each node executes this code in parallel.

offset the advantage of parallelization because each node needs to receive information about the classes that are not on the node in the inner-most routine of the update procedure.

The inner-most routine should compute:

$$p(c|vt_i, n_i) = p(vt_i|c)p(n_i|c)p(c)/Z, \quad (3)$$

for each class  $c$ , where  $Z = \sum_c p(vt_i|c)p(n_i|c)p(c)$  is a normalizing constant. However,  $Z$  cannot be calculated without knowing the results of other cluster nodes. Thus, if we use MPI for parallelization, the parallelized version of this routine should resemble the algorithm shown in Figure 1. This routine first computes  $p(vt_i|c_l)p(n_i|c_l)p(c_l)$  for each  $c_l \in \mathcal{C}_l$ , and stores the sum of these values as  $localZ$ . The routine uses an MPI function, MPI\_Allreduce, to sum up  $localZ$  of the all cluster nodes and to set  $Z$  with the resulting sum. We can compute  $p(c_l|vt_i, n_i)$  by using this  $Z$  to normalize the value. Although the above is the essence of our parallelization, invoking MPI\_Allreduce in the inner-most loop is very expensive because the communication setup is not so cheap. Therefore, our implementation calculates  $p(c_l|vt_i, n_i)$  in batches of  $B$  examples and calls MPI\_Allreduce at every  $B$  examples.<sup>7</sup> We used a value of  $B = 4,096$  in this study.

By using this parallelization, we successfully performed the clustering with  $|\mathcal{N}| = 500,000$ ,  $|\mathcal{VT}| = 500,000$ ,  $|\mathcal{C}| = 3,000$ , and  $I = 150$ , on 8 cluster nodes with a 2.6 GHz Opteron processor and 8 GB of memory. This clustering took about a week. To our knowledge, no one else has performed EM-based clustering of this type on this scale. The resulting MN clusters are shown in Figure 2. In terms of speed, our experiments are still at a preliminary

<sup>7</sup>MPI\_Allreduce can also take array arguments and apply the operation to each element of the array in one call.

Class 791	Class 2760

スイフト (SWIFT)	ハマ/スタ (Yokohama Stadium [abb.])

Figure 2: Clean MN clusters with named entity entries (Left: car brand names. Right: stadium names). Names are sorted on the basis of  $p(c|n)$ . Stadium names are examples of multi-word nouns (word boundaries are indicated by “/”) and also include abbreviated expressions (marked by [abb.] ).

stage. We have observed 5 times faster execution, when using 8 cluster nodes with a relatively small setting,  $|\mathcal{N}| = |\mathcal{VT}| = 50,000$ ,  $|\mathcal{C}| = 2,000$ .

## 2.4 Induction from Wikipedia

Defining sentences in a dictionary or an encyclopedia have long been used as a source of hyponymy relations (Tsurumaru et al., 1991; Herbelot and Copestake, 2006).

Kazama and Torisawa (2007) extracted hyponymy relations from the first sentences (i.e., defining sentences) of Wikipedia articles and then used them as a gazetteer for NER. We used this method to construct the Wikipedia gazetteer.

The method described by Kazama and Torisawa (2007) is to first extract the first (base) noun phrase after the first “is”, “was”, “are”, or “were” in the first sentence of a Wikipedia article. The last word in the noun phrase is then extracted and becomes the hypernym of the entity described by the article. For example, from the following defining sentence, it extracts “guitarist” as the hypernym for “Jimi Hendrix”.

Jimi Hendrix (November 27, 1942) was an American guitarist, singer and songwriter.

The second noun phrase is used when the first noun phrase ends with “one”, “kind”, “sort”, or “type”, or it ended with “name” followed by “of”. This rule is for treating expressions like “... is one of the landlocked countries.” By applying this method of extraction to all the articles in Wikipedia, we

	# instances
page titles processed	550,832
articles found (found by redirection)	547,779 (189,222)
first sentences found	545,577
hypernyms extracted	482,599

Table 1: Wikipedia gazetteer extraction

construct a gazetteer that maps an MN (a title of a Wikipedia article) to its hypernym.<sup>8</sup> When the hypernym extraction failed, a special hypernym symbol, e.g., “UNK”, was used.

We modified this method for Japanese. After pre-processing the first sentence of an article using a morphological analyzer, MeCab<sup>9</sup>, we extracted the *last* noun after the appearance of Japanese postposition “は (wa)” ( $\approx$  “is”). As in the English case, we also refrained from extracting expressions corresponding to “one of” and so on.

From the Japanese Wikipedia entries of April 10, 2007, we extracted 550,832 gazetteer entries (482,599 entries have hypernyms other than UNK). Various statistics for this extraction are shown in Table 1. The number of distinct hypernyms in the gazetteer was 12,786. Although this Wikipedia gazetteer is much smaller than the English version used by Kazama and Torisawa (2007) that has over 2,000,000 entries, it is the largest gazetteer that can be freely used for Japanese NER. Our experimental results show that this Wikipedia gazetteer can be used to improve the accuracy of Japanese NER.

## 3 Using Gazetteers as Features of NER

Since Japanese has no spaces between words, there are several choices for the token unit used in NER. Asahara and Motsumoto (2003) proposed using characters instead of morphemes as the unit to alleviate the effect of segmentation errors in morphological analysis and we also used their character-based method. The NER task is then treated as a tagging task, which assigns IOB tags to each character in a sentence.<sup>10</sup> We use Conditional Random Fields (CRFs) (Lafferty et al., 2001) to perform this tagging.

The information of a gazetteer is incorporated

<sup>8</sup>They handled “redirections” as well by following redirection links and extracting a hypernym from the article reached.

<sup>9</sup><http://mecab.sourceforge.net>

<sup>10</sup>Precisely, we use IOB2 tags.

<i>ch</i>	に	ソ	ニ	一	が	開	発	...
match	O	B	I	I	O	O	O	...
(w/ class)	O	B-会社	I-会社	I-会社	O	O	O	...

Figure 3: Gazetteer features for Japanese NER. Here, ‘ソニ一’ means ‘‘SONY’’, ‘‘会社’’ means ‘‘company’’, and ‘‘開発’’ means ‘‘to develop’’.

as features in a CRF-based NE tagger. We follow the method used by Kazama and Torisawa (2007), which encodes the matching with a gazetteer entity using IOB tags, with the modification for Japanese. They describe using two types of gazetteer features. The first is a matching-only feature, which uses bare IOB tags to encode only matching information. The second uses IOB tags that are augmented with classes (e.g., B-country and I-country).<sup>11</sup> When there are several possibilities for making a match, the left-most longest match is selected. The small differences from their work are: (1) We used characters as the unit as we described above, (2) While Kazama and Torisawa (2007) checked only the word sequences that start with a capitalized word and thus exploited the characteristics of English language, we checked the matching at every character, (3) We used a TRIE to make the look-up efficient.

The output of gazetteer features for Japanese NER are thus as those shown in Figure 3. These annotated IOB tags can be used in the same way as other features in a CRF tagger.

## 4 Experiments

### 4.1 Data

We used the CRL NE dataset provided in the IREX competition (Sekine and Isahara, 2000). In the dataset, 1,174 newspaper articles are annotated with 8 NE categories: ARTIFACT, DATE, LOCATION, MONEY, ORGANIZATION, PERCENT, PERSON, and TIME.<sup>12</sup> We converted the data into the CoNLL 2003 format, i.e., each row corresponds to a character in this case. We obtained 11,892 sentences<sup>13</sup> with 18,677 named entities. We split this data into the training set (9,000 sentences), the de-

<sup>11</sup>Here, we call the value returned by a gazetteer a ‘‘class’’. Features are not output when the returned class is UNK in the case of the Wikipedia gazetteer. We did not observe any significant change if we also used UNK.

<sup>12</sup>We ignored OPTIONAL category.

<sup>13</sup>This number includes the number of -DOCSTART- tokens in CoNLL 2003 format.

Name	Description
ch	character itself
ct	character type: uppercase alphabet, lowercase alphabet, katakana, hiragana, Chinese characters, numbers, numbers in Chinese characters, and spaces
m_mo	bare IOB tag indicating boundaries of morphemes
m_mm	IOB tag augmented by morpheme string, indicating boundaries and morphemes
m_mp	IOB tag augmented by morpheme type, indicating boundaries and morpheme types (POSs)
bm	bare IOB tag indicating ‘‘bunsetsu’’ boundaries (Bunsetsu is a basic unit in Japanese and usually contains content words followed by function words such as postpositions)
bi	bunsetsu-inner feature. See (Nakano and Hirai, 2004).
bp	adjacent-bunsetsu feature. See (Nakano and Hirai, 2004).
bh	head-of-bunsetsu features. See (Nakano and Hirai, 2004).

Table 2: Atomic features used in baseline model.

velopment set (1,446 sentences), and the testing set (1,446 sentences).

### 4.2 Baseline Model

We extracted the atomic features listed in Table 2 at each character for our baseline model. Though there may be slight differences, these features are based on the standard ones proposed and used in previous studies on Japanese NER such as those by Asahara and Motsumoto (2003), Nakano and Hirai (2004), and Yamada (2007). We used MeCab as a morphological analyzer and CaboCha<sup>14</sup> (Kudo and Matsumoto, 2002) as the dependency parser to find the boundaries of the bunsetsu. We generated the node and the edge features of a CRF model as described in Table 3 using these atomic features.

### 4.3 Training

To train CRF models, we used Taku Kudo’s CRF++ (ver. 0.44)<sup>15</sup> with some modifications.<sup>16</sup> We

<sup>14</sup><http://chasen.org/~taku/software/CaboCha>

<sup>15</sup><http://chasen.org/~taku/software/CRF++>

<sup>16</sup>We implemented scaling, which is similar to that for HMMs (Rabiner, 1989), in the forward-backward phase and replaced the optimization module in the original package with the

<b>Node features:</b>
$\{"" , x_{-2}, x_{-1}, x_0, x_{+1}, x_{+2}\} \times y_0$ where $x = \text{ch, ct, m\_mm, m\_mo, m\_mp, bi, bp, and bh}$
<b>Edge features:</b>
$\{"" , x_{-1}, x_0, x_{+1}\} \times y_{-1} \times y_0$ where $x = \text{ch, ct, and m\_mp}$
<b>Bigram node features:</b>
$\{x_{-2}x_{-1}, x_{-1}x_0, x_0x_{+1}\} \times y_0$ $x = \text{ch, ct, m\_mo, m\_mp, bm, bi, bp, and bh}$

Table 3: Baseline features. Value of node feature is determined from current tag,  $y_0$ , and surface feature (combination of atomic features in Table 2). Value of edge feature is determined by previous tag,  $y_{-1}$ , current tag,  $y_0$ , and surface feature. Subscripts indicate relative position from current character.

used Gaussian regularization to prevent overfitting. The parameter of the Gaussian,  $\sigma^2$ , was tuned using the development set. We tested 10 points:  $\{0.64, 1.28, 2.56, 5.12, \dots, 163.84, 327.68\}$ . We stopped training when the relative change in the log-likelihood became less than a pre-defined threshold, 0.0001. Throughout the experiments, we omitted the features whose surface part described in Table 3 occurred less than twice in the training corpus.

#### 4.4 Effect of Gazetteer Features

We investigated the effect of the cluster gazetteer described in Section 2.1 and the Wikipedia gazetteer described in Section 2.4, by adding each gazetteer to the baseline model. We added the matching-only and the class-augmented features, and we generated the node and the edge features in Table 3.<sup>17</sup> For the cluster gazetteer, we made several gazetteers that had different vocabulary sizes and numbers of classes. The number of clustering iterations was 150 and the initial parameters were set randomly with a Dirichlet distribution ( $\alpha_i = 1.0$ ).

The statistics of each gazetteer are summarized in Table 4. The number of entries in a gazetteer is given by “# entries”, and “# matches” is the number of matches that were output for the training set. We define “# e-matches” as the number of matches that also match a boundary of a named entity in the training set, and “# optimal” as the optimal number of “# e-matches” that can be achieved when we know the

oracle of entity boundaries. Note that this cannot be realized because our matching uses the left-most longest heuristics. We define “pre.” as the precision of the output matches (i.e., # e-matches/# matches), and “rec.” as the recall (i.e., # e-matches/# NEs). Here, # NEs = 14,056. Finally, “opt.” is the optimal recall (i.e., # optimal/# NEs). “# classes” is the number of distinct classes in a gazetteer, and “# used” is the number of classes that were output for the training set. Gazetteers are as follows: “wikip(m)” is the Wikipedia gazetteer (matching only), and “wikip(c)” is the Wikipedia gazetteer (with class-augmentation). A cluster gazetteer, which is constructed by the clustering with  $|\mathcal{N}| = |\mathcal{VT}| = X \times 1,000$  and  $|\mathcal{C}| = Y \times 1,000$ , is indicated by “cXk-Yk”. Note that “# entries” is slightly smaller than the vocabulary size since we removed some duplications during the conversion to a TRIE.

These gazetteers cover 40 - 50% of the named entities, and the cluster gazetteers have relatively wider coverage than the Wikipedia gazetteer has. The precisions are very low because there are many erroneous matches, e.g., with a entries for a hiragana character.<sup>18</sup> Although this seems to be a serious problem, removing such one-character entries does not affect the accuracy, and in fact, makes it worsen slightly. We think this shows one of the strengths of machine learning methods such as CRFs. We can also see that our current matching method is not an optimal one. For example, 16% of the matches were lost as a result of using our left-most longest heuristics for the case of the c500k-2k gazetteer.

A comparison of the effect of these gazetteers is shown in Table 5. The performance is measured by the F-measure. First, the Wikipedia gazetteer improved the accuracy as expected, i.e., it reproduced the result of Kazama and Torisawa (2007) for Japanese NER. The improvement for the testing set was 1.08 points. Second, all the tested cluster gazetteers improved the accuracy. The largest improvement was 1.55 points with the c300k-3k gazetteer. This was larger than that of the Wikipedia gazetteer. The results for c300k-Yk gazetteers show a peak of the improvement at some number of clusters. In this case,  $|\mathcal{C}| = 3,000$  achieved the best improvement. The results of cXk-2k gazetteers in-

LMVM optimizer of TAO (version 1.9) (Benson et al., 2007)

<sup>17</sup>Bigram node features were not used for gazetteer features.

<sup>18</sup>Wikipedia contains articles explaining each hiragana character, e.g., “あ is a hiragana character”.

Table 6: Effect of combination. Figures with \* mean that accuracy was improved by combining gazetteers.

dicating that the larger a gazetteer is, the larger the improvement. However, the accuracies of the c300k-3k and c500k-3k gazetteers seem to contradict this tendency. It might be caused by the accidental low quality of the clustering that results from random initialization. We need to investigate this further.

#### 4.5 Effect of Combining the Cluster and the Wikipedia Gazetteers

We have observed that using the cluster gazetteer and the Wikipedia one improves the accuracy of Japanese NER. The next question is whether these gazetteers improve the accuracy further when they are used together. The accuracies of models that use the Wikipedia gazetteer and one of the cluster gazetteers at the same time are shown in Table 6. The accuracy was improved in most cases. How-

ever, there were some cases where the accuracy for the development set was degraded. Therefore, we should state at this point that while the benefit of combining these gazetteers is not consistent in a strict sense, it seems to exist. The best performance,  $F = 89.26$  (dev.) /  $89.19$  (test.), was achieved when we combined the Wikipedia gazetteer and the cluster gazetteer, c500k-2k. This means that there was a 1.77-point improvement from the baseline for the testing set.

## 5 Comparison with Previous Studies

Since many previous studies on Japanese NER used 5-fold cross validation for the IREX dataset, we also performed it for some of our models that had the best  $\sigma^2$  found in the previous experiments. The results are listed in Table 7 with references to the results of recent studies. These results not only reconfirmed the effects of the gazetteer features shown in the previous experiments, but they also showed that our best model is comparable to the state-of-the-art models. The system recently proposed by Sasano and Kurohashi (2008) is currently the best system for the IREX dataset. It uses many structural features that are not used in our model. Incorporating

such features might improve our model further.

## 6 Related Work and Discussion

There are several studies that used automatically extracted gazetteers for NER (Shinzato et al., 2006; Talukdar et al., 2006; Nadeau et al., 2006; Kazama and Torisawa, 2007). Most of the methods (Shinzato et al., 2006; Talukdar et al., 2006; Nadeau et al., 2006) are oriented at the NE category. They extracted a gazetteer for each NE category and utilized it in a NE tagger. On the other hand, Kazama and Torisawa (2007) extracted hyponymy relations, which are independent of the NE categories, from Wikipedia and utilized it as a gazetteer. The effectiveness of this method was demonstrated for Japanese NER as well by this study.

Inducing features for taggers by clustering has been tried by several researchers (Kazama et al., 2001; Miller et al., 2004). They constructed word clusters by using HMMs or Brown’s clustering algorithm (Brown et al., 1992), which utilize only information from neighboring words. This study, on the other hand, utilized MN clustering based on verb-MN dependencies (Rooth et al., 1999; Torisawa, 2001). We showed that gazetteers created by using such richer semantic/syntactic structures improves the accuracy for NER.

The size of the gazetteers is also a novel point of this study. The previous studies, with the exception of Kazama and Torisawa (2007), used smaller gazetteers than ours. Shinzato et al. (2006) constructed gazetteers with about 100,000 entries in total for the “restaurant” domain; Talukdar et al. (2006) used gazetteers with about 120,000 entries in total, and Nadeau et al. (2006) used gazetteers with about 85,000 entries in total. By parallelizing the clustering algorithm, we successfully constructed a cluster gazetteer with up to 500,000 entries from a large amount of dependency relations in Web documents. To our knowledge, no one else has performed this type of clustering on such a large scale. Wikipedia also produced a large gazetteer of more than 550,000 entries. However, comparing these gazetteers and ours precisely is difficult at this point because the detailed information such as the precision and the recall of these gazetteers were not reported.<sup>19</sup> Recently, Inui et al. (2007) investi-

<sup>19</sup>Shinzato et al. (2006) reported some useful statistics about

gated the relation between the size and the quality of a gazetteer and its effect. We think this is one of the important directions of future research.

Parallelization has recently regained attention in the machine learning community because of the need for learning from very large sets of data. Chu et al. (2006) presented the MapReduce framework for a wide range of machine learning algorithms, including the EM algorithm. Newman et al. (2007) presented parallelized Latent Dirichlet Allocation (LDA). However, these studies focus on the distribution of the training examples and relevant computation, and ignore the need that we found for the distribution of model parameters. The exception, which we noticed recently, is a study by Wolfe et al. (2007), which describes how each node stores only those parameters relevant to the training data on each node. However, some parameters need to be duplicated and thus their method is less efficient than ours in terms of memory usage.

We used the left-most longest heuristics to find the matching gazetteer entries. However, as shown in Table 4 this is not an optimal method. We need more sophisticated matching methods that can handle multiple matching possibilities. Using models such as Semi-Markov CRFs (Sarawagi and Cohen, 2004), which handle the features on overlapping regions, is one possible direction. However, even if we utilize the current gazetteers optimally, the coverage is upper bounded at 70%. To cover most of the named entities in the data, we need much larger gazetteers. A straightforward approach is to increase the number of Web documents used for the MN clustering and to use larger vocabularies.

## 7 Conclusion

We demonstrated that a gazetteer obtained by clustering verb-MN dependencies is a useful feature for a Japanese NER. In addition, we demonstrated that using the cluster gazetteer and the gazetteer extracted from Wikipedia (also shown to be useful) can together further improves the accuracy in several cases. Future work will be to refine the matching method and to construct even larger gazetteers.

their gazetteers.

## Abstract

*Roget's* Thesaurus has gone through many revisions since it was first published 150 years ago. But how do these revisions affect *Roget's* usefulness for NLP? We examine the differences in content between the 1911 and 1987 versions of *Roget's*, and we test both versions with each other and *WordNet* on problems such as synonym identification and word relatedness. We also present a novel method for measuring sentence relatedness that can be implemented in either version of *Roget's* or in *WordNet*. Although the 1987 version of the Thesaurus is better, we show that the 1911 version performs surprisingly well and that often the differences between the versions of *Roget's* and *WordNet* are not statistically significant. We hope that this work will encourage others to use the 1911 *Roget's* Thesaurus in NLP tasks.

## 1 Introduction

*Roget's* Thesaurus, first introduced over 150 years ago, has gone through many revisions to reach its current state. We compare two versions, the 1987 and 1911 editions of the Thesaurus with each other and with *WordNet* 3.0. *Roget's* Thesaurus has a unique structure, quite different from *WordNet*, of which the NLP community has yet to take full advantage. In this paper we demonstrate that although the 1911 version of the Thesaurus is very old, it can give results comparable to systems that use *WordNet* or newer versions of *Roget's* Thesaurus.

The main motivation for working with the 1911 Thesaurus instead of newer versions is that it is in

the public domain, along with related NLP-oriented software packages. For applications that call for an NLP-friendly thesaurus, *WordNet* has become the de-facto standard. Although *WordNet* is a fine resource, we believe that ignoring other thesauri is a serious oversight. We show on three applications how useful the 1911 Thesaurus is. We ran the well-established tasks of determining semantic relatedness of pairs of terms and identifying synonyms (Jarmasz and Szpakowicz, 2004). We also proposed a new method of representing the meaning of sentences or other short texts using either *WordNet* or *Roget's* Thesaurus, and tested it on the data set provided by Li et al. (2006). We hope that this work will encourage others to use *Roget's* Thesaurus in their own NLP tasks.

Previous research on the 1987 version of *Roget's* Thesaurus includes work of Jarmasz and Szpakowicz (2004). They propose a method of determining semantic relatedness between pairs of terms. Terms that appear closer together in the Thesaurus get higher weights than those farther apart. The experiments aimed at identifying synonyms using a modified version of the proposed semantic similarity function. Similar experiments were carried out using *WordNet* in combination with a variety of semantic relatedness functions. *Roget's* Thesaurus was found generally to outperform *WordNet* on these problems. We have run similar experiments using the 1911Thesaurus.

Lexical chains have also been developed using the 1987 *Roget's* Thesaurus (Jarmasz and Szpakowicz, 2003). The procedure maps words in a text to the Head (a *Roget's* concept) from which they are most likely to come. Although we did not experiment

with lexical chains here, they were an inspiration for our sentence relatedness function.

*Roget's* Thesaurus does not explicitly label the relations between its terms, as *WordNet* does. Instead, it groups terms together with implied relations. Kennedy and Szpakowicz (2007) show how disambiguating one of these relations, hypernymy, can help improve the semantic similarity functions in (Jarmasz and Szpakowicz, 2004). These hypernym relations were also put towards solving analogy questions.

This is not the first time the 1911 version of *Roget's* Thesaurus has been used in NLP research. Cassidy (2000) used it to build the semantic network FACTOTUM. This required significant (manual) restructuring, so FACTOTUM cannot really be considered a true version of *Roget's* Thesaurus.

The 1987 data come from *Penguin's Roget's Thesaurus* (Kirkpatrick, 1987). The 1911 version is available from Project Gutenberg<sup>1</sup>. We use *WordNet* 3.0, the latest version (Fellbaum, 1998). In the experiments we present here, we worked with an interface to *Roget's* Thesaurus implemented in Java 5.0<sup>2</sup>. It is built around a large index which stores the location in the thesaurus of each word or phrase; the system individually indexes all words within each phrase, as well as the phrase itself. This was shown to improve results in a few applications, which we will discuss later in the paper.

## 2 Content comparison of the 1911 and 1987 Thesauri

Although the 1987 and 1911 Thesauri are very similar in structure, there are a few differences, among them, the number of levels and the number of parts-of-speech represented. For example, the 1911 version contains some pronouns as well as more sections dedicated to phrases.

There are nine levels in *Roget's* Thesaurus hierarchy, from Class down to Word. We show them in Table 1 along with the counts of instances of each level. An example of a Class in the 1911 Thesaurus is “Words Expressing Abstract Relations”, a Section in that Class is “Quantity” with a Subsection “Comparative Quantity”. Heads can be thought of as the heart of the Thesaurus because it is at this level that

<sup>1</sup><http://www.gutenberg.org/ebooks/22>

<sup>2</sup><http://rogets.site.uottawa.ca/>

Hierarchy	1911	1987
Class	8	8
Section	39	39
Subsection	97	95
Head Group	625	596
Head	1044	990
Part-of-speech	3934	3220
Paragraph	10244	6443
Semicolon Group	43196	59915
Total Words	98924	225124
Unique Words	59768	100470

Table 1: Frequencies of each level of the hierarchy in the 1911 and 1987 Thesauri.

the lexical material, organized into approximately a thousand concepts, resides. Head Groups often pair up opposites, for example Head #1 “Existence” and Head #2 “Nonexistence” are found in the same Head Group in both versions of the Thesaurus. Terms in the Thesaurus may be labelled with cross-references to other words in different Heads. We did not use these references in our experiments.

The part-of-speech level is a little confusing, since clearly no such grouping contains an exhaustive list of all nouns, all verbs etc. We will write “POS” to indicate a structure in *Roget's* and “part-of-speech” to indicate the word category in general. The four main parts-of-speech represented in a POS are nouns, verbs, adjectives and adverbs. Interjections are also included in both the 1911 and 1987 thesauri; they are usually phrases followed by an exclamation mark, such as “for God’s sake!” and “pshaw!”. The Paragraph and Semicolon Group are not given names, but can often be represented by the first word.

The 1911 version also contains phrases (mostly quotations), prefixes and pronouns. There are only three prefixes – “tri-”, “tris-”, “laevo-” – and six pronouns – “he”, “him”, “his”, “she”, “her”, “hers”.

Table 2 shows the frequency of paragraphs, semicolon groups and both total and unique words in a given type of POS. Many terms occur both in the 1911 and 1987 Thesauri, but many more are unique to either. Surprisingly, quite a few 1911 terms do not appear in the 1987 data, as shown in Table 3; many of them may have been considered obsolete and thus dropped from the 1987 version. For example “ingrafted” appears in the same semicolon group as

POS	Paragraph		Semicolon Grp	
	1911	1987	1911	1987
Noun	4495	2884	19215	31174

Int.	68	416	315
Phr.	0	2038	0

Table 3: Frequencies of terms in either the 1911 or 1987 Thesaurus, and in both; we omitted prefixes and pronouns.

“implanted” in the older but not the newer version. Some mismatches may be due to small changes in spelling, for example, “Nirvana” is capitalized in the 1911 version, but not in the 1987 version.

The lexical data in Project Gutenberg’s 1911 *Roget’s* appear to have been somewhat added to. For example, the citation “Go ahead, make my day!” from the 1971 movie *Dirty Harry* appears twice (in Heads #715-Defiance and #761-Prohibition) within the *Phrase* POS. It is not clear to what extent new terms have been added to the original 1911 *Roget’s* Thesaurus, or what the criteria for adding such new elements could have been.

In the end, there are many differences between the 1987 and 1911 *Roget’s* Thesauri, primarily in con-

tent rather than in structure. The 1987 Thesaurus is largely an expansion of the 1911 version, with three POSs (phrases, pronouns and prefixes) removed.

### 3 Comparison on applications

In this section we consider how the two versions of *Roget’s* Thesaurus and *WordNet* perform in three applications – measuring word relatedness, synonym identification, and sentence relatedness.

#### 3.1 Word relatedness

Relatedness can be measured by the closeness of the words or phrases – henceforth referred to as *terms* – in the structure of the thesaurus. Two terms in the same semicolon group score 16, in the same paragraph – 14, and so on (Jarmasz and Szpakowicz, 2004). The score is 0 if the terms appear in different classes, or if either is missing. Pairs of terms get higher scores for being closer together. When there are multiple senses of two terms  $A$  and  $B$ , we want to select senses  $a \in A$  and  $b \in B$  that maximize the relatedness score. We define a distance function:

$$semDist(A, B) = \max_{a \in A, b \in B} 2 * (depth(lca(a, b)))$$

*lca* is the *lowest common ancestor* and *depth* is the depth in the *Roget’s* hierarchy; a Class has depth 0, Section 1, ..., Semicolon Group 8. If we think of the function as counting edges between concepts in the *Roget’s* hierarchy, then it could also be written as:

$$semDist(A, B) = \max_{a \in A, b \in B} 16 - edgesBetween(a, b)$$

We do not count links between words in the same semicolon group, so in effect these methods find distances between semicolon groups, that is to say, these two functions will give the same results.

The 1911 and 1987 Thesauri were compared with *WordNet* 3.0 on the three data sets containing pairs of words with manually assigned similarity scores: 30 pairs (Miller and Charles, 1991), 65 pairs (Rubenstein and Goodenough, 1965) and 353 pairs<sup>3</sup> (Finkelstein et al., 2001). We assume that all terms are nouns, so that we can have a fair comparison of the two Thesauri with *WordNet*. We measure the correlation with Pearson’s Correlation Coefficient.

<sup>3</sup><http://www.cs.technion.ac.il/~gabr/resources/data/wordsim353/wordsim353.html>

Year	Miller & Charles	Rubenstein & Goodenough	Finkelstein et. al
Index words and phrase			
1911	0.7846	0.7313	0.3449
1987	0.7984	0.7865	0.4214
Index phrase only			
1911	0.7090	0.7168	0.3373
1987	0.7471	0.7777	0.3924

Table 4: Pearson’s coefficient values when not breaking / breaking phrases up.

A preliminary experiment set out to determine whether there is any advantage to indexing the words in a phrase separately, for example, whether the phrase “change of direction” should be indexed only as a whole, or as all of “change”, “of”, “direction” and “change of direction”. The outcome of this experiment appears in Table 4. There is a clear improvement: breaking phrases up gives superior results on all three data sets, for both versions of *Roget’s*. In the remaining experiments, we have each word in a phrase indexed.

We compare the results for the 1911 and 1987 *Roget’s* Thesauri with a variety of *WordNet*-based semantic relatedness measures – see Table 5. We consider 10 measures, noted in the table as J&C (Jiang and Conrath, 1997), Resnik (Resnik, 1995), Lin (Lin, 1998), W&P (Wu and Palmer, 1994), L&C (Leacock and Chodorow, 1998), H&SO (Hirst and St-Onge, 1998), Path (counts edges between synsets), Lesk (Banerjee and Pedersen, 2002), and finally Vector and Vector Pair (Patwardhan, 2003). The latter two work with large vectors of co-occurring terms from a corpus, so *WordNet* is only part of the system. We used Pedersen’s Semantic Distance software package (Pedersen et al., 2004).

The results suggest that neither version of *Roget’s* is best for these data sets. In fact, the Vector method is superior on all three sets, and the Lesk algorithm performs very closely to *Roget’s* 1987. Even on the largest set (Finkelstein et al., 2001), however, the differences between *Roget’s* Thesaurus and the Vector method are not statistically significant at the  $p < 0.05$  level for either thesaurus on a two-tailed test<sup>4</sup>. The difference between the 1911 Thesaurus and Vector *would* be statistically signifi-

cant at  $p < 0.07$ .

On the (Miller and Charles, 1991) and (Rubenstein and Goodenough, 1965) data sets the best system did not show a statistically significant improvement over the 1911 or 1987 *Roget’s* Thesauri, even at  $p < 0.1$  for a two-tailed test. These data sets are too small for a meaningful comparison of systems with close correlation scores.

### 3.2 Synonym identification

In this problem we take a term  $q$  and we seek the correct synonym  $s$  from a set  $C$ . There are two steps. We used the system from (Jarmasz and Szpakowicz, 2004) for identifying synonyms with *Roget’s*. First we find a set of terms  $B \subseteq C$  with the maximum relatedness between  $q$  and each term  $x \in C$ :

$$B = \{x \mid \operatorname{argmax}_{x \in C} \operatorname{semDist}(x, q)\}$$

Next, we take the set of terms  $A \subseteq B$  where each  $a \in A$  has the maximum number of shortest paths between  $a$  and  $q$ .

$$A = \{x \mid \operatorname{argmax}_{x \in B} \operatorname{numberShortestPaths}(x, q)\}$$

If  $s \in A$  and  $|A| = 1$ , the correct synonym has been selected. Often the sets  $A$  and  $B$  will contain just one item. If  $s \in A$  and  $|A| > 1$ , there is a tie. If  $s \notin A$  then the selected synonyms are incorrect. If a multi-word phrase  $c \in C$  of length  $n$  is not found,

Table 6: Synonym selection experiments.

it is replaced by each of its words  $c_1, c_2, \dots, c_n$ , and each of these words is considered in turn. The  $c_i$  that is closest to  $q$  is chosen to represent  $c$ . When searching for a word in *Roget's* or *WordNet*, we look for all forms of the word.

The results of these experiments appear in Table 6. “Yes” indicates correct answers, “No” – incorrect answers, and “Tie” is for ties. QNF stands for “Question word Not Found”, ANF for “Answer word Not Found” and ONF for “Other word Not Found”. We used three data sets for this application: 80 questions taken from the Test of English as a Foreign Language (TOEFL) (Landauer and Dumais, 1997), 50 questions – from the English as a Second Language test (ESL) (Turney, 2001) and 300 questions – from the Reader’s Digest Word Power Game (RDWP) (Lewis, 2000 and 2001).

Lesk and the Vector-based systems perform better than all others, including *Roget's* 1911 and 1987. Even so, both versions of *Roget's* Thesaurus performed well, and were never worse than the worst *WordNet* systems. In fact, six of the ten *WordNet*-based methods are consistently worse than the 1911 Thesaurus. Since the two Vector-based systems make use of additional data beyond *WordNet*, Lesk is the only completely *WordNet*-based system to outperform *Roget's* 1987. One advantage of *Roget's* Thesaurus is that both versions generally have fewer missing terms than *WordNet*, though Lesk, Hirst & St-Onge and the two vector based methods had fewer missing terms than *Roget's*. This may be because the other *WordNet* methods will only work for nouns and verbs.

### 3.3 Sentence relatedness

Our final experiment concerns sentence relatedness. We worked with a data set from (Li et al., 2006)<sup>5</sup>. They took a subset of the term pairs from (Rubenstein and Goodenough, 1965) and chose sentences to represent these terms; the sentences are definitions from the Collins Cobuild dictionary (Sinclair, 2001). Thirty people were then asked to assign relatedness scores to these sentences, and the average of these similarities was taken for each sentence.

Other methods of determining sentence semantic relatedness expand term relatedness functions to

<sup>5</sup><http://www.docm.mmu.ac.uk/STAFF/D.McLean/SentenceResults.htm>

create a sentence relatedness function (Islam and Inkpen, 2007; Mihalcea et al., 2006). We propose to approach the task by exploiting in other ways the commonalities in the structure of *Roget's* Thesaurus and of *WordNet*. We use the OpenNLP toolkit<sup>6</sup> for segmentation and part-of-speech tagging.

We use a method of sentence representation that involves mapping the sentence into weighted concepts in either *Roget's* or *WordNet*. We mean a concept in *Roget's* to be either a Class, Section, ..., Semicolon Group, while a concept in *WordNet* is any synset. Essentially a concept is a grouping of words from either resource. Concepts are weighted by two criteria. The first is how frequently words from the sentence appear in these concepts. The second is the depth (or specificity) of the concept itself.

### 3.3.1 Weighting based on word frequency

Each word and punctuation mark  $w$  in a sentence is given a score of 1. (Naturally, only open-category words will be found in the thesaurus.) If  $w$  has  $n$  word senses  $w_1, \dots, w_n$ , each sense gets a score of  $1/n$ , so that  $1/n$  is added to each concept in the *Roget's* hierarchy (semicolon group, paragraph, ..., class) or *WordNet* hierarchy that contains  $w_i$ . We weight concepts in this way simply because, unable to determine which sense is correct, we assume that all senses are equally probable. Each concept in *Roget's* Thesaurus and *WordNet* gets the sum of the scores of the concepts below it in its hierarchy.

We will define the scores recursively for a concept  $c$  in a sentence  $s$  and sub-concepts  $c_i$ . For example, in *Roget's* if the concept  $c$  were a Class, then each  $c_i$  would be a Section. Likewise, in *WordNet* if  $c$  were a synset, then each  $c_i$  would be a hyponym synset of  $c$ . Obviously if  $c$  is a word sense  $w_i$  (a word in either a synset or a Semicolon Group), then there can be no sub-concepts  $c_i$ . When  $c = w_i$ , the score for  $c$  is the sum of all occurrences of the word  $w$  in sentence  $s$  divided by the number of senses of the word  $w$ .

$$\text{score}(c, s) = \begin{cases} \frac{\text{instancesOf}(w, s)}{\text{sensesOf}(w)} & \text{if } c = w_i \\ \sum_{c_i \in c} \text{score}(c_i, s) & \text{otherwise} \end{cases}$$

See Table 7 for an example of how this sentence representation works. The sentence “A gem is a jewel or stone that is used in jewellery.” is represented using the 1911 *Roget's*. A concept is identi-

<sup>6</sup><http://opennlp.sourceforge.net>

fied by a name and a series of up to 9 numbers that indicate where in the thesaurus it appears. The first number represents the Class, the second the Section, ..., the ninth the word. We only show concepts with weights greater than 1.0. Words not in the thesaurus keep a weight of 1.0, but this weight will not increase the weight of any concepts in *Roget's* or *WordNet*. Apart from the function words “or”, “in”, “that” and “a” and the period, only the word “jewellery” had a weight above 1.0. The categories labelled 6, 6.2 and 6.2.2 are the only ancestors of the word “use” that ended up with the weights above 1.0. The words “gem”, “is”, “jewel”, “stone” and “used” all contributed weight to the categories shown in Table 7, and to some categories with weights lower than 1.0, but no sense of the words themselves had a weight greater than 1.0.

It is worth noting that this method only relies on the hierarchies in *Roget's* and *WordNet*. We do not take advantage of other *WordNet* relations such as hyponymy, nor do we use any cross-reference links that exist in *Roget's* Thesaurus. Including such relations might improve our sentence relatedness system, but that has been left for future work.

### 3.3.2 Weighting based on specificity

To determine sentence relatedness, one could, for example, flatten the structures like those in Table 7 into vectors and measure their closeness by some vector distance function such as cosine similarity. There is a problem with this, though. A concept inherits the weights of all its sub-concepts, so the concepts that appear closer to the root of the tree will far outweigh others. Some sort of weighting function should be used to re-adjust the weights of particular concepts. Were this an Information Retrieval task, weighting schemes such as *tf.idf* for each concept could apply, but for sentence relatedness we propose an *ad hoc* weighting scheme based on assumptions about which concepts are most important to sentence representation. This weighting scheme is the second element of our sentence relatedness function.

We weight a concept in *Roget's* and in *WordNet* by how many words in a sentence give weight to it. We need to re-weight it based on how specific it is. Clearly, concepts near the leaves of the hierarchy are more specific than those close to the root of the hierarchy. We define specificity as the distance in levels between a given word and each concept found above

Identifier	Concept	Weight
6	Words Relating to the Voluntary Powers - Individual Volition	2.125169028274
6.2	Prospective Volition	1.504066255252
6.2.2	Subservience to Ends	1.128154077172
8	Words Relating to the Sentiment and Moral Powers	3.13220884041
8.2	Personal Affections	1.861744448402
8.2.2	Discriminative Affections	1.636503978149
8.2.2.2	Ornament/Jewelry/Blemish [Head Group]	1.452380952380
8.2.2.2.886	Jewelry [Head]	1.452380952380
8.2.2.2.886.1	Jewelry [Noun]	1.452380952380
8.2.2.2.886.1.1	jewel [Paragraph]	1.452380952380
8.2.2.2.886.1.1.1	jewel [Semicolon Group]	1.166666666666
8.2.2.2.886.1.1.1.3	jewellery [Word Sense]	1.0
or	-	1.0
in	-	1.0
that	-	1.0
a	-	2.0
.	-	1.0

Table 7: “A gem is a jewel or stone that is used in jewellery.” as represented using *Roget’s* 1911.

it in the hierarchy. In *Roget’s* Thesaurus there are exactly 9 levels from the term to the class. In *WordNet* there will be as many levels as a word has ancestors up the hypernymy chain. In *Roget’s*, a term has specificity 1, a Semicolon Group 2, a Paragraph 3, ..., a Class 9. In *WordNet*, the specificity of a word is 1, its synset – 2, the synset’s hypernym – 3, its hypernym – 4, and so on. Words not found in the Thesaurus or in *WordNet* get specificity 1.

We seek a function that, given  $s$ , assigns to all concepts of specificity  $s$  a weight progressively larger than to their neighbours. The weights in this function should be assigned based on specificity, so that all concepts of the same specificity receive the same score. Weights will differ depending on a combination of specificity and how frequently words that signal the concepts appear in a sentence. The weight of concepts with specificity  $s$  should be the highest, of those with specificity  $s \pm 1$  – lower, of those with specificity  $s \pm 2$  lower still, and so on. In order to achieve this effect, we weight the concepts using a normal distribution, where the mean is  $s$ :

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{\left(-\frac{(x-s)^2}{2\sigma^2}\right)}$$

Since the Head is often considered the main category in *Roget’s*, we expect a specificity of 5 to be best, but we decided to test the values 1 through 9 as a possible setting for specificity. We do not claim that this weighting scheme is optimal; other weighting schemes might do better. For the purpose of

comparing the 1911 and 1987 Thesauri and *WordNet*, however, this method appears sufficient.

With this weighting scheme, we determine the distance between two sentences using cosine similarity:

$$\text{cosSim}(A, B) = \frac{\sum a_i * b_i}{\sqrt{\sum a_i^2} * \sqrt{\sum b_i^2}}$$

For this problem we used the MIT Java *WordNet* Interface version 1.1.1<sup>7</sup>.

### 3.3.3 Sentence similarity results

We used this method of representation for *Roget’s* of 1911 and of 1987, as well as for *WordNet* 3.0 – see Figure 1. For comparison, we also implemented a baseline method that we refer to as Simple: we built vectors out of words and their count.

It can be seen in Figure 1 that each system is superior for at least one of the nine specificities. The Simple method is best at a specificity of 1, 8 and 9, *Roget’s* Thesaurus 1911 is best at 6, *Roget’s* Thesaurus 1987 is best at 4, 5 and 7, and *WordNet* is best at 2 and 3. The systems based on *Roget’s* and *WordNet* more or less followed a bell-shaped curve, with the curves of the 1911 and 1987 Thesauri following each other fairly closely and peaking close together. *WordNet* clearly peaked first and then fell the farthest.

<sup>7</sup><http://www.mit.edu/~markaf/projects/wordnet/>

The best correlation result for the 1987 *Roget's* Thesaurus is 0.8725 when the mean is 4, the POS. The maximum correlation for the 1911 Thesaurus is 0.8367, where the mean is 5, the Head. The maximum for *WordNet* is 0.8506, where the mean is 3, or the first hypernym synset. This suggests that the POS and Head are most important for representing text in *Roget's* Thesaurus, while the first hypernym is most important for representing text using *WordNet*. For the Simple method, we found a more modest correlation of 0.6969.

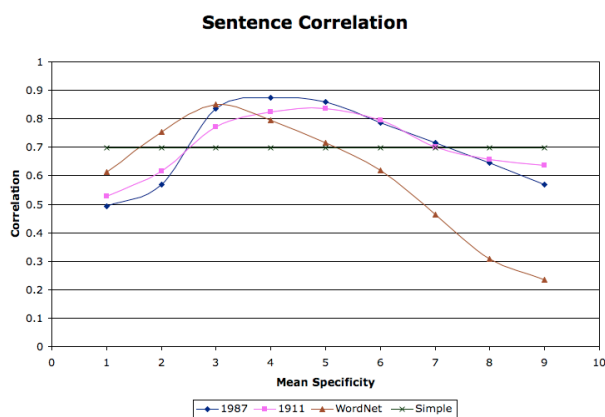

Figure 1: Correlation data for all four systems.

Several other methods have given very good scores on this data set. For the system in (Li et al., 2006), where this data set was first introduced, a correlation of 0.816 with the human annotators was achieved. The mean of all human annotators had a score of 0.825, with a standard deviation of 0.072. In (Islam and Inkpen, 2007), an even better system was proposed, with a correlation of 0.853.

Selecting the mean that gives the best correlation could be considered as training on test data. However, were we simply to have selected a value somewhere in the middle of the graph, as was our original intuition, it would have given an unfair advantage to either version of *Roget's* Thesaurus over *WordNet*. Our system shows good results for both versions of *Roget's* Thesauri and *WordNet*. The 1987 Thesaurus once again performs better than the 1911 version and than *WordNet*. Much like (Miller and Charles, 1991), the data set used here is not large enough to determine if any system's improvement is statistically significant.

## 4 Conclusion and future work

The 1987 version of *Roget's* Thesaurus performed better than the 1911 version on all our tests, but we did not find the differences to be statistically significant. It is particularly interesting that the 1911 Thesaurus performed as well as it did, given that it is almost 100 years old. On problems such as semantic word relatedness, the 1911 Thesaurus performance was fairly close to that of the 1987 Thesaurus, and was comparable to many *WordNet*-based measures. For problems of identifying synonyms both versions of *Roget's* Thesaurus performed relatively well compared to most *WordNet*-based methods.

We have presented a new method of sentence representation that attempts to leverage the structure found in *Roget's* Thesaurus and similar lexical ontologies (among them *WordNet*). We have shown that given this style of text representation both versions of *Roget's* Thesaurus work comparably to *WordNet*. All three perform fairly well compared to the baseline Simple method. Once again, the 1987 version is superior to the 1911 version, but the 1911 version still works quite well.

We hope to investigate further the representation of sentences and other short texts using *Roget's* Thesaurus. These kinds of measurements can help with problems such as identifying relevant sentences for extractive text summarization, or possibly paraphrase identification (Dolan et al., 2004). Another – longer-term – direction of future work could be merging *Roget's* Thesaurus with *WordNet*.

We also plan to study methods of automatically updating the 1911 *Roget's* Thesaurus with modern words. Some work has been done on adding new terms and relations to *WordNet* (Snow et al., 2006) and FACTOTUM (O'Hara and Wiebe, 2003). Similar methods could be used for identifying related terms and assigning them to a correct semicolon group or paragraph.

## Acknowledgments

Our research is supported by the Natural Sciences and Engineering Research Council of Canada and the University of Ottawa. We thank Dr. Diana Inkpen, Anna Kazantseva and Oana Frunza for many useful comments on the paper.

Johns Hopkins University, Baltimore, MD 21218, USA  
zhifei.work@gmail.com and yarowsky@cs.jhu.edu

## Abstract

Chinese abbreviations are widely used in modern Chinese texts. Compared with English abbreviations (which are mostly acronyms and truncations), the formation of Chinese abbreviations is much more complex. Due to the richness of Chinese abbreviations, many of them may not appear in available parallel corpora, in which case current machine translation systems simply treat them as unknown words and leave them untranslated. In this paper, we present a novel *unsupervised* method that automatically extracts the relation between a full-form phrase and its abbreviation from monolingual corpora, and induces translation entries for the abbreviation by using its full-form as a bridge. Our method does not require any additional annotated data other than the data that a regular translation system uses. We integrate our method into a state-of-the-art baseline translation system and show that it consistently improves the performance of the baseline system on various NIST MT test sets.

## 1 Introduction

The modern Chinese language is a highly abbreviated one due to the mixed use of ancient single-character words with modern multi-character words and compound words. According to Chang and Lai (2004), approximately 20% of sentences in a typical news article have abbreviated words in them. Abbreviations have become even more popular along with the development of Internet media (e.g., online chat, weblog, newsgroup, and so on). While English words are normally abbreviated by either their

Full-form	Abbreviation	Translation
香港 总督	港督	Hong Kong Governor
安全 理事会	安理会	Security Council

Figure 1: Chinese Abbreviations Examples

first letters (i.e. acronyms) or via truncation, the formation of Chinese abbreviations is much more complex. Figure 1 shows two examples for Chinese abbreviations. Clearly, an abbreviated form of a word can be obtained by selecting *one or more* characters from this word, and the selected characters can be at *any* position in the word. In an extreme case, there are even re-ordering between a full-form phrase and its abbreviation.

While the research in statistical machine translation (SMT) has made significant progress, most SMT systems (Koehn et al., 2003; Chiang, 2007; Galley et al., 2006) rely on parallel corpora to extract translation entries. The richness and complexness of Chinese abbreviations imposes challenges to the SMT systems. In particular, many Chinese abbreviations may not appear in available parallel corpora, in which case current SMT systems treat them as unknown words and leave them untranslated. This affects the translation quality significantly.

To be able to translate a Chinese abbreviation that is unseen in available parallel corpora, one may annotate more parallel data. However, this is very expensive as there are too many possible abbreviations and new abbreviations are constantly created. Another approach is to transform the abbreviation

into its full-form for which the current SMT system knows how to translate. For example, if the baseline system knows that the translation for “香港总督” is “Hong Kong Governor”, and it also knows that “港督” is an abbreviation of “香港总督”, then it can translate “港督” to “Hong Kong Governor”.

Even if an abbreviation has been seen in parallel corpora, it may still be worth to consider its full-form phrase as an *additional* alternative to the abbreviation since abbreviated words are normally semantically ambiguous, while its full-form contains more context information that helps the MT system choose a right translation for the abbreviation.

Conceptually, the approach of translating an abbreviation by using its full-form as a bridge involves four components: identifying abbreviations, learning their full-forms, inducing their translations, and integrating the abbreviation translations into the baseline SMT system. None of these components is trivial to realize. For example, for the first two components, we may need manually annotated data that tags an abbreviation with its full-form. We also need to make sure that the baseline system has at least one valid translation for the full-form phrase. On the other hand, integrating an additional component into a baseline SMT system is notoriously tricky as evident in the research on integrating word sense disambiguation (WSD) into SMT systems: different ways of integration lead to conflicting conclusions on whether WSD helps MT performance (Chan et al., 2007; Carpuat and Wu, 2007).

In this paper, we present an unsupervised approach to translate Chinese abbreviations. Our approach exploits the *data co-occurrence* phenomena and does not require any additional annotated data except the parallel and monolingual corpora that the baseline SMT system uses. Moreover, our approach integrates the abbreviation translation component into the baseline system in a natural way, and thus is able to make use of the minimum-error-rate training (Och, 2003) to automatically adjust the model parameters to reflect the change of the integrated system over the baseline system. We carry out experiments on a state-of-the-art SMT system, i.e., Moses (Koehn et al., 2007), and show that the abbreviation translations consistently improve the translation performance (in terms of BLEU (Papineni et al., 2002)) on various NIST MT test sets.

## 2 Background: Chinese Abbreviations

In general, Chinese abbreviations are formed based on three major methods: *reduction*, *elimination* and *generalization* (Lee, 2005; Yin, 1999). Table 1 presents examples for each category.

Among the three methods, *reduction* is the most popular one, which generates an abbreviation by selecting one or more characters from each of the words in the full-form phrase. The selected characters can be at any position of the word. Table 1 presents examples to illustrate how characters at different positions are selected to generate abbreviations. While the abbreviations mostly originate from noun phrases (in particular, named entities), other general phrases are also abbreviatable. For example, the second example “Save Energy” is a verb phrase. In an extreme case, reordering may happen between an abbreviation and its full-form phrase. For example, for the seventh example in Table 1, a monotone abbreviation should be “一核厂”, however, “核一厂” is a more popular ordering in Chinese texts.

In *elimination*, one or more words of the original full-form phrase are eliminated and the rest parts remain as an abbreviation. For example, in the full-form phrase “清华大学”, the word “大学” is eliminated and the remaining word “清华” alone becomes the abbreviation.

In *generalization*, an abbreviation is created by generalizing parallel sub-parts of the full-form phrase. For example, “三防 (three preventions)” in Table 1 is an abbreviation for the phrase “防火、防盗、防交通事故 (fire prevention, theft prevention, and traffic accident prevention)”. The character “防 (prevention)” is common to the three sub-parts of the full-form, so it is being generalized.

## 3 Unsupervised Translation Induction for Chinese Abbreviations

In this section, we describe an *unsupervised* method to induce translation entries for Chinese abbreviations, even when these abbreviations never appear in the Chinese side of the parallel corpora. Our basic idea is to automatically extract the relation between a full-form phrase and its abbreviation (we refer the relation as *full-abbreviation*) from monolingual corpora, and then induce translation entries for the abbreviation by using its full-form phrase as a bridge.

Category	Full-form	Abbreviation	Translation
<b>Reduction</b>	北京 大学	北大	Peking University
	节约 能源	节能	Save Energy
	香港 总督	港督	Hong Kong Governor
	外交 部长	外长	Foreign Minister
	人民 警察	民警	People’s Police
	安全 理事会	安理会	Security Council
	第二 核能 发电厂	核一厂	No.1 Nuclear Energy Power Plant
<b>Elimination</b>	清华 大学	清华	Tsinghua University
<b>Generalization</b>	防火、防盗、防交通事故	三防	Three Preventions

Table 1: Chinese Abbreviation: Categories and Examples

Our approach involves five major steps:

- Step-1: extract a list of English entities from English monolingual corpora;
- Step-2: translate the list into Chinese using a baseline translation system;
- Step-3: extract *full-abbreviation* relations from Chinese monolingual corpora by treating the Chinese translations obtained in Step-2 as full-form phrases;
- Step-4: induce translation entries for Chinese abbreviations by using their full-form phrases as bridges;
- Step-5: augment the baseline system with translation entries obtained in Step-4.

Clearly, the main purpose of Step-1 and -2 is to obtain a list of Chinese entities, which will be treated as full-form phrases in Step-3. One may use a named entity tagger to obtain such a list. However, this relies on the existence of a Chinese named entity tagger with high-precision. Moreover, obtaining a list using a dedicated tagger does not guarantee that the baseline system knows how to translate the list. On the contrary, in our approach, since the Chinese entities are translation outputs for the English entities, it is ensured that the baseline system has translations for these Chinese entities.

Regarding the data resource used, Step-1, -2, and -3 rely on the English monolingual corpora, parallel corpora, and the Chinese monolingual corpora, *respectively*. Clearly, our approach does not require any additional annotated data compared with

the baseline system. Moreover, our approach utilizes both Chinese and English monolingual data to help MT, while most SMT systems utilizes only the English monolingual data to build a language model. This is particularly interesting since we normally have enormous monolingual data, but a small amount of parallel data. For example, in the translation task between Chinese and English, both the Chinese and English Gigaword have billions of words, but the parallel data has only about 30 million words.

Step-4 and -5 are natural ways to integrate the abbreviation translation component with the baseline translation system. This is critical to make the abbreviation translation get performance gains over the baseline system as will be clear later.

In the remainder of this section, we will present a specific instantiation for each step.

### 3.1 English Entity Extraction from English Monolingual Corpora

Though one can exploit a sophisticated named-entity tagger to extract English entities, in this paper we identify English entities based on the capitalization information. Specifically, to be considered as an entity, a continuous span of English words must satisfy the following conditions:

- all words must start from a capital letter except for function words “of”, “the”, and “and”;
- each function word can appear only once;
- the number of words in the span must be smaller than a threshold (e.g., 10);
- the occurrence count of this span must be greater than a threshold (e.g., 1).

### 3.2 English Entity Translation

For the Chinese-English language pair, most MT research is on translation from Chinese to English, but here we need the reverse direction. However, since most of statistical translation models (Koehn et al., 2003; Chiang, 2007; Galley et al., 2006) are *symmetrical*, it is relatively easy to train a translation system to translate from English to Chinese, except that we need to train a Chinese language model from the Chinese monolingual data.

It is worth pointing out that the baseline system may not be able to translate all the English entities. This is because the entities are extracted from the English monolingual corpora, which has a much larger vocabulary than the English side of the parallel corpora. Therefore, we should remove all the Chinese translations that contain any untranslated English words before proceeding to the next step. Moreover, it is desirable to generate an n-best list instead of a 1-best translation for the English entity.

### 3.3 Full-abbreviation Relation Extraction from Chinese Monolingual Corpora

We treat the Chinese entities obtained in Section 3.2 as full-form phrases. To identify their abbreviations, one can employ an HMM model (Chang and Teng, 2006). Here we propose a much simpler approach, which is based on the *data co-occurrence* intuition.

#### 3.3.1 Data Co-occurrence

In a monolingual corpus, relevant words tend to appear together (i.e., co-occurrence). For example, *Bill Gates* tends to appear together with *Microsoft*. The co-occurrence may imply a relationship (e.g., *Bill Gates* is the founder of *Microsoft*). By inspection of the Chinese text, we found that the *data co-occurrence* phenomena also applies to the *full-*

Title	都灵冬奥会开幕式将激情上演
Text	新华社都灵2月9日电(记者丁莹 阎涛)第20届冬季奥运会的开幕式将于当地时间10日晚8点在都灵奥林匹克体育场正式揭开神秘的面纱。

Table 2: Data Co-occurrence Example for the *Full-abbreviation Relation* (冬季奥运会, 冬奥会) meaning “winter olympics”

*abbreviation* relation. Table 2 shows an example, where the abbreviation “冬奥会” appears in the title while its full-form “冬季奥运会” appears in the text of the same document. In general, the occurrence distance between an abbreviation and its full-form varies. For example, they may appear in the same sentence, or in the neighborhood sentences.

#### 3.3.2 Full-abbreviation Relation Extraction Algorithm

By exploiting the *data co-occurrence* phenomena, we identify possible abbreviations for full-form phrases. Figure 2 presents the pseudocode of the *full-abbreviation* relation extraction algorithm.

#### Relation-Extraction(*Corpus*, *Full-list*)

```

1 contexts ← NIL
2 for i ← 1 to length[Corpus]
3   sent1 ← Corpus[i]
4   contexts ← UPDATE(contexts, Corpus, i)
5   for full in sent1
6     if full in Full-list
7       for sent2 in contexts
8         for abbr in sent2
9           if RL(full, abbr) = TRUE
10            Count[abbr, full]++
11 return Count

```

Figure 2: *Full-abbreviation* Relation Extraction

Given a monolingual corpus and a list of full-form phrases (i.e., *Full-list*, which is obtained in Section 3.2), the algorithm returns a *Count* that contains *full-abbreviation* relations and their occurrence counts. Specifically, the algorithm linearly scans over the whole corpus as indicated by line 1. Along the linear scan, the algorithm maintains *contexts* of the current sentence (i.e., *sent1*), and the *contexts* remember the sentences from where the algorithm identifies possible abbreviations. In our implementation, the *contexts* include current sentence, the title of current document, and previous and next sentence in the document. Then, for each ngram (i.e., *full*) of the current sentence (i.e., *sent1*) and for each ngram (i.e., *abbr*) of a context sentence (i.e., *sent2*), the algorithm calls a function *RL*, which decides whether the *full-abbreviation* relation holds between *full* and *abbr*. If *RL* returns TRUE, the count table

(i.e., *Count*) is incremented by one for this relation. Note that the filtering through the full-form phrases list (i.e., *Full-list*) as shown in line 6 is the key to make the algorithm efficient enough to run through large-size monolingual corpora.

In function RL, we run a simple alignment algorithm that links the characters in *abbr* with the words in *full*. In the alignment, we assume that there is no reordering between *full* and *abbr*. To be considered as a valid *full-abbreviation* relation, *full* and *abbr* must satisfy the following conditions:

- *abbr* must be shorter than *full* by a relative threshold (e.g., 1.2);
- each character in *abbr* must be aligned to *full*;
- each word in *full* must have at least one character aligned to *abbr*;
- *abbr* must *not* be a continuous sub-part of *full*;

Clearly, due to the above conditions, our approach may not be able to handle all possible abbreviations (e.g., the abbreviations formed by the *generalization* method described in Section 2). One can modify the conditions and the alignment algorithm to handle more complex *full-abbreviation* relations.

With the count table *Count*, we can calculate the relative frequency and get the following probability,

$$P(full|abbr) = \frac{Count[abbr, full]}{\sum Count[abbr, *]} \quad (1)$$

### 3.4 Translation Induction for Chinese Abbreviations

Given a Chinese abbreviation and its full-form, we induce English translation entries for the abbreviation by using the full-form as a bridge. Specifically, we first generate n-best translations for each full-form Chinese phrase using the baseline system.<sup>1</sup> We then post-process the translation outputs such that they have the same format (i.e., containing the same set of model features) as a regular phrase entry in

<sup>1</sup>In our method, it is guaranteed that each Chinese full-form phrase will have at least one English translation, i.e., the English entity that has been used to produce this full-form phrase. However, it does not mean that this English entity is the *best* translation that the baseline system has for the Chinese full-form phrase. This is mainly due to the *asymmetry* introduced by the different LMs in different translation directions.

the baseline phrase table. Once we get the translation entries for the full-form, we can replace the full-form Chinese with its abbreviation to generate translation entries for the abbreviation. Moreover, to deal with the case that an abbreviation may have several candidate full-form phrases, we normalize the feature values using the following equation,

$$\Phi_j(e, abbr) = \Phi_j(e, full) \times P(full|abbr) \quad (2)$$

where *e* is an English translation, and  $\Phi_j$  is the *j*-th model feature indexed as in the baseline system.

### 3.5 Integration with Baseline Translation System

Since the obtained translation entries for abbreviations have the same format as the regular translation entries in the baseline phrase table, it is relatively easy to add them into the baseline phrase table. Specifically, if a translation entry (signed by its Chinese and English strings) to be added is not in the baseline phrase table, we simply add the entry into the baseline table. On the other hand, if the entry is already in the baseline phrase table, then we *merge* the entries by *enforcing* the translation probability as we obtain the same translation entry from two different knowledge sources (one is from parallel corpora and the other one is from the Chinese monolingual corpora).

Once we obtain the augmented phrase table, we should run the minimum-error-rate training (Och, 2003) with the augmented phrase table such that the model parameters are properly adjusted. As will be shown in the experimental results, this is critical to obtain performance gain over the baseline system.

## 4 Experimental Results

### 4.1 Corpora

We compile a parallel dataset which consists of various corpora distributed by the Linguistic Data Consortium (LDC) for NIST MT evaluation. The parallel dataset has about 1M sentence pairs, and about 28M words. The monolingual data we use includes the English Gigaword V2 (LDC2005T12) and the Chinese Gigaword V2 (LDC2005T14).

### 4.2 Baseline System Training

Using the toolkit Moses (Koehn et al., 2007), we built a phrase-based baseline system by following

the standard procedure: running GIZA++ (Och and Ney, 2000) in both directions, applying refinement rules to obtain a many-to-many word alignment, and then extracting and scoring phrases using heuristics (Och and Ney, 2004). The baseline system has eight feature functions (see Table 8). The feature functions are combined under a log-linear framework, and the weights are tuned by the minimum-error-rate training (Och, 2003) using BLEU (Papineni et al., 2002) as the optimization metric.

To handle different directions of translation between Chinese and English, we built two trigram language models with modified Kneser-Ney smoothing (Chen and Goodman, 1998) using the SRILM toolkit (Stolcke, 2002).

### 4.3 Statistics on Intermediate Steps

As described in Section 3, our approach involves five major steps. Table 3 reports the statistics for each intermediate step. While about 5M English entities are extracted and 2-best Chinese translations are generated for each English entity, we get only 4.7M Chinese entities. This is because many of the English entities are untranslatable by the baseline system. The number of *full-abbreviation* relations<sup>2</sup> extracted from the Chinese monolingual corpora is 51K. For each full-form phrase we generate 5-best English translations, however only 210k ( $<51K \times 5$ ) translation entries are obtained. This is because the baseline system may have less than 5 unique translations for some of the full-form phrases. Lastly, the number of translation entries added due to abbreviations is very small compared with the total number of translation entries (i.e., 50M).

Measure	Value
number of English entities	5M
number of Chinese entities	4.7M
number of <i>full-abbreviation</i> relations	51K
number of translation entries added	210K
total number of translation entries	50M

Table 3: Statistics on Intermediate Steps

<sup>2</sup>Note that many of the “abbreviations” extracted by our algorithm are not true abbreviations in the linguistic sense, instead they are just continuous-span of words. This is analogous to the concept of “phrase” in phrase-based MT.

### 4.4 Precision on *Full-abbreviation* Relations

Table 4 reports the precision on the extracted *full-abbreviation* relations. We classify the relations into several classes based on their occurrence counts. In the second column, we list the fraction of the relations in the given class among all the relations we have extracted (i.e., 51K relations). For each class, we randomly select 100 relations, manually tag them as correct or wrong, and then calculate the precision. Intuitively, a class that has a higher occurrence count should have a higher precision, and this is generally true as shown in the fourth column of Table 4. In comparison, Chang and Teng (2006) reports a precision of 50% over relations between *single-word* full-forms and *single-character* abbreviations. One can imagine a much lower precision on general relations (e.g., the relations between *multi-word* full-forms and *multi-character* abbreviations) that we consider here. Clearly, our results are very competitive<sup>3</sup>.

Count	Fraction (%)	Precision (%)	
		Baseline	Ours
(0, 1]	35.2	8.9	42.6
(1, 5]	33.8	7.8	54.4
(5, 10]	10.7	8.9	60.0
(10, 100]	16.5	7.6	55.9
(100, +∞)	3.8	12.1	59.9
<b>Average Precision (%)</b>		8.4	<b>51.3</b>

Table 4: *Full-abbreviation* Relation Extraction Precision

To further show the advantage of our relation extraction algorithm (see Section 3.3), in the third column of Table 4 we report the results on a simple baseline. To create the baseline, we make use of the *dominant* abbreviation patterns shown in Table 5, which have been reported in Chang and Lai (2004). The abbreviation pattern is represented using the format “(*bit pattern*|*length*)” where the *bit pattern* encodes the information about how an abbreviated form is obtained from its original full-form *word*, and the *length* represents the number of characters in the full-form *word*. In the *bit pattern*, a “1” indicates that the character at the corresponding position of the full-form word is kept in the abbreviation, while a “0” means the character is deleted. Now we dis-

<sup>3</sup>However, it is not a strict comparison because the dataset is different and the *recall* may also be different.

Pattern	Fraction (%)	Example
(1 1)	100	(中, 中)
(10 2)	87	(亚洲, 亚)
(101 3)	44	(理事会, 理会)
(1010 4)	56	(公民投票, 公投)

Table 5: Dominant Abbreviation Patterns reported in Chang and Lai (2004)

cuss how to create the baseline. For each full-form phrase in the randomly selected relations, we generate a baseline hypothesis (i.e., abbreviation) as follows. We first generate an abbreviated form for each *word* in the full-form *phrase* by using the dominant abbreviation pattern, and then concatenate these abbreviated words to form a baseline abbreviation for the full-form *phrase*. As shown in Table 4, the baseline performs significantly worse than our relation extraction algorithm. Compared with the baseline, our relation extraction algorithm allows arbitrary abbreviation patterns as long as they satisfy the alignment constraints. Moreover, our algorithm exploits the *data co-occurrence* phenomena to generate and rank hypothesis (i.e., abbreviation). The above two reasons explain the large performance gain.

It is interesting to examine the statistics on abbreviation patterns over the relations automatically extracted by our algorithm. Table 6 reports the statistics. We obtain the statistics on the relations that are manually tagged as correct before, and there are in total 263 unique *words* in the corresponding full-form *phrases*. Note that the results here are highly biased to our relation extraction algorithm (see Section 3.3). For the statistics on *manually* collected examples, please refer to Chang and Lai (2004).

## 4.5 Results on Translation Performance

### 4.5.1 Precision on Translations of Chinese Full-form Phrases

For the relations manually tagged as correct in Section 4.4, we manually look at the top-5 translations for the full-form phrases. If the top-5 translations contain at least one correct translation, we tag it as correct, otherwise as wrong. We get a precision of 97.5%. This precision is extremely high because the BLEU score (precision with brevity penalty) that one obtains for a Chinese sentence is normally between 30% to 50%. Two reasons explain such a high

Pattern	Fraction (%)	Example
(1 1)	100	(中, 中)
(10 2)	74.3	(亚洲, 亚)
(01 2)	7.6	(北京, 京)
(11 2)	18.1	(早餐, 早餐)
(100 3)	58.5	(伊拉克, 伊)
(010 3)	3.1	(行政院, 政)
(001 3)	4.6	(研究所, 所)
(110 3)	13.8	(奥运会, 奥运)
(101 3)	3.1	(理事会, 理会)
(111 3)	16.9	(科学家, 科学家)

Table 6: Statistics on Abbreviation Patterns

precision. Firstly, the full-form phrase is short compared with a regular Chinese sentence, and thus it is easier to translate. Secondly, the full-form phrase itself contains enough context information that helps the system choose a right translation for it. In fact, this shows the importance of considering the full-form phrase as an *additional* alternative to the abbreviation even if the baseline system already has translation entries for the abbreviation.

### 4.5.2 BLEU on NIST MT Test Sets

We use MT02 as the development set<sup>4</sup> for minimum error rate training (MERT) (Och, 2003). The MT performance is measured by lower-case 4-gram BLEU (Papineni et al., 2002). Table 7 reports the results on various NIST MT test sets. As shown in the table, our Abbreviation Augmented MT (AAMT) systems perform consistently better than the baseline system (described in Section 4.2).

Task	Baseline	AAMT	
		No MERT	With MERT
MT02	29.87	29.96	<b>30.46</b>
MT03	29.03	29.23	<b>29.71</b>
MT04	29.05	29.88	<b>30.55</b>
<b>Average Gain</b>		+0.52	<b>+1.18</b>

Table 7: MT Performance measured by BLEU Score

As clear in Table 7, it is important to re-run MERT (on MT02 only) with the augmented phrase table in order to get performance gains. Table 8 reports

<sup>4</sup>On the dev set, about 20K (among 210K) abbreviation translation entries are matched in the Chinese side.

the MERT weights with different phrase tables. One may notice the change of the weight in *word penalty* feature. This is very intuitive in order to prevent the hypothesis being too long due to the expansion of the abbreviations into their full-forms.

Feature	Baseline	AAMT
language model	0.137	0.133
phrase translation	0.066	0.023
lexical translation	0.061	0.078
reverse phrase translation	0.059	0.103
reverse lexical translation	0.112	0.090
phrase penalty	-0.150	-0.162
<b>word penalty</b>	<b>-0.327</b>	<b>-0.356</b>
distortion model	0.089	0.055

Table 8: Weights obtained by MERT

## 5 Related Work

Though automatically extracting the relations between full-form Chinese phrases and their abbreviations is an interesting and important task for many natural language processing applications (e.g., machine translation, question answering, information retrieval, and so on), not much work is available in the literature. Recently, Chang and Lai (2004), Chang and Teng (2006), and Lee (2005) have investigated this task. Specifically, Chang and Lai (2004) describes a hidden markov model (HMM) to model the relationship between a full-form phrase and its abbreviation, by treating the abbreviation as the *observation* and the full-form words as *states* in the model. Using a set of manually-created *full-abbreviation* relations as training data, they report experimental results on a *recognition* task (i.e., given an abbreviation, the task is to obtain its full-form, or the vice versa). Clearly, their method is *supervised* because it requires the *full-abbreviation* relations as training data.<sup>5</sup> Chang and Teng (2006) extends the work in Chang and Lai (2004) to automatically extract the relations between full-form phrases and their abbreviations. However, they have only considered relations between single-word phrases and single-character abbreviations. Moreover, the HMM model is computationally-expensive and unable to exploit the *data co-occurrence* phenomena that we

<sup>5</sup>However, the HMM model aligns the characters in the abbreviation to the words in the full-form in an *unsupervised* way.

have exploited efficiently in this paper. Lee (2005) gives a summary about how Chinese abbreviations are formed and presents many examples. Manual rules are created to expand an abbreviation to its full-form, however, no quantitative results are reported.

None of the above work has addressed the Chinese abbreviation issue in the context of a machine translation task, which is the primary goal in this paper. To the best of our knowledge, our work is the first to systematically model Chinese abbreviation expansion to improve machine translation.

The idea of using a bridge (i.e., full-form) to obtain translation entries for unseen words (i.e., abbreviation) is similar to the idea of using paraphrases in MT (see Callison-Burch et al. (2006) and references therein) as both are trying to introduce *generalization* into MT. At last, the goal that we aim to exploit monolingual corpora to help MT is in-spirit similar to the goal of using non-parallel corpora to help MT as aimed in a large amount of work (see Munteanu and Marcu (2006) and references therein).

## 6 Conclusions

In this paper, we present a novel method that automatically extracts relations between full-form phrases and their abbreviations from monolingual corpora, and induces translation entries for these abbreviations by using their full-form as a bridge. Our method is *scalable* enough to handle large amount of monolingual data, and is essentially *unsupervised* as it does not require any additional annotated data than the baseline translation system. Our method exploits the *data co-occurrence* phenomena that is very useful for relation extractions. We integrate our method into a state-of-the-art phrase-based baseline translation system, i.e., Moses (Koehn et al., 2007), and show that the integrated system consistently improves the performance of the baseline system on various NIST machine translation test sets.

## Abstract

In this work, we develop and evaluate a wide range of feature spaces for deriving Levin-style verb classifications (Levin, 1993). We perform the classification experiments using Bayesian Multinomial Regression (an efficient log-linear modeling framework which we found to outperform SVMs for this task) with the proposed feature spaces. Our experiments suggest that subcategorization frames are not the most effective features for automatic verb classification. A mixture of syntactic information and lexical information works best for this task.

## 1 Introduction

Much research in lexical acquisition of verbs has concentrated on the relation between verbs and their argument frames. Many scholars hypothesize that the behavior of a verb, particularly with respect to the expression of arguments and the assignment of semantic roles is to a large extent driven by deep semantic regularities (Dowty, 1991; Green, 1974; Goldberg, 1995; Levin, 1993). Thus measurements of verb frame patterns can perhaps be used to probe for linguistically relevant aspects of verb meanings. The correspondence between meaning regularities and syntax has been extensively studied in Levin (1993) (hereafter Levin). Levin's verb classes are based on the ability of a verb to occur or not occur in pairs of syntactic frames that are in some sense meaning preserving (*diathesis alternation*). The focus is on verbs for which distribution of syntactic frames is a useful indicator of class membership,

and, correspondingly, on classes which are relevant for such verbs. By using Levin's classification, we obtain a window on some (but not all) of the potentially useful semantic properties of verbs.

Levin's verb classification, like others, helps reduce redundancy in verb descriptions and enables generalizations across semantically similar verbs with respect to their usage. When the information about a verb type is not available or sufficient for us to draw firm conclusions about its usage, the information about the class to which the verb type belongs can compensate for it, addressing the pervasive problem of data sparsity in a wide range of NLP tasks, such as automatic extraction of subcategorization frames (Korhonen, 2002), semantic role labeling (Swier and Stevenson, 2004; Gildea and Jurafsky, 2002), natural language generation for machine translation (Habash et al., 2003), and deriving predominant verb senses from unlabeled data (Lapata and Brew, 2004).

Although there exist several manually-created verb lexicons or ontologies, including Levin's verb taxonomy, VerbNet, and FrameNet, automatic verb classification (AVC) is still necessary for extending existing lexicons (Korhonen and Briscoe, 2004), building and tuning lexical information specific to different domains (Korhonen et al., 2006), and bootstrapping verb lexicons for new languages (Tsang et al., 2002).

AVC helps avoid the expensive hand-coding of such information, but appropriate features must be identified and demonstrated to be effective. In this work, our primary goal is not necessarily to obtain the optimal classification, but rather to investigate

the linguistic conditions which are crucial for lexical semantic classification of verbs. We develop feature sets that combine syntactic and lexical information, which are in principle useful for any Levin-style verb classification. We test the general applicability and scalability of each feature set to the distinctions among 48 verb classes involving 1,300 verbs, which is, to our knowledge, the largest investigation on English verb classification by far. To preview our results, a feature set that combines both syntactic information and lexical information works much better than either of them used alone. In addition, mixed feature sets also show potential for scaling well when dealing with larger number of verbs and verb classes. In contrast, subcategorization frames, at least on their own, are largely ineffective for AVC, despite their evident effectiveness in supporting Levin's initial intuitions.

## 2 Related Work

Earlier work on verb classification has generally adopted one of the two approaches for devising statistical, corpus-based features.

**Subcategorization frame (SCF):** Subcategorization frames are obviously relevant to alternation behaviors. It is therefore unsurprising that much work on verb classification has adopted them as features (Schulte im Walde, 2000; Brew and Schulte im Walde, 2002; Korhonen et al., 2003). However, relying solely on subcategorization frames also leads to the loss of semantic distinctions. Consider the frame NP-V-PP*with*. The semantic interpretation of this frame depends to a large extent on the NP argument selected by the preposition *with*. In (1), the same surface form NP-V-PP*with* corresponds to three different underlying meanings. However, such semantic distinctions are totally lost if lexical information is disregarded.

- (1) a. I ate with *a fork*. [INSTRUMENT]  
 b. I left with *a friend*. [ACCOMPANIMENT]  
 c. I sang with *confidence*. [MANNER]

This deficiency of unlexicalized subcategorization frames leads researchers to make attempts to incorporate lexical information into the feature representation. One possible improvement over subcategorization frames is to enrich them with lexical information. Lexicalized frames are usually obtained

by augmenting each syntactic slot with its head noun (2).

- (2) a. NP(I)-V-PP(*with:fork*)  
 b. NP(I)-V-PP(*with:friend*)  
 c. NP(I)-V-PP(*with:confidence*)

With the potentially improved discriminatory power also comes increased exposure to sparse data problems. Trying to overcome the problem of data sparsity, Schulte im Walde (2000) explores the additional use of selectional preference features by augmenting each syntactic slot with the concept to which its head noun belongs in an ontology (e.g. WordNet). Although the problem of data sparsity is alleviated to certain extent (3), these features do not generally improve classification performance (Schulte im Walde, 2000; Joanis, 2002).

- (3) a. NP(PERSON)-V-PP(*with:ARTIFACT*)  
 b. NP(PERSON)-V-PP(*with:PERSON*)  
 c. NP(PERSON)-V-PP(*with:FEELING*)

**JOANIS07:** Incorporating lexical information directly into subcategorization frames has proved inadequate for AVC. Other methods for combining syntactic information with lexical information have also been attempted (Merlo and Stevenson, 2001; Joanis et al., 2007). These studies use a small collection of features that require some degree of expert linguistic analysis to devise. The deeper linguistic analysis allows their feature set to cover a variety of indicators of verb semantics, beyond that of frame information. Joanis et al. (2007) reports an experiment that involves 15 Levin verb classes. They define a general feature space that is supposed to be applicable to all Levin classes. The features they use fall into four different groups: *syntactic slots*, *slot overlaps*, *tense*, *voice and aspect*, and *animacy of NPs*.

- *Syntactic slots*: They encode the frequency of the syntactic positions (e.g. SUBJECT, OBJECT, PPat). They are considered approximation to subcategorization frames.
- *Slot overlaps*: They are supposed to capture the properties of alternation by identifying if a given noun can occur in different syntactic positions relative to a particular verb. For instance, in the alternation *The ice melted* and

*The sun melted the ice*, *ice* occurs in the subject position in the first sentence but in the object position in the second sentence. An overlap feature records that there is a subject-object alternation for *melt*.

- *Tense, voice and aspect*: Verb meaning and alternations also interact in interesting ways with *tense*, *voice*, and *aspect*. For example, *middle* construction is usually used in present tense (e.g. *The bread cuts easily*).
- *Animacy of NPs*: The animacy of the semantic role corresponding to the head noun in each syntactic slot can also distinguish classes of verbs.

Joanis et al. (2007) demonstrates that the general feature space they devise achieves a rate of error reduction ranging from 48% to 88% over a chance baseline accuracy, across classification tasks of varying difficulty. However, they also show that their general feature space does not generally improve the classification accuracy over subcategorization frames (see table 1).

Experimental Task	All Features	SCF
Average 2-way	83.2	80.4
Average 3-way	69.6	69.4
Average ( $\geq 6$ )-way	61.1	62.8

Table 1: Results from Joanis et al. (2007) (%)

### 3 Integration of Syntactic and Lexical Information

In this study, we explore a wider range of features for AVC, focusing particularly on various ways to mix syntactic with lexical information.

**Dependency relation (DR)**: Our way to overcome data sparsity is to break lexicalized frames into *lexicalized slots* (a.k.a. dependency relations). Dependency relations contain both syntactic and lexical information (4).

- (4)
- SUBJ(*I*), PP(*with:fork*)
  - SUBJ(*I*), PP(*with:friend*)
  - SUBJ(*I*), PP(*with:confidence*)

However, augmenting PP with nouns selected by the preposition (e.g. PP(*with:fork*)) still gives rise

to data sparsity. We therefore decide to break it into two individual dependency relations: PP(*with*), PP(*fork*). Although dependency relations have been widely used in automatic acquisition of lexical information, such as detection of polysemy (Lin, 1998) and WSD (McCarthy et al., 2004), their utility in AVC still remains untested.

**Co-occurrence (CO)**: CO features mostly convey lexical information only and are generally considered not particularly sensitive to argument structures (Rohde et al., 2004). Nevertheless, it is worthwhile testing whether the meaning components that are brought out by syntactic alternations are also correlated to the neighboring words. In other words, Levin verbs may be distinguished on the dimension of neighboring words, in addition to argument structures. A test on this claim can help answer the question of whether verbs in the same Levin class also tend to share their neighboring words.

**Adapted co-occurrence (ACO)**: Conventional CO features generally adopt a stop list to filter out function words. However, some of the function words, prepositions in particular, are known to carry great amount of syntactic information that is related to lexical meanings of verbs (Schulte im Walde, 2003; Brew and Schulte im Walde, 2002; Joanis et al., 2007). In addition, whereas most verbs tend to put a strong selectional preference on their nominal arguments, they do not care much about the identity of the verbs in their verbal arguments. Based on these observations, we propose to adapt the conventional CO features by (1) keeping all prepositions (2) replacing all verbs in the neighboring contexts of each target verb with their part-of-speech tags. ACO features integrate at least some degree of syntactic information into the feature space.

**SCF+CO**: Another way to mix syntactic information with lexical information is to use subcategorization frames and co-occurrences together in hope that they are complementary to each other, and therefore yield better results for AVC.

## 4 Experiment Setup

### 4.1 Corpus

To collect each type of features, we use the Gigaword Corpus, which consists of samples of recent newswire text data collected from four distinct in-

ternational sources of English newswire.

## 4.2 Feature Extraction

We evaluate six different feature sets for their effectiveness in AVC: **SCF**, **DR**, **CO**, **ACO**, **SCF+CO**, and **JOANIS07**. **SCF** contains mainly syntactic information, whereas **CO** lexical information. The other four feature sets include both syntactic and lexical information.

**SCF** and **DR**: These more linguistically informed features are constructed based on the grammatical relations generated by the C&C CCG parser (Clark and Curran, 2007). Take *He broke the door with a hammer* as an example. The grammatical relations generated are given in table 2.

<i>he broke the door with a hammer.</i>
(det door.3 the.2)
( <b>dobj</b> _ broke.1 door.3)
(det hammer.6 a.5)
( <b>dobj</b> with.4 hammer.6)
( <b>iobj</b> broke.1 with.4)
( <b>ncsubj</b> broke.1 He.0 _)

Table 2: grammatical relations generated by the parser

We first build a lexicalized frame for the verb *break*: NP1(*he*)-V-NP2(*door*)-PP(*with:hammer*). This is done by matching each grammatical label onto one of the traditional syntactic constituents. The set of syntactic constituents we use is summarized in table 3.

constituent	remark
NP1	subject of the verb
NP2	object of the verb
NP3	indirect object of the verb
PPp	prepositional phrase
TO	infinitival clause
GER	gerund
THAT	sentential complement headed by <i>that</i>
WH	sentential complement headed by a <i>wh</i> -word
ADJP	adjective phrase
ADVP	adverb phrase

Table 3: Syntactic constituents used for building SCFs

Based on the lexicalized frame, we construct an SCF NP1-NP2-PP*with* for *break*. The set of DRs generated for *break* is [SUBJ(*he*), OBJ(*door*), PP(*with*), PP-*hammer*].

**CO**: These features are collected using a flat 4-word window, meaning that the 4 words to the

left/right of each target verb are considered potential CO features. However, we eliminate any CO features that are in a stopword list, which consists of about 200 closed class words including mainly prepositions, determiners, complementizers and punctuation. We also lemmatize each word using the English lemmatizer as described in Minnen et al. (2000), and use lemmas as features instead of words.

**ACO**: As mentioned before, we adapt the conventional CO features by (1) keeping all prepositions (2) replacing all verbs in the neighboring contexts of each target verb with their part-of-speech tags. (3) keeping words in the left window only if they are tagged as a nominal.

**SCF+CO**: We combine the SCF and CO features.

**JOANIS07**: We use the feature set proposed in Joanis et al. (2007), which consists of 224 features. We extract features on the basis of the output generated by the C&C CCG parser.

## 4.3 Verb Classes

Our experiments involve two separate sets of verb classes:

**Joanis15**: Joanis et al. (2007) manually selects pairs, or triples of classes to represent a range of distinctions that exist among the 15 classes they investigate. For example, some of the pairs/triples are syntactically dissimilar, while others show little syntactic distinction across the classes.

**Levin48**: Earlier work has focused only on a small set of verbs or a small number of verb classes. For example, Schulte im Walde (2000) uses 153 verbs in 30 classes, and Joanis et al. (2007) takes on 835 verbs and 15 verb classes. Since one of our primary goals is to identify a general feature space that is not specific to any class distinctions, it is of great importance to understand how the classification accuracy is affected when attempting to classify more verbs into a larger number of classes. In our automatic verb classification, we aim for a larger scale experiment. We select our experimental verb classes and verbs as follows: We start with all Levin 197 verb classes. We first remove all verbs that belong to at least two Levin classes. Next, we remove any verb that does not occur at least 100 times in the English Gigaword Corpus. All classes that are left with at least 10 verbs are chosen for our experi-

ment. This process yields 48 classes involving about 1,300 verbs. In our automatic verb classification experiment, we test the applicability of each feature set to distinctions among up to 48 classes<sup>1</sup>. To our knowledge, this is, by far, the largest investigation on English verb classification.

## 5 Machine Learning Method

### 5.1 Preprocessing Data

We represent the semantic space for verbs as a matrix of frequencies, where each row corresponds to a Levin verb and each column represents a given feature. We construct a semantic space with each feature set. Except for **JONAS07** which only contains 224 features, all the other feature sets lead to a very high-dimensional space. For instance, the semantic space with **CO** features contains over one million columns, which is too huge and cumbersome. One way to avoid these high-dimensional spaces is to assume that most of the features are irrelevant, an assumption adopted by many of the previous studies working with high-dimensional semantic spaces (Burgess and Lund, 1997; Pado and Lapata, 2007; Rohde et al., 2004). Burgess and Lund (1997) suggests that the semantic space can be reduced by keeping only the  $k$  columns (features) with the highest variance. However, Rohde et al. (2004) have found it is simpler and more effective to discard columns on the basis of feature frequency, with little degradation in performance, and often some improvement. Columns representing low-frequency features tend to be noisier because they only involve few examples. We therefore apply a simple frequency cutoff for feature selection. We only use features that occur with a frequency over some threshold in our data.

In order to reduce undue influence of outlier features, we employ the four normalization strategies in table 4, which help reduce the range of extreme values while having little effect on others (Rohde et al., 2004). The raw frequency ( $w_{v,f}$ ) of a verb  $v$  occurring with a feature  $f$  is replaced with the normal-

ized value ( $w'_{v,f}$ ), according to each normalization method. Our experiments show that using correlation for normalization generally renders the best results. The results reported below are obtained from using correlation for normalization.

	$w'_{v,f} =$
row	$\frac{w_{v,f}}{\sum_j w_{v,j}}$
column	$\frac{w_{v,f}}{\sum_i w_{i,f}}$
length	$\frac{w_{v,f}}{\sum_j w_{v,j}^2}^{1/2}$
correlation	$\frac{T w_{v,f} - \sum_j w_{v,j} \sum_i w_{i,f}}{(\sum_j w_{v,j} (T - \sum_j w_{v,j}) \sum_i w_{i,f} (T - \sum_i w_{i,f}))^{1/2}}$
	$T = \sum_i \sum_j w_{i,j}$

Table 4: Normalization techniques

To preprocess data, we first apply a frequency cutoff to our data set, and then normalize it using the correlation method. To find the optimal threshold for frequency cut, we consider each value between 0 and 10,000 at an interval of 500. In our experiments, results on training data show that performance declines more noticeably when the threshold is lower than 500 or higher than 10,000. For each task and feature set, we select the frequency cut that offers the best accuracy on the preprocessed training set according to  $k$ -fold stratified cross validation<sup>2</sup>.

### 5.2 Classifier

For all of our experiments, we use the software that implements the Bayesian multinomial logistic regression (a.k.a BMR). The software performs the so-called 1-of- $k$  classification (Madigan et al., 2005). BMR is similar to Maximum Entropy. It has been shown to be very efficient with handling large numbers of features and extremely sparsely populated matrices, which characterize the data we have for AVC<sup>3</sup>. To begin, let  $x = [x_1, \dots, x_j, \dots, x_d]^T$  be a vector of feature values characterizing a verb to be classified. We encode the fact that a verb belongs to a class  $k \in 1, \dots, K$  by a  $K$ -dimensional 0/1 valued vector  $y = (y_1, \dots, y_K)^T$ , where  $y_k = 1$  and all other coordinates are 0. Multinomial logistic regres-

<sup>1</sup>In our experiment, we only use monosemous verbs from these 48 verb classes. Due to the space limit, we do not list the 48 verb classes. The size of the most classes falls in the range between 10 to 30, with a couple of classes having a size over 100.

<sup>2</sup>10-fold for Joanis15 and 9-fold for Levin48. We use a balanced training set, which contains 20 verbs from each class in Joanis15, but only 9 verbs from each class in Levin48.

<sup>3</sup>We also tried Chang and Lin (2001)'s LIBSVM library for Support Vector Machines (SVMs), however, BMR generally outperforms SVMs.

sion is a conditional probability model of the form, parameterized by the matrix  $\beta = [\beta_1, \dots, \beta_K]$ . Each column of  $\beta$  is a parameter vector corresponding to one of the classes:  $\beta_k = [\beta_{k1}, \dots, \beta_{kd}]^T$ .

$$P(y_k = 1 | \beta_k, x) = \exp(\beta_k^T x) / \sum_{k_i} \exp(\beta_{k_i}^T x)$$

## 6 Results and Discussion

### 6.1 Evaluation Metrics

Following Joanis et al. (2007), we adopt a single evaluation measure - macro-averaged recall - for all of our classification tasks. As discussed below, since we always use balanced training sets for each individual task, it makes sense for our accuracy metric to give equal weight to each class. Macro-averaged recall treats each verb class equally, so that the size of a class does not affect macro-averaged recall. It usually gives a better sense of the quality of classification across all classes. To calculate macro-averaged recall, the recall value for each individual verb class has to be computed first.

$$recall = \frac{\text{no. of test verbs in class } c \text{ correctly labeled}}{\text{no. of test verbs in class } c}$$

With a recall value computed for each verb class, the macro-averaged recall can be defined by:

$$macro\text{-averaged recall} = \frac{1}{|C|} \sum_{c \in C} recall \text{ for class } c$$

$C$  : a set of verb classes

$c$  : an individual verb class

$|C|$  : the number of verb classes

### 6.2 Joanis15

With those manually-selected 15 classes, Joanis et al. (2007) conducts 11 classification tasks including six 2-way classifications, two 3-way classifications, one 6-way classification, one 8-way classification, and one 14-way classification. In our experiments, we replicate these 11 classification tasks using the proposed six different feature sets. For each classification task in this task set, we randomly select 20 verbs from each class as the training set. We

repeat this process 10 times for each task. The results reported for each task is obtained by averaging the results of the 10 trials. Note that for each trial, each feature set is trained and tested on the same training/test split.

The results for the 11 classification tasks are summarized in table 5. We provide a chance baseline and the accuracy reported in Joanis et al. (2007)<sup>4</sup> for comparison of our results. A few points are worth noting:

- Although widely used for AVC, **SCF**, at least when used alone, is not the most effective feature set. Our experiments show that the performance achieved by using **SCF** is generally worse than using the feature sets that mix syntactic and lexical information. As a matter of fact, it even loses to the simplest feature set **CO** on 4 tasks, including the 14-way task.
- The two feature sets (**DR**, **SCF+CO**) we propose that combine syntactic and lexical information generally perform better than those feature sets (**SCF**, **CO**) that only include syntactic or lexical information. Although there is not a clear winner, **DR** and **SCF+CO** generally outperform other feature sets, indicating that they are effective ways for combining syntactic and lexical information. In particular, these two feature sets perform comparatively well on the tasks that involve more classes (e.g. 14-way), exhibiting the tendency to scale well with larger number of verb classes and verbs. Another feature set that combines syntactic and lexical information, **ACO**, which keeps function words in the feature space to preserve syntactic information, outperforms the conventional **CO** on the majority of tasks. All these observations suggest that how to mix syntactic and lexical information is one of keys to an improved verb classification.
- Although **JOANIS07** also combines syntactic and lexical information, its performance is not comparable to that of other feature sets that mix syntactic and lexical information. In fact, **SCF**

<sup>4</sup>Joanis et al. (2007) is different from our experiments in that they use a chunker for feature extraction and the Support Vector Machine for classification.

Experimental Task	Random Baseline	As Reported in Joanis et al. (2007)	Feature Set					
			SCF	DR	CO	ACO	SCF+CO	JOANIS07
1) Benefactive/Recipient	50	86.4	88.6	88.4	88.2	89.1	<b>90.7</b>	88.9
2) Admire/Amuse	50	93.9	96.7	<b>97.5</b>	92.1	90.5	96.4	96.6
3) Run/Sound	50	86.8	85.4	89.6	<b>91.8</b>	90.2	90.5	87.1
4) Light/Sound	50	75.0	74.8	<b>90.8</b>	86.9	89.7	88.8	82.1
5) Cheat/Steal	50	76.5	77.6	<b>80.6</b>	72.1	75.5	77.8	76.4
6) Wipe/Steal	50	80.4	<b>84.8</b>	80.6	79.0	79.4	84.4	83.9
7) Spray/Fill/Putting	33.3	65.6	73.0	72.8	59.6	66.6	<b>73.8</b>	69.6
8) Run/State Change/Object drop	33.3	74.2	74.8	77.2	76.9	77.6	<b>80.5</b>	75.5
9) Cheat/Steal/Wipe/Spray/Fill/Putting	16.7	64.3	64.9	<b>65.1</b>	54.8	59.1	65.0	64.3
10) 9)/Run/Sound	12.5	61.7	62.3	65.8	55.7	60.8	<b>66.9</b>	63.1
11) 14-way (all except Benefactive)	7.1	58.4	56.4	65.7	57.5	59.6	<b>66.3</b>	57.2

Table 5: Experimental results for Joanis15 (%)

and **JOANIS07** yield similar accuracy in our experiments, which agrees with the findings in Joanis et al. (2007) (compare table 1 and 5).

### 6.3 Levin48

Recall that one of our primary goals is to identify the feature set that is generally applicable and scales well while we attempt to classify more verbs into a larger number of classes. If we could exhaust all the possible  $n$ -way ( $2 \leq n \leq 48$ ) classification tasks with the 48 Levin classes we will investigate, it will allow us to draw a firmer conclusion about the general applicability and scalability of a particular feature set. However, the number of classification tasks grows really huge when  $n$  takes on certain value (e.g.  $n = 20$ ). For our experiments, we set  $n$  to be 2, 5, 10, 20, 30, 40, or 48. For the 2-way classification, we perform all the possible 1,028 tasks. For the 48-way classification, there is only one possible task. We randomly select 100  $n$ -way tasks each for  $n = 5, 10, 20, 30, 40$ . We believe that this series of tasks will give us a reasonably good idea of whether a particular feature set is generally applicable and scales well.

The smallest classes in Levin48 have only 10 verbs. We therefore reduce the number of training verbs to 9 for each class. For each  $n = 2, 5, 10, 20, 30, 40, 48$ , we will perform certain number of  $n$ -way classification tasks. For each  $n$ -way task, we randomly select 9 verbs from each class as training data, and repeat this process 10 times. The accuracy for each  $n$ -way task is then computed by averaging the results from these 10 trials. The accuracy reported for the overall  $n$ -way classification for each selected  $n$ , is obtained by averaging the results from each in-

dividual  $n$ -way task for that particular  $n$ . Again, for each trial, each feature set is trained and tested on the same training/test split.

The results for Levin48 are presented in table 6, which clearly reveals the general applicability and scalability of each feature set.

- Results from Levin48 reconfirm our finding that **SCF** is not the most effective feature set for AVC. Although it achieves the highest accuracy on the 2-way classification, its accuracy drops drastically as  $n$  gets bigger, indicating that SCF does not scale as well as other feature sets when dealing with larger number of verb classes. On the other hand, the co-occurrence feature (**CO**), which is believed to convey only lexical information, outperforms **SCF** on every  $n$ -way classification when  $n \geq 10$ , suggesting that verbs in the same Levin classes tend to share their neighboring words.
- The three feature sets we propose that combine syntactic and lexical information generally scale well. Again, **DR** and **SCF+CO** generally outperform all other feature sets on all  $n$ -way classifications, except the 2-way classification. In addition, **ACO** achieves a better performance on every  $n$ -way classification than **CO**. Although **SCF** and **CO** are not very effective when used individually, they tend to yield the best performance when combined together.
- Again, **JOANIS07** does not match the performance of other feature sets that combine both syntactic and lexical information, but yields similar accuracy as **SCF**.

Experimental Task	No of Tasks	Random Baseline	Feature Set					
			SCF	DR	CO	ACO	SCF+CO	JOANIS07
2-way	1,028	50	<b>84.0</b>	83.4	77.8	80.9	82.9	82.4
5-way	100	20	71.9	76.4	70.4	73.0	<b>77.3</b>	72.2
10-way	100	10	65.8	<b>73.7</b>	68.8	71.2	72.8	65.9
20-way	100	5	51.4	65.1	58.8	60.1	<b>65.8</b>	50.7
30-way	100	3.3	46.7	56.9	48.6	51.8	<b>57.8</b>	47.1
40-way	100	2.5	43.6	54.8	47.3	49.9	<b>55.1</b>	44.2
48-way	1	2.2	39.1	51.6	42.4	46.8	<b>52.8</b>	38.9

Table 6: Experimental results for Levin48 (%)

## 6.4 Further Discussion

Previous studies on AVC have focused on using SCFs. Our experiments reveal that SCFs, at least when used alone, compare poorly to the feature sets that mix syntactic and lexical information. One explanation for the poor performance could be that we use all the frames generated by the CCG parser in our experiment. A better way of doing this would be to use some expert-selected SCF set. Levin classifies English verbs on the basis of 78 SCFs, which should, at least in principle, be good at separating verb classes. To see if Levin-selected SCFs are more effective for AVC, we match each SCF generated by the C&C CCG parser (**CCG-SCF**) to one of 78 Levin-defined SCFs, and refer to the resulting SCF set as **unfiltered-Levin-SCF**. Following studies on automatic SCF extraction (Brent, 1993), we apply a statistical test (Binomial Hypothesis Test) to the **unfiltered-Levin-SCF** to filter out noisy SCFs, and denote the resulting SCF set as **filtered-Levin-SCF**. We then perform the 48-way task (one of Levin48) with these two different SCF sets. Recall that using **CCG-SCF** gives us a macro-averaged recall of 39.1% on the 48-way task. Our experiments show that using **unfiltered-Levin-SCF** and **filtered-Levin-SCF** raises the accuracy to 39.7% and 40.3% respectively. Although a little performance gain has been obtained by using expert-defined SCFs, the accuracy level is still far below that achieved by using a feature set that combines syntactic and semantic information. In fact, even the simple co-occurrence feature (CO) yields a better performance (42.4%) than these Levin-selected SCF sets.

## 7 Conclusion and Future Work

We have performed a wide range of experiments to identify which features are most informative in

AVC. Our conclusion is that both syntactic and lexical information are useful for verb classification. Although neither **SCF** nor **CO** performs well on its own, a combination of them proves to be the most informative feature for this task. Other ways of mixing syntactic and lexical information, such as **DR**, and **ACO**, work relatively well too. What makes these mixed feature sets even more appealing is that they tend to scale well in comparison to **SCF** and **CO**. In addition, these feature sets are devised on a general level without relying on any knowledge about specific classes, thus potentially applicable to a wider range of class distinctions. Assuming that Levin’s analysis is generally applicable across languages in terms of the linking of semantic arguments to their syntactic expressions, these mixed feature sets are potentially useful for building verb classifications for other languages.

For our future work, we aim to test whether an automatically created verb classification can be beneficial to other NLP tasks. One potential application of our verb classification is parsing. Lexicalized PCFGs (where head words annotate phrasal nodes) have proved a key tool for high performance PCFG parsing, however its performance is hampered by the sparse lexical dependency exhibited in the Penn Treebank. Our experiments on verb classification have offered a class-based approach to alleviate data sparsity problem in parsing. It is our goal to test whether this class-based approach will lead to an improved parsing performance.

## 8 Acknowledgments

This study was supported by NSF grant 0347799. We are grateful to Eric Fosler-Lussier, Detmar Meurers, Mike White and Kirk Baker for their valuable comments.

## Abstract

Question answering research has only recently started to spread from short factoid questions to more complex ones. One significant challenge is the evaluation: manual evaluation is a difficult, time-consuming process and not applicable within efficient development of systems. Automatic evaluation requires a corpus of questions and answers, a definition of what is a correct answer, and a way to compare the correct answers to automatic answers produced by a system. For this purpose we present a Wikipedia-based corpus of Why-questions and corresponding answers and articles. The corpus was built by a novel method: paid participants were contacted through a Web-interface, a procedure which allowed dynamic, fast and inexpensive development of data collection methods. Each question in the corpus has several corresponding, partly overlapping answers, which is an asset when estimating the correctness of answers. In addition, the corpus contains information related to the corpus collection process. We believe this additional information can be used to post-process the data, and to develop an automatic approval system for further data collection projects conducted in a similar manner.

## 1 Introduction

Automatic question answering (QA) is an alternative to traditional word-based search engines. Instead of returning a long list of documents more or less related to the query parameters, the aim of a QA system is to isolate the exact answer as accurately as

possible, and to provide the user only a short text clip containing the required information.

One of the major development challenges is evaluation. The conferences such as TREC<sup>1</sup>, CLEF<sup>2</sup> and NTCIR<sup>3</sup> have provided valuable QA evaluation methods, and in addition produced and distributed corpora of questions, answers and corresponding documents. However, these conferences have focused mainly on fact-based questions with short answers, so called factoid questions. Recently more complex tasks such as list, definition and discourse-based questions have also been included in TREC in a limited fashion (Dang et al., 2007). More complex how- and why-questions (for Asian languages) were also included in the NTCIR07, but the provided data comprised only 100 questions, of which some were also factoids (Fukumoto et al., 2007). Not only is the available non-factoid data quite limited in size, it is also questionable whether the data sets are usable in development outside the conferences. Lin and Katz (2006) suggest that training data has to be more precise, and, that it should be collected, or at least cleaned, manually.

Some corpora of why-questions have been collected manually: corpora described in (Verberne et al., 2006) and (Verberne et al., 2007) both comprise fewer than 400 questions and corresponding answers (one or two per question) formulated by native speakers. However, we believe one answer per question is not enough. Even with factoid questions it is sometimes difficult to define what is a correct

<sup>1</sup><http://trec.nist.gov/>

<sup>2</sup><http://www.clef-campaign.org/>

<sup>3</sup><http://research.nii.ac.jp/ntcir/>

answer, and complex questions result in a whole new level of ambiguity. Correctness depends greatly on the background knowledge and expectations of the person asking the question. For example, a correct answer to the question “Why did Mr. X take Ms. Y to a coffee shop?” could be very different depending on whether we knew that Mr. X does not drink coffee or that he normally drinks it alone, or that Mr. X and Ms. Y are known enemies.

The problem of several possible answers and, in consequence, automatic evaluation has been tackled for years within another field of study: automatic summarisation (Hori et al., 2003; Lin and Hovy, 2003). We believe that the best method of providing “correct” answers is to do what has been done in that field: combine a multitude of answers to ensure both diversity and consensus among the answers.

Correctness of an answer is also closely related to the required level of detail. The Internet FAQ pages were successfully used to develop QA-systems (Jijikoun and de Rijke, 2005; Soricut and Brill, 2006), as have the human-powered question sites such as Answers.com, Yahoo Answers and Google Answers, where individuals can post questions and receive answers from peers (Mizuno et al., 2007). Both resources can be assumed to contain adequately error-free information. FAQ pages are created so as to answer typical questions well enough that the questions do not need to be repeated. Question sites typically rank the answers and offer bonuses for people providing good ones. However, both sites suffer from excess of information. FAQ-pages tend to also answer questions which are not asked, and also contain practical examples. Human-powered answers often contain unrelated information and discourse-like elements. Additionally, the answers do not always have a connection to the source material from which they could be extracted.

One purpose of our project was to take part in the development of QA systems by providing the community with a new type of corpus. The corpus includes not only the questions with multiple answers and corresponding articles, but also certain additional information that we believe is essential to enhance the usability of the data.

In addition to providing a new QA corpus, we hope our description of the data collection process will provide insight, resources and motivation for

further research and projects using similar collection methods. We collected our corpus through Amazon Mechanical Turk service <sup>4</sup> (*MTurk*). The MTurk infrastructure allowed us to distribute our tasks to a multitude of workers around the world, without the burden of advertising. The system also allowed us to test the workers suitability, and to reward the work without the bureaucracy of employment. To our knowledge, this is the first time that the MTurk service has been used in equivalent purpose.

We conducted the data collection in three steps: generation, answering and rephrasing of questions. The workers were provided with a set of Wikipedia articles, based on which the questions were created and the answers determined by sentence selection. The WhyQA-corpus consists of three parts: original questions along with their rephrased versions, 8-10 partly overlapping answers for each question, and the Wikipedia articles including the ones corresponding to the questions. The WhyQA-corpus is in XML-format and can be downloaded and used under the GNU Free Documentation License from [www.furui.cs.titech.ac.jp/](http://www.furui.cs.titech.ac.jp/).

## 2 Setup

Question-answer pairs have previously been generated for example by asking workers to both ask a question and then answer it based on a given text (Verberne et al., 2006; Verberne et al., 2007). We decided on a different approach for two reasons. Firstly, based on our experience such an approach is not optimal in the MTurk framework. The tasks that were welcomed by workers required a short attention span, and reading long texts was negatively received with many complaints, sloppy work and slow response times. Secondly, we believe that the aforementioned approach can produce unnatural questions that are not actually based on the information need of the workers.

We divided the QA-generation task into two phases: question-generation (*QGenHIT*) and answering (*QAHIT*). We also trimmed the amount of the text that the workers were required to read to create the questions. These measures were taken both in order to lessen the cognitive burden of the task

<sup>4</sup><http://www.mturk.com>

and to produce more natural questions.

In the first phase the workers generated the questions based on a part of Wikipedia article. The resulting questions were then uploaded to the system as new HITs with the corresponding articles, and answered by available (different) workers. Our hypothesis is that the questions are more natural if their answer is not known at the time of the creation.

Finally, in an additional third phase, 5 rephrased versions of each question were created in order to gain variation (*QRepHIT*). The data quality was ensured by requiring the workers to achieve a certain result from a test (or a *Qualification*) before they could work on the aforementioned tasks.

Below we explain the MTurk system, and then our collection process in detail.

## 2.1 Mechanical Turk

Mechanical Turk is a Web-based service, offered by Amazon.com, Inc. It provides an API through which employers can obtain a connection to people to perform a variety of simple tasks. With tools provided by Amazon.com, the employer creates tasks, and uploads them to the MTurk Web-site. Workers can then browse the tasks and, if they find them profitable and/or interesting enough, work on them. When the tasks are completed, the employer can download the results, and accept or reject them. Some key concepts of the system are listed below, with short descriptions of the functionality.

- **HIT** Human Intelligence Task, the unit of a payable chore in MTurk.
- **Requester** An “employer”, creates and uploads new *HITs* and rewards the *workers*. Requesters can upload simple *HITs* through the MTurk Requester web site, and more complicated ones through the MTurk Web Service APIs.
- **Worker** An “employee”, works on the hits through the MTurk Workers’ web site.
- **Assignment.** One *HIT* consists of one or more assignments. One worker can complete a single *HIT* only once, so if the requester needs multiple results per *HIT*, he needs to set the assignment-count to the desired figure. A *HIT* is considered completed when all the assignments have been completed.

- **Rewards** At upload time, each *HIT* has to be assigned a fixed reward, that cannot be changed later. Minimum reward is \$0.01. Amazon.com collects a 10% (or a minimum of \$0.05) service fee per each paid reward.

- **Qualifications** To improve the data quality, a *HIT* can also be attached to certain tests, “qualifications” that are either system-provided or created by the requester. An example of a system-provided qualification is the average approval ratio of the worker.

Even if it is possible to create tests that workers have to pass before being allowed to work on a *HIT* so as to ensure the worker’s ability, it is impossible to test the motivation (for instance, they cannot be interviewed). Also, as they are working through the Web, their working conditions cannot be controlled.

## 2.2 Collection process

The document collection used in our research was derived from the Wikipedia XML Corpus by Denoyer and Gallinari (2006). We selected a total of 84 articles, based on their length and contents. A certain length was required so that we could expect the article to contain enough interesting material to produce a wide selection of natural questions. The articles varied in topic, degree of formality and the amount of details; from “Horror film” and “Christmas worldwide” to “G-Man (Half-Life)” and “History of London”. Articles consisting of bulleted lists were removed, but filtering based on the topic of the article was not performed. Essentially, the articles were selected randomly.

### 2.2.1 QGenHIT

The first phase of the question-answer generation was to generate the questions. In QGenHIT we presented the worker with only part of a Wikipedia article, and instructed them to think of a why-question that they felt could be answered based on the original, whole article which they were not shown. This approach was expected to lead to natural curiosity and questions. Offering too little information would have lead to many questions that would finally be left unanswered, and it also did not give the workers enough to work on. Giving too much information

<b>Qualification</b>	The workers were required to pass a test before working on the HITs.
<b>QGenHIT</b>	Questions were generated based on partial Wikipedia articles. These questions were then used to create the QAHITs.
<b>QAHIT</b>	Workers were presented with a question and a corresponding article. The task was to answer the questions (if possible) through sentence selection.
<b>QRepHIT</b>	To ensure variation in the questions, each question was rephrased by 5 different workers.

Table 1: Main components of the corpus collection process.

<b>Article topic: Fermi paradox</b>
<b>Original question</b> Why is the moon crucial to the rare earth hypothesis?
<b>Rephrased Q 1</b> How does the rare earth theory depend upon the moon?
<b>Rephrased Q 2</b> What makes the moon so important to rare earth theory?
<b>Rephrased Q 3</b> What is the crucial regard for the moon in the rare earth hypothesis?
<b>Rephrased Q 4</b> Why is the moon so important in the rare earth hypothesis?
<b>Rephrased Q 5</b> What makes the moon necessary, in regards to the rare earth hypothesis?
<b>Answer 1. Sentence ids: 20,21. Duplicates: 4.</b> The moon is important because its gravitational pull creates tides that stabilize Earth’s axis. Without this stability, its variation, known as precession of the equinoxes, could cause weather to vary so dramatically that it could potentially suppress the more complex forms of life.
<b>Answer 2. Sentence ids: 18,19,20. Duplicates: 2.</b> The popular Giant impact theory asserts that it was formed by a rare collision between the young Earth and a Mars-sized body, usually referred to as Orpheus or Theia, approximately 4.45 billion years ago. The collision had to occur at a precise angle, as a direct hit would have destroyed the Earth, and a shallow hit would have deflected the Mars-sized body. The moon is important because its gravitational pull creates tides that stabilize Earth’s axis.
<b>Answer 3. Sentence ids: 20,21,22. Duplicates: 2.</b> The moon is important because its gravitational pull creates tides that stabilize Earth’s axis. Without this stability, its variation, known as precession of the equinoxes, could cause weather to vary so dramatically that it could potentially suppress the more complex forms of life. The heat generated by the Earth/Theia impact, as well as subsequent Lunar tides, may have also significantly contributed to the total heat budget of the Earth’s interior, thereby both strengthening and prolonging the life of the dynamos that generate Earth’s magnetic field Dynamo 1.
<b>Answer 4. Sentence ids: 18,20,21. No duplicates.</b> The popular Giant impact theory asserts that it was formed by a rare collision between the young Earth and a Mars-sized body, usually referred to as Orpheus or Theia, approximately 4.45 billion years ago. The moon is important because its gravitational pull creates tides that stabilize Earth’s axis. Without this stability, its variation, known as precession of the equinoxes, could cause weather to vary so dramatically that it could potentially suppress the more complex forms of life.
<b>Answer 5. Sentence ids: 18,21. No duplicates.</b> The popular Giant impact theory asserts that it was formed by a rare collision between the young Earth and a Mars-sized body, usually referred to as Orpheus or Theia, approximately 4.45 billion years ago. Without this stability, its variation, known as precession of the equinoxes, could cause weather to vary so dramatically that it could potentially suppress the more complex forms of life.

Table 2: Data example: Question with rephrased versions and answers.

(long excerpts from the articles) was severely disliked among the workers simply because it took a long time to read.

We finally settled on a solution where the partial content consisted of the title and headers of the article, along with the first sentences of each paragraph. The instructions to the questions demanded rigidly that the question starts with the word “Why”, as it was surprisingly difficult to explain what we meant by why-questions if the question word was not fixed.

The reward per HIT was \$0.04, and 10 questions were collected for each article. We did not force the questions to be different, and thus in the later phase some of the questions were removed manually as they were deemed to mean exactly the same thing. However, there were less than 30 of these duplicate questions in the whole data set.

### 2.2.2 QAHIT

After generating the questions based on partial articles, the resulting questions were uploaded to the system as HITs. Each of these QAHITs presented a single question with the corresponding original article. The worker’s task was to select either 1-3 sentences from the text, or a No-answer-option (*NoA*). Sentence selection was conducted with Javascript functionality, so the workers had no chance to include freely typed information within the answer (although a comment field was provided). The reward per HIT was \$0.06. At the beginning, we collected 10 answers per question, but we cut that down to 8 because the HITs were not completed fast enough.

The workers for QAHITs were drawn from the same pool as the workers for QGenHIT, and it was possible for the workers to answer the questions they had generated themselves.

### 2.2.3 QRepHIT

As the final step 5 rephrased versions of each question were generated. This was done to compensate the rigid instructions of the QGenHIT and to ensure variation in the questions. We have not yet measured how well the rephrased questions match the answers of their original versions. In the final QRepHIT questions were grouped into groups of 5. Each HIT consisted of 5 assignments, and a \$0.05 reward was offered for each HIT.

QRepHIT required the least amount of design and

trials, and workers were delighted with the task. The HITs were completed fast and well even in the case when we accidentally uploaded a set of HITs with no reward.

As with QAHIT, the worker pool for creating and rephrasing questions was the same. The questions were rephrased by their creator in 4 cases.

## 2.3 Qualifications

To improve the data quality, we used the qualifications to test the workers. For the QGenHITs we only used the system-provided “HIT approval rate”-qualification. Only workers whose previous work had been approved in 80% of the cases were able to work on our HITs.

In addition to the system-provided qualification, we created a why-question-specific qualification. The workers were presented with 3 questions, and they were to answer each by either selecting 1-3 most relevant sentences from a list of about 10 sentences, or by deciding that there is no answer present. The possible answer-sentences were divided into groups of essential, OK and wrong, and one of the questions did quite clearly have no answer. The scoring was such that it was impossible to get approved results if not enough essential sentences were included. Selecting sentences from the OK-group only was not sufficient, and selecting sentences from the wrong-group was penalized. A minimum score per question was required, but also the total score was relevant – component scores could compensate each other up to a point. However, if the question with no answer was answered, the score could not be of an approvable level. This qualification was, in addition to the minimum HIT approval rate of 80%, a prerequisite for both the QRepHITs and the QAHITs.

A total of 2355 workers took the test, and 1571 (67%) of them passed it, thus becoming our available worker pool. However, in the end the actual number of different workers was only 173.

Examples of each HIT, their instructions and the Qualification form are included in the final corpus. The collection process is summarised in Table 1.

### 3 Corpus description

The final corpus consists of questions with their rephrased versions and answers. There are total of 695 questions, of which 159 were considered unanswerable based on the articles, and 536 that have 8-10 answers each. The total cost of producing the corpus was about \$350, consisting of \$310 paid in workers rewards and \$40 in Mechanical Turk fees, including all the trials conducted during the development of the final system.

Also included is a set of Wikipedia documents (*WikiXML*, about 660 000 articles or 670MB in compressed format), including the ones corresponding to the questions (84 documents). The source of WikiXML is the English part of the Wikipedia XML Corpus by Denoyer and Gallinari (2006). In the original data some of the HTML-structures like lists and tables occurred within sentences. Our sentence-selection approach to QA required a more fine-grained segmentation and for our purpose, much of the HTML-information was redundant anyway. Consequently we removed most of the HTML-structures, and the table-cells, list-items and other similar elements were converted into sentences. Apart from sentence-information, only the section-title information was maintained. Example data is shown in Table 2.

#### 3.1 Task-related information

Despite the Qualifications and other measures taken in the collection phase of the corpus, we believe the quality of the data remains open to question. However, the Mechanical Turk framework provided additional information for each assignment, for example the time workers spent on the task. We believe this information can be used to analyse and use our data better, and have included it in the corpus to be used in further experiments.

- **Worker Id** Within the MTurk framework, each worker is assigned a unique id. Worker id can be used to assign a reliability-value to the workers, based on the quality of their previous work. It was also used to examine whether the same workers worked on the same data in different phases: Of the original questions, only 7 were answered and 4 other rephrased by the same worker they were created by. However, it has

to be acknowledged that it is also possible for one worker to have had several accounts in the system, and thus be working under several different worker ids.

- **Time On Task** The MTurk framework also provides the requester the time it took for the worker to complete the assignment after accepting it. This information is also included in the corpus, although it is impossible to know precisely how much time the workers actually spent on each task. For instance, it is possible that one worker had several assignments open at the same time, or that they were not concentrating fully on working on the task. A high value of Time On Task thus does not necessarily mean that the worker actually spent a long time on it. However, a low value indicates that he/she did only spend a short time on it.
- **Reward** Over the period spent collecting the data, we changed the reward a couple of times to speed up the process. The reward is reported per HIT.
- **Approval Status** Within the collection process we encountered some clearly unacceptable work, and rejected it. The rejected work is also included in the corpus, but marked as rejected. The screening process was by no means perfect, and it is probable that some of the approved work should have been rejected.
- **HIT id, Assignment id, Upload Time** HIT and assignment ids and original upload times of the HITs are provided to make it possible to retrace the collection steps if needed.
- **Completion Time** Completion time is the timestamp of the moment when the task was completed by a worker and returned to the system. The time between the completion time and the upload time is presumably highly dependent on the reward, and on the appeal of the task in question.

#### 3.2 Quality experiments

As an example of the post-processing of the data, we conducted some preliminary experiments on the answer agreement between workers.

Out of the 695 questions, 159 were filtered out in the first part of QAHIT. We first uploaded only 3 assignments, and the questions that 2 out of 3 workers deemed unanswerable were filtered out. This left 536 questions which were considered answered, each one having 8-10 answers from different workers. Even though in the majority of cases (83% of the questions) one of the workers replied with the NoA, the ones that answered did agree up to a point: of all the answers, 72% were such that all of their sentences were selected by at least two different workers. On top of this, an additional 17% of answers shared at least one sentence that was selected by more than one worker.

To understand the agreement better, we also calculated the average agreement of selected sentences based on sentence ids and N-gram overlaps between the answers. In both of these experiments, only those 536 questions that were considered answerable were included.

### 3.2.1 Answer agreement on sentence ids

As the questions were answered by means of sentence selection, the simplest method to check the agreement between the workers was to compare the ids of the selected sentences. The agreement was calculated as follows: each answer was compared to all the other answers for the same question. For each case, the agreement was defined as  $Agreement = \frac{CommonIds}{AllIds}$ , where *CommonIds* is the number of sentence ids that existed in both answers, and *AllIds* is the number of different ids in both answers. We calculated the overall average agreement ratio (*Total Avg*) and the average of the best matches between two assignments within one HIT (*Best Match*). We ran the test for two data sets: The most typical case of the workers cheating was to mark the question unanswerable. Because of this the first data set included only the real answers, and the NoAs were removed (*NoA not included*, 3872 answers). If an answer was compared with a NoA, the agreement was 0, and if two NoAs were compared, the agreement was 1. We did, however, also include the figures for the whole data set (*NoA included*, 4638 answers). The results are shown in Table 3.

The Best Match -results were quite high compared to the Total Avg. From this we can conclude

	Total Avg	Best Match
NoA not included	0.39	0.68
NoA included	0.34	0.68

Table 3: Answer agreement based on sentence ids.

that in the majority of cases, there was at least one quite similar answer among those for that HIT. However, comparing the sentence ids is only an indicative measure, and it does not tell the whole story about agreement. For each document there may exist several separate sentences that contain the same kind of information, and so two answers can be alike even though the sentence ids do not match.

### 3.2.2 Answer agreement based on ROUGE

Defining the agreement over several passages of texts has for a long time been a research problem within the field of automatic summarisation. For each document it is possible to create several summarisations that can each be considered correct. The problem has been approached by using the ROUGE-metric: calculating the N-gram overlap between manual, “correct” summaries, and the automatic summaries. ROUGE has been proven to correlate well with human evaluation (Lin and Hovy, 2003).

Overlaps of higher order N-grams are more usable within speech summarisation as they take the grammatical structure and fluency of the summary into account. When selecting sentences, this is not an issue, so we decided to use only unigram and bigram counts (Table 4: *R-1*, *R2*), as well as the skip-bigram values (*R-SU*) and the longest common N-gram metric R-L. We calculated the figures for two data sets in the same way as in the case of sentence id agreement. Finally, we set a lower bound for the results by comparing the answers to each other randomly (the NoAs were also included).

The final F-measures of the ROUGE results are presented in Table 4. The figures vary from 0.37 to 0.56 for the first data set, and from 0.28 to 0.42 to the second. It is debatable how the results should be interpreted, as we have not defined a theoretical upper bound to the values, but the difference to the randomised results is substantial. In the field of automatic summarisation, the overlap of the automatic

results and corresponding manual summarisations is generally much lower than the overlap between our answers (Chali and Kolla, 2004). However, it is difficult to draw detailed conclusions based on comparison between these two very different tasks.

	R-1	R-2	R-SU	R-L
NoA not included	0.56	0.46	0.37	0.52
NoA included	0.42	0.35	0.28	0.39
Random Answers	0.13	0.01	0.02	0.09

Table 4: Answer agreement: ROUGE-1, -2, -SU and -L.

The sentence agreement and ROUGE-figures do not tell us much by themselves. However, they are an example of a procedure that can be used to post-process the data and in further projects of similar nature. For example, the ROUGE similarity could be used in the data collection phase as a tool of automatic approval and rejection of workers’ assignments.

#### 4 Discussion and future work

During the initial trials of data collection we encountered some unexpected phenomena. For example, increasing the reward did have a positive effect in reducing the time it took for HITs to be completed, however it did not correlate in desirable way with data quality. Indeed the quality actually decreased with increasing reward. We believe that this unexpected result is due to the distributed nature of the worker pool in Mechanical Turk. Clearly the motivation of some workers is other than monetary reward. Especially if the HIT is interesting and can be completed in a short period of time, it seems that there are people willing to work on them even for free.

MTurk requesters cannot however rely on this voluntary workforce. From MTurk Forums it is clear that some of the workers rely on the money they get from completing the HITs. There seems to be a critical reward-threshold after which the “real workforce”, i.e. workers who are mainly interested in performing the HITs as fast as possible, starts to participate. When the motivation changes from voluntary participation to maximising the monetary gain, the quality of the obtained results often understandably suffers.

It would be ideal if a requester could rely on the voluntary workforce alone for results, but in many cases this may result either in too few workers and/or too slow a rate of data acquisition. Therefore it is often necessary to raise the reward and rely on efficient automatic validation of the data.

We have looked into the answer agreement of the workers as an experimental post-processing step. We believe that further work in this area will provide the tools required for automatic data quality control.

#### 5 Conclusions

In this paper we have described a dynamic and inexpensive method of collecting a corpus of questions and answers using the Amazon Mechanical Turk framework. We have provided to the community a corpus of questions, answers and corresponding documents, that we believe can be used in the development of QA-systems for why-questions. We propose that combining several answers from different people is an important factor in defining the “correct” answer to a why-question, and to that goal have included several answers for each question in the corpus.

We have also included data that we believe is valuable in post-processing the data: the work history of a single worker, the time spent on tasks, and the agreement on a single HIT between a set of different workers. We believe that this information, especially the answer agreement of workers, can be successfully used in post-processing and analysing the data, as well as automatically accepting and rejecting workers’ submissions in similar future data collection exercises.

## Abstract

We present a simple linguistically-motivated method for characterizing the semantic relations that hold between two nouns. The approach leverages the vast size of the Web in order to build lexically-specific features. The main idea is to look for verbs, prepositions, and coordinating conjunctions that can help make explicit the hidden relations between the target nouns. Using these features in instance-based classifiers, we demonstrate state-of-the-art results on various relational similarity problems, including mapping noun-modifier pairs to abstract relations like TIME, LOCATION and CONTAINER, characterizing noun-noun compounds in terms of abstract linguistic predicates like CAUSE, USE, and FROM, classifying the relations between nominals in context, and solving SAT verbal analogy problems. In essence, the approach puts together some existing ideas, showing that they apply generally to various semantic tasks, finding that verbs are especially useful features.

## 1 Introduction

Despite the tremendous amount of work on word similarity (see (Budanitsky and Hirst, 2006) for an overview), there is surprisingly little research on the important related problem of *relational similarity* – semantic similarity between pairs of words. Students who took the SAT test before 2005 or who

are taking the GRE test nowadays are familiar with an instance of this problem – verbal analogy questions, which ask whether, e.g., the relationship between *ostrich* and *bird* is more similar to that between *lion* and *cat*, or rather between *primate* and *monkey*. These analogies are difficult, and the average test taker gives a correct answer 57% of the time (Turney and Littman, 2005).

Many NLP applications could benefit from solving relational similarity problems, including but not limited to question answering, information retrieval, machine translation, word sense disambiguation, and information extraction. For example, a relational search engine like TextRunner, which serves queries like “find all X such that X causes wrinkles”, asking for all entities that are in a particular relation with a given entity (Cafarella et al., 2006), needs to recognize that *laugh wrinkles* is an instance of CAUSE-EFFECT. While there are not many success stories so far, measuring semantic similarity has proven its advantages for textual entailment (Tatu and Moldovan, 2005).

In this paper, we introduce a novel linguistically-motivated Web-based approach to relational similarity, which, despite its simplicity, achieves state-of-the-art performance on a number of problems. Following Turney (2006b), we test our approach on SAT verbal analogy questions and on mapping noun-modifier pairs to abstract relations like TIME, LOCATION and CONTAINER. We further apply it to (1) characterizing noun-noun compounds using abstract linguistic predicates like CAUSE, USE, and FROM, and (2) classifying the relation between pairs of nominals in context.

## 2 Related Work

### 2.1 Characterizing Semantic Relations

Turney and Littman (2005) characterize the relationship between two words as a vector with coordinates corresponding to the Web frequencies of 128 fixed phrases like “*X for Y*” and “*Y for X*” instantiated from a fixed set of 64 joining terms like *for*, *such as*, *not the*, *is* \*, etc. These vectors are used in a nearest-neighbor classifier to solve SAT verbal analogy problems, yielding 47% accuracy. The same approach is applied to classifying noun-modifier pairs: using the *Diverse* dataset of Nastase and Szpakowicz (2003), Turney&Littman achieve F-measures of 26.5% with 30 fine-grained relations, and 43.2% with 5 course-grained relations.

Turney (2005) extends the above approach by introducing the latent relational analysis (LRA), which uses automatically generated synonyms, learns suitable patterns, and performs singular value decomposition in order to smooth the frequencies. The full algorithm consists of 12 steps described in detail in (Turney, 2006b). When applied to SAT questions, it achieves the state-of-the-art accuracy of 56%. On the *Diverse* dataset, it yields an F-measure of 39.8% with 30 classes, and 58% with 5 classes.

Turney (2006a) presents an unsupervised algorithm for mining the Web for patterns expressing implicit semantic relations. For example, CAUSE (e.g., *cold virus*) is best characterized by “*Y \* causes X*”, and “*Y in \* early X*” is the best pattern for TEMPORAL (e.g., *morning frost*). With 5 classes, he achieves F-measure=50.2%.

### 2.2 Noun-Noun Compound Semantics

Lauer (1995) reduces the problem of noun compound interpretation to choosing the best paraphrasing preposition from the following set: *of*, *for*, *in*, *at*, *on*, *from*, *with* or *about*. He achieved 40% accuracy using corpus frequencies. This result was improved to 55.7% by Lapata and Keller (2005) who used Web-derived *n*-gram frequencies.

Barker and Szpakowicz (1998) use syntactic clues and the identity of the nouns in a nearest-neighbor classifier, achieving 60-70% accuracy.

Rosario and Hearst (2001) used a discriminative classifier to assign 18 relations for noun compounds from biomedical text, achieving 60% accuracy.

Rosario et al. (2002) reported 90% accuracy with a “descent of hierarchy” approach which characterizes the relationship between the nouns in a bio-science noun-noun compound based on the MeSH categories the nouns belong to.

Girju et al. (2005) apply both classic (SVM and decision trees) and novel supervised models (semantic scattering and iterative semantic specialization), using *WordNet*, word sense disambiguation, and a set of linguistic features. They test their system against both Lauer’s 8 prepositional paraphrases and another set of 21 semantic relations, achieving up to 54% accuracy on the latter.

In a previous work (Nakov and Hearst, 2006), we have shown that the relationship between the nouns in a noun-noun compound can be characterized using verbs extracted from the Web, but we provided no formal evaluation.

Kim and Baldwin (2006) characterized the semantic relationship in a noun-noun compound using the verbs connecting the two nouns by comparing them to predefined seed verbs. Their approach is highly resource intensive (uses *WordNet*, *CoreLex* and *Moby’s thesaurus*), and is quite sensitive to the seed set of verbs: on a collection of 453 examples and 19 relations, they achieved 52.6% accuracy with 84 seed verbs, but only 46.7% with 57 seed verbs.

### 2.3 Paraphrase Acquisition

Our method of extraction of paraphrasing verbs and prepositions is similar to previous paraphrase acquisition approaches. Lin and Pantel (2001) extract paraphrases from dependency tree paths whose ends contain semantically similar sets of words by generalizing over these ends. For example, given “*X solves Y*”, they extract paraphrases like “*X finds a solution to Y*”, “*X tries to solve Y*”, “*X resolves Y*”, “*Y is resolved by X*”, etc. The approach is extended by Shinyama et al. (2002), who use named entity recognizers and look for anchors belonging to matching semantic classes, e.g., LOCATION, ORGANIZATION. The idea is further extended by Nakov et al. (2004), who apply it in the biomedical domain, imposing the additional restriction that the sentences from which the paraphrases are extracted cite the same target paper.

## 2.4 Word Similarity

Another important group of related work is on using syntactic dependency features in a vector-space model for measuring *word* similarity, e.g., (Alshawi and Carter, 1994), (Grishman and Sterling, 1994), (Ruge, 1992), and (Lin, 1998). For example, given a noun, Lin (1998) extracts verbs that have that noun as a subject or object, and adjectives that modify it.

## 3 Method

Given a pair of nouns, we try to characterize the semantic relation between them by leveraging the vast size of the Web to build linguistically-motivated lexically-specific features. We mine the Web for sentences containing the target nouns, and we extract the connecting verbs, prepositions, and coordinating conjunctions, which we use in a vector-space model to measure relational similarity.

The process of extraction starts with exact phrase queries issued against a Web search engine (*Google*) using the following patterns:

“*infl*<sub>1</sub> THAT \* *infl*<sub>2</sub>”  
 “*infl*<sub>2</sub> THAT \* *infl*<sub>1</sub>”  
 “*infl*<sub>1</sub> \* *infl*<sub>2</sub>”  
 “*infl*<sub>2</sub> \* *infl*<sub>1</sub>”

where: *infl*<sub>1</sub> and *infl*<sub>2</sub> are inflected variants of *noun*<sub>1</sub> and *noun*<sub>2</sub> generated using the *Java WordNet Library*<sup>1</sup>; THAT is a complementizer and can be *that*, *which*, or *who*; and \* stands for 0 or more (up to 8) instances of *Google*’s star operator.

The first two patterns are subsumed by the last two and are used to obtain more sentences from the search engine since including e.g. *that* in the query changes the set of returned results and their ranking.

For each query, we collect the text snippets from the result set (up to 1,000 per query). We split them into sentences, and we filter out all incomplete ones and those that do not contain the target nouns. We further make sure that the word sequence following the second mentioned target noun is nonempty and contains at least one nonnoun, thus ensuring the snippet includes the entire noun phrase: snippets representing incomplete sentences often end with a period anyway. We then perform POS tagging using the *Stanford POS tagger* (Toutanova et al., 2003)

<sup>1</sup>JWNL: <http://jwordnet.sourceforge.net>

Freq.	Feature	POS	Direction
2205	of	P	2 → 1
1923	be	V	1 → 2
771	include	V	1 → 2
382	serve on	V	2 → 1
189	chair	V	2 → 1
189	have	V	1 → 2
169	consist of	V	1 → 2
148	comprise	V	1 → 2
106	sit on	V	2 → 1
81	be chaired by	V	1 → 2
78	appoint	V	1 → 2
77	on	P	2 → 1
66	and	C	1 → 2
66	be elected	V	1 → 2
58	replace	V	1 → 2
48	lead	V	2 → 1
47	be intended for	V	1 → 2
45	join	V	2 → 1
...	...	...	...
4	be signed up for	V	2 → 1

Table 1: **The most frequent Web-derived features for *committee member*.** Here *V* stands for verb (possibly +preposition and/or +particle), *P* for preposition and *C* for coordinating conjunction; 1 → 2 means *committee* precedes the feature and *member* follows it; 2 → 1 means *member* precedes the feature and *committee* follows it.

and shallow parsing with the *OpenNLP tools*<sup>2</sup>, and we extract the following types of features:

**Verb:** We extract a verb if the subject NP of that verb is headed by one of the target nouns (or an inflected form), and its direct object NP is headed by the other target noun (or an inflected form). For example, the verb *include* will be extracted from “The *committee* includes many *members*.” We also extract verbs from relative clauses, e.g., “This is a *committee* which includes many *members*.” Verb particles are also recognized, e.g., “The *committee* must rotate off 1/3 of its *members*.” We ignore modals and auxiliaries, but retain the passive *be*. Finally, we lemmatize the main verb using *WordNet*’s morphological analyzer *Morphy* (Fellbaum, 1998).

**Verb+Preposition:** If the subject NP of a verb is headed by one of the target nouns (or an inflected form), and its indirect object is a PP containing an NP which is headed by the other target noun (or an inflected form), we extract the verb and the preposi-

<sup>2</sup>OpenNLP: <http://opennlp.sourceforge.net>

tion heading that PP, e.g., “The thesis advisory *committee* consists of three qualified *members*.” As in the verb case, we extract verb+preposition from relative clauses, we include particles, we ignore modals and auxiliaries, and we lemmatize the verbs.

**Preposition:** If one of the target nouns is the head of an NP containing a PP with an internal NP headed by the other target noun (or an inflected form), we extract the preposition heading that PP, e.g., “The *members of the committee* held a meeting.”

**Coordinating conjunction:** If the two target nouns are the heads of coordinated NPs, we extract the coordinating conjunction.

In addition to the lexical part, for each extracted feature, we keep a direction. Therefore the preposition *of* represents two different features in the following examples “*member of the committee*” and “*committee of members*”. See Table 1 for examples.

We use the above-described features to calculate relational similarity, i.e., similarity between pairs of nouns. In order to downweight very common features like *of*, we use TF.IDF-weighting:

$$w(x) = TF(x) \times \log \left( \frac{N}{DF(x)} \right) \quad (1)$$

In the above formula,  $TF(x)$  is the number of times the feature  $x$  has been extracted for the target noun pair,  $DF(x)$  is the total number of training noun pairs that have that feature, and  $N$  is the total number of training noun pairs.

Given two nouns and their TF.IDF-weighted frequency vectors  $A$  and  $B$ , we calculate the similarity between them using the following generalized variant of the Dice coefficient:

$$Dice(A, B) = \frac{2 \times \sum_{i=1}^n \min(a_i, b_i)}{\sum_{i=1}^n a_i + \sum_{i=1}^n b_i} \quad (2)$$

Other variants are also possible, e.g., Lin (1998).

## 4 Relational Similarity Experiments

### 4.1 SAT Verbal Analogy

Following Turney (2006b), we use *SAT verbal analogy* as a benchmark problem for relational similarity. We experiment with the 374 SAT questions collected by Turney and Littman (2005). Table 2 shows two sample questions: the top word pairs

<b>ostrich:bird</b>		<b>palatable:toothsome</b>	
(a)	<i>lion:cat</i>	(a)	rancid:fragrant
(b)	goose:flock	(b)	chewy:textured
(c)	ewe:sheep	(c)	<i>coarse:rough</i>
(d)	cub:bear	(d)	solitude:company
(e)	primate:monkey	(e)	no choice

Table 2: **SAT verbal analogy: sample questions.** The stem is in **bold**, the correct answer is in *italic*, and the distractors are in plain text.

are called *stems*, the ones in italic are the *solutions*, and the remaining ones are *distractors*. Turney (2006b) achieves 56% accuracy on this dataset, which matches the average human performance of 57%, and represents a significant improvement over the 20% random-guessing baseline.

Note that the righthand side example in Table 2 is missing one distractor; so do 21 questions. The dataset also mixes different parts of speech: while *solitude* and *company* are nouns, all remaining words are adjectives. Other examples contain verbs and adverbs, and even relate pairs of different POS. This is problematic for our approach, which requires that both words be nouns<sup>3</sup>. After having filtered all examples containing nonnouns, we ended up with 184 questions, which we used in the evaluation.

Given a verbal analogy example, we build six feature vectors – one for each of the six word pairs. We then calculate the relational similarity between the stem of the analogy and each of the five candidates, and we choose the pair with the highest score; we make no prediction in case of a tie.

The evaluation results for a leave-one-out cross-validation are shown in Table 3. We also show 95%-confidence intervals for the accuracy. The last line in the table shows the performance of Turney’s LRA when limited to the 184 noun-only examples. Our best model  $v + p + c$  performs a bit better, 71.3% vs. 67.4%, but the difference is not statistically significant. However, this “inferred” accuracy could be misleading, and the LRA could have performed better if it was restricted to solve *noun-only* analogies, which seem easier than the general ones, as demonstrated by the significant increase in accuracy for LRA when limited to nouns: 67.4% vs. 56%.

<sup>3</sup>It can be extended to handle adjective-noun pairs as well, as demonstrated in section 4.2 below.

Model	✓	×	∅	Accuracy	Cover.
$v + p + c$	129	52	3	<b>71.3±7.0</b>	<b>98.4</b>
$v$	122	56	6	68.5±7.2	96.7
$v + p$	119	61	4	66.1±7.2	97.8
$v + c$	117	62	5	65.4±7.2	97.3
$p + c$	90	90	4	50.0±7.2	97.8
$p$	84	94	6	47.2±7.2	96.7
baseline	37	147	0	20.0±5.2	100.0
LRA	122	59	3	67.4±7.1	98.4

Table 3: **SAT verbal analogy: 184 noun-only examples.**  $v$  stands for verb,  $p$  for preposition, and  $c$  for coordinating conjunction. For each model, the number of correct (✓), wrong (×), and nonclassified examples (∅) is shown, followed by accuracy and coverage (in %s).

Model	✓	×	∅	Accuracy	Cover.
$v + p$	240	352	8	<b>40.5±3.9</b>	<b>98.7</b>
$v + p + c$	238	354	8	40.2±3.9	98.7
$v$	234	350	16	40.1±3.9	97.3
$v + c$	230	362	8	38.9±3.8	98.7
$p + c$	114	471	15	19.5±3.0	97.5
$p$	110	475	15	19.1±3.0	97.5
baseline	49	551	0	8.2±1.9	100.0
LRA	239	361	0	39.8±3.8	100.0

Table 4: **Head-modifier relations, 30 classes:** evaluation on the *Diverse* dataset, micro-averaged (in %s).

## 4.2 Head-Modifier Relations

Next, we experiment with the *Diverse* dataset of Barker and Szpakowicz (1998), which consists of 600 head-modifier pairs: noun-noun, adjective-noun and adverb-noun. Each example is annotated with one of 30 fine-grained relations, which are further grouped into the following 5 coarse-grained classes (the fine-grained relations are shown in parentheses): CAUSALITY (*cause, effect, purpose, detraction*), TEMPORALITY (*frequency, time\_at, time\_through*), SPATIAL (*direction, location, location\_at, location\_from*), PARTICIPANT (*agent, beneficiary, instrument, object, object\_property, part, possessor, property, product, source, stative, whole*) and QUALITY (*container, content, equative, material, measure, topic, type*). For example, *exam anxiety* is classified as *effect* and therefore as CAUSALITY, and *blue book* is *property* and therefore also PARTICIPANT.

Some examples in the dataset are problematic for our method. First, in three cases, there are two mod-

ifiers, e.g., *infectious disease agent*, and we had to ignore the first one. Second, seven examples have an adverb modifier, e.g., *daily exercise*, and 262 examples have an adjective modifier, e.g., *tiny cloud*. We treat them as if the modifier was a noun, which works in many cases, since many adjectives and adverbs can be used predicatively, e.g., ‘*This exercise is performed daily.*’ or ‘*This cloud looks very tiny.*’

For the evaluation, we created a feature vector for each head-modifier pair, and we performed a leave-one-out cross-validation: we left one example for testing and we trained on the remaining 599 ones, repeating this procedure 600 times so that each example be used for testing. Following Turney and Littman (2005) we used a 1-nearest-neighbor classifier. We calculated the similarity between the feature vector of the testing example and each of the training examples’ vectors. If there was a unique most similar training example, we predicted its class, and if there were ties, we chose the class predicted by the majority of tied examples, if there was a majority.

The results for the 30-class *Diverse* dataset are shown in Table 4. Our best model achieves 40.5% accuracy, which is slightly better than LRA’s 39.8%, but the difference is not statistically significant.

Table 4 shows that the verbs are the most important features, yielding about 40% accuracy regardless of whether used alone or in combination with prepositions and/or coordinating conjunctions; not using them results in 50% drop in accuracy.

The reason coordinating conjunctions do not help is that head-modifier relations are typically expressed with verbal or prepositional paraphrases. Therefore, coordinating conjunctions only help with some infrequent relations like *equative*, e.g., *finding player and coach* on the Web suggests an equative relation for *player coach* (and for *coach player*).

As Table 3 shows, this is different for SAT verbal analogy, where verbs are still the most important feature type and the only whose presence/absence makes a statistical difference. However, this time coordinating conjunctions (with prepositions) do help a bit (the difference is not statistically significant) since SAT verbal analogy questions ask for a broader range of relations, e.g., antonymy, for which coordinating conjunctions like *but* are helpful.

Model	Accuracy
$v + p + c + sent + query$ (type <i>C</i> )	<b>68.1±4.0</b>
$v$	67.9±4.0
$v + p + c$	67.8±4.0
$v + p + c + sent$ (type <i>A</i> )	<b>67.3±4.0</b>
$v + p$	66.9±4.0
$sent$ (sentence words only)	59.3±4.2
$p$	58.4±4.2
Baseline (majority class)	57.0±4.2
$v + p + c + sent + query$ ( <i>C</i> ), 8 stars	67.0±4.0
$v + p + c + sent$ ( <i>A</i> ), 8 stars	65.4±4.1
Best type <i>C</i> on <i>SemEval</i>	67.0±4.0
Best type <i>A</i> on <i>SemEval</i>	66.0±4.1

Table 5: **Relations between nominals:** evaluation on the *SemEval* dataset. Accuracy is macro-averaged (in %s), up to 10 *Google* stars are used unless otherwise stated.

### 4.3 Relations Between Nominals

We further experimented with the *SemEval'07* task 4 dataset (Girju et al., 2007), where each example consists of a sentence, a target semantic relation, two nominals to be judged on whether they are in that relation, manually annotated *WordNet* senses, and the Web query used to obtain the sentence:

```
"Among the contents of the
<e1>vessel</e1> were a set of
carpenter's <e2>tools</e2>, several
large storage jars, ceramic utensils,
ropes and remnants of food, as well
as a heavy load of ballast stones."
WordNet(e1) = "vessel%1:06:00::",
WordNet(e2) = "tool%1:06:00::",
Content-Container(e2, e1) = "true",
Query = "contents of the * were a"
```

The following nonexhaustive and possibly overlapping relations are possible: Cause-Effect (e.g., *hormone-growth*), Instrument-Agency (e.g., *laser-printer*), Theme-Tool (e.g., *workforce*), Origin-Entity (e.g., *grain-alcohol*), Content-Container (e.g., *bananas-basket*), Product-Producer (e.g., *honey-bee*), and Part-Whole (e.g., *leg-table*). Each relation is considered in isolation; there are 140 training and at least 70 test examples per relation.

Given an example, we reduced the target entities  $e_1$  and  $e_2$  to single nouns by retaining their heads only. We then mined the Web for sentences con-

taining these nouns, and we extracted the above-described feature types: verbs, prepositions and coordinating conjunctions. We further used the following problem-specific contextual feature types:

**Sentence words:** after stop words removal and stemming with the Porter (1980) stemmer;

**Entity words:** lemmata of the words in  $e_1$  and  $e_2$ ;

**Query words:** words part of the query string.

Each feature type has a specific prefix which prevents it from mixing with other feature types; the last feature type is used for type *C* only (see below).

The *SemEval* competition defines four types of systems, depending on whether the manually annotated *WordNet* senses and the *Google* query are used: *A* (WordNet=no, Query=no), *B* (WordNet=yes, Query=no), *C* (WordNet=no, Query=yes), and *D* (WordNet=yes, Query=yes). We experimented with types *A* and *C* only since we believe that having the manually annotated *WordNet* sense keys is an unrealistic assumption for a real-world application.

As before, we used a 1-nearest-neighbor classifier with TF.IDF-weighting, breaking ties by predicting the majority class on the training data. The evaluation results are shown in Table 5. We studied the effect of different subsets of features and of more *Google* star operators. As the table shows, using up to ten *Google* stars instead of up to eight (see section 3) yields a slight improvement in accuracy for systems of both type *A* (65.4% vs. 67.3%) and type *C* (67.0% vs. 68.1%). Both results represent a statistically significant improvement over the majority class baseline and over using sentence words only, and a slight improvement over the best type *A* and type *C* systems on *SemEval'07*, which achieved 66% and 67% accuracy, respectively.<sup>4</sup>

### 4.4 Noun-Noun Compound Relations

The last dataset we experimented with is a subset of the 387 examples listed in the appendix of (Levi, 1978). Levi's theory is one of the most important linguistic theories of the syntax and semantics of *complex nominals* – a general concept grouping

<sup>4</sup>The best type *B* system on *SemEval* achieved 76.3% accuracy using the manually-annotated *WordNet* senses in context for each example, which constitutes an additional data source, as opposed to an additional resource. The systems that used *WordNet* as a resource only, i.e., ignoring the manually annotated senses, were classified as type *A* or *C*. (Girju et al., 2007)

Model	USING THAT				NOT USING THAT			
	Accuracy	Cover.	ANF	ASF	Accuracy	Cover.	ANF	ASF

Table 6: **Noun-noun compound relations, 12 classes:** evaluation on *Levi-214* dataset. Shown are micro-averaged accuracy and coverage in %s, followed by average number of features (ANF) and average sum of feature frequencies (ASF) per example. The righthand side reports the results when the query patterns involving THAT were not used. For comparison purposes, the top rows show the performance with the human-proposed verbs used as features.

together the partially overlapping classes of nominal compounds (e.g., *peanut butter*), nominalizations (e.g., *dream analysis*), and nonpredicate noun phrases (e.g., *electric shock*).

In Levi’s theory, complex nominals can be derived from relative clauses by removing one of the following 12 abstract predicates: CAUSE<sub>1</sub> (e.g., *tear gas*), CAUSE<sub>2</sub> (e.g., *drug deaths*), HAVE<sub>1</sub> (e.g., *apple cake*), HAVE<sub>2</sub> (e.g., *lemon peel*), MAKE<sub>1</sub> (e.g., *silkworm*), MAKE<sub>2</sub> (e.g., *snowball*), USE (e.g., *steam iron*), BE (e.g., *soldier ant*), IN (e.g., *field mouse*), FOR (e.g., *horse doctor*), FROM (e.g., *olive oil*), and ABOUT (e.g., *price war*). In the resulting nominals, the modifier is typically the object of the predicate; when it is the subject, the predicate is marked with the index 2. The second derivational mechanism in the theory is nominalization; it produces nominals whose head is a nominalized verb.

Since we are interested in noun compounds only, we manually cleansed the set of 387 examples. We first excluded all concatenations (e.g., *silkworm*) and examples with adjectival modifiers (e.g., *electric shock*), thus obtaining 250 noun-noun compounds (*Levi-250* dataset). We further filtered out all nominalizations for which the dataset provides no abstract predicate (e.g., *city planner*), thus ending up with 214 examples (*Levi-214* dataset).

As in the previous experiments, for each of the 214 noun-noun compounds, we mined the Web for sentences containing both target nouns, from which we extracted paraphrasing verbs, prepositions

and coordinating conjunctions. We then performed leave-one-out cross-validation experiments with a 1-nearest-neighbor classifier, trying to predict the correct predicate for the testing example. The results are shown in Table 6. As we can see, using prepositions alone yields about 33% accuracy, which is a statistically significant improvement over the majority-class baseline. Overall, the most important features are the verbs: they yield 45.8% accuracy when used alone, and 50% together with prepositions. Adding coordinating conjunctions helps a bit with verbs, but not with prepositions. Note however that none of the differences between the different feature combinations involving verbs are statistically significant.

The righthand side of the table reports the results when the query patterns involving THAT (see section 3) were not used. We can observe a small 1-3% drop in accuracy for all models involving verbs, but it is not statistically significant.

We also show the average number of distinct features and sum of feature counts per example: as we can see, there is a strong positive correlation between number of features and accuracy.

## 5 Comparison to Human Judgments

Since in all above tasks the most important features were the verbs, we decided to compare our Web-derived verbs to human-proposed ones for all noun-noun compounds in the *Levi-250* dataset. We asked human subjects to produce verbs, possibly

followed by prepositions, that could be used in a paraphrase involving *that*. For example, *olive oil* can be paraphrased as ‘*oil that comes from olives*’, ‘*oil that is obtained from olives*’ or ‘*oil that is from olives*’. Note that this implicitly allows for prepositional paraphrases – when the verb is to *be* and is followed by a preposition, as in the last paraphrase.

We used the *Amazon Mechanical Turk* Web service<sup>5</sup> to recruit human subjects, and we instructed them to propose at least three paraphrasing verbs per noun-noun compound, if possible. We randomly distributed the noun-noun compounds into groups of 5 and we requested 25 different human subjects per group. Each human subject was allowed to work on any number of groups, but not on the same one twice. A total of 174 different human subjects produced 19,018 verbs. After filtering the bad submissions and normalizing the verbs, we ended up with 17,821 verbs. See (Nakov, 2007) for further details on the process of extraction and cleansing. The dataset itself is freely available (Nakov, 2008).

We compared the human-proposed and the Web-derived verbs for *Levi-214*, aggregated by relation. Given a relation, we collected all verbs belonging to noun-noun compounds from that relation together with their frequencies. From a vector-space model point of view, we summed their corresponding frequency vectors. We did this separately for the human- and the program-generated verbs, and we compared the resulting vectors using Dice coefficient with TF.IDF, calculated as before. Figure 1 shows the cosine correlations using all human-proposed verbs and the first verb from each judge. We can see a very-high correlation (mid-70% to mid-90%) for relations like CAUSE<sub>1</sub>, MAKE<sub>1</sub>, BE, but low correlations of 11-30% for reverse relations like HAVE<sub>2</sub> and MAKE<sub>2</sub>. Interestingly, using the first verb only improves the results for highly-correlated relations, but negatively affects low-correlated ones.

Finally, we repeated the cross-validation experiment with the *Levi-214* dataset, this time using the human-proposed verbs<sup>6</sup> as features. As Table 6 shows, we achieved 78.4% accuracy using all verbs (and and 72.3% with the first verb from each worker), which is a statistically significant improve-

<sup>5</sup><http://www.mturk.com>

<sup>6</sup>Note that the human subjects proposed their verbs without any context and independently of our Web-derived sentences.

Figure 1: **Cosine correlation (in %s) between the human- and the program- generated verbs by relation:** using all human-proposed verbs vs. the first verb.

ment over the 50% of our best Web-based model. This result is strong for a 12-way classification problem, and confirms our observation that verbs and prepositions are among the most important features for relational similarity problems. It further suggests that the human-proposed verbs might be an upper bound on the accuracy that could be achieved with automatically extracted features.

## 6 Conclusions and Future Work

We have presented a simple approach for characterizing the relation between a pair of nouns in terms of linguistically-motivated features which could be useful for many NLP tasks. We found that verbs were especially useful features for this task. An important advantage of the approach is that it does not require knowledge about the semantics of the individual nouns. A potential drawback is that it might not work well for low-frequency words.

The evaluation on several relational similarity problems, including SAT verbal analogy, head-modifier relations, and relations between complex nominals has shown state-of-the-art performance. The presented approach can be further extended to other combinations of parts of speech: not just noun-noun and adjective-noun. Using a parser with a richer set of syntactic dependency features, e.g., as proposed by Padó and Lapata (2007), is another promising direction for future work.

## Abstract

Rapid and inexpensive techniques for automatic transcription of speech have the potential to dramatically expand the types of content to which information retrieval techniques can be productively applied, but limitations in accuracy and robustness must be overcome before that promise can be fully realized. Combining retrieval results from systems built on various errorful representations of the same collection offers some potential to address these challenges. This paper explores that potential by applying Generalized Additive Models to optimize the combination of ranked retrieval results obtained using transcripts produced automatically for the same spoken content by substantially different recognition systems. Topic-averaged retrieval effectiveness better than any previously reported for the same collection was obtained, and even larger gains are apparent when using an alternative measure emphasizing results on the most difficult topics.

## 1 Introduction

Speech retrieval, like other tasks that require transforming the representation of language, suffers from both random and systematic errors that are introduced by the speech-to-text transducer. Limitations in signal processing, acoustic modeling, pronunciation, vocabulary, and language modeling can be accommodated in several ways, each of which make different trade-offs and thus induce different

error characteristics. Moreover, different applications produce different types of challenges and different opportunities. As a result, optimizing a single recognition system for all transcription tasks is well beyond the reach of present technology, and even systems that are apparently similar on average can make different mistakes on different sources. A natural response to this challenge is to combine retrieval results from multiple systems, each imperfect, to achieve reasonably robust behavior over a broader range of tasks. In this paper, we compare alternative ways of combining these ranked lists. Note, we do not assume access to the internal workings of the recognition systems, or even to the transcripts produced by those systems.

System combination has a long history in information retrieval. Most often, the goal is to combine results from systems that search different content (“collection fusion”) or to combine results from different systems on the same content (“data fusion”). When working with multiple *transcriptions* of the same content, we are again presented with new opportunities. In this paper we compare some well known techniques for combination of retrieval results with a new evidence combination technique based on a general framework known as *Generalized Additive Models* (GAMs). We show that this new technique significantly outperforms several well known information retrieval fusion techniques, and we present evidence that it is the ability of GAMs to combine inputs non-linearly that at least partly explains our improvements.

The remainder of this paper is organized as follows. We first review prior work on evidence com-

\* Dept. of Mathematics/AMSC, UMD

† College of Information Studies, UMD

bination in information retrieval in Section 2, and then introduce Generalized Additive Models in Section 3. Section 4 describes the design of our experiments with a 589 hour collection of conversational speech for which information retrieval queries and relevance judgments are available. Section 5 presents the results of our experiments, and we conclude in Section 6 with a brief discussion of implications of our results and the potential for future work on this important problem.

## 2 Previous Work

One approach for combining ranked retrieval results is to simply linearly combine the multiple system scores for each topic and document. This approach has been extensively applied in the literature (Bartell et al., 1994; Callan et al., 1995; Powell et al., 2000; Vogt and Cottrell, 1999), with varying degrees of success, owing in part to the potential difficulty of normalizing scores across retrieval systems. In this study, we partially abstract away from this potential difficulty by using the same retrieval system on both representations of the collection documents (so that we don't expect score distributions to be significantly different for the combination inputs).

Of course, many fusion techniques using more advanced score normalization methods have been proposed. Shaw and Fox (1994) proposed a number of such techniques, perhaps the most successful of which is known as CombMNZ. CombMNZ has been shown to achieve strong performance and has been used in many subsequent studies (Lee, 1997; Montague and Aslam, 2002; Beitzel et al., 2004; Lillis et al., 2006). In this study, we also use CombMNZ as a baseline for comparison, and following Lillis et al. (2006) and Lee (1997), compute it in the following way. First, we normalize each score  $s_i$  as  $norm(s_i) = \frac{s_i - min(s)}{max(s) - min(s)}$ , where  $max(s)$  and  $min(s)$  are the maximum and minimum scores seen in the input result list. After normalization, the CombMNZ score for a document  $d$  is computed as

$$CombMNZ_d = \sum_{\ell} N_{s,d} \times |N_d > 0|.$$

Here,  $\mathcal{L}$  is the number of ranked lists to be combined,  $N_{\ell,d}$  is the normalized score of document  $d$

in ranked list  $\ell$ , and  $|N_d > 0|$  is the number of non-zero normalized scores given to  $d$  by any result set.

Manmatha et al. (2001) showed that retrieval scores from IR systems could be modeled using a Normal distribution for relevant documents and exponential distribution for non-relevant documents. However, in their study, fusion results using these comparatively complex normalization approaches achieved performance no better than the much simpler CombMNZ.

A simple rank-based fusion technique is *interleaving* (Voorhees et al., 1994). In this approach, the highest ranked document from each list is taken in turn (ignoring duplicates) and placed at the top of the new, combined list.

Many probabilistic combination approaches have also been developed, a recent example being Lillis et al. (2006). Perhaps the most closely related proposal, using logistic regression, was made first by Savoy et al. (1988). Logistic regression is one example from the broad class of models which GAMs encompass. Unlike GAMs in their full generality however, logistic regression imposes a comparatively high degree of linearity in the model structure.

### 2.1 Combining speech retrieval results

Previous work on single-collection result fusion has naturally focused on combining results from multiple retrieval systems. In this case, the potential for performance improvements depends critically on the uniqueness of the different input systems being combined. Accordingly, small variations in the same system often do not combine to produce results better than the best of their inputs (Beitzel et al., 2004).

Errorful document collections such as conversational speech introduce new difficulties and opportunities for data fusion. This is so, in particular, because even the same system can produce drastically different retrieval results when multiple representations of the documents (e.g., multiple transcript hypotheses) are available. Consider, for example, Figure 1 which shows, for each term in each of our title queries, the proportion of relevant documents containing that term *in only one* of our two transcript hypotheses. Critically, by plotting this proportion against the term's inverse document frequency, we observe that the most discriminative query terms are often not available in both document represen-

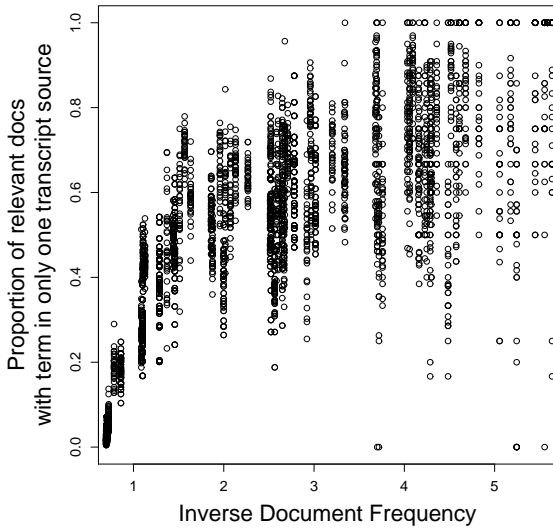

Figure 1: For each term in each query, the proportion of relevant documents containing the term vs. inverse document frequency. For increasingly discriminative terms (higher *idf*), we observe that the probability of only one transcript containing the term increases dramatically.

tations. As these high-*idf* terms make large contributions to retrieval scores, this suggests that even an identical retrieval system may return a large score using one transcript hypothesis, and yet a very low score using another. Accordingly, a linear combination of scores is unlikely to be optimal.

A second example illustrates the difficulty. Suppose recognition system *A* can recognize a particular high-*idf* query term, but system *B* never can. In the extreme case, the term may simply be out of vocabulary, although this may occur for various other reasons (e.g., poor language modeling or pronunciation dictionaries). Here again, a linear combination of scores will fail, as will rank-based interleaving. In the latter case, we will alternate between taking a plausible document from system *A* and an inevitably worse result from the crippled system *B*.

As a potential solution for these difficulties, we consider the use of generalized additive models for retrieval fusion.

### 3 Generalized Additive Models

*Generalized Additive Models* (GAMs) are a generalization of *Generalized Linear Models* (GLMs),

while GLMs are a generalization of the well known linear model. In a GLM, the distribution of an observed random variable  $Y_i$  is related to the linear predictor  $\eta_i$  through a smooth monotonic *link function*  $g$ ,

$$g(\mu_i) = \eta_i = \mathbf{X}_i\beta.$$

Here,  $\mathbf{X}_i$  is the  $i^{\text{th}}$  row of the model matrix  $\mathbf{X}$  (one set of observations corresponding to one observed  $y_i$ ) and  $\beta$  is a vector of unknown parameters to be learned from the data. If we constrain our link function  $g$  to be the identity transformation, and assume  $Y_i$  is Normal, then our GLM reduces to a simple linear model.

But GLMs are considerably more versatile than linear models. First, rather than only the Normal distribution, the response  $Y_i$  is free to have any distribution belonging to the exponential family of distributions such as the Binomial, Normal, Gamma, and Poisson. Secondly, by allowing non-identity link functions  $g$ , some degree of non-linearity may be incorporated in the model structure.

A well known GLM in the NLP community is *logistic regression* (which may alternatively be derived as a maximum entropy classifier). In logistic regression, the response is assumed to be Binomial and the chosen link function is the logit transformation,

$$g(\mu_i) = \text{logit}(\mu_i) = \log\left(\frac{\mu_i}{1 - \mu_i}\right)$$

Generalized additive models allow for additional model flexibility by allowing the linear predictor to now also contain learned smooth functions  $f_j$  of the covariates  $x_k$ . For example,

$$g(\mu_i) = \mathbf{X}_i^*\theta + f_1(x_{1i}) + f_2(x_{2i}) + f_3(x_{3i}, x_{4i}).$$

As in a GLM,  $\mu_i \equiv \mathbb{E}(Y_i)$  and  $Y_i$  belongs to the exponential family. Strictly parametric model components are still permitted, which we represent as a row of the model matrix  $\mathbf{X}_i^*$  (with associated parameters  $\theta$ ).

GAMs may be thought of as GLMs where one or more covariate has been transformed by a basis expansion,  $f(x) = \sum_j^q b_j(x)\beta_j$ . Given a set of  $q$  basis functions  $b_j$  spanning a  $q$ -dimensional space

of smooth transformations, we are back to the linear problem of learning coefficients  $\beta_j$  which “optimally” fit the data. If we knew the appropriate transformation of our covariates (say the logarithm), we could simply apply it ourselves. GAMs allow us to learn these transformations from the data, when we expect some transformation to be useful but don’t know its form *a priori*. In practice, these smooth functions may be represented and the model parameters may be learned in various ways. In this work, we use the excellent open source package `mgcv` (Wood, 2006), which uses penalized likelihood maximization to prevent arbitrarily “wiggly” smooth functions (i.e., overfitting). Smooths (including multidimensional smooths) are represented by thin plate regression splines (Wood, 2003).

### 3.1 Combining speech retrieval results with GAMs

The chief difficulty introduced in combining ranked speech retrieval results is the severe disagreement introduced by differing document hypotheses. As we saw in Figure 1, it is often the case that the most discriminative query terms occur in only one transcript source.

#### 3.1.1 GLM with factors

Our first new approach for handling differences in transcripts is an extension of the logistic regression model previously used in data fusion work, (Savoy et al., 1988). Specifically, we augment the model with the first-order interaction of scores  $x_1x_2$  and the factor  $\alpha_i$ , so that

$$\text{logit}\{\mathbb{E}(R_i)\} = \beta_0 + \alpha_i + x_1\beta_1 + x_2\beta_2 + x_1x_2\beta_3,$$

where the relevance  $R_i \sim \text{Binomial}$ . A factor is essentially a learned intercept for different subsets of the response. In this case,

$$\alpha_i = \begin{cases} \beta_{BOTH} & \text{if both representations matched } q_i \\ \beta_{IBM} & \text{only } d_{i,IBM} \text{ matched } q_i \\ \beta_{BBN} & \text{only } d_{i,BBN} \text{ matched } q_i \end{cases}$$

where  $\alpha_i$  corresponds to data row  $i$ , with associated document representations  $d_{i,source}$  and query  $q_i$ . The intuition is simply that we’d like our model to have different biases for or against relevance

based on which transcript source retrieved the document. This is a small-dimensional way of dampening the effects of significant disagreements in the document representations.

#### 3.1.2 GAM with multidimensional smooth

If a document’s score is large in both systems, we expect it to have high probability of relevance. However, as a document’s score increases linearly in one source, we have no reason to expect its probability of relevance to also increase linearly. Moreover, because the most discriminative terms are likely to be found in only one transcript source, even an absent score for a document does not ensure a document is not relevant. It is clear then that the mapping from document scores to probability of relevance is in general a complex nonlinear surface. The limited degree of nonlinear structure afforded to GLMs by non-identity link functions is unlikely to sufficiently capture this intuition.

Instead, we can model this non-linearity using a generalized additive model with multidimensional smooth  $f(x_{IBM}, x_{BBN})$ , so that

$$\text{logit}\{\mathbb{E}(R_i)\} = \beta_0 + f(x_{IBM}, x_{BBN}).$$

Again,  $R_i \sim \text{Binomial}$  and  $\beta_0$  is a learned intercept (which, alternatively, may be absorbed by the smooth  $f$ ).

Figure 2 shows the smoothing transformation  $f$  learned during our evaluation. Note the small decrease in predicted probability of relevance as the retrieval score from one system decreases, while the probability curves upward again as the disagreement increases. This captures our intuition that systems often disagree strongly because discriminative terms are often not recognized in all transcript sources.

We can think of the probability of relevance mapping learned by the factor model of Section 3.1.1 as also being a surface defined over the space of input document scores. That model, however, was constrained to be linear. It may be visualized as a collection of affine planes (with common normal vectors, but each shifted upwards by their factor level’s weight and the common intercept).

## 4 Experiments

### 4.1 Dataset

Our dataset is a collection of 272 oral history interviews from the MALACH collection. The task is to retrieve short speech segments which were manually designated as being topically coherent by professional indexers. There are 8,104 such segments (corresponding to roughly 589 hours of conversational speech) and 96 assessed topics. We follow the topic partition used for the 2007 evaluation by the Cross Language Evaluation Forum’s cross-language speech retrieval track (Pecina et al., 2007). This gives us 63 topics on which to train our combination systems and 33 topics for evaluation.

### 4.2 Evaluation

#### 4.2.1 Geometric Mean Average Precision

Average precision (AP) is the average of the precision values obtained after each document relevant to a particular query is retrieved. To assess the effectiveness of a system across multiple queries, a commonly used measure is mean average precision (MAP). Mean average precision is defined as the arithmetic mean of per-topic average precision,  $MAP = \frac{1}{n} \sum_n AP_n$ . A consequence of the arithmetic mean is that, if a system improvement doubles AP for one topic from 0.02 to 0.04, while simultaneously decreasing AP on another from 0.4 to 0.38, the MAP will be unchanged. If we prefer to highlight performance differences on the lowest performing topics, a widely used alternative is the geometric mean of average precision (GMAP), first introduced in the TREC 2004 robust track (Voorhees, 2006).

$$GMAP = \sqrt[n]{\prod_n AP_n}$$

Robertson (2006) presents a justification and analysis of GMAP and notes that it may alternatively be computed as an arithmetic mean of logs,

$$GMAP = \exp \frac{1}{n} \sum_n \log AP_n.$$

#### 4.2.2 Significance Testing for GMAP

A standard way of measuring the significance of system improvements in MAP is to compare average precision (AP) on each of the evaluation queries

using the Wilcoxon signed-rank test. This test, while not requiring a particular distribution on the measurements, does assume that they belong to an interval scale. Similarly, the arithmetic mean of MAP assumes AP has interval scale. As Robertson (2006) has pointed out, it is in no sense clear that AP (prior to any transformation) satisfies this assumption. This becomes an argument for GMAP, since it may also be defined using an arithmetic mean of log-transformed average precisions. That is to say, the logarithm is simply one possible monotonic transformation which is arguably as good as any other, including the identify transform, in terms of whether the transformed value satisfies the interval assumption. This log transform (and hence GMAP) is useful simply because it highlights improvements on the most difficult queries.

We apply the same reasoning to test for statistical significance in GMAP improvements. That is, we test for significant improvements in GMAP by applying the Wilcoxon signed rank test to the paired, transformed average precisions, log AP. We handle tied pairs and compute exact  $p$ -values using the Streitberg & Röhmel Shift-Algorithm (1990). For topics with  $AP = 0$ , we follow the Robust Track convention and add  $\epsilon = 0.00001$ . The authors are not aware of significance tests having been previously reported on GMAP.

### 4.3 Retrieval System

We use Okapi BM25 (Robertson et al., 1996) as our basic retrieval system, which defines a document  $D$ ’s retrieval score for query  $Q$  as

$$s(D, Q) = \sum_{i=1}^n idf(q_i) \frac{\left(\frac{k_3+1}{k_3+qf_i}\right) f(q_i, D) (k_1 + 1)}{f(q_i, D) + k_1(1 - b + b \frac{|D|}{avgdl})},$$

where the inverse document frequency ( $idf$ ) is defined as

$$idf(q_i) = \log \frac{N - n(q_i) + 0.5}{n(q_i) + 0.5},$$

$N$  is the size of the collection,  $n(q_i)$  is the document frequency for term  $q_i$ ,  $qf_i$  is the frequency of term  $q_i$  in query  $Q$ ,  $f(q_i, D)$  is the term frequency of query term  $q_i$  in document  $D$ ,  $|D|$  is the length of the matching document, and  $avgdl$  is the average length of a document in the collection. We set the

Figure 2: The two dimensional smooth  $f(s_{IBM}, s_{BBN})$  learned to predict relevance given input scores from IBM and BBN transcripts.

parameters to  $k_1 = 1$ ,  $k_3 = 1$ ,  $b = .5$ , which gave good results on a single transcript.

#### 4.4 Speech Recognition Transcripts

Our first set of speech recognition transcripts was produced by IBM for the MALACH project, and used for several years in the CLEF cross-language speech retrieval (CL-SR) track (Pecina et al., 2007). The IBM recognizer was built using a manually produced pronunciation dictionary and 200 hours of transcribed audio. The resulting interview transcripts have a reported mean word error rate (WER) of approximately 25% on held out data, which was obtained by priming the language model with metadata available from pre-interview questionnaires. This represents significant improvements over IBM transcripts used in earlier CL-SR evaluations, which had a best reported WER of 39.6% (Byrne et al., 2004). This system is reported to have run at approximately 10 times real time.

##### 4.4.1 New Transcripts for MALACH

We were graciously permitted to use BBN Technology’s speech recognition system to produce a second set of ASR transcripts for our experiments (Prasad et al., 2005; Matsoukas et al., 2005). We selected the one side of the audio having largest RMS

amplitude for training and decoding. This channel was down-sampled to 8kHz and segmented using an available broadcast news segmenter. Because we did not have a pronunciation dictionary which covered the transcribed audio, we automatically generated pronunciations for roughly 14k words using a rule-based transliterator and the CMU lexicon. Using the same 200 hours of transcribed audio, we trained acoustic models as described in (Prasad et al., 2005). We use a mixture of the training transcripts and various newswire sources for our language model training. We did not attempt to prime the language model for particular interviewees or otherwise utilize any interview metadata. For decoding, we ran a fast (approximately 1 times real time) system, as described in (Matsoukas et al., 2005). Unfortunately, as we do not have the same development set used by IBM, a direct comparison of WER is not possible. Testing on a small held out set of 4.3 hours, we observed our system had a WER of 32.4%.

#### 4.5 Combination Methods

For baseline comparisons, we ran our evaluation on each of the two transcript sources (IBM and our new transcripts), the linear combination chosen to optimize MAP (LC-MAP), the linear combination chosen to optimize GMAP (LC-GMAP), interleaving (IL), and CombMNZ. We denote our additive factor model as Factor GLM, and our multidimensional smooth GAM model as MD-GAM.

Linear combination parameters were chosen to optimize performance on the training set, sweeping the weight for each source at intervals of 0.01. For the generalized additive models, we maximized the penalized likelihood of the training examples under our model, as described in Section 3.

## 5 Results

Table 1 shows our complete set of results. This includes baseline scores from our new set of transcripts, each of our baseline combination approaches, and results from our proposed combination models. Although we are chiefly interested in improvements on difficult topics (i.e., GMAP), we present MAP for comparison. Results in bold indicate the largest mean value of the measure (either AP or log AP), while daggers (†) indicate the

Type	Model	MAP	GMAP
T	IBM	0.0531 (-.2)	0.0134 (-11.8)
-	BBN	0.0532	0.0152

Table 1: MAP and GMAP for each combination approach, using the evaluation query set from the CLEF-2007 CL-SR (MALACH) collection. Shown in parentheses is the relative improvement in score over the best single transcripts results (i.e., using our new set of transcripts). The best (mean) score for each condition is in bold.

combination is a statistically significant improvement ( $\alpha = 0.05$ ) over our new transcript set (that is, over the best single transcript result). Tests for statistically significant improvements in GMAP are computed using our paired log AP test, as discussed in Section 4.2.2.

First, we note that the GAM model with multi-dimensional smooth gives the largest GMAP improvement for both title and title-description runs. Secondly, it is the only combination approach able to produce statistically significant relative improvements on both measures for both conditions. For GMAP, our measure of interest, these improvements are 18.4% and 16.2% respectively.

One surprising observation from Table 1 is that the mean improvement in log AP for interleaving is fairly large and yet not statistically significant (it is in fact a larger *mean* improvement than several other baseline combination approaches which *are* significant improvements. This may suggest that interleaving suffers from a large disparity between its best and worst performance on the query set.

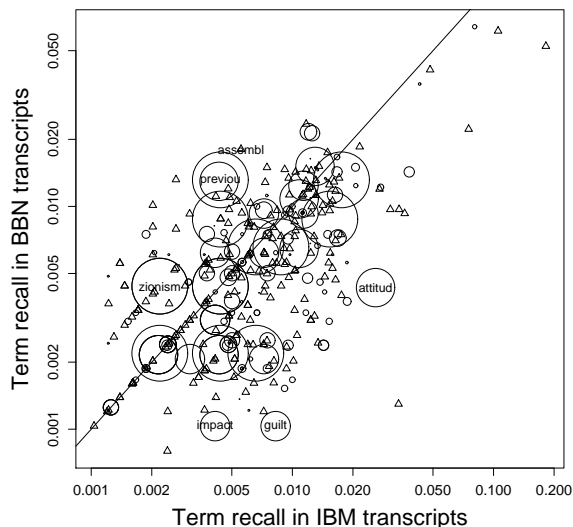

Figure 3: The proportion of relevant documents returned in IBM and BBN transcripts for discriminative title words (title words occurring in less than .01 of the collection). Point size is proportional to the improvement in average precision using (1) the best linear combination chosen to optimize GMAP ( $\triangle$ ) and (2) the combination using MD-GAM ( $\circ$ ).

Figure 3 examines whether our improvements come systematically from only one of the transcript sources. It shows the proportion of relevant documents in each transcript source containing the most discriminative title words (words occurring in less than .01 of the collection). Each point represents one term for one topic. The size of the point is proportional to the difference in AP observed on that topic by using MD-GAM and by using LC-GMAP. If the difference is positive (MD-GAM wins), we plot  $\circ$ , otherwise  $\triangle$ . First, we observe that, when it wins, MD-GAM tends to increase AP much more than when LC-GMAP wins. While there are many wins also for LC-GMAP, the effects of the larger MD-GAM improvements will dominate for many of the most difficult queries. Secondly, there does not appear to be any evidence that one transcript source has much higher term-recall than the other.

## 5.1 Oracle linear combination

A chief advantage of our MD-GAM combination model is that it is able to map input scores nonlinearly onto a probability of document relevance.

Type	Model	GMAP
T	Oracle-LC-GMAP	0.0168
-	MD-GAM	<b>0.0180 (+7.1)</b>
TD	Oracle-LC-GMAP	0.0222
-	MD-GAM	<b>0.0223 (+0.5)</b>

Table 2: GMAP results for an oracle experiment in which MD-GAM was fairly trained and LC-GMAP was unfairly optimized on the test queries.

To make an assessment of how much this capability helps the system, we performed an oracle experiment where we again constrained MD-GAM to be fairly trained but allowed LC-GMAP to cheat and choose the combination *optimizing* GMAP *on the test data*. Table 2 lists the results. While the improvement with MD-GAM is now not statistically significant (primarily because of our small query set), we found it still out-performed the oracle linear combination. For title-only queries, this improvement was surprisingly large at 7.1% relative.

## 6 Conclusion

While speech retrieval is one example of retrieval under errorful document representations, other similar tasks may also benefit from these combination models. This includes the task of cross-language retrieval, as well as the retrieval of documents obtained by optical character recognition.

Within speech retrieval, further work also remains to be done. For example, various other features are likely to be useful in predicting optimal system combination. These might include, for example, confidence scores, acoustic confusability, or other strong cues that one recognition system is unlikely to have properly recognized a query term. We look forward to investigating these possibilities in future work.

The question of how much a system should expose its internal workings (e.g., its document representations) to external systems is a long standing problem in meta-search. We've taken the rather narrow view that systems might only expose the list of scores they assigned to retrieved documents, a plausible scenario considering the many systems now emerging which are effectively doing this already. Some examples include *EveryZing*,<sup>1</sup> the MIT *Lec-*

<sup>1</sup><http://www.everyzing.com/>

*ture Browser*,<sup>2</sup> and Comcast's video search.<sup>3</sup> This trend is likely to continue as the underlying representations of the content are themselves becoming increasingly complex (e.g., word and subword level lattices or confusion networks). The cost of exposing such a vast quantity of such complex data rapidly becomes difficult to justify.

But if the various representations of the content are available, there are almost certainly other combination approaches worth investigating. Some possible approaches include simple linear combinations of the putative term frequencies, combinations of one best transcript hypotheses (e.g., using ROVER (Fiscus, 1997)), or methods exploiting word-lattice information (Evermann and Woodland, 2000).

Our planet's 6.6 billion people speak many more words every day than even the largest Web search engines presently index. While much of this is surely not worth hearing again (or even once!), some of it is surely precious beyond measure. Separating the wheat from the chaff in this cacophony is the *raison d'etre* for information retrieval, and it is hard to conceive of an information retrieval challenge with greater scope or greater potential to impact our society than improving our access to the spoken word.

## Abstract

We assess the current state of the art in speech summarization, by comparing a typical summarizer on two different domains: lecture data and the SWITCHBOARD corpus. Our results cast significant doubt on the merits of this area's accepted evaluation standards in terms of: baselines chosen, the correspondence of results to our intuition of what "summaries" should be, and the value of adding speech-related features to summarizers that already use transcripts from automatic speech recognition (ASR) systems.

## 1 Problem definition and related literature

Speech is arguably the most basic, most natural form of human communication. The consistent demand for and increasing availability of spoken audio content on web pages and other digital media should therefore come as no surprise. Along with this availability comes a demand for ways to better navigate through speech, which is inherently more linear or sequential than text in its traditional delivery.

*Navigation* connotes a number of specific tasks, including search, but also browsing (Hirschberg et al., 1999) and skimming, which can involve far more analysis and manipulation of content than the spoken document retrieval tasks of recent NIST fame (1997 2000). These would include time compression of the speech signal and/or "dichotic" presentations of speech, in which a different audio track is presented to either ear (Cherry and Taylor, 1954; Ranjan et al., 2006). Time compression of speech, on the other hand, excises small slices of digitized

speech data out of the signal so that the voices speak all of the content but more quickly. The excision can either be fixed rate, for which there have been a number of experiments to detect comprehension limits, or variable rate, where the rate is determined by pause detection and shortening (Arons, 1992), pitch (Arons, 1994) or longer-term measures of linguistic salience (Tucker and Whittaker, 2006). A very short-term measure based on spectral entropy can also be used (Ajmal et al., 2007), which has the advantage that listeners cannot detect the variation in rate, but they nevertheless comprehend better than fixed-rate baselines that preserve pitch periods. With or without variable rates, listeners can easily withstand a factor of two speed-up, but Likert response tests definitively show that they absolutely hate doing it (Tucker and Whittaker, 2006) relative to word-level or utterance-level excisive methods, which would include the summarization-based strategy that we pursue in this paper.

The strategy we focus on here is summarization, in its more familiar construal from computational linguistics and information retrieval. We view it as an extension of the text summarization problem in which we use automatically prepared, imperfect textual transcripts to summarize speech. Other details are provided in Section 2.2. Early work on speech summarization was either domain-restricted (Kameyama and Arima, 1994), or prided itself on not using ASR at all, because of its unreliability in open domains (Chen and Withgott, 1992). Summaries of speech, however, can still be delivered audially (Kikuchi et al., 2003), even when (noisy) transcripts are used.

The purpose of this paper is not so much to introduce a new way of summarizing speech, as to critically reappraise how well the current state of the art really works. The earliest work to consider open-domain speech summarization seriously from the standpoint of text summarization technology (Valenza et al., 1999; Zechner and Waibel, 2000) approached the task as one of speech transcription followed by text summarization of the resulting transcript (weighted by confidence scores from the ASR system), with the very interesting result that transcription and summarization errors in such systems tend to offset one another in overall performance. In the years following this work, however, some research by others on speech summarization (Maskey and Hirschberg, 2005; Murray et al., 2005; Murray et al., 2006, *inter alia*) has focussed *de rigueur* on striving for and measuring the improvements attainable over the transcribe-then-summarize baseline with features available from non-transcriptional sources (e.g., pitch and energy of the acoustic signal) or those, while evident in textual transcripts, not germane to texts other than spoken language transcripts (e.g., speaker changes or question-answer pair boundaries).

These “novel” features do indeed seem to help, but not by nearly as much as some of this recent literature would suggest. The experiments and the choice of baselines have largely been framed to illuminate the value of various knowledge sources (“prosodic features,” “named entity features” etc.), rather than to optimize performance *per se* — although the large-dimensional pattern recognition algorithms and classifiers that they use are inappropriate for descriptive hypothesis testing.

First, most of the benefit attained by these novel sources can be captured simply by measuring the lengths of candidate utterances. Only one paper we are aware of (Christensen et al., 2004) has presented the performance of length on its own, although the objective there was to use length, position and other simple textual feature baselines (no acoustics) to distinguish the properties of various genres of spoken audio content, a topic that we will return to in Section 2.1.<sup>1</sup> Second, maximal marginal relevance

(MMR) has also fallen by the wayside, although it too performs very well. Again, only one paper that we are aware of (Murray et al., 2005) provides an MMR baseline, and there MMR significantly outperforms an approach trained on a richer collection of features, including acoustic features. MMR was the method of choice for utterance selection in Zechner and Waibel (2000) and their later work, but it is often eschewed perhaps because textbook MMR does not directly provide a means to incorporate other features. There is a simple means of doing so (Section 2.3), and it is furthermore very resilient to low word-error rates (WERs, Section 3.3).

Third, as inappropriate uses of optimization methods go, the one comparison that has not made it into print yet is that of the more traditional “what-is-said” features (MMR, length in words and named-entity features) vs. the avant-garde “how-it-is-said” features (structural, acoustic/prosodic and spoken-language features). Maskey & Hirschberg (2005) divide their features into these categories, but only to compute a correlation coefficient between them (0.74). The former in aggregate still performs significantly better than the latter in aggregate, even if certain members of the latter do outperform certain members of the former. This is perhaps the most reassuring comparison we can offer to text summarization and ASR enthusiasts, because it corroborates the important role that ASR still plays in speech summarization in spite of its imperfections.

Finally, and perhaps most disconcertingly, we can show that current speech summarization performs just as well, and in some respects even better, with SWITCHBOARD dialogues as it does with more coherent spoken-language content, such as lectures. This is not a failing of automated systems themselves — even *humans* exhibit the same tendency under the experimental conditions that most researchers have used to prepare evaluation gold standards. What this means is that, while speech summarization systems may arguably be useful and are indeed consistent with whatever it is that humans are doing when they are enlisted to rank utterances, this evaluation regime simply does not reflect how well the “summaries” capture the goal-orientation or

---

<sup>1</sup>Length features are often mentioned in the text of other work as the most beneficial single features in more hetero-

---

geneous systems, but without indicating their performance on their own.
